

The production Function

Firms can turn inputs into outputs in a variety of ways, using various combinations of labor, materials, and capital. We can describe the relationship between the input into the production process and the resulting output by the production function.

Production function: The mathematical relationship between inputs and outputs.

A *production function* indicates the highest output q that a firm can produce for every specified combination of inputs. Although in practice firms use a wide variety of inputs, we will keep our analysis simple by focusing on only two, labor L and capital K . we can then write the production function as:

$$q = F(K, L)$$

This equation relates the quantity of output to the quantities of the two inputs, capital and labor. Because the production function allows input to be combined in varying proportions, output can be produced in many ways. For the production function equation this could mean using more capital and less labor, or vice versa.

Average and Marginal Products

Average product: Output per unit of a particular input.

The average product is calculated by dividing the total output q by the input of labor L . The average product of labor measures the productivity of the firm workforce in terms of how much output each worker produces in average.

$$\text{Average product of labor (APL)} = \frac{\text{Output}}{\text{labor input}} = \frac{q}{L}$$

Marginal product: Additional output produced as an input is increased by one unit.

$$\text{Marginal product of labor (MPL)} = \frac{\text{Change in Output}}{\text{Change in labor input}} = \frac{\Delta q}{\Delta L} = \frac{\partial q}{\partial L}$$

Marginal product of capital (MPK) is the extra output obtained by using one more machine while holding the number of workers constant.

$$\text{Marginal product of labor (MPK)} = \frac{\text{Change in Output}}{\text{Change in capital input}} = \frac{\Delta q}{\Delta K} = \frac{\partial q}{\partial K}$$

Example

Suppose that the hourly output of chili at a barbecue (q measured in pounds) is characterized by: $q = 2KL + L$, where K is the capital input used each hours, and L is the number of worker hours employed. Suppose also that the amount of capital is fixed at 12.

- a. How much L is needed to produce 100 pound per hour?

$$q = L(2K + 1) \Rightarrow 100 = L(2 * 12 + 1)$$

$$\Rightarrow 100 = 25L \quad \Rightarrow \quad L = 100/25 = 4$$

- b. What is the average product of labor to produce 100 pound per hour?

$$\text{When } K = 12, \text{ and } q = 100 \Rightarrow L = 4$$

$$\text{Average product of labor (APL)} = \frac{\text{Output}}{\text{labor input}} = \frac{q}{L} = \frac{100}{4} = 25$$

- c. What is the marginal product of labor when the firm employing 100 workers?

$$\text{When } K = 12 \Rightarrow q = 24L + L \Rightarrow q = 25L$$

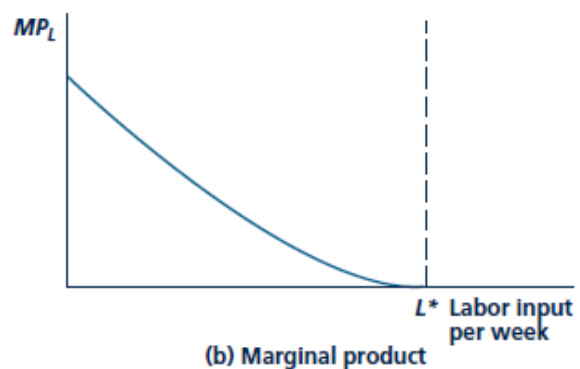

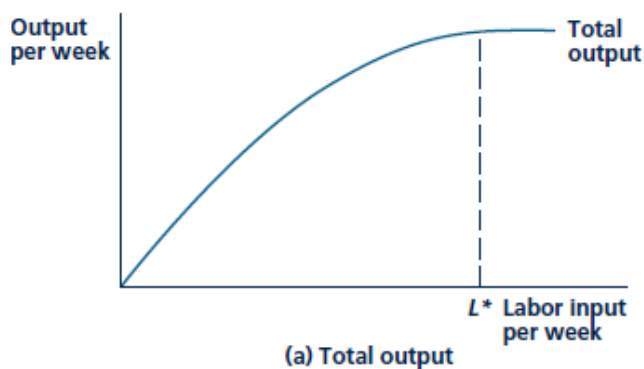

$$\text{Marginal product of labor (MPL)} = \frac{\partial q}{\partial L} = 25$$

Diminishing Marginal Product

Adding new workers increases output significantly, but these gains diminish as even more labor is added and the fixed amount of capital becomes over utilized. The concave shape of the total output curve in panel a therefore reflects the economic principle of diminishing marginal product.

Marginal Product Curve

A geometric interpretation of the marginal product concept is straightforward—it is the slope of the total product curve. The decreasing slope of the curve shows diminishing marginal product. For higher values of labor input, the total curve is nearly flat—adding more labor raises output only slightly.

Panel a shows the relationship between output and labor input, holding other inputs constant. Panel b shows the marginal product of labor input, which is also the slope of the curve in panel a. Here, MPL diminishes as labor input increases. MPL reaches zero at L^* .

Isoquant

A curve that shows the various combinations of inputs that will produce the same amount of output.

For example, isoquant q_1 shows all combinations of labor and capital per year those together yield 10 units of output per year. Two of these points, A and B. At A, 1 unit of labor and 3 units of capital yield 10 units of output; at B, the same output is produced from 3 units of labor and 1 unit of capital.

Isoquant map

Graph combining a number of isoquants, used to describe a production function.

Output increases as we move from isoquant q_1 (at which 10 units are produced), to isoquant q_2 (20 units), and to isoquant q_3 (30 units).

Example:

The production function for puffed rice is given by: $q = 100\sqrt{LK}$

Where q is the number of boxes produce per hour, K is the number of puffing guns used each hour, and L is the number of workers hired each hour.

a. Calculate the $q = 1,000$ isoquant for this production function and show it on a graph.

$$q = 100\sqrt{LK} \Rightarrow 1,000 = 100\sqrt{LK} \Rightarrow 10 = \sqrt{LK}$$

$$\Rightarrow 100 = LK \Rightarrow K = \frac{100}{L}$$

L	K
1	100
2	50
3	33.4
4	25

Marginal rate of technical substitution (RTS)

The amount by which one input can be reduced when one more unit of another input is added while holding output constant. The negative of the slope of an isoquant.

The slope of each isoquant indicates how the quantity of one input can be traded off against the quantity of the other, while output is held constant. When the negative sign is removed, we call the slope the *marginal rate of technical substitution (RTS)*.

$$RTS = \frac{-\text{Change in capital input}}{\text{Change in labor input}} = \frac{-\Delta K}{\Delta L} \text{ for a fixed level of } q$$

The isoquant has a negative slope) because the firm can decrease its use of capital if one more unit of labor is employed.

The RTS (of labor for capital) between points A and B:

$$RTS = \frac{-\Delta K}{\Delta L} = \frac{-(3-5)}{(2-1)} = \frac{2}{1} = 2$$

This means that if the firm adds one unit of labor, the firm should decrease the used of capital by 2 units to keep output level constant.

Diminishing RTS:

Along any isoquant the (negative) slope become flatter and the RTS diminishes. The MRTS falls as we move down along an isoquant. The mathematical implication is that isoquants are convex or bowed inward.

The diminishing MRTS tells us that the productivity of any one input is limited. As more and more labor is added to the production process in place of capital, the productivity of labor falls.

The RTS and Marginal Products

The RTS is closely related to the marginal products of labor MPL and capital MPK. To see how, imagine adding some labor and reducing the amount of capital sufficient to keep output constant. The additional output resulting from the increased labor input is equal to the additional output per unit of additional labor (the marginal product of labor) times the number of units of additional labor:

$$\text{Additional output from increased use of labor} = (MP_L)(\Delta L)$$

Similarly, the decrease in output resulting from the reduction in capital is the loss of output per unit reduction in capital (the marginal product of capital) times the number of units of capital reduction:

$$\text{Reduction in output from decreased use of capital} = (MP_K)(\Delta K)$$

Because we are keeping output constant by moving along an isoquant, the total change in output must be zero. Thus,

$$(MPL)(\Delta L) + (MPK)(\Delta K) = 0$$

Now, by rearranging terms we see that

$$\frac{MPL}{MPK} = \frac{-\Delta K}{\Delta L} = RTS$$

This equation tells us that the marginal rate of technical substitution between two inputs is equal to the ratio of the marginal products of the inputs.

Example

A firm's marginal product of labor is 4 and its marginal product of capital is 5. if the firm adds one unit of labor, but does not want its output quantity to change, the firm should:

- (a) Use five fewer units of capital.
- (b) Use 0.8 fewer units of capital
- (c) Use 1.25 fewer units of capital
- (d) Add 1.25 units of capital

$$\text{MRTS (of L for K)} = \frac{MPL}{MPK} = \frac{4}{5} = 0.8$$

MRTS = 0.8 means that if the firm adds one unit of labor, then the firm should decrease the used of capital by 0.8 unit to keep output level constant.

Example

The production function for soy beans is $q = 10 K L$. calculate the RTS of labor for capital when the firm using 4 labor and 2 capital.

$$RTS \text{ (of } L \text{ for } K) = \frac{MPL}{MPK}$$

$$MPL = \frac{\partial q}{\partial L} = 10K$$

$$MPK = \frac{\partial q}{\partial K} = 10L$$

$$\Rightarrow RTS \text{ (of } L \text{ for } K) = \frac{MPL}{MPK} = \frac{10K}{10L} = \frac{K}{L} = \frac{2}{4} = \frac{1}{2}$$

Production Functions–Two Special Cases

It may be the case that absolutely no substitution between inputs is possible. This case is shown in figure. If K_1 units of capital are used, exactly L_1 units of labor are required to produce q_1 units of output. If K_1 units of capital are used and less than L_1 units of labor are used, q_1 cannot be produced

If K_1 units of capital are used and more than L_1 units of labor are used, no more than q_1 units of output are produced. With $K = K_1$, the marginal physical product of labor is zero beyond L_1 units of labor. The q_1 isoquant is horizontal beyond L_1 . Similarly, with L_1 units of labor, the marginal physical product of capital is zero beyond K_1 resulting in the vertical portion of the isoquant.

This type of production function is called a *fixed-proportion production function* because the inputs must be used in a fixed ratio to one another.

The mathematical notation is represent by: $q(K, L) = \min(K, L)$

Isoquants with Inputs are Perfect Substitutes

When the isoquants are straight lines, the RTS is constant. Thus the rate at which capital and labor can be substituted for each other is the same no matter what level of inputs is being used. Points *A*, *B*, and *C* represent three different capital-labor combinations that generate the same output q_3 .

The mathematical notation is represented by: $q(K, L) = aL + bK$

Changes in Technology

Technical progress is a shift in the production function that allows a given output level to be produced using fewer inputs.

The improvement in technology is represented in the Figure by the shift of the q_0 isoquant to q'_0 .

Technical progress shifts the q_0 isoquant to q'_0 . Whereas previously it required K_0 , L_0 to produce q_0 now, with the same amount of capital, only L_1 units of labor are required. This result can be contrasted to capital-labor substitution, in which the required labor input for q_0 also declines to L_1 and more capital (K_1) is used.

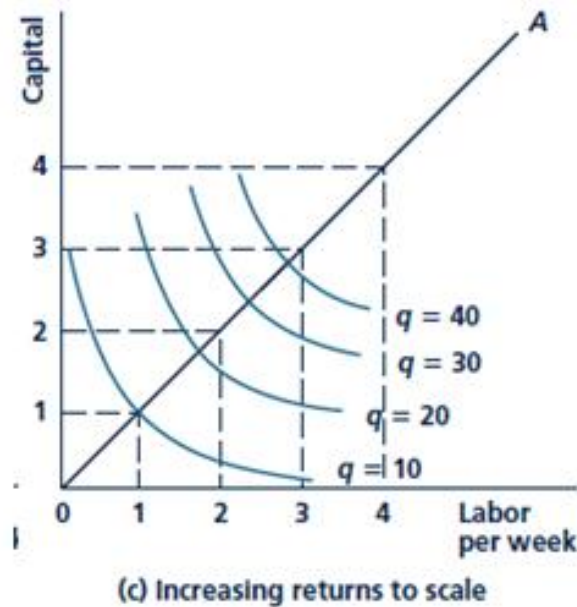

Returns to Scale

Returns to scale is the rate at which output increases in response to proportional increases in all inputs.

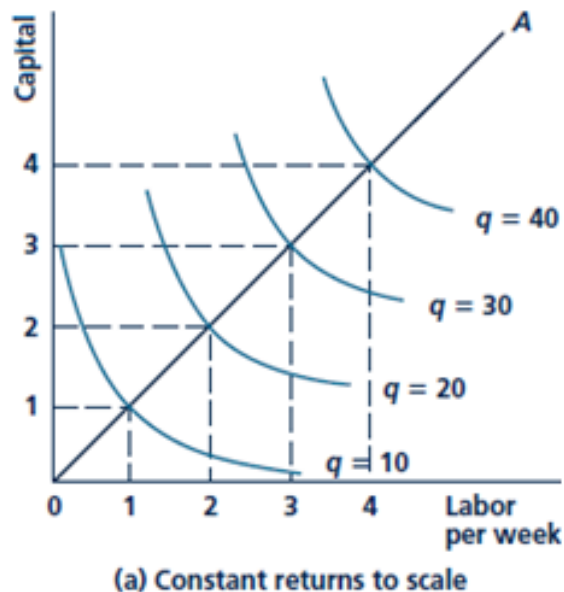

Increasing Return to Scale:

If output more than doubles when inputs are doubled, there are increasing returns to scale. This might arise because the larger scale of operation allows managers and workers to specialize in their tasks and to make use of more sophisticated, large-scale factories and equipment. The automobile assembly line is a famous example of increasing returns.

Constant Return to Scale:

Situation in which output doubles when all inputs are doubled are called constant return to scale. With constant returns to scale, the size of the firm's operation does not affect the productivity of its factors: Because one plant using a particular production process can easily be replicated, two plants produce twice as much output.

Decreasing returns to scale

Situation in which output less than doubles when all inputs are doubled are called constant return to scale. This case of decreasing returns to scale applies to some firms with large-scale operations.

(b) Decreasing returns to scale

Numerical Examples

1. The production function for soy beans is $q = 40\sqrt{LK}$. Dose this production function have constant, increasing or decreasing return to scale?

$$q(K, L) = 40\sqrt{LK}, \text{ when we doubling of all inputs } \Rightarrow q(2K, 2L) = 40\sqrt{(2L)(2K)}$$

$$\Rightarrow q(2K, 2L) = 40\sqrt{4LK} = 2 \times 40\sqrt{LK} = 2q \Rightarrow \text{constant return to scale.}$$

2. The production function for soy beans is $q = KL$. Dose this production function have constant, increasing or decreasing return to scale?

$$q(K, L) = KL, \text{ when we doubling of all inputs } \Rightarrow q(2K, 2L) = (2K) \times (2L)$$

$$\Rightarrow q(2K, 2L) = (2K) \times (2L) = 4(KL) = 4q > 2q \Rightarrow \text{Increasing return to scale.}$$

3. The production function for soy beans is $q = 2K + L$. Dose this production function have constant, increasing or decreasing return to scale?

$$q(K, L) = 2K + L, \text{ when we doubling of all inputs } \Rightarrow q(2K, 2L) = 2(2K) + (2L)$$

$$q(2K, 2L) = 2(2K + L) = 2q \Rightarrow \text{constant return to scale.}$$

4. The production function for soy beans is $q = K^{0.5}L^{0.3}$. Dose this production function have constant, increasing or decreasing return to scale?

$$q(K, L) = K^{0.5}L^{0.3}, \text{ when we doubling of all inputs } \Rightarrow q(2K, 2L) = (2K)^{0.5}(2L)^{0.3}$$

$$\Rightarrow q(2K, 2L) = (2)^{0.5} (K)^{0.5} (2)^{0.3} (L)^{0.3}$$

$$= 2^{0.8} \{(K)^{0.5} (L)^{0.3}\} = 2^{0.8} q < 2q \Rightarrow \text{decreasing return to scale.}$$

If the productions function is given by: $q = K^\alpha L^\beta$ where $0 \leq \alpha, \beta \leq 1$, is called a Cobb-Douglas production function.

- If $\alpha + \beta = 1$ \Rightarrow the productions function constant return to scale
- If $\alpha + \beta > 1$ \Rightarrow the productions function increasing return to scale
- If $\alpha + \beta < 1$ \Rightarrow the productions function decreasing return to scale
