Skin testing is done to detect the presence of IgE in the skin, or to isolate an antigen (allergen) to which the IgE is responding or to which a child is sensitive. When an allergen is introduced into the child's skin and the child is sensitive to that allergen, a wheal or flare response appears at the site of the test. This is because of the release of histamine, which leads to local vasodilation. Because this reaction appears quickly, the test should be read in 20 minutes. Systemic or aerosol administration of an antihistamine will inhibit the flare response, so the child should not receive these drugs for 8 hours before skin testing. Corticosteroid therapy does not affect immediate skin reactivity and so may be continued during skin testing.

Skin testing may be done by applying a patch or using a scratch or an intracutaneous injection technique. Patch testing has become the method of choice because it is painless and more efficient. For the child with rare allergies not typically provided by commercial patches, scratch or intracutaneous testing still may be necessary. Scratch testing is done by placing a drop of allergen solution on the skin, then scratching through the drop of liquid with a sterile needle. A relatively concentrated extract of allergen must be used for scratch testing because little allergen enters the child's skin.

Intracutaneous injections are done by injecting a small amount of a solution of allergen below the epidermis of the skin. This is usually done on the forearm so that if a sensitivity reaction does occur, a tourniquet can be applied proximal to the test site to prevent further absorption of the antigen. If the categories to be tested are extensive, the back can be used. Solutions used for intracutaneous injections are more dilute than those used for scratch testing (1:500 dilution compared with 1:5 for scratch testing). This means that the allergen extracts are not interchangeable from a group prepared for scratch testing to a group prepared for intracutaneous injections (or vice versa).

Because intracutaneous injections are given just below the epidermal layer of skin, they are almost painless. This is the same phenomenon as passing a needle or pin under the top layer of skin of a fingertip, a trick every school-age child does at least once to the horror of friends. The child needs a great deal of support for this type of skin testing, however, because it looks as if it will be painful, and the sight of a needle is frightening.

After all forms of skin testing, if the child is allergic to the test solution, a wheal and erythema (redness) will occur at the test site (Fig. 42.4). The size of the reaction is measured and graded as 1+ to 4+ or as slight, moderate, or marked. The allergens chosen for skin testing depend on the child's symptoms. Few children need more than 30 test media tried. This is because most allergies are worse at certain times of the year, and only the allergens prevalent at that time of year need to be evaluated.

Have a syringe filled with 1 mL epinephrine (Adrenalin) 1:1000 on hand to counteract an unexpected anaphylactic reaction from skin testing. Epinephrine is given subcutaneously in doses of 0.01 mg/kg, up to 0.5 mg. Children should stay in the health care setting for at least 30 minutes after skin testing so they are there when such a reaction is most apt to occur.

Skin testing with food extracts is largely ineffective. Food allergies are best identified by eliminating a suspected

FIGURE 42.4 Allergy skin testing. Note the positive reactions. (© SPL/Custom Medical Stock Photograph.)

food from the diet and observing whether there is an improvement in symptoms. After a time of improvement, the food is reintroduced. If it is one to which the child is allergic, symptoms will return with its reintroduction (termed "rechallenging").

Therapeutic Management

No matter what the symptoms of a child's allergy, there are three goals for therapy: reduce the child's exposure to the allergen, hyposensitize the child to produce a state of increased clinical **tolerance** (a state of not responding) to the allergen, and modify the child's response to the allergen with a pharmacologic agent.

Reducing the child's exposure to the allergen is possible when the offending allergen is a drug, food, or irritant. Reducing exposure is much more difficult when the child is found to be allergic to allergens such as molds, dust, feathers, or other substances found almost everywhere.

Environmental Control

Environmental control means removal of as many common allergens as possible from a child's environment. Common measures of environmental control are shown in Table 42.4 and Box 42.6. Some parents carry out instructions to reduce potential allergens in their house without difficulty, but for others the process seems too involved to undertake. Help parents understand that environmental control can make a great deal of difference in their child's

TABLE 42.4 ✻ Common Measures for Environmental Control of Allergens

Area of Concern	Measures	Rationale
Child's bedroom	Encase mattress and pillow in sturdy plastic.	Reduces dust and dust mites
	Cover the zipper of plastic pillow and mattress case with adhesive tape.	Keeps dust confined
	Use blankets or quilts made of or stuffed with smooth, synthetic material; avoid wool.	Minimizes dust; wool is a good dust collector or may be an allergen itself
	Take down any ornamental items, such as a bed canopy.	Prevents dust collection
	Remove stuffed chairs and replace with wooden ones.	Removes dust collectors
	Remove venetian blinds and curtains that need to be dry-cleaned; replace with easily laundered types.	Removes dust collectors
	Remove stuffed toys unless filled with synthetic material.	Removes dust collectors and possible sources of allergens
	Remove aquariums and plants.	Removes mold spores
	Clean closet so it contains only currently used items.	Eliminates dust collectors
	Remove any fur or woolen items from child's wardrobe.	Removes possible allergens
Living room	Remove all carpets. If a rug is necessary, replace an animal hair pad with a foam rubber one.	Avoids containers for dust collection
	Provide a wooden chair for sitting.	Provides space free from allergens
	Vacuum frequently.	Minimizes dust collection
	Use linoleum or plastic laminate surface on carpet if child sits on the floor.	Provides space free from allergens
	Discourage child from lying on rug.	Reduces exposure to allergens
Bathroom	Use nonscented toilet paper, soaps, cleaners.	Minimizes exposure to potential irritants
School room	Have child sit away from blackboard, caged animals, or fish tanks.	Minimizes exposure to chalk, mold spores, and animal dander, which are allergens
	Keep locker free of collectibles	Reduces dust collection
General	Purchase a dehumidifier; add compounds to paint to decrease mold spores.	Reduces mold spores
	Use HEPA filters on furnaces, vacuums.	Filters air of possible allergens
	Do not keep a pet.	Reduces exposure to animal dander
	Dust daily with a moist cloth.	Controls dust better than dry dusting

BOX 42.6 * Focus on Communication

The Goodenough family has been instructed on environmental control measures because Dexter has severe allergic rhinitis. Despite this, Dexter's symptoms have not improved. You meet with his parents to confirm they are carrying out these measures.

Less Effective Communication

Nurse: Have you made the changes around your house that we discussed to reduce dust?
Mrs. Goodenough: As many as we can.
Nurse: What about Dexter's bedroom? Do you have the mattress covered? Any frilly curtains down? Any stuffed animals taken out?
Mrs. Goodenough: I've done everything I can.
Nurse: In the living room, it's important he has a protected floor space, also that he doesn't sit in overstuffed chairs.
Mrs. Goodenough: I've done everything I can.
Nurse: Okay, you sound in good shape. It's puzzling, though, why, in the face of all you've done, Dexter's symptoms haven't improved.

More Effective Communication

Nurse: Have you made the changes around your house that we discussed to reduce dust?
Mrs. Goodenough: As many as we can.
Nurse: What about Dexter's bedroom? Do you have the mattress covered? Any frilly curtains down? Any stuffed animals taken out?
Mrs. Goodenough: I've done everything I can.
Nurse: It's puzzling why Dexter's symptoms haven't improved. Why don't you tell me exactly what steps you've taken?
Mrs. Goodenough: I covered the mattress. I had to leave the curtains up, though, because they match the rug. I took out a lot of the toys, but I had to leave the stuffed bears because they match the wallpaper.
Nurse: Let's review again what environmental control means and the effect it can have on reducing Dexter's symptoms.

By taking the parent's statement that she has done "everything possible" to mean she has done everything that needs to be done, the nurse makes an incorrect assumption. Following up by asking the parents to be more specific reveals better information.

symptoms. If environmental control is effective with a child, this is preferable to hyposensitization, which involves many visits to the doctor and many injections.

Hyposensitization

Hyposensitization, or immunotherapy, is done when the child's allergy symptoms cannot be controlled by avoidance of an allergen or conventional drug therapy. Because it is expensive and may not be successful, it is usually considered only after environmental control has been tried.

Hyposensitization works by increasing the plasma concentration of IgG antibodies. IgG acts to prevent or block IgE antibodies from coming in contact with the allergen. After specific allergens have been recognized with skin testing, small amounts of the allergy extract (dilute enough to be clinically subreactive) are injected into the child subcutaneously at 3- to 5-day intervals. The dose of antigen is increased in strength each time until a peak concentration is reached. The peak dose corresponds to the greatest strength that does not give clinical symptoms after injection. Following this, the child's allergy symptoms should be greatly reduced or absent. The child then needs periodic injections every 3 to 4 weeks to maintain hyposensitization to the allergen. If a child is going to have an anaphylactic reaction to an injected allergen, it generally occurs within 30 minutes after the injection. Therefore, always have children wait in the health care setting for 30 minutes after injection before going home.

Immunotherapy is generally continued for 2 to 3 years because the longer it is used, the longer the period of relief from symptoms after it is stopped. Be certain that parents know at the beginning of therapy that this therapy will not "cure" their child. It will make the child symptom-free or will decrease symptoms for a length of time, however, and it may prevent a mild atopic disorder such as hay fever (allergic rhinitis) from turning into a severe atopic disorder such as asthma (see Chapter 40). Be certain children have adequate preparation for the procedure. Help them understand the importance of returning for additional injections.

A newer technique of immunotherapy is the sublingual administration of chosen allergen solutions. SLIT (sublingual immunotherapy) is administered for an equal length of time as injection therapy, but SLIT has the advantage of being painless while producing equal results.

Pharmacologic Therapy

Several pharmacologic preparations can be used to reduce the symptoms of childhood allergies. Like hyposensitization procedures, these drugs do not change the sensitivity to allergens; they only relieve the symptoms.

Antihistamines block histamine release and as a result control itching, sneezing, and rhinorrhea. Diphenhydramine hydrochloride (Benadryl) is the prototype of this drug class (Box 42.7). It is effective but causes severe drowsiness. Second- and third-generation antihistamines, such as cetirizine (Zyrtec) and loratadine (Claritin), cause less drowsiness and provide a longer effect.

Decongestants, such as pseudoephedrine (Sudafed), decrease nasal edema and can help enlarge breathing space. Intranasal corticosteroids reduce inflammation, producing an effect similar to decongestants. Intranasal cromolyn sodium can be used prophylactically to prevent symptoms.

COMMON IMMUNE REACTIONS

Anaphylactic Shock

Anaphylactic shock is an immediate, life-threatening, type I hypersensitivity reaction that occurs after exposure to an

BOX 42.7 ✻ Focus on Pharmacology

Diphenhydramine Hydrochloride (Benadryl)

Classification: Diphenhydramine is a first-generation antihistamine.

Action: Blocks the effects of histamine at H_1 receptor sites, resulting in relief of symptoms associated with histamine release disorders such as allergic rhinitis (Karch, 2009).

Pregnancy risk category: B

Dosage: 12.5 to 25 mg three times to four times daily or 5 mg/kg/day or 150 mg/m^2/day orally (in children weighing over 10 kg [20 lb]) up to a maximum dose of 300 mg/day

Possible adverse effects: Drowsiness, dizziness, sedation, epigastric distress, dry mouth, thickening of bronchial secretions, hypotension

Nursing Implications

- Administer drug with food if gastrointestinal upset occurs.
- Use a humidifier to keep nasal mucosa moist.
- Be alert for drowsiness, which may interfere with school or sports performance; notify the health care provider for possible change in dosage or drug.
- Encourage the child to suck on sugarless lozenges to combat dry mouth.
- Notify health care provider if child develops a lower respiratory tract disorder. Antihistamines should not be used when secretions need to be kept moist to enhance expectoration.
- Do not use this drug if the child has glucose-6-phosphate dehydrogenase deficiency. Severe hemolysis may occur.

allergen in a previously sensitized child. Within minutes of antigen invasion (being stung by an insect or receiving an injection of a drug to which a child has been sensitized), symptoms begin (Boguniewicz, 2008).

Assessment

Initially, a child may become nauseated, with vomiting and diarrhea, because of the sudden increase in gastrointestinal secretions produced by the stimulation of histamine. This is followed by urticaria and angioedema. Bronchospasm can become so severe the child becomes dyspneic and hypoxemic. Continued bronchospasm leads to hypoxia. As blood vessels dilate, the blood pressure and pulse rate fall. Seizures and death may follow as soon as 10 minutes after the allergen was introduced into the child's body.

It is sometimes difficult to distinguish anaphylactic shock from fainting (syncope). Children, as a rule, however, do not faint after an injection or a bee sting. Syncope rarely occurs if a person is lying down, so if the reaction occurred while the child was lying on the treatment table, it is most likely that the reaction is anaphylactic. With syncope, although the child falls and is momentarily unconscious, the pulse and blood pressure remain normal. The child appears pale and may have intense perspiration, but can be roused readily after breathing amyl nitrite (smelling salts). The child with an anaphylactic reaction cannot be roused this way.

Therapeutic Management

Preventing and recognizing anaphylaxis are as important as knowing how to respond when it occurs. Before giving drugs that are known to have a high incidence of anaphylactic reactions such as penicillin, aspirin, or antitoxin serums, be certain to ask parents if their child has ever had a reaction to the drug before. If in doubt, withhold the drug until its safety can be confirmed. Check the child's chart to be certain that no prior reactions are noted. People who have hypersensitivity reactions to any injectable substance should wear a bracelet or necklace identifying the drug to which they are allergic. Some children object to this safety measure because they do not want to look conspicuous, but assure them this is important. Generally, children who have hypersensitivity reactions to insect stings are advised to undergo hyposensitization therapy because they cannot totally avoid insects.

Epinephrine is the drug of choice to treat anaphylaxis (Box 42.8) (Pongracic & Kim, 2007). Additional emergency interventions for anaphylactic shock are summarized in

BOX 42.8 ✻ Focus on Pharmacology

Epinephrine Hydrochloride (Adrenalin)

Classification: Epinephrine is a sympathomimetic drug.

Action: Acts on both alpha- and beta-receptor sites of sympathetic receptor cells to cause increased blood pressure and heart rate. It also relaxes the smooth muscles of the bronchi. It is used to counteract the symptoms of anaphylaxis (Karch, 2009).

Pregnancy risk category: C

Dosage: 0.01 mg/kg or 0.3 mL/m^2 of a 1:1000 solution subcutaneously every 20 min or more often if needed for 4 hours, not to exceed 0.5 mL (0.5 mg) in a single dose (for children and infants); 0.005 mL/kg (0.025 mg/kg) subcutaneously of a 1:200 suspension (in infants and children 1 mo to 1 y)

Possible adverse effects: Anxiety, restlessness, headache, nausea, arrhythmias, hypertension, palpitations, pallor

Nursing Implications

- Be sure to calculate the drug dosage and check the solution strength carefully; solution is available in different concentrations, and epinephrine is a very potent drug.
- Obtain blood pressure, pulse, and respirations and auscultate breath sounds before and immediately after administration. Assess the child for signs indicating resolution of anaphylaxis.
- Rotate injection sites to prevent necrosis.
- Have a rapidly acting alpha-adrenergic blocking agent or vasodilator readily available in case of hypertensive reaction; have a beta-adrenergic blocking agent readily available in case of arrhythmias.
- Protect the drug from light and heat. Use only solutions that are clear and colorless.

BOX 42.9 ✻ Emergency Measures for Anaphylactic Shock

Anaphylaxis is an emergency, and fast action is necessary.

- Position the child with head even with the body to counteract hypotension.
- Administer aqueous epinephrine (Adrenalin) 1:1000 subcutaneously at a dosage of 0.01 mg per kilogram of body weight up to 0.5 mg. This relieves laryngeal edema and severe bronchospasm.
- Administer nebulized bronchodilators such as albuterol to halt wheezing.
- If hypoxia is present, administer oxygen by mask or nasal cannula.
- Notify the cardiac arrest team because both respiratory and cardiac arrest may occur.
- Anticipate use of diphenhydramine (Benadryl) IM or IV as a secondary medication, particularly if urticaria (itching and swelling) is present.
- Anticipate the need for an IV fluid line as a route for a vasopressor such as dopamine and fluid to help restore blood pressure.
- If the child is experiencing seizures, prepare to administer phenobarbital or diazepam.
- Be prepared to administer corticosteroids as second-line drugs. Corticosteroids do not act immediately but reduce inflammation, which is necessary. IV methylprednisolone is a typical drug given.
- Keep the child and family members calm; anxiety adds to bronchospasm and decreases breathing ability.

Box 42.9. If anaphylaxis follows an injection or an insect sting, give the epinephrine in the opposite arm. Place a tourniquet on the extremity of the allergenic injection or sting proximal to the injection site to prevent further absorption of the allergen. Release the tourniquet every 15 minutes for a few seconds to avoid totally compromising blood flow.

If a sensitized child receives an injection or is stung by an insect while at home, parents must know the proper procedure to follow so they can give their child immediate help. In place of a tourniquet, they can apply ice to the injection or sting site to slow absorption. If a child has been prescribed an antihistamine, they should give that. Then the parents should notify their emergency response system (911) that their child is having a severe reaction. Caution them not to attempt to give an oral medication if the child is comatose. Parents may purchase an emergency kit (Ana-Kit), an insect sting treatment kit that contains measured doses of epinephrine (often in a device called an EpiPen, which injects the epinephrine; Box 42.10) and an antihistamine. Parents and children need practice to inject EpiPens correctly or they can accidentally puncture their thumb. If that happens, the vasoconstriction action of the epinephrine could disrupt circulation in their thumb (Mehr, Robinson, & Tang, 2007).

Evaluation of the child after an anaphylactic reaction involves not only a physical examination but also evaluation to help the child avoid such a serious reaction from occurring again. This involves health teaching about the substance that caused the reaction and related substances that could have the same effect.

✔ Checkpoint Question 42.2

Any child can have an anaphylactic reaction to a food or drug. What is the drug of choice you would want to have available to treat anaphylactic reactions?

a. Prednisone.
b. Epinephrine.
c. Penicillin.
d. Ibuprofen.

BOX 42.10 ✻ Focus on Family Teaching

Guidelines for Using an EpiPen

Q. Dexter's father says to you, "If my child is stung by a bee, I'm supposed to inject epinephrine. How do I do that?"

A. It is important you think about this in advance, because at the moment your child is stung, it will be an emergency situation.

- Purchase an EpiPen, a commercial syringe with a designated dose of epinephrine for use in emergencies.
- If necessary, purchase additional EpiPens so you have one at home, provide one for your child's school, and maybe keep one in your car to avoid having to remember to carry a single one with you.
- Store EpiPens at room temperature; don't refrigerate.
- Inspect the color of the solution in the EpiPen once a month; replace it if it is cloudy or discolored.
- If your child is stung, remove the gray safety cap from the device and wipe the outer fleshy portion of your child's thigh with an alcohol wipe.
- Place the EpiPen against the thigh until the device activates, injecting the solution into your child's thigh. If necessary, you can place the device on top of your child's clothing. The needle is long enough to pass through the clothing and into your child's skin.
- Be careful before injecting that you are holding the EpiPen with the needle toward your child. If not, you will accidentally inject your own thumb (a serious circumstance, as the dose of epinephrine could seriously injure your thumb).
- Keep in mind that the EpiPen is designed so that not all the solution in the pen will be ejected. Do not try to give the remainder of the solution.
- Remember that epinephrine will control symptoms for about 20 minutes. After administering the dose, therefore, call 911 for transportation assistance or transport your child to an emergency facility for further care.

Urticaria and Angioedema

Urticaria, or hives, refers to flat wheals surrounded by erythema arising from the chorion layer of skin; they are intensely pruritic (often described as a burning sensation). Elevations may occur so close together they tend to coalesce (blend together). Urticaria occurs from a type I or immediate hypersensitivity reaction created by the release of histamine from an antibody–antigen reaction, similar to but of lesser intensity than anaphylaxis. In chronic urticaria, no causative allergen may be found. There is dilatation of capillaries and venules with increased permeability.

Angioedema is edema of the skin and subcutaneous tissue. This occurs most frequently on the eyelids, hands, feet, genitalia, and lips—areas where skin is loosely bound by subcutaneous tissue. Angioedema can be distinguished from other edemas because it is not dependent, is generally asymmetrically distributed, and usually occurs with urticaria. One type is inherited as an autosomal disorder on chromosome 11 (Chawla & Riederer, 2007). With severe angioedema, the larynx may be involved. This is serious because laryngeal edema may lead to airway obstruction and subsequently asphyxiation and death.

The allergens that most frequently cause urticaria and angioedema include drugs, foods, and insect stings. Exposure to hot or cold can also cause these reactions. The cause of the reaction should be identified so it can be avoided in the future. Although hot and cold exposure is a rare cause, children with this form must be identified because if they swim in cold water, the sudden release of histamine could cause dizziness so severe that they could drown. Therapy for urticaria or angioedema is subcutaneous epinephrine or an oral antihistamine.

Serum Sickness

Serum sickness is a type III hypersensitivity response of the body to a foreign serum antigen or drug (Segal, 2007). Examples of foreign sera given to children include tetanus antitoxin, diphtheria antitoxin, and rabies antiserum. These are obtained from horse serum. Children may also experience a serum sickness reaction to a drug such as penicillin, but this is rare.

Assessment

Symptoms of serum sickness begin 7 to 12 days after the serum injection. If the child has received the same type of foreign serum previously, symptoms may occur as early as 1 to 5 days. Children notice itching, edema, and erythema at the injection site. There is generalized urticaria (hives) with or without angioedema (generalized edema). Erythematous maculopapular rashes, erythema multiforme (a generalized macular eruption with dark red papules), or purpura (hemorrhage into the skin) may result.

There may be fever and arthralgia (joint pain). Swollen lymph nodes may be present, especially of the regional nodes near the site of the injection. The child may have weight gain, nausea, vomiting, and abdominal pain. In more extreme instances, the child's nervous system may be involved and optic neuritis, stupor, and coma may occur. If edema is severe, laryngeal edema will become the paramount symptom that needs treatment.

Therapeutic Management

Serum sickness lasts days or weeks. In its usual form (symptoms of urticaria, edema, arthralgia, or pruritus), the treatment is only symptomatic because the condition will improve by itself with time. However, an antihistamine such as diphenhydramine (Benadryl) or epinephrine may be helpful in relieving symptoms. A nonsteroidal anti-inflammatory drug (NSAID) such as ibuprofen (Motrin) or a corticosteroid may be necessary to relieve the fever and joint pain.

Like anaphylactic reactions, serum sickness reactions are frightening to a child and parents. Parents need an explanation of why the reaction occurred (their child has a low threshold of sensitization to this particular substance), that it was not anyone's fault, and that it did not occur from administration of the wrong compound (assuming that proper precautions to ascertain sensitivity to the solution were taken before the incident). Because serum sickness mimics so many other disorders, parents need reassurance that it is not arthritis (the arthralgia may make them think it is) and that their child will not have long-term effects from it.

The child should not receive the foreign serum or drug that was responsible for this primary occurrence of serum sickness again. Otherwise, if administered again, the manifestation of the reaction may be anaphylaxis. Children should wear a bracelet or necklace stating the solutions to which they are hypersensitive. Children should have their immunizations (and records) kept current so there is never a need to give sera such as tetanus or diphtheria antitoxins.

ATOPIC DISORDERS

Individuals with atopy are prone to all allergic responses. Three disorders occur most frequently: hay fever (allergic rhinitis), eczema (atopic dermatitis), and asthma (discussed in Chapter 40). Although these diseases show a familial tendency, different family members may have different symptoms. In one family, for example, the father may have allergic rhinitis, one child may have asthma, and another may have atopic dermatitis.

The gene responsible for an immune response is located near the human leukocyte antigen that is responsible for graft rejection. In certain children, a tendency for sensitivity to antigens or abnormality of this gene is apparently inherited. These children have a higher-than-normal production of IgE antibody that makes them more responsive to allergens than other people. However, there is also a strong environmental component to these diseases. Children whose parents smoke have a greater incidence of atopic disorders compared with children of parents who do not smoke (Goodwin, 2007).

Allergic Rhinitis

Allergic rhinitis is caused by a type I or immediate hypersensitivity immune response. It occurs in 10% to 40% of children (Al Sayyad et al., 2009).

Assessment

Common symptoms of allergic rhinitis include sneezing, nasal engorgement, and a profuse watery nasal discharge. The mucous membrane of the nose is generally paler than normal. It may be edematous, adding to nasal congestion.

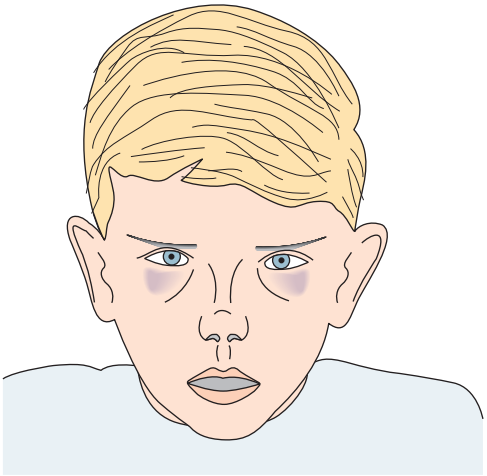

FIGURE 42.5 Back-pressure to the blood circulation around the eye orbit from allergic rhinitis may lead to dark areas under the eyes (allergic shiners). The frequent rubbing of the nose in an upward direction can lead to a peculiar horizontal crease (Dennie's line).

The eyes tend to water. The conjunctivae may be pruritic, often with a distinctive pebbly appearance. Children constantly rub their noses in an upward motion, termed an allergic salute. Over a long period, rubbing the nose this way leads to a horizontal crease across the tip of the nose, called an allergic crease. Because of congestion in the nose, there tends to be back-pressure to the blood circulation around the eye orbit, which leads to blackened areas under the eyes, termed allergic shiners (Fig. 42.5).

Children older than 6 years (when frontal sinuses develop) may report a full frontal headache. This becomes more marked with adolescence. Some children feel exhausted and lethargic and cannot function well in school. Recurrent otitis media may occur because of the swollen pharyngeal tissue (eustachian tubes are blocked to the middle ear). A smear of the nasal discharge will reveal an increased eosinophil count (more than 10% of the white cell count). RAST analysis may reveal the offending allergens.

The allergens that cause allergic rhinitis are generally pollens or molds rather than foods or drugs. Many of these children are brought to a health care setting during peak pollen months because parents think they have a "summer cold." However, with an upper respiratory infection, the mucous membrane of the nose is more apt to be reddened than pale, and the secretions draining from the nose are apt to be thick white or yellow rather than the thin, watery secretions of allergic rhinitis. Children with an upper respiratory infection often have a fever; children with allergic rhinitis do not. With an upper respiratory infection, a sore throat and cervical adenopathy may be present, but these are rare with allergic rhinitis.

Therapeutic Management

Allergic rhinitis is managed by avoidance of allergens, use of pharmacologic agents (antihistamines, leukotriene inhibitors, or corticosteroids), or immunotherapy. Parents usually ask how sick children should be before they need to see an allergist about skin testing and definite treatment (an expensive, time-consuming, and potentially painful procedure). Individual circumstances dictate the direction of treatment. As a rule, a child whose symptoms are increasing in intensity, who has associated lower respiratory tract involvement, or whose condition interferes with activities in which the child wants to participate needs definitive testing and treatment. Others can be managed by environmental control and medications to reduce symptoms.

Intranasal corticosteroids or antihistamines are effective in reducing symptoms in most children. Caution children and parents that antihistamines tend to cause sleepiness. Assess whether this will interfere with schoolwork or if an adolescent, if it could interfere with driving an automobile. Be certain that parents understand that if nasal antihistamine sprays are given for more than 3 days, a rebound effect may occur (the nasal mucosa becomes more edematous rather than less edematous).

Avoidance of allergens may be ineffective with allergic rhinitis because a child has a sensitivity to many different pollens or grasses. If children always show symptoms at one particular time of the year, parents may be able to carry out environmental control for that period of the year. Some children with allergic rhinitis are more comfortable in air-conditioned buildings; others have strong symptoms in the presence of air conditioning, probably accounting for the high incidence of headaches that occur at school (Aamodt et al., 2007).

Allergic rhinitis is often considered a minor illness by parents, something that children will outgrow. However, for children who have the condition, it may not be a minor illness and it may keep them from interacting with other children during certain months because they dread going outside and initiating symptoms. Help parents understand the importance of avoiding allergens and the need for conscientious administration of intranasal corticosteroids or antihistamines to minimize symptoms (see Focus on Nursing Care Planning Box 42.11).

Perennial Allergic Rhinitis

Allergic rhinitis becomes perennial (year-round) when the allergen is one that is capable of affecting the child year-round, such as house dust mites or pet hair. Although the child's symptoms may not result in the obvious distress associated with seasonal allergic rhinitis, the child needs treatment just as much because the symptoms occur constantly. Because the agent that causes perennial allergic rhinitis is often house dust, environmental control plays a big role in the control of the disorder. Serous otitis media may be a long-term consequence of perennial allergic rhinitis (see Chapter 50).

Atopic Dermatitis (Infantile Eczema)

Atopic dermatitis is primarily a disease of infants, beginning as early as the second month of life and possibly lasting until the child is 2 to 3 years old. It may be related to food allergy because it tends to occur more often in formula-fed infants than in breastfed infants and is more common if infants are fed solid food before 6 months. Sweating, heat, tight clothing, and contact irritants such as soap increase the pruritus. Symptoms may be more annoying in the winter, when additional irritating clothing is present, with marked improvement in the summer.

BOX 42.11 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Child With Allergic Rhinitis

Dexter Goodenough is a 6-year-old boy you meet in an ambulatory setting. Dexter is diagnosed as having allergic rhinitis (hay fever). "Thank heavens," his mother exclaims. "I thought when I heard he had an immune system disease he had AIDS. What a relief to know it's only an allergy."

Family Assessment ✻ Child lives with his mother and his stepfather in a beach-front cottage. Also in the family is a brother, 8 years; a stepbrother, 16 years; and a paternal grandmother. His stepfather owns a jewelry store. His mother is a stay-at-home mom. Finances are rated as "not a problem."

Client Assessment ✻ Child's eyes are reddened and watery; his nose drains a clear discharge. His mother tells you he frequently has a headache and is constantly listless, and other children make fun of him because of his appearance. His grades are "terrible" because the minute he gets to school, his symptoms begin. Dexter is prescribed an antihistamine and environmental control.

Nursing Diagnosis ✻ Situational low self-esteem related to feelings of inadequacy and embarrassment

Outcome Criteria ✻ Client states he is able to function in school in spite of allergy symptoms and discomfort; is taking active measures to avoid allergens.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Assess what Dexter's classroom is like to identify potential allergens, as child's symptoms are most intense when he is at school.	Discuss potential source of allergens with mother; ask her to meet with teacher to see if modifications could be made.	Environmental control can reduce the number of allergens causing symptoms.	Child describes classroom. Mother visits classroom as necessary to suggest changes.
		Consultations		
Physician	Assess if child's symptoms could be reduced with hyposensitization.	Consult with allergist about possibility of hyposensitization.	Hyposensitization can greatly reduce allergy symptoms if specific allergens can be identified.	Parent and child agree to hyposensitization if prescribed.
		Procedures/Medications		
Nurse	Assess if child has had experience with taking medicine before.	Help mother set up a medicine chart that will help with antihistamine adherence.	Allergy medicine is most effective when it is taken conscientiously.	Parent states she will be conscientious about antihistamine administration.
		Nutrition		
Nurse	Assess if there are any foods child or mother feel contribute to allergy symptoms.	If foods are identified, review with mother list of foods to avoid.	Respiratory allergens are more likely involved in allergic rhinitis, but foods should be ruled out.	Mother and child describe any foods that cause discomfort for child and measures to avoid them.

		Patient/Family Education		
Nurse	Assess environmental aspects at home that could be causing child's symptoms.	Discuss environmental control with parents.	Reducing allergens in the home can also aid in reducing child's symptoms.	Parents agree to any modifications necessary in their home.
Nurse	Assess if the child is exposed to secondary smoke in home.	Educate family on the damage that secondary smoke can cause.	Secondary smoke is a potent allergen and also may contribute to lung and heart disease.	Parents agree to make home smoke-free.
		Psychosocial/Spiritual/Emotional Needs		
Nurse	Assess the extent of ridicule child undergoes at school.	Discuss coping measures with child. Urge mother to report bullying to school authorities.	Psychological health is as important as physical health.	Child describes experiences at school. States he is no longer bullied.
		Discharge Planning		
Nurse	Assess if parent has other questions about child's allergies.	Schedule a follow-up visit for reevaluation of new medication.	Allergy control can involve a range of medicine, so it can be confusing for children or parents.	Mother states she understands the importance of follow-up visit and will keep appointment.

Assessment

With infantile atopic dermatitis, capillary permeability increases, causing a loss of serous fluid out into the tissues. Children develop papular and vesicular skin eruptions with surrounding erythema. The vesicles rupture and exude yellow, sticky secretions that form crusts on the skin as they dry. Because the lesions are extremely pruritic, the child scratches and further irritates the lesions, causing linear excoriations. Secondary infections of open lesions may then occur. As the infected lesions heal, the skin becomes depigmented and lichenified (shiny), and dry, flaky scales form. If secondary infection occurs, local lymph nodes will be swollen. The child may have a low-grade fever. An increased eosinophil count reveals that the condition is allergy-based.

The common sites for lesions include the scalp and forehead, the cheeks, neck, behind the ears, and the extensor surfaces of the extremities (Fig. 42.6). The palms of the hands and the soles of the feet are uninvolved. Because the lesions are uncomfortable, children with infantile atopic dermatitis may be overly fussy and irritable. They may not eat well because of this generalized discomfort.

Although infantile atopic dermatitis is generally diagnosed while taking the family history (considering other allergic individuals in the family) and noticing the characteristic lesions and their patterns, it is sometimes difficult to distinguish from seborrheic dermatitis (cradle cap; see Chapter 29). The findings in seborrheic dermatitis and infantile atopic dermatitis are compared in Table 42.5. Seborrheic dermatitis is a benign condition of infants, requiring little treatment other than frequent shampooing of the hair and soaking the lesions in mineral oil and combing them away (Smoker, 2007). A child with infantile atopic dermatitis, on the other hand, will not respond to these measures but must be referred for additional treatment. Also, children with infantile atopic dermatitis should have a repeat test for phenylketonuria (PKU) done because children with PKU often have atopic dermatitis (Itin & Goldsmith, 2008).

Skin testing is ineffective because the allergen causing infantile atopic dermatitis is often a food allergen. However, it may also be caused by pollens, dust, or mold spores. For this reason, skin testing may be attempted to isolate a causative allergen.

Therapeutic Management

The treatment of atopic dermatitis is aimed at reducing the amount of allergen exposure, if such allergens can be identified. The most likely foods to which infants are allergic are

FIGURE 42.6 Infant with atopic dermatitis. (From Sauer, G. C., & Hall, J. C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven Publishers.)

TABLE 42.5 ✻ Comparison of Seborrheic Dermatitis and Atopic Dermatitis

Finding	Seborrheic Dermatitis	Atopic Dermatitis
Age at onset	0–6 months	2–6 months
Length of disease	Rarely 1 year	2–3 years
Mood of child	Happy; parents happy	Irritable; parents tired
Location of lesions	Scalp, behind ears, near umbilicus	Cheeks, extensor surfaces, some flexor surfaces
Types of lesions	Salmon-colored erythematous lesions with greasy scales	Papulovesicular erythematous lesions with weeping and crusting
Itching	No	Severe
Depigmentation	No	Yes
Lichenification	No	Yes
White dermographism	No	Yes
Eosinophilia	No nasal mucus or blood eosinophilia	Nasal mucus or blood eosinophilia
IgE serum levels	Low	High

milk, eggs, wheat, chocolate, fish, tomatoes, and peanuts. The use of elimination diets to identify food allergens is discussed later in this chapter. A second major consideration in treatment is aimed at reducing pruritus so children do not irritate lesions and cause secondary infections by scratching. Hydrating the skin by bathing or applying wet dressings (wet with tap water or Burow's solution) for 15 to 20 minutes, followed by application of a hydrating emollient such as petroleum jelly (Vaseline) or even vegetable shortening (Crisco), is helpful. Do not allow infants to become chilled if a large portion of the body is to be covered with wet dressings. A stockinette dressing with holes cut out for the eyes, nose, and mouth pulled over the head will hold wet dressings in place on the face and neck. To prevent corneal irritation, be careful that such dressings do not come in contact with the eyes.

Some infants need an antihistamine to reduce itching. Topical steroids such as 1% hydrocortisone cream do a great deal to relieve the discomfort and appearance of lesions by reducing the inflammation and pruritus. If the lesions are dry, a corticosteroid ointment is most effective; if moist, a lotion may be most effective. Applying the cream or lotion and then covering the area with an occlusive dressing such as plastic wrap overnight may speed the healing process. If the lesions are secondarily infected, hydrocortisone mixed with an antibiotic (generally neomycin) and a suitable base is prescribed. Caution parents not to discontinue application of cortisone cream abruptly. Although absorption with topical application is limited, some does occur. This reduces adrenal gland functioning. If the cream is discontinued abruptly, the infant's adrenal response (ability to produce epinephrine) in an emergency might be limited. Also caution the parents not to overuse the cortisone cream. More is not better and may increase the risk of systemic absorption. Because of the complications that steroid creams can create, the new immunomodulators tacrolimus (Protopic) and pimecrolimus (Elidel) may be prescribed for children over 2 years of age. Because these drugs have been associated with the development of skin cancer, they are FDA approved but with a "Black Box" warning that they should be prescribed at the lowest possible dose (Patel, Greer, & Skinner, 2007).

Nursing Diagnoses and Related Interventions ✻

Nursing Diagnosis: Risk for impaired parenting related to feelings of inadequacy secondary to infant's chronic atopic dermatitis

Outcome Evaluation: Parents express confidence in their ability to follow recommended therapy; express positive aspects of infant; hold infant close and smile and talk to infant.

Parents of children with infantile atopic dermatitis need a great deal of support through the course of the disease because infants can be irritable from the constant pruritus. No matter how hard parents try, they cannot seem to make their child happy. Parents need a listening ear so they can vent these concerns and maintain their self-esteem as parents. Support groups also can help meet this need.

Nursing Diagnosis: Impaired skin integrity related to infantile atopic dermatitis

Outcome Evaluation: Infant does not scratch lesions; parents state infant is less irritable and easier to care for. Lesions show signs of healing.

When lesions begin to heal, a skin emollient and moisturizer, such as Eucerin, or baths with a substance to lubricate the skin, such as Alpha-Keri, are prescribed to prevent excessive skin dryness. The infant should soak in the bath with the lubricant for approximately 15 minutes, then be patted, not rubbed, dry so the lesions are not aggravated. Caution parents not to use soap, because it can be drying.

Suggest that parents trim their infant's fingernails short or cover hands with cotton socks to prevent scratching. Exposure to the herpes virus can cause a generalized reaction. Caution parents to screen babysitters or alert child care personnel with active herpes lesions not to care for their infants while atopic dermatitis is active.

In most infants, the lesions of infantile atopic dermatitis clear by the time a child is 3 years old. Unless secondary infection with scarring results, the skin surface will not be marked. Many of these children go on to develop other allergies, however, as they grow older. In the preschool years, the child's parents may report that the child has "one cold after another" (allergic rhinitis). By early school years, the child may show signs of asthma.

Atopic Dermatitis in the Older Child

Atopic dermatitis in the older child may occur at any age, but frequently it occurs at puberty or late adolescence (Horii et al., 2007). Atopic dermatitis that occurs at these later ages is prominent on the flexor surface of the extremities and on the dorsal surfaces of the wrists and ankles. It often occurs in the eyebrows; if the child scratches the lesions, the child may be left with scant eyebrows. Depigmentation or hyperpigmentation is usually present, and lichenification is marked. The fingernails often have a glossy sheen from the buffing action of constant rubbing and scratching. In some children, an itch–scratch cycle in response to stress may lead to an exacerbation of symptoms. For example, children begin to feel pressured in school or upset because they are left out of the neighborhood group of children. Children rub their skin, a nervous, comforting mannerism, and the rubbing or scratching leads to irritation of lesions. Then the lesions itch, and the child scratches vigorously because of discomfort. The more a child scratches, the worse the lesions become; the more lesions there are, the more the child scratches, and so on.

Therapeutic Management

Atopic dermatitis is a difficult disease for older children. Because they can see that the scratching leads to depigmentation or lichenification, they know they should stop scratching to keep the disorder under control. The itching is so intense, however, that they wake at night scratching and cannot stop. Adolescents are acutely aware of their appearance, so this is an especially difficult illness for them. Suggest they not use soap or use only a prescription soap to prevent skin drying. They should avoid swimming in chlorinated pools. Encourage other summer sports if possible. If children are required to swim in school, encourage them to shower well afterward to remove chlorine from the skin and apply a skin emollient and moisturizer such as Eucerin after swimming. After a period of activity in which sweating occurs, suggest that the child take a shower to remove perspiration, which is irritating to skin. Avoiding tight clothing at the flexor portions of the extremities may also help. Caution children not to use medication intended for acne cover-up on atopic dermatitis lesions because these medications are designed to dry the skin and will increase itching.

Medical treatment is basically the same as for the infant with atopic dermatitis: keeping the skin hydrated and identifying allergens and any psychological problems that are initiating an itch–scratch cycle. Application of hydrocortisone cream can make a big difference in helping lesions improve. Phototherapy with ultraviolet light may be prescribed.

Evaluation for the older child with atopic dermatitis should include evaluating how well the lesions are healing and also how well the child is adjusting to school and family. A child who enters adulthood with poor self-esteem because of a chronic allergic disorder during childhood could have difficulty achieving a high level of adult wellness.

What if... Dexter's atopic dermatitis is worse every December and every June at the end of school semesters? What might you suspect as the cause of an itch–scratch cycle at this time?

DRUG AND FOOD ALLERGIES

Drug Allergies

One of the hazards of giving any medication is the risk that a child may experience a reaction to it or exhibit allergic symptoms. Because reactions to drugs differ, it is important to be familiar with the symptoms of an allergic reaction, a toxic reaction, or a known side effect to a drug.

A *toxic reaction* is one that occurs when a child has received too much of a drug. *Side effects* of drugs are those that are known to occur in addition to a therapeutic effect. When an *allergic effect* occurs, unpredictable symptoms occur. The drug itself may not be an allergen, but when the drug combines with body protein, it becomes an allergen. This is why allergic responses occur not with the initial administration of a drug but only after the protein interaction (hapten formation or sensitivity) has occurred. When drugs are applied to skin or mucous membrane, the chance of a drug allergy is highest. With the exception of acetylsalicylic acid (aspirin), allergy occurs rarely to orally administered drugs. Children with atopic diseases appear to be most prone to allergic drug reactions, although anyone can have such a reaction.

Reactions to drugs differ, but skin manifestations seen frequently include urticaria, angioedema, allergic contact dermatitis, pruritus, and purpura. Respiratory symptoms include wheezing or rhinitis. Thrombocytopenia and hemolytic anemia may develop. Anaphylactic shock and serum sickness may occur. Children with a known drug allergy should wear a medical identification bracelet stating the drug to which they are sensitive.

Drugs that are frequently involved in allergic reactions are parenteral penicillin and vaccines. In most instances, discontinuing the drug or never again administering the vaccine is the only therapy needed. If urticaria or serum sickness occurs, an antihistamine (such as diphenhydramine hydrochloride [Benadryl]) is needed to relieve the symptoms. If anaphylaxis results, the treatment would be the same as for any anaphylaxis.

Food Allergies

Food allergies manifest themselves differently from one child to another, but urticaria, angioedema, pruritus, stomach pain, colic, cramps, diarrhea, respiratory symptoms, and atopic dermatitis are common symptoms (Roberts, 2007).

A symptom such as urticaria begins to manifest itself only minutes after an offending food is eaten. Other symptoms may be delayed, making the offending food difficult to recognize. Whole protein is probably the cause of immediate reactions; delayed reactions are probably the result of sensitivity to some protein breakdown product.

Skin testing is unreliable with food allergies because it is done with whole protein extracts. Delayed reactions, therefore, will not be detected this way. The most common foods that cause immediate allergy symptoms include egg white, fish and other seafood, berries, and nuts. Delayed food reactions are commonly caused by cereals (wheat and corn), milk, chocolate, pork, legumes, white potatoes, beef, food additives and colorings, and oranges. If children are allergic to milk, caution them that they are probably allergic to milk products as well. Children who are allergic to eggs often cannot eat any foods that contain egg, such as pudding or baked goods. As some vaccines have an egg ingredient, children with an egg hypersensitivity should not routinely receive these vaccines (Allen, Campbell, & Kemp, 2007).

Assessment

Young children cannot describe why they do not enjoy eating because they do not know the word for "headache," "stomachache," or "itchiness," but they tend to avoid foods that affect them. This gives them a reputation of being "fussy eaters." This is not diagnostic of food allergies, however, because children may refuse to eat foods as a form of toddler rebellion or may be reported as fussy eaters because parents are expecting them to eat more than their small size requires.

Encouraging a child or parents to keep a food diary or a record of everything a child eats each day often is the best way to spot offending foods. They should note the presence of symptoms, if any. A food that is found on lists when symptoms were few, but not on days when the child is in distress, is not an offending food. A food that appears only on "bad days," however, can be strongly suspected as an allergen.

An elimination diet is another method that can be used to detect food allergens. For this, parents feed the child only foods that rarely cause allergy, such as rice, lamb, carrots, peas, and sweet potatoes, for about 7 days. Then they add, one by one, at 2- to 3-day intervals, foods that are suspected of causing allergy. When a food is introduced this way, the child must be encouraged to eat a lot of it that day. If symptoms occur, the food is then eliminated from the child's meals on a permanent basis. If no symptoms occur, the child can continue to eat the food.

Therapeutic Management

The treatment of food allergy is to permanently eliminate offending foods from the child's diet. This is relatively easy to do if there are only a few offending foods, but it becomes difficult when the foods are great in number or, like milk, wheat, or eggs, are found in many products. Parents must become careful shoppers, reading labels carefully to be certain the foods they are buying do not contain products to which their child is sensitive. Help school-age children learn to choose foods they can safely eat at the school cafeteria or at summer camp.

Milk Hypersensitivity

The true incidence of milk hypersensitivity is probably not as high as the number of diagnoses made. Allergy to milk is typified by failure to gain weight, diarrhea, perhaps vomiting, and abdominal pain. Because these symptoms may also occur in a gastroenteritis infection, an infant may be misdiagnosed with an infection. Some infants with colic (characterized by abdominal pain, no change in stools, and no failure to gain weight) or those with lactase deficiency (they cannot ingest the lactose in milk) may also be incorrectly diagnosed as having a milk allergy. If milk allergy is suspected, children are given a casein hydrolysate or soybean formula (Sondheimer, 2008). When this is done, symptoms are usually dramatically relieved.

Caution parents to read food labels carefully to be certain that frozen foods or hot dogs do not contain milk as milk can be used as a filler in these products. As milk is a major source of vitamin D and calcium, children who have to avoid all milk may need a vitamin and calcium supplement. To establish whether the problem is truly a milk allergy, milk should be reintroduced at a later date. If the problem is a true milk allergy, signs will recur.

Peanut Hypersensitivity

A growing number of children are identified yearly as being so allergic to peanuts that even smelling peanut butter in a cafeteria or another child's lunch can provoke acute wheezing or anaphylaxis (Banerjee et al., 2007). School nurses need to be very aware of this danger and may need to advocate for "peanut-free" lunch rooms. Desensitization to peanuts can minimize children's responses.

STINGING INSECT HYPERSENSITIVITY

Children may have severe hypersensitivity reactions to stings from bees, wasps, hornets, or yellow jackets. Although a serum sickness reaction may occur, the usual reaction to these stings is an immediate type I hypersensitivity reaction (anaphylaxis). They can receive so many stings from "killer bees" the reaction is fatal. The peak season for insect stings is summer, and more boys than girls have allergic reactions to insect stings (Bledsoe, 2007).

Assessment

The first time a child is stung, the total reaction is probably only local edema at the site. The second time, generalized urticaria, pruritus, and edema may develop. The third time, symptoms may progress to wheezing and dyspnea. The next time, the reaction could be so severe that shock and death result. The progression of symptoms may be slower than this (involving 10 to 12 stings) if the stings occur far apart; if the stings are received close together (1 or 2 days apart, or even 3 weeks apart), the progression to fatal symptoms may occur as early as the second or third exposure.

The time interval between the fatal sting and death is extremely short, approximately 10 minutes. For this reason, these children must be identified and given medication to combat shock immediately (there is no time to transport them for emergency care).

Therapeutic Management

The best way to protect children with allergies to stinging insects is to begin hyposensitization against insect stings after the first reaction. An extract of wasp, yellow jacket, hornet, and honeybee venom accomplishes this.

The child who has not been hyposensitized must be treated immediately after the sting. This can be done by subcutaneous injection of epinephrine, which will give rapid relief (EpiPens are available for self-injection; see Box 42.10). If children are going on a hiking or camping expedition away from parents, caution parents that children need to learn to administer this to themselves, or be certain that a responsible adult accompanying them will be able to do it. Someone at school should be given the responsibility of administering this if a child is stung during recess or an outside gym period. If a school nurse is in attendance, this certainly is the nurse's responsibility. In schools where there is no full-time nurse, another person must be designated and taught how to give the injection. If the child has antihistamine medication in addition to epinephrine, this should be taken also. Ice applied to the site minimizes the amount of venom absorbed. The child should then be transported to the nearest hospital in case additional epinephrine is needed (the initial injection will be effective for only approximately 20 minutes).

Teach children who are allergic to stinging insects not to use scented preparations such as hair spray, deodorants, lotions, or perfume because these attract bees and wasps. They should not go outside barefoot because bees are often found in ground clover. They should not be assigned household chores such as mowing the lawn or weeding the garden, actions that might stir up bees. Because insects tend to cluster around garbage containers, taking out the trash is also an inappropriate chore for these children. Caution a child to have a fast-acting insecticide handy when out of doors to use on flying insects. Encourage a child to refrain from drinking from open soda cans at picnics and outside activities; bees and wasps are drawn to the sugar in the soda, and the child may be unaware that an insect has entered the open can.

✔ Checkpoint Question 42.3

Dexter is atopic or prone to allergies. In the hospital he has no toys. What would be a poor choice of a toy to make for him?

a. A paper deck of cards.
b. A cloth beanbag.
c. A latex glove balloon.
d. A tongue-blade puppet.

CONTACT DERMATITIS

Contact dermatitis is an example of a delayed or type IV hypersensitivity response; it is a reaction to skin contact with an allergen (a substance irritating to the child only with prior sensitization). The first reaction is generally erythema, followed by intensely pruritic papules and then vesicles. The allergen causing the irritation is often suggested by the part of the child's body that is affected. For example, dermatitis from a diaper-washing compound appears in the diaper area. Allergy to cosmetics appears on the face. Oozing at the site of pierced ears suggests an allergy to the nickel used in earring posts. Poison ivy appears on the hands and arms where the child brushed against the plant (Fig. 42.7). Many children, especially those who have had many surgical procedures such as children with spina bifida as well as health care providers, are developing reactions to latex gloves (Cremer et al., 2007). Footwear, because of the chemicals used to tan leather, is also a frequent offender.

FIGURE 42.7 Poison ivy on a child's hand. (© Beckman/Custom Medical Stock Photograph.)

Assessment

Patch testing may be used to identify contact dermatitis allergens. A child should not be taking a corticosteroid at the time of patch testing because these drugs reduce delayed hypersensitivity reactions. However, a child may continue to take antihistamines or sympathomimetic drugs because these do not interfere with delayed reactions. After 48 hours, the patches used for testing are removed and the reactions are graded 1+ to 4+, the same as in regular skin testing.

Therapeutic Management

Treatment for contact dermatitis consists of removing the identified allergen from the child's environment. In children, this is generally not difficult to do. In adults, because allergens may be job-related, this is much more difficult.

Dressings moistened with water, saline, or Burow's solution relieve itching. Calamine or Caladryl lotion are also generally effective. Hydrocortisone lotions or creams reduce itching and also promote healing. Baths with baking soda or oatmeal in the water may be helpful if a large area of the body is involved. Some children need a sedative to relieve their discomfort during the period of intense pruritus.

What if... Dexter, who is allergic to leather, develops an erythematous, pruritic area on his right buttock? What would be a likely object causing the irritation?

Key Points for Review

- An antigen is a foreign substance capable of stimulating an immune response. The immune system protects the body from invasion by foreign substances.
- Humoral immunity refers to immunity created by antibody production. B lymphocytes are involved in this type of reaction. Cell-mediated immunity refers to T-lymphocyte involvement.
- Autoimmunity results from an inability to distinguish self from nonself, causing the immune system to carry out immune responses against normal cells.

- Immunodeficiency disorders can be primary, such as B-lymphocyte and T-lymphocyte deficiencies, or secondary, such as acquired immunodeficiency syndrome (AIDS). HIV/AIDS is spread by the retrovirus HIV through blood and body secretions. Conscientious use of standard infection precautions is essential to prevent transmission.
- Allergic disorders occur as a result of an abnormal antigen–antibody response. As many as 15% to 30% of children have some form of allergy.
- Immune disorders, as a category, are long-term disorders, and children must participate in their own care to remain well such as avoiding allergens and conscientiously taking an antihistamine to remain well. Involving children from the start helps them play an active role in their own care.
- Anaphylactic shock is an acute type I hypersensitivity reaction characterized by extreme vasodilation and bronchoconstriction. If action is not taken immediately, the reaction can be fatal. Subcutaneous epinephrine is the drug of choice to reduce symptoms.
- Atopic disorders include allergic rhinitis (hay fever), atopic dermatitis, and asthma.
- Environmental control refers to ways to reduce the number of allergens to which children are exposed. Hyposensitization is a method to increase the plasma concentration of IgG antibodies to prevent or block IgE antibody formation and allergic symptoms.
- Promoting breastfeeding may be a prime intervention to help prevent food allergies in allergy-prone families.

CRITICAL THINKING EXERCISES

1. Dexter, the 6-year-old boy you met at the beginning of the chapter, was diagnosed as having allergic rhinitis. His symptoms begin when he arrives at school. Knowing this problem is worse at school, what environmental control measures would you suggest for Dexter?
2. When Dexter had atopic dermatitis (infantile eczema) as an infant, almost his entire face was covered with weeping, crusting lesions. His forehead was lined with scratch marks. His mother was exhausted because Dexter never slept because of the constant itching. What suggestions could you have made to his mother to make him more comfortable? What would you have suggested she do for herself?
3. Dexter's mother was concerned he might have AIDS. What would you want to explain to Dexter's mother about how the HIV virus is spread?
4. Examine the National Health Goals related to immune disorders and children. Most government-sponsored funds for nursing research are allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to Dexter's family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to immune system disorders in children. Confirm your answers are correct by reading the rationales.

Chapter 43

Nursing Care of a Family When a Child Has an Infectious Disorder

KEY TERMS

- catarrhal stage
- chain of infection
- convalescent period
- enanthem
- exanthem
- exotoxin
- fomites
- incubation period
- interferon
- Koplik's spots
- means of transmission
- portal of entry
- portal of exit
- prodromal period
- reservoir
- septicemia
- susceptible host

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe the causes and course of common infectious disorders of childhood.
2. Identify National Health Goals related to infectious disorders in children that nurses could help the nation achieve.
3. Use critical thinking to analyze ways that care of a child with an infectious disorder could be more family centered.
4. Assess a child with an infectious disorder.
5. Formulate nursing diagnoses for a child with an infectious disorder.
6. Establish outcomes for the care of a child with an infectious disorder.
7. Plan nursing care for a child with an infectious disorder.
8. Implement nursing care specific to the child with an infectious disorder, such as helping alleviate the pruritus of a rash.
9. Evaluate expected outcomes for achievement and effectiveness of care.
10. Identify areas of nursing care related to children with infectious diseases that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of infectious diseases and nursing process to achieve quality maternal and child health nursing care.

Marty Ireland, a 10-year-old boy, was admitted to the hospital for appendicitis. The morning after surgery, his throat was painful and his arms were covered by a very itchy, red, macular rash. Marty was diagnosed as having scarlet fever. "How could this have happened?" his mother asks you. "He's not a bad kid. How could two bad things happen to him at once?"

Previous chapters described the growth and development of well children. This chapter adds information about the dramatic changes, both physical and psychosocial, that can occur when children contract an infectious disorder. This is important information to protect child health because many of these disorders spread easily to other children.

What advice would you give Marty's mother? Is it likely that Marty contracted this new disease while he was in the hospital, or before he was admitted? What is a measure you would recommend to help reduce the itching?

Despite the number of preventive measures available, infectious diseases remain a leading cause of morbidity in children. Nurses play a key role in educating parents and the public about common childhood infectious disorders and appropriate preventive steps. They must be able to identify the symptoms of common infectious diseases of childhood, because nurses are often the first to see evidence of infection. For example, a school nurse is asked to be an expert on screening children for potentially communicable infections such as impetigo or tinea capitis (ringworm). In health care settings, nurses often perform triage, identifying children who must be seen immediately, those who can wait to be seen, and those who should not stay in a waiting room with other children because they may have an infectious disorder. Occasionally, children admitted to an inpatient unit develop diarrhea soon after admission. It is vital that a nurse quickly recognize that this could be contagious so other children in the hospital, especially those who are immunosuppressed, can be protected (Chambers, 2009).

Several National Health Goals, shown in Box 43.1, are related to the prevention of infectious disorders in children.

BOX 43.1 ✻ Focus on National Health Goals

Several National Health Goals address ways to prevent and reduce the incidence of infectious disease in children. Examples of these are:

- Reduce the annual incidence of Lyme disease from a baseline of 17.4 per 100,000 to a target of 9.7 per 100,000 population.
- Reduce the rate of hospital-acquired central line–associated bloodstream infections among people in intensive care units from 5.3 per 1000 days stay to 4.8 per 1000 days stay.
- Reduce the rate of hospital-acquired central line–associated bloodstream infections among infants weighing 1000 grams or less at birth in intensive care from 12.2 per 1000 days stay to 11 per 1000 days stay.
- Achieve and maintain the rate of effective vaccination coverage levels for universally recommended vaccines among young children, such as varicella vaccine, from a baseline of 43% to a target level of 90% (http://www.nih.gov).

Nurses can help the nation achieve these goals by educating parents about the importance of immunizations and ways to avoid infections such as Lyme disease. They can also help prevent the spread of infection in hospital units by adhering scrupulously to infection control precautions.

Nursing research that could increase understanding in this area includes studies aimed at answering questions such as the following: What precautions can summer camps or camp sites take to discourage children from petting wild animals to prevent contracting rabies or being exposed to ticks? What information do parents need to convince them to obtain full immunizations for children? What types of orientation do new staff nurses need to help them learn or better follow infection prevention techniques?

Nursing Process Overview

For a Child With an Infectious Disorder

Assessment

Many infectious diseases begin subtly. Parents report symptoms such as, "he doesn't act like himself" or "she's so listless." In many syndromes, children are infectious during this time. Following the prodomal period, an **exanthem** (rash) can develop. Rashes can be difficult to identify, so it is important to obtain as full a description and history of a rash as possible.

Nursing Diagnosis

Common nursing diagnoses used with children directly related to the infectious process are:

- Pain related to pruritus from skin lesions
- Impaired skin integrity related to rash, pruritus, and scratching
- Risk for infection related to presence of infective organism in sibling
- Altered body temperature, fever, related to systemic infection
- Fluid volume deficit related to insensible fluid loss from increased body temperature

Additional diagnoses when children must be separated from others to prevent infection transmission might include:

- Social isolation related to precautions required to prevent infection transmission
- Deficient diversional activity related to activity restriction and precautions to prevent disease transmission

Outcome Identification and Planning

When establishing outcomes for care of children with infectious disorders, include those that help parents deal with the current infection and also prevent another infection such as teaching about necessary infection control precautions and immunizations. Parents often ask about communicability to their other children and to the infected child's playmates or schoolmates, so these issues need to be addressed. Planning care for a child who requires restrictions to prevent disease transmission requires thoughtful consideration to prevent boredom. Two organizations helpful for referral are the National Foundation for Infectious Diseases (http://www.nfid.org) and the Centers for Disease Control (http://www.cdc.gov).

Implementation

Nursing responsibilities when caring for a child with an infectious disorder depend on the setting in which the child is seen. Often, a child will not be brought into a clinic if the disease can be easily identified over the telephone. Counseling parents about techniques to relieve the irritation of rashes and other symptoms of infectious illness can then be given over the telephone as well. Administering antibiotics and being alert for potential adverse effects are other major nursing responsibilities.

Outcome Evaluation

Evaluation of outcomes for the child with an infectious disease should determine not only whether the child is

returning to wellness but also whether the child and family have learned more about ways to prevent infectious diseases. If one member of the family is receiving steroid therapy or has an immune system dysfunction, prevention of transmission takes on even greater importance.

Examples of expected outcomes that would indicate achievement of goals are:

- Child states pain from pruritus and skin lesions is at a tolerable level.
- Sibling remains free of signs and symptoms of infectious disorder.
- Parent names activities he has planned to provide diversional activities.

THE INFECTIOUS PROCESS

A *pathogen* is any organism that causes disease. Pathogens can be classified into five types of microorganisms: viruses, bacteria, rickettsiae, helminths, and fungi. The properties of these organisms are discussed in conjunction with the common diseases that they cause.

Stages of Infectious Disease

Infectious diseases follow certain stages during which the communicability (ability to be spread to others) or severity of the illness can be predicted (Fig. 43.1).

- The **incubation period** is the time between the invasion of an organism and the onset of symptoms of infection. During this time, microorganisms grow and multiply. The incubation period varies depending on the pathogen. A common interval is 7 to 10 days, but it can be longer. The incubation period for tetanus, for example, is 2 to 21 days.
- A **prodromal period** is a time between the beginning of nonspecific symptoms and disease-specific ones. Nonspecific symptoms include lethargy, low-grade fever, fatigue, and malaise. Children are infectious (capable of spreading the microorganisms to others) during this time, but because their symptoms are so vague they do not generally take any precautions against spreading disease. Therefore, during a prodromal period, infectious diseases spread readily through communities to any susceptible individuals. Prodromal stages are generally short, ranging from hours to a few days.
- *Illness* is the stage during which specific symptoms are evident. Most illnesses have local symptoms related to the body organ affected and also systemic symptoms that affect the entire body, such as fever, increased white blood cell count, or headache. Many childhood infections have an accompanying rash on the skin (exanthem) or mucous membrane **(enanthem)** (Box 43.2).
- The **convalescent period** is the interval between when symptoms first begin to fade and the child returns to full wellness. Because fatigue is often an accompanying symptom of infection, the convalescent period, or the time until full energy is restored, is often longer than anticipated.

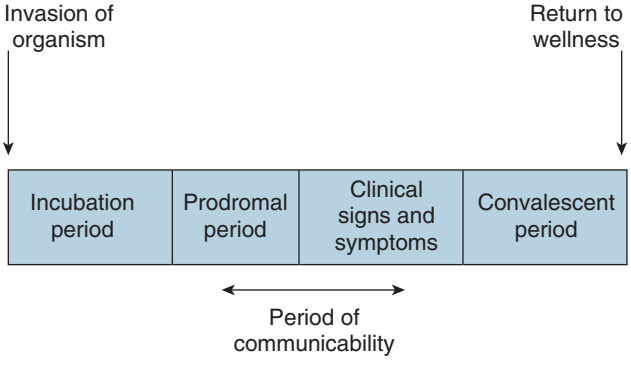

FIGURE 43.1 Time frame for infectious diseases. Period of communicability is the time during which the disease can be transmitted to other people.

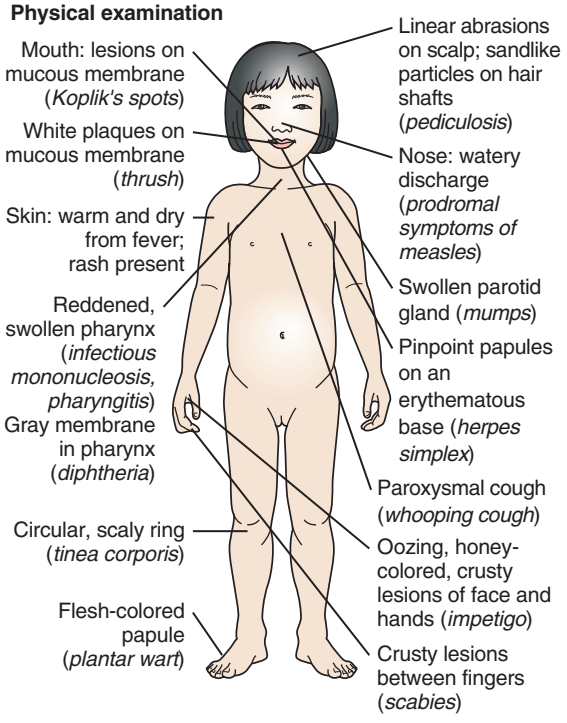
Box 43.2 Assessment

Assessing a Child With Common Signs and Symptoms of Infectious Disorders

History

Chief concern: Does child have a fever, general malaise, vomiting, or diarrhea? Was child recently exposed to someone with an infection?
Past medical history: Are child's immunizations current?

Physical examination



Chain of Infection

Chain of infection is the method by which organisms are spread and enter a new individual to cause disease. An important method of preventing infection is to break the chain of infection. Nurses are instrumental in teaching parents how to prevent the spread of infection in homes and how to carry

out safe practices so infection does not spread in health care facilities.

Reservoir

The **reservoir** is the container or place in which organisms grow and reproduce. The source of a human pathogen could be another human with the disease, a human carrying the disease, soil, or an animal or insect. Immunizations are helpful in limiting organisms' use of children as reservoirs for growth.

Portal of Exit

The **portal of exit** is the method by which organisms leave an infected child's body to be spread to others. This could be by upper respiratory excretions, feces, vomitus, saliva, urine, vaginal secretions, blood, or lesion secretions (Table 43.1). To break a chain of infection at this point, follow good aseptic technique and prescribed transmission-based precautions such as wearing a gown, gloves, or mask as appropriate. Teach parents good handwashing technique after the use of a bathroom or after handling diapers. Be sure to supply an adequate number of disposable tissues so droplet or airborne spread from coughing or sneezing can be limited.

Means of Transmission

The **means of transmission** is the way that infection is spread. This can be by direct or indirect contact. **Fomites** are inanimate objects such as soil, food, water, bedding, towels, combs, or drinking glasses that lead to indirect spread. Insects, rats, or other vermin (vectors) also cause indirect spread.

Head lice (tinea capitis) can be spread by a fomite such as a comb if it is passed from one child to another. Insects carry and spread rickettsial diseases. Soil always contains some anaerobic organisms (those that grow without oxygen), such as tetanus bacilli. When a child receives a puncture wound, such as from stepping on a rusty nail, some dirt may be left in the closed wound, and tetanus bacilli contained in the soil can begin to multiply in the closed area. Staphylococcal gastrointestinal disorders can be spread by improperly refrigerated food.

Direct contact implies body-to-body touching. Sexually transmitted infections (STIs) and skin disorders are spread this way. The most common means of indirect contact is the spread of mouth and nose secretions (droplet infection) through talking, sneezing, coughing, breathing, and kissing. Some droplets containing pathogenic organisms are spread immediately to another individual in this way. Some droplets fall to the ground, where the organisms dry and then are spread by dust. If small, the organisms become suspended in the air (airborne transmission) and can move with the wind to infect people at a distance. Common respiratory tract infections, for example, are spread by indirect contact.

To break a chain of infection at this point, use transmission-based precautions as appropriate and wash hands before, between, and after client care. Teach parents and children good handwashing technique and other measures as necessary.

Portal of Entry

The **portal of entry** or the opening through which a pathogen can enter a child's body can be by inhalation, ingestion, or breaks in the skin such as bites, abrasions, and burns. To break a chain of infection at this point, teach children to wash their hands after sneezing or coughing and before eating and after using the bathroom. Teach girls to wipe their perineum from front to back after defecating or voiding to prevent organisms from spreading from the rectum to the urethra. Teach parents to wash cuts and abrasions before bandaging them.

Susceptible Host

For infection to occur, a child must be susceptible to the infection **(susceptible host).** Certain characteristics make some individuals more prone to infection than others:

- Age—infection occurs most readily in the very young and the very old

TABLE 43.1 ✻ Methods by Which Infections Spread

Portal of Exit	Means of Transmission	Portal of Entry	Prevention Measures
Blood	Arthropod vectors	Injection into the bloodstream	Decreasing vector incidence
	Blood sampling		Careful handling of blood sampling equipment
	Transfusion		Screening of transfused blood for organisms such as human immunodeficiency virus (HIV) or hepatitis B
Respiratory secretions	Airborne droplets	Respiratory tract	Wearing mask
	Fomites		Droplet precautions
			Airborne precautions
			Handwashing
Feces	Water, food	Gastrointestinal tract	Handwashing before eating, after using bathroom, or handling diapers
	Fomites		
	Vectors such as flies		
Exudate from lesions	Direct contact	Skin, mucous membranes	Contact precautions
	Contact with soiled dressings		Self-screening for sexual contacts
			Gloves

TABLE 43.2 ✻ Types and Functions of White Blood Cells (Leukocytes)

Type	Percentage of Total Count	Origin	Function
Granular Forms			
Neutrophils	60 at birth 33 at 2 years 60 thereafter	Bone marrow	Active in acute bacterial infections
Eosinophils	1–4	Bone marrow	Increased in parasitic infection
Basophils	0.0–0.5	Bone marrow	Increased with inflammation
Nongranular Forms			
Lymphocytes	30 at birth 50 at 2 years 30 thereafter	Bone marrow Divides into B cells and T cells	Direct reaction with antigens (T lymphocytes—centered in thymus gland); antibody production by B lymphocytes against antigens
Monocytes	5–10	Bone marrow	Backup for neutrophils in acute infection; macrophages are mature form

- Gender—girls, for example, have more urinary tract infections than boys
- Virulence—some organisms are stronger than others or cause disease more readily
- Body defenses present—physical, chemical, and immune responses all protect against foreign invaders. Children with immunosuppression are more susceptible than others.

Immune Response to Organisms

When a foreign organism (antigen) is identified, it can be destroyed by the phagocytic (cell-engulfing) action of white blood cells or by activation of the body's immune system. Phagocytes are unique white blood cells that are capable of cell destruction. The cells chiefly responsible for this function are neutrophils. Monocytes serve as backup cells for phagocytosis. The action of all white blood cells is summarized in Table 43.2.

The action of phagocytes on organisms produces pus (remnants of the organisms, phagocytes, and destroyed tissue). Children and parents alike may need a review of the purpose of pus because they think its presence indicates that an infection is becoming worse. More likely, it indicates that phagocytosis is occurring and the infection is resolving.

If bacteria escape the action of the phagocytes, they enter the blood and lymph systems and are then transported to other body locations, activating the immune system. Pathogenic organisms in the bloodstream create **septicemia,** which is always a serious development because it means the organism is being spread systemically.

With activation of the immune system, B lymphocytes (humoral immunity) and T lymphocytes (cell-mediated immunity) are produced. B lymphocytes form antibodies specific to offending antigens that either actively destroy cells or activate *complement*, a special body protein that is capable of lysing cells (see Chapter 42).

T lymphocytes (thymus-dependent) can destroy antigens by direct contact or release of lymphokines. An example of a lymphokine is **interferon,** a substance that prevents cells from being host to more than one virus at a time. This is why it is rare to see a child with two viral diseases at the same time, although it is not impossible to see a child with both a viral and a bacterial disease (perhaps scarlet fever and a common cold) at the same time. This is also why two virus vaccines are not given to a child at the same time unless they are specially designed to be given together (such as measles, mumps, and rubella). (See Chapter 42 for a more detailed discussion of the immune response and Chapter 34 for a discussion of immunizations.)

HEALTH PROMOTION AND RISK MANAGEMENT

Preventing infectious diseases is important because these disorders are responsible for a high percentage of hospital admissions in children (Box 43.3). Prevention begins with being certain all children are in general good health. Adequate nutrition is important to provide protein and vitamins to supply adequate white blood cells so that both phagocytic and antibody-producing B lymphocytes are available to destroy invading organisms.

A second important step is to be certain all parents are aware of the need for their children to be immunized. Nurses need to ensure that immunizations are offered to children at well-child and many illness health care visits.

It is important that parents also understand that although diseases such as scarlet fever, chickenpox (varicella), and mumps (infectious parotitis) are referred to as "common" childhood illnesses, they have the potential to be serious illnesses, leading to complications such as pneumonia and encephalitis. When children develop these common communicable diseases, they need to be seen by a primary health care provider to minimize the risk for these complications.

The responsibility expected of parents and children to help prevent the spread of communicable diseases differs from country to country and varies among cultures. In the United States, both federal and state governments have taken an active role in preventing the spread of infectious disease by requiring children to have immunizations against the most common illnesses. Parents are expected to obtain such immunizations for children by school age. Schools and school nurses, as the school system's front-line health officers, take an active role in enforcing these regulations. Community

BOX 43.3 ✻ Focus on Evidence-Based Practice

Is infectious disease still a major reason for hospitalization in infants?

Because children receive so many immunizations today, many parents are surprised to learn their child has an infectious disease. The are shocked when they are told their child needs to be hospitalized as a part of therapy. To discover what is the rate of hospitalization for infectious diseases today in infants, researchers analyzed the reason for hospital admission of infants in the United States for a full year. Results of this analysis revealed that 42.8% of all hospitalizations for infants were for infectious diseases. This averages about 1 hospitalization for every 14 infants in the United States. The rates of hospitalization were highest for boys and nonwhite infants and averaged 3 days in length. The most commonly seen diagnoses among the infant infectious disease hospitalizations were lower respiratory tract infections (59.0%), kidney, urinary tract, and bladder infections (7.6%), upper respiratory tract infections (6.5%), and septicemia (6.5%). The median cost of an infectious disease hospitalization was $2235, with total annual hospital costs of approximately $690 million, among infants in the United States.

Based on the above study, would you assure the parents of an infant diagnosed with an infectious disease that the child can be cared for safely at home?

Source: Yorita, K. L., et al. (2008). Infectious disease hospitalizations among infants in the United States. *Pediatrics, 121*(2), 244–252.

health nurses are also instrumental in administering immunizations and counseling families on how to prevent the spread of disease in their home. Nurses can also make certain that parents are aware of the latest studies available on the safety of vaccines so they do not associate common vaccines with the development of autism, for example.

War-torn countries have a great deal of difficulty maintaining this same level of disease prevention. Remember when caring for children newly arrived from another country that the child may not have the same level of immunization as usually seen. This opens an important area of health teaching, as the parents may not be aware of the importance of immunizations, which ones are required, or what community services are available to supply them.

Preventing the Spread of Infections

Nosocomial or health care-associated infections (HAI) are infections that are contracted while in a hospital or other health care setting. They represent a major threat to hospitalized children. The overall rate of nosocomial, or hospital-acquired, infection in children ranges from 0% in low-risk settings to 23% in high-risk settings such as intensive care units. Children younger than 2 years, children with a nutritional deficit, those who are immunosuppressed, those who have indwelling vascular lines or catheters, those receiving multiple antibiotic therapy, or those who remain in the hospital for longer than 72 hours are at highest risk for contracting such an infection. Nurses provide a line of defense against such infections by adhering to strict aseptic technique, such as frequent and thorough handwashing, and by following protective transmission-based precautions when indicated (Mark, Harless, & Berman, 2007). Nurses and other health care providers must also take precautions to protect themselves from acquiring communicable diseases, including HIV and hepatitis, by adhering to standard infection precautions recommended by the Centers for Disease Control and Prevention (CDC, 2008a). Box 43.4 and Appendix I summarize standard infection precautions and transmission-based infection control precautions (CDC, 2008b).

CARING FOR THE CHILD WITH AN INFECTIOUS DISEASE

As almost all childhood infectious diseases include a fever or rash, nursing care must address identification and relief of these symptoms.

Nursing Diagnoses and Related Interventions ✻

Nursing Diagnosis: Pain related to pruritus from skin lesions

Outcome Evaluation: Child states he is more comfortable; reports less itching; is not seen scratching rash; no signs of excessive scratching or bleeding are present.

Providing comfort for the pruritus of skin lesions is important for many childhood infections. No matter what agent is causing the disease, a rash tends to be extremely itchy and uncomfortable. Fortunately, several simple remedies are available for reducing discomfort. Because pruritus is a minimal form of pain, an analgesic, such as acetaminophen (Tylenol), may be helpful. An antihistamine, such as diphenhydramine hydrochloride (Benadryl), is extremely helpful. Calamine lotion is a nonprescription lotion that is cooling and soothing and often helps to relieve itching. Colloidal baths, such as baking soda or oatmeal (approximately 1 cup to 3 inches of bath water), are soothing for some children. Warn parents to take precautions to prevent clogging the drain if oatmeal is used. Caution parents to use only lukewarm water, not hot, because heat usually increases the sensation of itching. Bathing serves two purposes: it can be not only soothing but also distracting. A child, especially a preschooler, may splash for 15 to 20 minutes in a bathtub without noticing the discomfort of a rash.

Some parents bundle up children with rashes, believing that the extra clothing brings out the rash, and that if a rash does not come out, it will go in and affect a child's heart or brain. In reality, bundling up only serves to make a rash more uncomfortable and probably increases any accompanying fever. Instead,

BOX 43.4 ✻ Standard and Transmission-Based Precautions for Infection Control

To reduce the risk of disease transmission in the health care setting:

1. Wash hands immediately with soap and water before and after examining patients and after any contact with blood, body fluids, and contaminated items—whether or not you wear gloves. Use of a plain, nonantimicrobial soap is recommended.
2. Wear clean, nonsterile gloves anytime contact with blood, body fluids, mucous membrane, or broken skin is likely. Change gloves between tasks or procedures on the same patient. Before going to another patient, remove gloves promptly and wash hands immediately and then put on new gloves.
3. Wear a mask, protective eyewear, and gown during any patient care activity when splashes or sprays of body fluids are likely. Remove the soiled gown as soon as possible and wash hands.
4. Handle needles and other sharp instruments safely. Do not recap needles. Make sure contaminated nondisposable equipment is not reused with another patient until it has been cleaned, disinfected, and sterilized properly. Dispose of nonreusable needles, syringes, and other sharp patient care instruments in puncture-resistant containers.
5. Routinely clean and disinfect frequently touched surfaces including beds, bedrails, examination tables, and bedside tables.
6. Do not touch linens soiled with blood or body fluids with bare hands. Use plastic bags to transport soiled linen.
7. Place a patient whose blood or body fluids are likely to contaminate surfaces or other patients in an isolation room or area.
8. Minimize the use of invasive procedures to avoid the potential for injury and accidental exposure. Use oral rather than injectable medications whenever possible.
9. When a specific diagnosis is made, find out how the disease is transmitted. Use precautions according to the transmission risk.

Airborne Precautions

Airborne precautions reduce the risk of small-particle organisms being transmitted through the air. Microorganisms carried by this route can be carried widely. If airborne transmission is possible:

1. Place the patient in an isolation room that is not air-conditioned or where air is not circulated to the rest of the health care facility. Make sure the room has a door that can be closed.
2. Wear a HEPA or other biosafety mask when working with the patient and in the patient's room.
3. Limit movement of the patient from the room to other areas. Place a surgical mask on the patient who must be moved.

Droplet Precautions

Droplet precautions reduce the risk of pathogens being spread through large-particle droplet contact by acts such as coughing, sneezing, and talking or through procedures such as suctioning or bronchoscopy. Large droplets do not remain suspended in the air for long periods and generally travel only short distances, so close proximity is required for spread of disease. If droplet transmission is possible:

1. Place the patient in an isolation room.
2. Wear a HEPA or other biosafety mask when working with the patient.
3. Limit movement of the patient from the room to other areas. If the patient must be moved, place a surgical mask on the patient.

Contact Precautions

Contact precautions reduce the risk of transmission of pathogens by direct contact such as skin-to-skin contact (shaking hands) or indirect contact through an intermediate object such as a comb or soiled dressing. If contact transmission is possible:

1. Place the patient in an isolation room and limit access.
2. Wear gloves during contact with patient and with infectious body fluids or contaminated items. Reinforce handwashing throughout the health facility.
3. Wear two layers of protective clothing.
4. Limit movement of the patient from the isolation room to other areas.
5. Avoid sharing equipment between patients. Designate equipment for each patient, if supplies allow. If sharing equipment is unavoidable, clean and disinfect it before use with the next patient.

Source: Centers for Disease Control and Prevention. (2008b). *Recommendations for isolation precautions in hospitals.* Washington, DC: Author.

dress a child in light cotton clothing. Remove wool blankets from the bed. Cut the child's fingernails short so scratching will not open up lesions, causing secondary infection. Placing cotton gloves on the child, especially at night, may help. Comfort measures of this type for relieving the discomfort of rashes are summarized in Box 43.5.

None of these measures is foolproof. Some may provide great relief to some children and little or none to others. Regardless of whether they offer direct relief, they do give a parent a constructive and comforting activity to carry out, providing parents with an opportunity to soothe their children and themselves.

BOX 43.5 ✻ Focus on Family Teaching

Relieving the Itchiness of a Rash

Q. Marty's mother says to you, "Our son is miserable because his rash is so itchy. What can we do to help him?"

A. Itching is a very uncomfortable sensation. Use the following to help relieve the itch of a rash:

- Dress your child in light cotton clothing so overheating and perspiration do not occur. Perspiration can make itching worse.
- Avoid wool clothing, because it can irritate skin and increase itching.
- Offer adequate fluid to maintain good hydration, because dry skin increases discomfort.
- Keep your child's fingernails short, to avoid injury to the skin from scratching.
- Teach your child to press on an itchy area rather than scratching to relieve discomfort; cold cloths applied to an area can also be helpful.
- Administer an analgesic, such as acetaminophen, as needed for comfort.
- Adding a few teaspoonfuls of baking soda to bath water can be soothing. Use lukewarm rather than hot water.
- Keep in mind that some children need an antihistamine such as diphenhydramine (Benadryl) to reduce itching. Ask your primary care provider about using it.

Most infectious diseases also involve fever. Measures to combat fever in children are discussed in Chapter 37.

Nursing Diagnosis: Social isolation related to required activity restriction associated with precautions to prevent disease transmission

Outcome Evaluation: Child states reasons for restrictions; expresses interest in activities proposed by nurses or parents.

A child who is restricted from others because of infection control precautions can begin to feel lonely and depressed unless stimulation and social needs are met.

Children easily associate isolation and restriction with being punished. In a hospital setting, make as few trips as possible in and out of the room to limit the possibility of pathogen spread; on the other hand, do not make care visits seem hurried. If there is a procedure scheduled at 9:00 AM and another at 9:30 AM, stay in the room rather than leave to return again, if possible. Use the time to read a story to the child, play a card game, or talk about how strange and lonely it feels to be separated from other people.

When a child is hospitalized and requires transmission-based infection control precautions, parents must follow these precautions just as all hospital personnel do when they visit. Some parents feel so self-conscious about having to gown and wash they may stay away rather than visit. Making them feel comfortable with these procedures is a nursing responsibility. Remember that when children are admitted to a hospital, parents may not hear everything that is said to them during admission because of their anxiety. If the gowning technique was explained on admission, therefore, do not expect parents to remember the next day what was said. Explain the technique as many times as necessary.

Parents may be reluctant to give children who require transmission-based precautions their favorite toy, thinking that the hospital will insist on destroying it after the precautions are discontinued. Few pathogens exist that are not destroyed by exposure to sunlight, however, and few articles are available that cannot be further gas-sterilized to ensure that pathogens have been removed, so there is no reason to restrict toys. Check the rooms of children requiring transmission-based precautions for favorite toys, therefore, the same as in all rooms. Never leave children in a room before checking that they have a toy to play with or an activity that will keep them busy for the length of time they will be alone. See Chapter 36 for a discussion of interventions that can be used to promote adequate stimulation for a child requiring transmission-based precautions.

VIRAL INFECTIONS

Viruses are the smallest infectious agents known, so small they cannot be seen through an ordinary microscope. They are actually not true cells because they contain either ribonucleic acid (RNA) or deoxyribonucleic acid (DNA), but not both. Because they are incomplete, viruses increase in number by replication inside bacteria, plant, animal, or human cells using the biochemical products of living cells to function. Although a body cell may not be outwardly altered by a virus invasion, it could fail to function or die because of lysis of internal components or rupture. Symptoms usually do not become apparent until many cells have been interrupted in this way, so the incubation period of viral infections can be long. Some viruses are capable of invading only specific cells. The Epstein-Barr virus, for example, invades only B lymphocytes, HIV viruses invade CD4 T lymphocytes, and influenza viruses affect specific receptor sites in tracheal cells.

Viral Exanthems

The majority of childhood exanthems (rashes) are caused by viruses, and each of these diseases has specific symptoms, characteristic lesions, and a specific distribution or pattern to the rash that allows it to be identified (Figs. 43.2 and 43.3).

Exanthem Subitum (Roseola Infantum)

- Causative agent: Human herpesvirus 6 (HHV-6)
- Incubation period: Approximately 10 days
- Period of communicability: During febrile period
- Mode of transmission: Unknown
- Immunity: Contracting the disease offers lasting natural immunity; no artificial immunity is available.

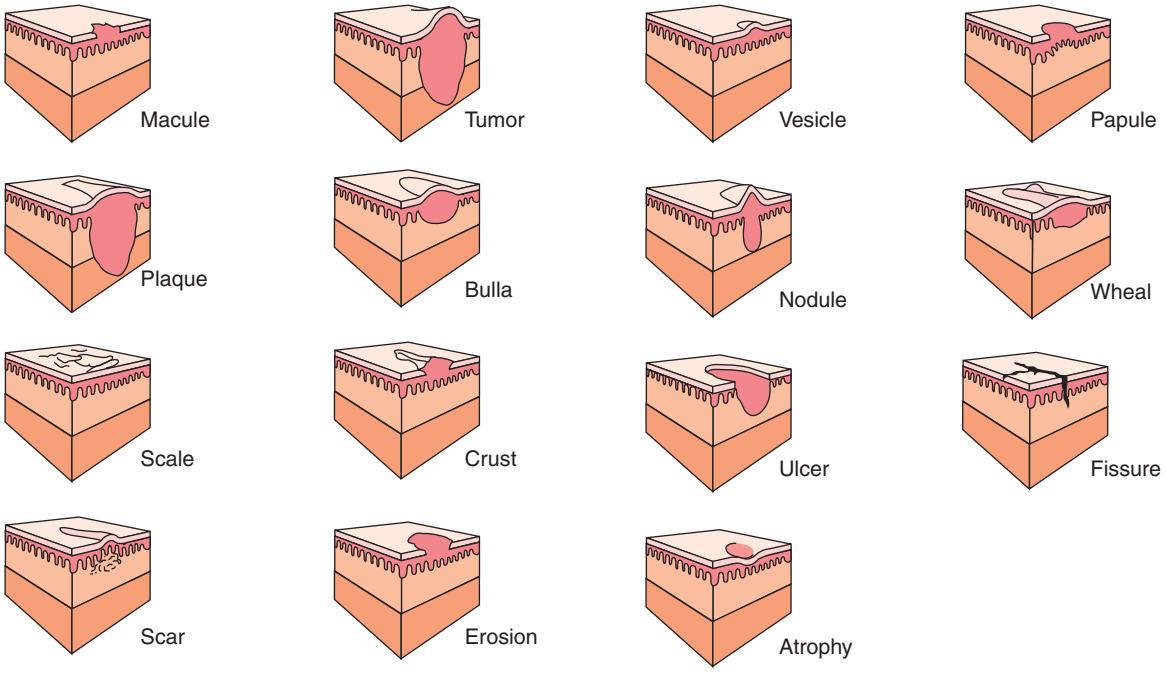


FIGURE 43.2 Primary and secondary skin lesions and their characteristics.

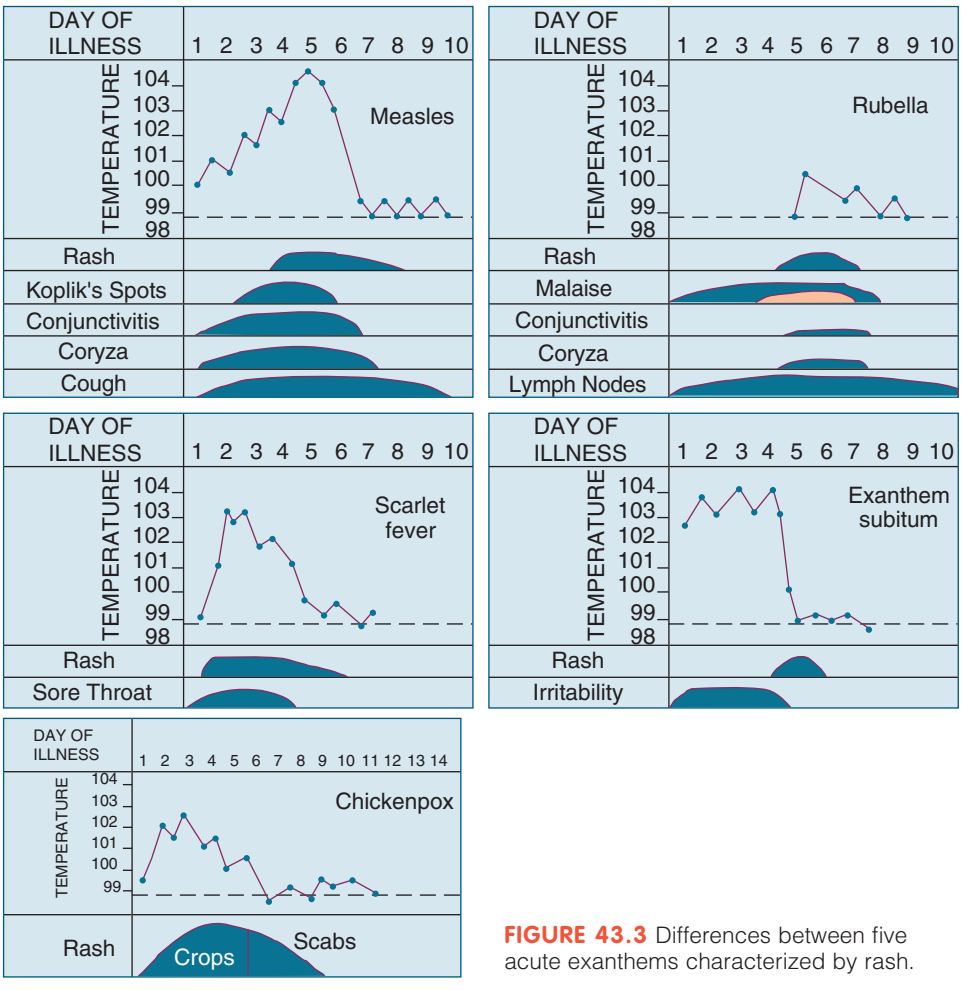

FIGURE 43.3 Differences between five acute exanthems characterized by rash.

Assessment. Roseola is a disease with symptoms that appear to be more severe than is warranted. It generally occurs in children between 6 months to 3 years, mainly in the spring and fall, although it can occur any time of the year. The first symptom is a high fever (104° to 105° F [40.0° to 40.6° C]). Infants may be irritable and anorexic but rarely appear as ill as this high a fever suggests. They usually remain playful and alert. The pharynx may be slightly inflamed. The occipital, cervical, and postauricular lymph nodes may be enlarged. The white blood count is usually decreased, with the proportion of lymphocytes increased.

After 3 or 4 days, the fever falls abruptly and a distinctive rash appears (see Fig. 43.3). The lesions are discrete, rose-pink macules approximately 2 to 3 mm in size. They fade on pressure and occur most prominently on the trunk. The rash resembles that of rubella or measles, but it is darker, and children have no accompanying coryza (upper respiratory symptoms), conjunctivitis, or cough. Because it occurs mainly on the child's trunk, parents may report it as a heat rash. The rash lasts 1 to 2 days. The diagnosis of roseola is based on the physical signs and symptoms. The hallmark of roseola is the appearance of a rash immediately after the sharp decline in fever (Dyer, 2007).

Therapeutic Management. Treatment focuses on measures to reduce the discomfort of the rash and fever. The fever will respond to acetaminophen (Tylenol) or ibuprofen (Motrin), but after 4 hours it is apt to rise again to the high level. The most frequent complication of roseola is a febrile seizure with the onset of the disease because the temperature rises so rapidly. Management of this type of seizure is discussed in Chapter 49.

There are no long-term effects of roseola. If an infant develops this exanthem in the hospital, follow standard infection precautions.

Rubella (German Measles)

- Causative agent: Rubella virus
- Incubation period: 14 to 21 days
- Period of communicability: 7 days before to approximately 5 days after the rash appears
- Mode of transmission: Direct and indirect contact with droplets
- Immunity: Contracting the disease offers lasting natural immunity; a high rubella titer reveals infection has occurred.
- Active artificial immunity: Attenuated live virus vaccine
- Passive artificial immunity: Immune serum globulin is considered for pregnant women.

Assessment. Rubella is a disease rarely seen today, but when it does occur, it affects older school-age and adolescent children; it occurs most commonly during the spring. The symptoms begin with a 1- to 5-day prodromal period, during which children or adolescents have a low-grade fever, headache, malaise, anorexia, mild conjunctivitis, possibly a sore throat, a mild cough, and swollen lymph nodes such as those in the suboccipital, postauricular, and cervical chains (Levin & Weinberg, 2008).

After the 1 to 5 days of prodromal signs, a discrete pink-red maculopapular rash (see Fig. 43.3) begins on the face, then spreads downward to the trunk and extremities. On the third day, the rash disappears. There is generally no desquamation (peeling); if present, it is primarily fine flaking of the skin.

Fever with rubella is not marked, although arthritis (joint pain) with effusion into the joints occurs in some children on the second or third day, lasting as long as 5 to 10 days.

Therapeutic Management. Children need comfort measures for the rash and an antipyretic such as acetaminophen (Tylenol) or ibuprofen (Motrin) for fever or joint pain. If a child develops rubella while in the hospital, follow droplet precautions for 7 days after the onset of the rash in addition to standard infection precautions.

If rubella occurs during pregnancy, it can cause extensive congenital malformation in the fetus (see Chapter 12). Because of this, it can never be considered a simple disease. It is important that girls be immunized against it before they reach child-bearing age (Thilo & Rosenberg, 2008).

Measles (Rubeola)

- Causative agent: Measles virus
- Incubation period: 10 to 12 days
- Period of communicability: Fifth day of incubation period through the first few days of rash
- Mode of transmission: Direct or indirect contact with droplets
- Immunity: Contracting the disease offers lasting natural immunity.
- Active artificial immunity: Attenuated live measles vaccine
- Passive artificial immunity: Immune serum globulin

Assessment. Measles is sometimes called brown or black, regular, or 7-day measles to differentiate it from rubella (German, or 3-day, measles). Like rubella, because of high vaccination rates, it is rarely seen today except for periodic outbreaks that occur in newly underimmunized immigrant populations or an underimmunized college-age population (Muller et al., 2007). The incidence of the disease is highest in the winter and spring.

The disease has a 10- to 11-day prodromal period, during which lymphoid tissue, particularly postauricular, cervical, and occipital lymph nodes, becomes enlarged. Children develop a high fever (103° to 104° F [39.5° to 40.0° C]) and malaise. By the second day of the prodromal period, coryza (rhinitis and a sore throat), conjunctivitis with photophobia (sensitivity to light), and a cough develop. **Koplik's spots** (small, irregular, bright-red spots with a blue-white center point) appear on the buccal membrane. Unfortunately, the coryza of measles is indistinguishable from that of a common cold (nasal congestion, a mucopurulent discharge, and a deep brassy, bronchial cough) when it begins. As a result, many children with measles are diagnosed as having a simple upper respiratory infection at this point.

Koplik's spots distinguish the disease because none of the other exanthems has this finding. They appear first on the buccal membrane opposite the molars and then extend to cover the entire buccal surface (Fig. 43.4). The raised base of the spots may coalesce so that the blue-white centers stand out as grains of salt on the erythematous membrane.

By the fourth day of fever, the rash appears. A deep-red maculopapular eruption begins at the hairline of the forehead, behind the ears, and at the back of the neck and then

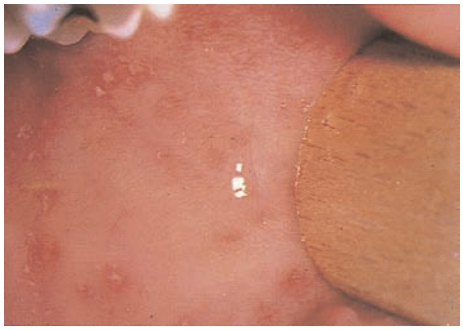

FIGURE 43.4 Koplik's spots on the oral mucous membrane. (SPL/Custom Medical Stock Photograph.)

spreads to the face, the neck, upper extremities, trunk, and finally the lower extremities (Fig. 43.5). After several days, the rash typically turns from red to brown. While the rash is red, it fades on pressure; when it is brown, it does not fade. This differentiates it from the rash of scarlet fever, which always fades on pressure. After 5 to 6 days, the rash completely fades. There is a fine desquamation after this. However, the skin of the hands and feet does not desquamate, a feature again differentiating it from scarlet fever.

Children with measles appear very ill because their cough is loud and frequent, the coryza is acute, the fever is high, and the rash is pruritic. Fortunately, on the third or fourth day of rash, when the temperature begins to fall, the other symptoms clear quickly and children feel better. Fever that lasts beyond the third or fourth day of rash or coughing that continues generally suggests that a complication of measles, such as pneumonia, has occurred.

FIGURE 43.5 The typical rash of measles on a child's upper body. (© NMSB/Custom Medical Stock Photograph.)

Therapeutic Management. Children with measles need comfort measures for the rash and an antipyretic for the fever. The coryza, which does not respond to decongestants, fortunately lasts only a few days. The skin below the nose may become excoriated from the constant nasal drainage. Applying a lubricating jelly or an emollient (A&D ointment) to the area may help prevent excoriation. A child may need a cough suppressant to control the cough; otherwise, the throat can become painful from frequent irritation. Because children with measles have photophobia, it is painful for them to look at bright lights, so it may be painful for them to watch television. They are often more comfortable with the shades or curtains drawn or wearing dark glasses, so these measures should be instituted. Children need to be seen by a health care provider because the complications of measles include otitis media (middle ear infection), pneumonia, airway obstruction, and acute encephalitis (Levin & Weinberg, 2008). If a child is hospitalized, follow airborne precautions for the duration of the illness in addition to standard infection precautions.

Chickenpox (Varicella)

- Causative agent: Varicella-zoster virus
- Incubation period: 10 to 21 days
- Period of communicability: 1 day before the rash to 5 to 6 days after its appearance, when all the vesicles have crusted
- Mode of transmission: Highly contagious; spread by direct or indirect contact of saliva or vesicles
- Immunity: Contracting the disease offers lasting natural immunity to chickenpox; because the same virus causes herpes zoster, it may be reactivated at a later time as herpes zoster (shingles).
- Active artificial immunity: Attenuated live virus vaccine
- Passive artificial immunity: There is little passive placental immunity to chickenpox. Children who are immunosuppressed, such as those with leukemia or HIV/AIDS, or those who are being treated with corticosteroids are given varicella-zoster immune globulin (VZIG). This may prevent or modify chickenpox if given within 72 hours of exposure.

Assessment. Chickenpox is another common childhood infection that is decreasing in incidence because of required immunization. The people most prone to it are those who have not been immunized, such as older children and college students. The disease is marked by a low-grade fever, malaise, and, in 24 hours, the appearance of a rash (see Fig. 43.3). The lesion begins as a macula, then progresses rapidly within 6 to 8 hours to a papule, then a vesicle that first becomes umbilicated and then forms a crust. Each lesion is approximately 2 to 3 mm in diameter and is surrounded by an erythematous area. When the first crop of lesions appears, the child's temperature may rise markedly to 104° or 105° F (40.0° or 40.6° C).

Most of the chickenpox lesions are found on the trunk, although the face, scalp, palate, and neck also may be involved. They appear in approximately three separate series or crops, with each new lesion moving through progressive stages (Fig. 43.6). At one time, all four stages of lesions (macule, papule, vesicle, and crust) are present.

FIGURE 43.6 An older school-age boy with varicella. (© Martin/Custom Medical Stock Photograph.)

Therapeutic Management. If the scabs from crusting are allowed to fall off naturally and lesions do not become secondarily infected, no scarring results. Scabs removed prematurely may leave a white, round, slightly indented scar at the site. For this reason, it is important that children not scratch and remove scabs, but because the rash of chickenpox is extremely pruritic, preventing scratching becomes a difficult problem for parents. A prescribed antihistamine usually helps to reduce the itchiness to a bearable level, and an antipyretic will counteract the high fever. Acyclovir may be prescribed to reduce the number of lesions and shorten the course of the illness (Koo & Shandera, 2009). The development of Reye syndrome has been associated with aspirin use during varicella and influenza virus illnesses (see Chapter 49), so caution parents to avoid aspirin and to use acetaminophen or ibuprofen to control fever instead.

If the child is hospitalized, follow airborne and contact precautions until all lesions are crusted, in addition to standard infection precautions. Children may return to school as soon as all the lesions are crusted (the crusts are not infectious). Complications include secondary infections of the lesions, pneumonia, and encephalitis.

Herpes Zoster

Herpes zoster is caused by the varicella-zoster virus, the same virus that causes chickenpox (Weinberg, 2007). Apparently, the first time the virus invades, children have symptoms of chickenpox. With a second invasion, herpes zoster symptoms appear due to reactivation of a latent virus. Herpes zoster tends to occur in older children or young adults, although it can occur at any age.

The first manifestations are pruritus and cutaneous vesicular lesions on erythematous bases that follow the distributions of the lumbar and thoracic nerves (usually on the trunk, face, or upper back) and cause deep nagging pain (Fig. 43.7).

Treatment for herpes zoster includes measures to reduce pruritus and analgesia for pain. Acyclovir, which inhibits viral DNA synthesis, may be effective in limiting the disease. VZIG may minimize symptoms.

Smallpox (Variola)

- Causative agent: Smallpox virus
- Incubation period: 7 to 17 days
- Period of communicability: From onset of rash until all crusts have been shed
- Mode of transmission: Direct or indirect contact
- Immunity: Lasting natural immunity after contracting the disease
- Active artificial immunity: No longer recommended
- Passive artificial immunity: Vaccinia immune globulin (VIG)

Smallpox is a disease that has been extinct in the world since 1995. However, health care providers need to be able to recognize symptoms of it because viruses, colonies of which are stored in various laboratories throughout the world, could be used as an agent of biologic terrorism.

The disease has a 3- to 4-day prodromal period of chills, fever, headache, and vomiting. A child appears extremely ill and exhausted. On day 3 or 4, a rash and high fever appear. The lesions, most prominent on the distal extremities and face, begin as macules, then progress to papules, vesicles, and pustules, eventually crusting over a 10- to 14-day period.

Although the lesions of smallpox resemble those of chickenpox, they can be differentiated by the appearance of the pustular stage (not seen with chickenpox) and the fact that they arise as one crop of lesions and all progress at the same rate (chickenpox occurs in stages). The crusts of chickenpox are not contagious; the crusts of smallpox are (Berger, 2009).

FIGURE 43.7 Herpes zoster on a child's back. (© Dr. P. Marazzi/SPL/Science Source/Photo Researchers.)

Smallpox is a serious illness: its mortality rate is as high as 50% and it can be spread readily from one infected person to another. Children are treated with VIG to suppress symptoms and an antibiotic to prevent secondary infection of lesions. They may need oxygen or other measures to support respiratory function and measures such as a cardiac glycoside to support cardiac function.

✔ Checkpoint Question 43.1

If a smallpox epidemic should occur, it will be important to be able to distinguish chickenpox (varicella) from smallpox. What are the stages of chickenpox lesions?

a. Macular, papular, vesicular, and crusting.
b. Macular, crusting, and extensive peeling.
c. Papular, vesicular, and pruritic crusting.
d. Maculopapular lesions with fine flaking.

Erythema Infectiosum ("Fifth Disease")

- Causative agent: Parvovirus B19
- Incubation period: 6 to 14 days
- Period of communicability: Uncertain
- Mode of transmission: Droplet
- Immunity: None

Assessment. Erythema infectiosum (the fifth important childhood exanthem) occurs most often in children 2 to 12 years of age. The first phase of the infection includes fever, headache, and malaise. A week later, a rash, which erupts in three stages, appears. The rash is intensely red and appears first on the face. The lesions are maculopapular and coalesce on the cheeks to form a "slapped face" appearance (Fig. 43.8). The facial lesions fade in 1 to 120 days (Servey, Reamy, & Hodge, 2007).

A day after the facial lesions appear, a rash appears on the extensor surfaces of the extremities. One day later, the rash appears on the flexor surfaces and the trunk. These lesions last for 1 week or more. When they fade, they fade from the center outward, giving the lesions a lacelike appearance. After the rash has faded, it may reappear if precipitated by skin irritation such as trauma, sunlight, hot, or cold. Some children develop a persistent arthritis.

Therapeutic Management. Treatment is typically supportive, with antipyretics and analgesics. Children also may need additional comfort measures for the rash (see Box 43.5). There are no known complications of fifth disease for a child; it is teratogenic in a fetus, however, so children with this disorder should avoid contact with pregnant women. Use droplet precautions in a hospital. Children can return to school as soon as the rash appears because they are no longer infectious after this point.

What if... Marty's parents tell you their doctor is ruling out fifth disease? What are the other four diseases that gave this disease its name?

Pityriasis Rosea

- Causative agent: Probably a virus, possibly herpesvirus 6 or 7
- Incubation period: Unknown
- Period of communicability: Unknown
- Mode of transmission: Unknown
- Immunity: Apparently none

Pityriasis rosea occurs in school-age and older children. Children may have a short, mild prodromal period of fever and sore throat. A herald patch, an erythematous round lesion with a scaly border, usually appearing on the trunk, is the first obvious lesion (Fig. 43.9). Approximately 1 week after the appearance of the herald patch, a generalized rash of papules, vesicles, or urticaria appears. This is generally also confined to the trunk. The rash follows skin lines, giving it the unique configuration of a Christmas tree (Morelli & Burch, 2008).

The rash lasts 6 to 8 weeks. It is pruritic and, because it lasts so long, is particularly worrisome to children and parents. Because the lesions, particularly the herald patch, are scaly at the edges, they are often confused with tinea corporis (ringworm). Treatment is limited to oral antihistamines and other comfort measures for rash.

Pityriasis rosea appears to have no sequelae or complications; in fact, it is difficult to demonstrate in what manner it is infectious. It is a baffling rash of childhood but needs to be differentiated from serious (severe) exanthems.

Enteroviruses

There are three main types of enteroviruses: echoviruses (33 subdivisions), coxsackievirus A (24 subdivisions) and coxsackievirus B (6 types), and polioviruses (3 subdivisions).

Echovirus Infections

The echoviruses are responsible for several childhood diseases, including aseptic meningitis, diarrhea, acute respiratory illness, and maculopapular rashes. Such infections are usually benign and self-limiting. Treatment involves supportive measures. If a child is hospitalized, follow contact precautions for the duration of the illness, in addition to standard infection precautions.

Coxsackievirus Infections

The coxsackievirus groups are responsible, like the echovirus groups, for a variety of diseases. One of the most frequently found diseases of children caused by coxsackievirus A is herpangina. With herpangina, children have an abrupt elevation of temperature, up to 104° or 105° F (40.0° or 40.6° C) for 1 to 4 days. Anorexia, difficulty swallowing, sore throat, and vomiting may be present. Children may have headache and abdominal pain. Small lesions, generally discrete grayish vesicles, pinpoint in size, appear on the tonsillar fauces, soft palate, and uvula (Koo & Shandera, 2009). Lesions may be present elsewhere in the mouth or throat as well. The lesions gradually change to shallow ulcers surrounded by a red areola. They disappear within a few days after the temperature returns to normal. There are generally no complications.

Children need to be maintained on soft or liquid foods while their mouth and throat are sore. They may need an antipyretic for fever. If a child is hospitalized, follow contact precautions for the duration of the illness, in addition to standard infection precautions.

Poliovirus Infections: Poliomyelitis (Infantile Paralysis)

- Causative agent: Poliovirus
- Incubation period: 7 to 14 days
- Period of communicability: Greatest shortly before and after onset of symptoms, when virus is present in the throat and feces (1 to 6 weeks)
- Mode of transmission: Direct and indirect contact
- Immunity: Contracting the disease causes active immunity against the one strain of virus causing the illness.
- Active artificial immunity: Inactivated polio virus vaccine (IPV)
- Passive artificial immunity: None

Polio is Greek for "gray," the color of the spinal cord after it atrophies from the effect of the poliomyelitis virus. No longer seen in the United States thanks to effective vaccination programs, poliomyelitis may be caused by any of the three strains of poliovirus, the rationale for immunizing children with the trivalent (three-strain) vaccine. Poliomyelitis still does occur in other parts of the world, and in war-torn or developing nations such as India and parts of Africa, the incidence is still high.

Assessment. The poliovirus enters the child's gastrointestinal tract, where it multiplies and produces symptoms such as fever, headache, nausea, vomiting, or abdominal pain. Moderate pain of the neck, back, and legs soon develops. The cerebrospinal fluid shows increased protein and lymphocytes.

These initial symptoms are followed by intense pain and tremors of the extremities and then paralysis, occurring either immediately or over a period of 1 to 7 days as the virus invades the central nervous system. Kernig's sign, a test for meningeal irritation, is positive (see Chapter 49). Children demonstrate a tripod sign—when sitting on the floor or on an examining table, they cannot sit without placing both the arms and hands behind them to brace themselves. Their deep tendon reflexes are hyperactive at first and then diminish as the central nervous system is fully invaded. Laryngeal paralysis makes swallowing or talking difficult, and respiratory paralysis can halt respiration (National Immunization Program, 2008).

Therapeutic Management. Treatment for poliomyelitis is bedrest with analgesia and moist hot packs to relieve pain. If the respiratory muscles are involved, long-term ventilation is necessary. Survivors tend to develop progressive muscle atrophy (postpoliomyelitis muscular atrophy syndrome) or severe arthritis in late adulthood, further reducing their ability to be self-sufficient (Sheth & Keenan, 2007).

Viral Infections of the Integumentary System

Viral infections of the skin include the herpes infections and warts (verrucae).

Herpesvirus Infections

Herpesviruses are responsible for several infections in children.

- Causative agent: Herpes simplex or herpes type 1 or type 2 virus
- Incubation period: 2 to 12 days
- Period of communicability: Greatest early in the course of the infection
- Mode of transmission: Direct contact
- Immunity: Immunity to a primary herpes response is gained after one incident. There is no immunity to recurrent herpes infections because the virus lies dormant in the body until it is activated by stress, sun exposure, fever, other illness, or menstruation.

About 30% of children in the United States are or have been infected by the herpes virus (Lauri, 2007). When children are first invaded by a herpesvirus, they have no antibodies against the virus, so a primary form of the disease such as herpetic gingivostomatitis occurs. The virus remains latent in the neurons of local sensory ganglia, or children become permanent carriers of the herpes simplex virus.

Acute Herpetic Gingivostomatitis. Acute herpetic gingivostomatitis is the most common form of herpes simplex invasion in young children (Berger, 2009). It is an example of the primary, not the recurrent, response. It occurs in children aged 1 to 4 years. Children have a high fever (104° to 105° F [40.0° to 40.6° C]), are restless, and have anorexia and a sore mouth. Their gumline is swollen and reddened and bleeds easily. White plaques or shallow ulcers with red areolae appear on the buccal mucosa, tongue, and palate and perhaps on the tonsillar fauces. The anterior

cervical lymph nodes are enlarged and tender. The disease runs its course in 5 to 7 days.

Children need an antipyretic to reduce fever. They also need soft, acid-free foods that they can eat with minimal irritation or abrasion. Popsicles are soothing against inflamed mucous membranes. Oral acyclovir helps with healing. Use contact precautions with hospitalized children.

Children with gingivostomatitis appear very ill. The disease can become very serious, especially in infants, if their mouths become so sore that they cannot swallow readily and they become malnourished and dehydrated.

Herpes Simplex (Herpes Labialis). Herpes simplex infection, popularly known as a cold sore or fever blister, represents the recurrent form of a type 1 herpesvirus invasion that has remained dormant in the ganglia of the trigeminal or fifth cranial nerve. Herpes simplex typically appears as clusters of painful, grouped vesicles surrounded by an erythematous base on the lips or skin surrounding the mouth. After 2 or 3 days, vesicles crust, then gradually dry. Keeping lesions dry helps them to fade sooner, but keeping them lubricated with an ointment reduces pain. Topical or oral acyclovir reduces pain and increases healing. Children feel conspicuous about the appearance of herpes simplex lesions. They may need counseling to assure them that the lesions are not as obvious to others as they seem to them (Berger, 2009).

Acute Herpetic Vulvovaginitis (Genital Herpes). Genital herpes is caused by the herpesvirus type 2, which remains dormant in the ganglia of the sacral nerves. Because this form is spread primarily by sexual contact, it is discussed in Chapter 47 with other STIs. The occurrence of this in a young child suggests child sexual abuse (Reading & Rannan-Eliya, 2007).

Warts (Verrucae)

Warts, one of the most common dermatologic diseases in children, are caused by the papillomavirus. The virus has an incubation period of 1 to 6 months. The mode of transmission is unknown, but it is probably by direct contact (Androphy & Lowy, 2008).

Warts are flesh-colored, dirty-appearing papules. They generally occur on the dorsal surface of the hands, although they may occur anywhere. Plantar warts appear on the soles of the feet and are painful when children walk. They may be differentiated from calluses in that they obliterate skin lines as they grow, whereas calluses do not.

Warts on the hands or the face are generally removed if they are cosmetically unattractive to children. Plantar warts may have to be removed because of the discomfort they cause. Parents can use over-the-counter wart-removing preparations, such as Compound W, to dissolve them. Application of 40% salicylic acid may be prescribed to remove plantar warts. Carbon dioxide snow, liquid nitrogen, electrodesiccation, and curettage are also effective for removal, but these methods are painful and rarely necessary.

Children need reassurance that people do not catch warts from frogs or toads and even if left without any treatment, warts will eventually fade by themselves after about 24 months. Anogenital warts need special consideration as they can be a mark of sexual abuse (Reading & Rannan-Eliya, 2007).

Viruses Causing Central Nervous System Diseases

Viruses are responsible for causing several central nervous system disorders such as rabies, encephalitis, and meningitis. Encephalitis and meningitis are discussed in Chapter 49.

Rabies

- Causative agent: Rabies virus
- Incubation period: 2 to 6 weeks, possibly as long as 12 months
- Period of communicability: 3 to 5 days before the onset of symptoms through the course of the disease
- Mode of transmission: The bite of rabid animals; rarely through saliva from infected animals being transferred to open lesions on a child's skin
- Immunity: Contracting the disease apparently offers active immunity, but few people have ever survived the illness to verify this.
- Active artificial immunity: Human diploid cell rabies vaccine
- Passive artificial immunity: Rabies immune globulin (RIG)

Any warm-blooded animal can contract rabies. Wild animals, such as skunks, squirrels, raccoons, and bats, constitute the most important sources of infection from rabies in the United States. However, children receive more bites and, therefore, more treatments for rabies from bites of dogs or cats. Bites of rodents are seldom found to be rabid. Bites from other children are not rabid, although therapy is required because such bites usually contain streptococci. In the animal infected with rabies, the virus can be cultured from the central nervous system, saliva, urine, lymph, and blood. When a child is bitten by an infected animal, the virus migrates from the bite area to the child's central nervous system. Cranial nerve and spinal cord nuclei become acutely damaged. Negri bodies (cytoplasmic inclusion bodies) can be isolated from nerve cells for diagnosis (Fishbein, 2008).

Assessment. The diagnosis of rabies is established largely from the history of an animal bite and the clinical symptoms. After the long incubation period of the virus, children begin to show prodromal signs of malaise, fever, anorexia, nausea, sore throat, drowsiness, irritability, and restlessness. They may notice numbness or hyperesthesia at the area of the bite and along the course of the involved nerves. The white blood cell count will show slight leukocytosis. The cerebrospinal fluid is usually normal, with perhaps only a slight elevation in protein and cells. As the symptoms increase, there is high fever, anxiety, and hyperexcitability. Involuntary twitching movements and generalized seizures may occur. When children try to drink, there are violent contractions of the muscles of the mouth. They may drool saliva rather than swallow it because swallowing is extremely painful. These two phenomena give the disease its popular name, hydrophobia ("water-fear") (Shandera & Corrales-Medina, 2009).

As symptoms progress, children become comatose, with possible total body paralysis. Peripheral vascular collapse and death follow quickly in only 5 or 6 days. Postmortem examination will reveal the diagnostic Negri bodies in brain cells.

Therapeutic Management. Once the disease process begins, rabies is almost invariably fatal. The key is preventing the active process. All children who receive an animal bite should be seen by a primary care provider to evaluate the circumstances surrounding the bite and to decide whether to begin rabies prevention measures. The decision to treat must be made immediately if treatment is to be effective.

Taking a history of the incident to determine the type of animal is of primary importance. Most children are sure they know the type of animal if it was a dog; they may be unsure if it was a wild animal. Do not lead children into naming an animal just to please. If asked, "Was it a skunk? A raccoon? A squirrel?" children may choose an animal name because they think that is the answer expected. Instead, ask children to describe the animal; from that description, establish the kind of animal that bit the child. It helps in rural health facilities to have a picture book of animals handy so that preschoolers, in particular, can identify the animal that bit them. A rabid animal usually does not act normally. It runs blindly, often staggering; it may dribble saliva rather than swallow it. It is easy to assess whether a household pet is acting this way. It is sometimes difficult to assess the actions of a wild animal because the fear it experiences at being trapped or cornered may make it run about frantically.

An unprovoked attack is highly suggestive that the animal is rabid, rather than if the bite happens during a provoked attack. Let children know that they will not be punished if they were provoking an animal so they feel free to say so. Statements such as "I was only hugging him" or "I was just feeding him" may sound innocent but may have constituted a provoked attack to the animal.

The kind of wound that a child receives also is instrumental in deciding whether to begin treatment. A bite mark is much more serious than a scratch from an animal's claws. The immunization status of the animal should be checked if available. Whether rabies exists in the community at the time of the attack will also influence the decision. An animal that has been properly immunized against rabies will rarely transmit the virus. If there have been no other reported instances in domestic animals, the chance that this dog bite is serious in terms of rabies is lower than if dogs with rabies have been reported in the area.

Inspect the wound carefully to see whether it was caused by teeth marks or scratch marks. Wash the wound well with an antiseptic. If puncture wounds are present, the wound must not be sutured and closed, because tetanus (organisms that are anaerobic and grow in deep, closed wounds, where oxygen does not reach) can develop in the wound. The animal that caused the bite should be located if possible and then confined for 5 to 10 days. If it develops any signs of rabies during this period, it will be destroyed and the brain examined for evidence of rabies. Domestic animals are not destroyed unless they show signs of rabies; if people are unaware of this, they may resist surrendering an animal for observation.

If the animal is found to be rabid, children receive both rabies vaccine and antirabies serum (RIG). This applies also if the animal escapes and its condition is unknown (it is assumed to be rabid). A portion of the RIG dose is injected into the wound site and the remainder is given intramuscularly. Antirabies vaccine is given immediately and then again on days 3, 7, 14, and 28 (Fishbein, 2008).

It may seem contradictory to give an active immunization serum (administering antigen to children) when they have received an animal bite (which administers antigen to them). This is done because the rabies virus has a long incubation period before antibody production is stimulated; administering RIG provides antibodies against the rabies virus immediately. Administering rabies vaccine allows the child to begin additional antibody formation so that by the time the rabies virus from the bite begins to have an effect (2 to 6 weeks after the bite), the child has developed sufficient antibodies to combat it and prevent the illness.

West Nile Virus Disease

Although the West Nile virus may be transmitted by contaminated blood products, it is usually spread by the bite of a mosquito after the mosquito has bitten, and acquired the infection from, a natural host such as an infected bird (CDC, 2007).

Fortunately, most children who contract the disease remain asymptomatic. A small number develop flulike symptoms such as fever, fatigue, and malaise. A few develop encephalitis, with symptoms such as mental confusion, lethargy, photophobia, headache, muscle weakness, and coma, leading to death. West Nile virus disease is diagnosed when antibodies to the virus are recovered from blood serum. There is no specific therapy for the disorder, except for supportive measures to maintain function.

Parents can help prevent the spread of West Nile disease in several important ways:

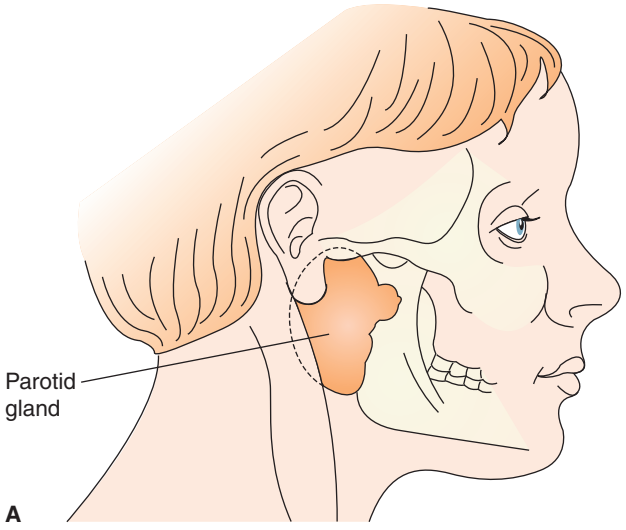
- Urge children to wear long sleeves and pants to avoid mosquito bites.
- Have children apply insect repellent with DEET if hiking near swampy areas where mosquitoes may breed.
- Urge children to avoid outside activities between dusk and dawn, when mosquitoes are most likely to bite.
- Empty potential stagnant water sources, such as bird baths, to prevent mosquitoes from breeding close to the house.

Other Viral Infections

Mumps (Epidemic Parotitis)

- Causative agent: Mumps virus
- Incubation period: 14 to 21 days
- Period of communicability: Shortly before and after onset of parotitis
- Mode of transmission: Direct or indirect contact
- Immunity: Contracting the disease gives lasting natural immunity.
- Active artificial immunity: Attenuated live mumps vaccine
- Passive artificial immunity: Mumps immune globulin

Assessment. Mumps is now a rare disease in the United States due to successful immunization programs. It is most likely to be seen in adolescents who have not been immunized. If the disease occurs, it begins with fever, headache, anorexia, and malaise. Within 24 hours, an "earache" occurs. When the child points to the site of the pain, however, the child points, not to the ear, but to the jawline just in front of the ear lobe. Chewing movements aggravate the pain. By the next day, the parotid gland (located just in



B

FIGURE 43.10 Infectious parotitis. (**A**) The parotid gland is located just in front of the ear. (**B**) A boy with parotitis (mumps). (© Morris Huberland/Science Source/Photo Researchers.)

front of the earlobe) is swollen and tender. As the parotid gland swells, it displaces the ear upward and backward. Boys also may develop testicular pain and swelling (orchitis).

It is often difficult to differentiate mumps from submaxillary adenitis (swelling of lymph nodes). The best method of differentiation is to place a hand along the child's jaw line. If the major amount of swelling is above the hand, it is probably mumps. If the largest amount of swelling is below the hand line, it is probably adenitis (Fig. 43.10).

Therapeutic Management. Because chewing movements are so painful, children may need soft or liquid foods until the major portion of the swelling recedes (about 6 days). It is also more difficult for them to swallow sour foods than sweet ones. They may need an analgesic for pain and an antipyretic for fever. If a child is hospitalized, follow droplet precautions in addition to standard infection precautions. Children are still infectious for at least 5 days after symptoms appear so shouldn't return to school until this time (Levin & Weinberg, 2008).

One attack of mumps gives lasting immunity. Some parents worry that because their child has swelling only on one side, the child will develop mumps on the opposite side in the future. If a child does appear to have mumps twice, the diagnosis was probably confused with cervical adenitis one of the two times.

Mumps is a potentially serious illness because several serious complications can occur. If mumps orchitis develops, it is generally unilateral. A single testis swells rapidly and is painful and tender. When the fever declines, testicular swelling also decreases, although the tenderness may exist for weeks. Atrophy of the testis may result leading to a low sperm count. The chance that mumps orchitis will lead to complete sterility is exaggerated, however (Butel, 2007).

The complication of meningoencephalitis occurs in a few children. Severe permanent hearing impairment is a rare complication that may occur because of neuritis of the auditory nerve.

✔ Checkpoint Question 43.2

Which is the best description of mumps (infectious parotitis)?

a. Cervical lymph nodes become swollen.
b. Swelling behind the child's ear occurs.
c. Swelling above the jaw line occurs.
d. The adenoid tonsils are red and swollen.

Infectious Mononucleosis

- Causative agent: Epstein-Barr virus
- Incubation period: Unknown; probably 2 to 8 weeks
- Period of communicability: Unknown; probably only during acute illness
- Mode of transmission: Direct and indirect contact
- Immunity: One episode apparently gives lasting immunity. No vaccination is available.

Infectious mononucleosis is also known as glandular fever or, because it was first discovered as a disease that is transferred readily from one person to another by kissing, the *kissing disease*. It occurs most commonly in adolescents and young adults, although it may occur in any age child (Butel, 2007).

Assessment. The beginning symptoms include chills, fever, headache, anorexia, and malaise. Children develop enlarged lymph nodes and a severe sore throat. The fever is generally high (103° F [39.5° C]) and lasts approximately 6 days.

The cervical lymph nodes, most markedly affected, feel firm and tender. The tonsils feel painful and are enlarged and erythematous. A thick, white membrane may cover the ton-

FIGURE 43.11 Appearance of the tonsils in a child with infectious mononucleosis. Note the degree of erythema, enlargement, and purulent covering. (© Dr. P. Marazzi/SPL/Science Source/Photo Researchers.)

sils and often petechiae appear on the palate (Fig. 43.11). If the mesenteric lymph nodes enlarge, children may experience abdominal pain so sharp it simulates appendicitis. The spleen enlarges, placing the child at risk for spontaneous rupture. Hepatitis, a maculopapular eruption similar to the rash of rubella, pneumonitis, and central nervous system involvement such as encephalitis, meningitis, or polyneuritis may occur.

Lymphocytosis, or lymphocytes representing more than 50% of the total white blood cell count, occurs. Of these lymphocytes, a significant number (more than 20%) are atypical; they are larger-than-normal, mature lymphocytes, and their nuclei are somewhat less dense. A serologic test, known as the heterophil antibody test, is based on the fact that the antibody produced in infectious mononucleosis will agglutinate sheep red blood cells. A technique known as the Monospot test has also been developed, using horse red blood cells. This test can be performed in minutes. A positive test, along with the increased number of atypical lymphocytes apparent on a blood slide, confirms the diagnosis of infectious mononucleosis. Epstein-Barr virus antibodies can be recovered from blood serum for a final diagnosis.

Therapeutic Management. Children with infectious mononucleosis need bedrest during the acute stage of the illness (7 to 10 days) because with the splenomegaly there is a danger of spleen rupture with any trauma to that area. If a child is hospitalized, follow standard infection precautions. Be careful in helping children with this disease turn in bed so that no pressure is placed over the splenic area. If palpating the spleen, do so gently to avoid inadvertent rupture.

Teach children and parents the importance of maintaining a good fluid intake despite the sore throat. Cool, nonacidic fluids are often tolerated best.

Neurologic complications such as meningitis or encephalitis may occur. Children may notice weakness and general fatigue for up to 6 weeks after the illness. Caution them to avoid contact sports as long as their spleen is enlarged. Because infectious mononucleosis occurs primarily in young adults, it may interrupt school or career plans. Help these young adults to voice their frustration with this illness. Offer support to help them through this unexpected interruption in their life.

✔ Checkpoint Question 43.3

For a child with infectious mononucleosis, why must abdominal palpation be performed gently?

a. Regional lymph nodes are painful.
b. The enlarged spleen can rupture.
c. Red cells pocket just under the skin.
d. Petechiae form easily from bruising.

Hantavirus Pulmonary Syndrome Infection

The hantavirus is a member of the arbovirus group. The virus infects small rodents and perhaps cats who have eaten mice. In the Far East, the virus produces an illness marked by extreme purpura from thrombocytopenia and severe gastrointestinal symptoms. In 1993, an outbreak of severe illness from a previously undiscovered hantavirus occurred in the United States. Outbreaks continue to occur sporadically. Major symptoms are fever, muscle aches, thrombocytopenia, gastrointestinal symptoms, and hypotension. Death can occur from rapid progressive pulmonary edema.

Supportive care is necessary, as antiviral medications do not seem to be effective (Koo & Shandera, 2009). Caution families not to touch dead mice and to have mice exterminated from their homes to avoid the possibility of contracting this disease.

BACTERIAL INFECTIONS

Bacteria reproduce by fission, in which one cell enlarges and duplicates itself, then divides into two equal parts. They are usually single-celled organisms occurring in three main shapes: spheres (cocci), rods (bacilli), and spirals (spirochetes). Bacteria are independent, living organisms. They have a nucleus, cytoplasm, and a cell wall, and they contain both DNA and RNA.

Bacteria are most commonly observed under a microscope after being fixed to a slide by heating followed by staining. Bacteria that stain violet are gram-positive organisms; those that stain red are gram-negative organisms. Those that cannot be decolorized with acid after being stained are acid-fast. As some bacteria grow, they produce **exotoxins,** or poisons. If this happens, disease symptoms arise not from the bacteria itself but from the effect of these toxins on the body. Tetanus, botulism, and diphtheria are diseases caused by the systemic spread of toxins produced by bacteria.

Some bacteria are capable of producing enzymes as they grow. Hemolytic streptococci, for example, produce streptokinase, which enables the bacteria to pass through blood clots. Penicillinase, an enzyme produced by certain bacteria, can destroy penicillin. Many first-generation penicillins are therefore ineffective against such organisms.

Streptococcal Diseases

Streptococci, gram-positive organisms, are found normally in the respiratory, alimentary, and female genital tracts. Most severe diseases in children result from infection with

Streptococcus pyogenes (beta-hemolytic streptococci, group A). Beta-hemolytic, group B streptococcal infection can be contracted from vaginal secretions at birth (see Chapter 26) and so tends to occur in newborns. Streptococcal pharyngeal infection is discussed in Chapter 40 with other throat infections. Rheumatic fever and glomerulonephritis, conditions that may result as an autoimmune response to streptococci, are discussed in Chapters 41 and 46, respectively.

Scarlet Fever

- Causative agent: Beta-hemolytic streptococci, group A
- Incubation period: 2 to 5 days
- Period of communicability: Greatest during acute phase of respiratory illness; 1 to 7 days
- Mode of transmission: Direct contact and large droplets
- Immunity: One episode of disease gives lasting immunity to scarlet fever toxin. No vaccination is available.

Assessment. Scarlet fever occurs most commonly in the 6- to 12-year-old age group, although it may be seen in preschoolers. The incidence is highest in temperate climates, and the disease occurs usually in late winter or early spring.

The symptoms of scarlet fever begin abruptly and are those of a streptococcal pharyngitis: fever, sore throat, perhaps headache, chills, and malaise. As the beta-hemolytic, group A streptococcus grows in the child's body, it produces several toxins; erythrogenic toxin is the one responsible for the rash of scarlet fever. The rash appears 12 to 48 hours after the onset of the pharyngeal symptoms (see Fig. 43.3). The fever is high (103° to 104° F [39.5° to 40.0° C]) on the first day of throat symptoms and again on the day the rash appears, and then gradually returns to normal. The pulse rate may be increased out of proportion to the fever.

The rash of scarlet fever is both enanthematous and exanthematous (on both mucous membrane and skin). The tonsils are inflamed and enlarged and usually covered with white exudate. The uvula and pharynx are beefy red. The palate is usually covered with erythematous punctiform (pinpoint) lesions and perhaps scattered petechiae. The tongue, during the first 2 days of the illness, is white and appears furry. By day 3, papillae enlarge and protrude through the white coat, giving the tongue a "white strawberry" appearance. By day 4 or 5, the white coat disappears and the prominent papillae of the tongue give it a "red strawberry" appearance. A "strawberry tongue" is distinctive for scarlet fever and helps to differentiate the disease from other rashes. A throat culture reveals streptococci.

The skin rash is typically red, pinpoint lesions that blanch on pressure and feel as rough as sandpaper. Lesions are densest on the trunk and in skin folds. Few lesions appear on the face. The area around the mouth tends to be abnormally pale (circumoral pallor). There are areas of hyperpigmentation in skin folds at the joints (Pastia's sign). The rash persists for approximately 1 week. It desquamates, with large areas of skin peeling off in fine flakes.

Therapeutic Management. Children with scarlet fever usually appear ill. They need a soft or liquid diet for a few days until their throat soreness has diminished. They may need an analgesic and antipyretic, such as acetaminophen (Tylenol) or children's ibuprofen (Motrin) for pain and fever. The rash of scarlet fever tends to be pruritic, so comfort measures are necessary. Because the underlying cause of the illness is a streptococcal infection, a course of penicillin is prescribed (Travers & Mousdicas, 2008). Caution parents to give the full amount prescribed for the full course to prevent the complications of beta-hemolytic, group A streptococcal infections (acute glomerulonephritis or rheumatic fever). If a child is hospitalized, follow droplet precautions until 24 hours after therapy is started, in addition to standard infection precautions (see Box 43.4).

Children who receive penicillin may not develop the typical extreme rash and do not have as severe a systemic illness as those who do not receive penicillin. As a result, scarlet fever is currently popularly termed scarlatina (a small, scarlet rash). Caution parents that regardless of the name, the consequences can be grave and penicillin therapy is necessary (see Focus on Nursing Care Planning Box 43.6).

✔ Checkpoint Question 43.4

Marty has developed scarlet fever. What is the mark of scarlet fever lesions?

a. They appear on skin and mucous membranes.
b. The crusts that form are mildly contagious.
c. The lesions weep a clear, sticky fluid.
d. Lesions are dark brown to black.

Impetigo

- Causative agent: Beta-hemolytic streptococcus, group A (nonbullous); *Staphylococcus aureus* (bullous)
- Incubation period: 2 to 5 days
- Period of communicability: From outbreak of lesions until lesions are healed
- Mode of transmission: Direct contact with lesions
- Immunity: None

Impetigo is only mildly infectious because it seems to be transmitted only by direct contact (Cole & Gazewood, 2007). It is not uncommon to see several children in a family with identical lesions, however. Parents may be upset at being told their child has impetigo because at one time the lesions (dirty and crusty-appearing) were associated with poverty and poor hygiene.

Assessment. Impetigo is a superficial infection of the skin. It begins as a single papulovesicular lesion surrounded by localized erythema. As more vesicles appear, they become purulent, ooze, and form honey-colored crusts (Fig. 43.12). They are found most commonly on the face and extremities. They are often seen as secondary infections of insect bites or in children who have body piercings. If there are several lesions, children may have local swollen lymph nodes.

Therapeutic Management. Treatment is oral administration of penicillin or erythromycin or the application of mupirocin (Bactroban) ointment for 7 to 10 days (Box 43.7). The lesions heal most quickly if a parent or the child washes the crusts daily with soap and water.

Although rare, complications of rheumatic fever or acute glomerulonephritis may occur after impetigo, as they may after other streptococcal infections. If a child develops impetigo while in the hospital, follow contact precautions until 24 hours after initiation of therapy.

(text continues on page 1279)

BOX 43.6 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Hospitalized Child With Scarlet Fever

Marty, a 10-year-old boy, was admitted to the hospital for appendicitis. The morning after surgery, his throat was painful and his arms were covered by a very itchy, red, macular rash. Marty was diagnosed as having scarlet fever. "How could this have happened?" his mother asks you. "He's not a bad kid. How could two bad things happen to him at once?"

Family Assessment ✻ Child has two siblings: a 6-year-old brother and a 10-day-old newborn. Parents are migrant crop workers. Move yearly from Florida to Connecticut to follow crops. Mother rates finances as: "We have no money."

Client Assessment ✻ Macular, pinpoint erythematous rash on abdomen, groin folds, and chest. Lesions blanch with pressure. Groin fold areas hyperpigmented. Child scratching lesions constantly. Uvula and pharynx beefy red. Tonsils inflamed and enlarged with white exudate. Temperature 103° F (39.5° C). Pinpoint lesions with two or three scattered petechiae noted on palate. Tongue white and furry. Throat culture positive for streptococcus. Other physical examination findings within normal limits for postoperative course. Child upset and crying. "I wish my Mom was here to stay with me. I'm all by myself. I can't even go to the playroom." Mother usually visits once a day in the late afternoon.

Nursing Diagnosis ✻ Social isolation related to required restrictions associated with infection control precautions

Outcome Evaluation ✻ Child states reason for restrictions; identifies time when restrictions will be lifted; expresses interest in activities proposed.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Assess what child understands about how communicable diseases are spread.	Explain the reasons for restrictions and infection control precautions. Institute droplet precautions.	Child may associate precautions and restrictions with feelings of being punished. Droplet precautions help reduce the spread of the disease.	Child states he understands reason for isolation. Cooperates to maintain infection precautions.
Nurse	Assess what play activity would provide stimulation.	Visit the child frequently, at least every hour, and provide him with opportunities for therapeutic play.	Frequent visits help to decrease feelings of being alone. Therapeutic play helps the child deal with resentment about condition.	Child states that although he wants to go to playroom, he has found an enjoyable activity to occupy his time in his hospital room.
		Consultations		
Physician	Determine whether hospital infection control committee is aware of contagious illness in a postoperative patient.	Consult with infection control members on the possibility surgical personnel may have been exposed to scarlet fever.	Scarlet fever is contagious for 2 to 7 days prior to outbreak of rash.	Infection control committee members state they are aware of possible spread of illness to health care personnel and institute needed precautions, such as prescribed penicillin for exposed health care personnel.

(continued)

BOX 43.6 ✻ Focus on Nursing Care Planning (continued)

		Procedures/Medications		
Nurse	Determine whether child has ever had a reaction to penicillin.	Begin antibiotic therapy (penicillin V) as prescribed.	Penicillin is effective for group A beta-hemolytic streptococcus, the causative organism of scarlet fever.	Child's parents are contacted and report child has not had a previous reaction to penicillin. Child cooperates to take oral penicillin as prescribed.
Nurse	Ask child to rate pain of sore throat and itchiness of rash on scales of 1 to 10.	Administer analgesia and antihistamine prescribed. Caution child antihistamine may make him feel sleepy.	An antihistamine such as Benadryl can greatly reduce the pruritus of a rash.	Child states the itchiness of rash and pain of sore throat have decreased to tolerable levels.
		Nutrition		
Nurse/ nutritionist	Assess what fluid child would find most appealing to drink.	Provide frequent oral fluids. When soft diet is begun (child is postop appendicitis), provide soft foods.	Adequate fluid intake is important to prevent skin dryness, which increases discomfort. A soft or liquid diet is less irritating to the child's sore throat.	Child identifies favorite fluid to drink. States he is able to eat soft foods even with painful throat.
		Patient/Family Education		
Nurse/ physician	Determine whether other members of family will need prophylactic antibiotic.	Explain the purpose of prophylactic penicillin for susceptible family members.	As family members were near child during prodromal period, they are susceptible to also contract the disease.	Parent identifies susceptible family members; states she will be able to fill prescription for susceptible family members and supervise them to ensure they take prescribed antibiotic.
		Psychosocial/Spiritual/Emotional Needs		
Nurse	Assess whether child and parent understand the cause of scarlet fever.	Discuss the spread of infectious diseases is not related to "good or bad."	Mother voiced she was concerned because two diseases happened to her child at the same time.	Mother and child state they understand diseases are caused by infectious organisms, not moral status.
		Discharge Planning		
Nurse	Assess if parent is aware child's rash will be itchy for about a week.	Discuss possible measures parent can take to reduce pruritus (loose clothing, cool compresses) and measures to reduce pain of sore throat (analgesic).	If children scratch pruritic lesions, they can cause secondary infection. Sore throats interfere with comfort and ability to eat well.	Parent states she understands common measures to reduce pruritus and will begin them.

FIGURE 43.12 Impetigo in a toddler. Note the honey-colored crust appearance of some of the lesions. (© Dr. P. Marazzi/SPL/Science Source/Photo Researchers.)

Cat-Scratch Disease

- Causative agent: *Bartonella henselae* bacteria
- Incubation period: 3 to 10 days
- Period of communicability: Unknown
- Mode of transmission: Bite or scratch from a cat or kitten
- Immunity: One episode of disease gives lasting immunity; no passive artificial immunity

Cat-scratch disease occurs most commonly in preschool children because children at that age play roughly with cats or pick them up against their will and so receive scratches. At the time the child contracts the disease, the cat does not appear ill.

The first symptom for the child is a single skin papule or pustule that lasts 1 to 3 weeks. Approximately 2 weeks after the scratch, a single but severe local swollen lymph node also develops. The node most markedly involved is of the head, neck, or axilla. The node enlargement generally lasts 2 to 3 months. In some children, there is node suppuration (a node breaks open to the skin and drains sterile pus) (Fisher, 2007).

Some children have a low-grade fever and malaise. Occasionally, central nervous system involvement, such as encephalitis or meningitis, occurs. A positive reaction to a skin test of cat-scratch disease antigen is present. This, along with the history of a cat scratch and the aspiration of sterile pus from the enlarged lymph node, is diagnostic. Treatment is symptomatic, although an antibiotic may be prescribed to help shorten the course of the disease. Children may need an analgesic to relieve pain from the swollen lymph node. Aspiration of the involved node may be necessary to relieve pain.

Parents may ask if the cat should be destroyed. Because an attack of cat-scratch disease gives lifetime immunity and fewer than 10% of children scratched by the same cat contract cat-scratch disease, there is no need to destroy the cat for an act it may have seen as defending its safety.

BOX 43.7 ✻ Focus on Pharmacology

Mupirocin (Bactroban)

Classification: Mupirocin is a topical antibiotic.

Action: Mupirocin is used to treat impetigo caused by *Staphylococcus aureus* and *Streptococcus pyogenes.*

Pregnancy risk category: B

Dosage: Small amount applied three times a day to the affected areas for 10 days

Possible adverse effects: Erythema, dry skin, pruritus, burning, stinging (Karch, 2009)

Nursing Implications

- Advise parents to wash the lesions with soap and water and pat dry before applying ointment, to soften crusts for better absorption.
- Caution parents that causative organisms are infectious by direct contact. Instruct them to wash their own hands before and after applying the ointment.
- Urge parents to continue to use the ointment to ensure eradication of the causative germs. The lesions may begin to improve before 10 days have elapsed.
- Instruct the parents to use caution when applying the ointment around the eyes. Ointment is irritating to the eyes.
- Teach the parents about the signs and symptoms of secondary fungal infection that may occur and instruct them to notify a health care provider should any occur.

Staphylococcal Infections

Staphylococcal organisms are gram-positive. Colonies of staphylococci are normally found on the skin, so they are generally the organisms involved in skin infections (pyodermas). Because the organisms grow rapidly in cream foods that are not well refrigerated, such as potato salad or cream pies, they are often the organisms involved in summer food poisoning episodes. Because food poisoning produces gastrointestinal symptoms, these infections are discussed in Chapter 45.

Furunculosis (Boils)

A furuncle is a staphylococcal infection of a hair follicle. A yellow pustule forms at the site. There is localized redness, pain, and edema of the surrounding skin. Moist heat for 20 minutes applied to the lesion can help relieve pain. Urge children not to rupture these lesions but rather to allow them to run their self-limiting course so the infection is not spread to surrounding tissue and does not become a cellulitis.

Cellulitis

Cellulitis is a staphylococcal inflammation of the deeper layers of skin. It occurs generally on the extremities or face, or surrounding wounds. The skin feels warm and is edematous and reddened. Cellulitis is treated with a systemic antibiotic. Warm soaks relieve pain and inflammation.

Methicillin-Resistant *Staphylococcus Aureus*

Methicillin-resistant *Staphylococcus aureus* (MRSA) is a strain of staphylococcus that causes skin infections and has become resistant to common broad-spectrum antibiotics. When an infection occurs in a health care setting, it is referred to as health care–associated MRSA or HA-MRSA. If it occurs in a community setting, it is CA-MRSA. Children with weakened immune systems are at most risk of contracting the infection.

An infection usually begins as a boil. It can spread to become a painful abscess or invade deeper body structures such as joints and heart valves. Children who are identified as having MRSA are isolated to help prevent spread of the bacteria to others. Vancomycin is the drug of choice for treatment of hospital based lesions because the bacteria are still susceptible to its design. Trimethoprim-sulfamethoxazole is commonly used with community infections. Use strict standard infection precaution measures when caring for a child with an MRSA infection. Teach children that the best way to prevent staphylococcal infections of the skin is good handwashing and reporting skin wounds to a health care provider before an open wound can become infected (Pallin et al., 2008).

Scalded Skin Disease

Scalded skin disease (Ritter's disease) is a staphylococcal infection seen primarily in newborns. Children develop rough-textured skin and general erythema. Large bullae (vesicles), filled with clear fluid, form. The epidermis separates in large sheets, leaving a red, glistening, scalded-looking surface. Children need intensive intravenous antibiotic therapy to survive this extreme infection (Painter, Trevillion, & Snape, 2007).

Other Bacterial Infections

Diphtheria

- Causative agent: *Corynebacterium diphtheriae* (Klebs-Löffler bacillus)
- Incubation period: 2 to 6 days
- Period of communicability: Rarely more than 2 weeks to 4 weeks in untreated persons; 1 to 2 days in children treated with antibiotics
- Mode of transmission: Direct or indirect contact
- Immunity: Contracting the disease gives lasting natural immunity.
- Active artificial immunity: Diphtheria toxin given as part of DTaP vaccine
- Passive artificial immunity: Diphtheria antitoxin

Assessment. Although diphtheria is an illness that should be extinct because of available immunization, it still occurs in isolated outbreaks. When diphtheria bacilli invade and grow in the nasopharynx of children, they produce an exotoxin (a potent protein poison) that causes massive cell necrosis and inflammation. The necrosing material lends itself well to the growth of the bacilli, so the bacilli reproduce rapidly. The inflammation and necrosing cells form a characteristic gray membrane on the nasopharynx. This may extend up into the nose and down into the major bronchi, causing a purulent nasal discharge and a brassy cough. The toxin is absorbed from the membrane surface and spread systemically by the bloodstream to affect major organs, such as the heart and nervous system. If untreated, myocarditis with heart failure and conduction disturbances may occur. Central nervous system involvement can include severe neuritis with paralysis of the diaphragm and pharyngeal and laryngeal muscles. The diagnosis of diphtheria is made based on clinical appearance and on a throat culture, which reveals the presence of the bacilli (Chambers, 2009).

Therapeutic Management. Treatment involves intravenous administration of antitoxin in large doses. In addition, children are given penicillin or erythromycin intravenously. Complete bedrest is crucial during the acute stage of the illness. Droplet precautions must be followed until cultures are negative. Children need careful observation at all times to prevent airway obstruction. If obstruction occurs, endotracheal intubation may be necessary.

Because the diphtheria vaccine is included in routine immunizations for infants, diphtheria is almost extinct in the United States. However, isolated instances do occur, and when they do, prompt recognition and treatment are necessary.

Whooping Cough (Pertussis)

- Causative agent: *Bordetella pertussis*
- Incubation period: 5 to 21 days
- Mode of transmission: Direct or indirect contact
- Period of communicability: Greatest in catarrhal (respiratory illness) stage
- Immunity: Contracting the disease offers lasting natural immunity.
- Active artificial immunity: Pertussis vaccine given as part of DTaP vaccine
- Passive artificial immunity: Pertussis immune serum globulin

Pertussis is a serious disease of childhood. Like diphtheria, pertussis has become quite rare because of required immunizations, but it still occurs sporadically and is actually making a comeback in some locales and in adolescents (Judelsohn & Koslap-Petraco, 2007). Those most susceptible are children who have not been immunized because a previous vaccine had possible side effects that led parents to refuse immunization.

Assessment. Pertussis manifests itself in three stages: catarrhal, paroxysmal, and convalescent. The **catarrhal stage** begins with upper respiratory symptoms such as coryza, sneezing, lacrimation, cough, and a low-grade fever. Children are irritable and listless. In some children, a mild cough is the only symptom during this stage. It lasts from 1 to 2 weeks (Knox, 2008).

The paroxysmal stage lasts 4 to 6 weeks. During this time, the cough changes from a mild one to a paroxysmal one, involving 5 to 10 short, rapid coughs, followed by a rapid inspiration, which causes the "whoop," or high-pitched crowing sound, of whooping cough. Children are in obvious distress while coughing. They may become cyanotic or red-faced, and their nose may drain thick, tenacious mucus. They often vomit after a paroxysm of coughing, and they are exhausted afterward from the effort. Attacks of coughing tend to be more severe at night.

During the convalescent stage, there is a gradual cessation of the coughing and vomiting. The cough may be present for

some time, but as single, not paroxysmal, coughs. During the next year, if children develop an upper respiratory infection, they may again have a return of the paroxysmal coughing with vomiting.

Pertussis is diagnosed by its striking symptoms, although in children younger than 6 months of age, the "whoop" of the cough may be absent, making it more difficult to diagnose. The *B. pertussis* bacillus may be cultured from nasopharyngeal secretions during the catarrhal and paroxysmal stages. The white cell count, particularly the lymphocyte count, increases with whooping cough: it may be as high as 20,000 to 30,000/mm^3 at the end of the catarrhal stage (normal is 5000 to 10,000/mm^3).

Therapeutic Management. Children with pertussis are maintained on bedrest until the paroxysms of coughing subside. They need to be secluded from environmental factors, such as cigarette smoke, dust, and strenuous activity, that initiate coughing episodes. Nutrition may be a problem if the child is constantly coughing and vomiting. As a rule, frequent small meals are vomited less than larger meals. Infants with pertussis may be admitted to a health care facility for observation because they may have such tenacious secretions with coughing episodes that they need airway suction. Place an intercom in the infant's room so personnel can listen for paroxysms of coughing.

A full 10-day course of erythromycin or azithromycin may be prescribed as these drugs have the potential to shorten the period of communicability and may shorten the duration of symptoms. Droplet precautions are used until 5 days after a child starts effective therapy. Complications of pertussis include pneumonia, atelectasis, or emphysema from plugged bronchioles. Seizures from asphyxia as a result of severe paroxysms of coughing may occur. Epistaxis, subconjunctival and subarachnoid bleeding from the force of coughing, may occur. If sufficient fluid intake cannot be maintained, alkalosis and dehydration from persistent vomiting can occur.

Prevention. Little passive immunity is transferred to the newborn, so children in their early months are particularly susceptible to this disease. This is why pertussis vaccine is one of the first immunizations scheduled. Infants who have not yet been immunized or are immunocompromised and are exposed may be given pertussis immune serum globulin to protect them from contracting the disease (Wood et al., 2008).

What if... An adolescent with pertussis vomits after an episode of coughing? Should you urge him to try to eat again immediately, or do you think he would be too nauseated to do so?

Anthrax

- Causative agent: *Bacillus anthracis,* a bacteria
- Incubation period: 1 to 7 days (inhalational), 1 to 12 days (cutaneous), 1 to 7 days (gastrointestinal)
- Mode of transmission: Originally contracted from contact with cow or sheep feces; not transmissible from person to person
- Immunity: Unstudied
- Active artificial immunity: A vaccine is available for people in high-risk occupations, such as veterinarians, but it is not recommended for children.
- Passive artificial immunity: Not available

Anthrax is an acute infectious disease that is contracted from exposure to the bacteria or its spores (Bravata et al., 2007). Such bacteria live in the feces of infected cows or sheep. As the organism grows inside the human body, a toxin is produced that is the actual source of the symptoms. Children, like adults, may be affected by all three clinical forms: cutaneous, inhalational, or gastrointestinal.

Inhalational anthrax begins with a brief prodromal period of flulike symptoms, followed shortly by dyspnea, severe systemic shock, and marked evidence of mediastinal widening and pleural effusion on radiography. The mortality for this form is over 90%. Because it can be fatal and spread through coughing, inhalational anthrax has been proposed as bacteria that could be used in bioterrorism (Place et al., 2007).

Cutaneous anthrax is characterized by a skin lesion that begins as a papule, then passes through a vesicle stage to a painless depressed black eschar. Fever, malaise, and headache and regional swollen lymph nodes may accompany the skin lesion. The mortality of cutaneous anthrax is as low as 1% with antibiotic therapy.

Gastrointestinal anthrax is contracted by eating undercooked meat infected with the organism. The child develops severe abdominal pain, fever, bloody diarrhea, and septicemia. Mortality is about 25%.

If a child is exposed to anthrax, prophylaxis with ciprofloxacin (Cipro) for those over 18 years and doxycycline for younger patients should be started. Drug therapy is continued for 60 days because of the potential persistence of spores.

Tetanus (Lockjaw)

- Causative agent: *Clostridium tetani*
- Incubation period: 3 days to 3 weeks
- Period of communicability: None
- Mode of transmission: Direct or indirect contamination of a closed wound
- Immunity: Development of the disease gives lasting natural immunity.
- Active artificial immunity: Tetanus toxoid contained in DTaP vaccine
- Passive artificial immunity: Tetanus immune globulin

Tetanus, a highly fatal disease if untreated, is caused by an anaerobic, spore-forming bacillus. The bacillus, found in soil and the excretions of animals, enters the body through a wound. If the wound is deep, such as a puncture wound, where the distal end of the wound is shut off from an oxygen source, the tetanus bacilli begin to reproduce. The organism may also enter through a burn site, which crusts, creating an anaerobic environment. As the bacilli grow, they produce exotoxins that cause the disease symptoms by affecting the motor nuclei of the central nervous system (Ogle & Anderson, 2008).

The entrance site of the bacillus does not appear infected (no pus or reddened area is present unless a secondary infection also exists). After the incubation period, the exotoxins have developed to such an extent, however, that they are ca-

pable of disrupting the nervous system. In the United States most children are vaccinated against tetanus; in developing countries it continues to have a high incidence, caused by infection of an entry point such as the umbilical cord at birth (Roper, Vandelaer, & Gasse, 2007).

Assessment. The first symptoms that are noticeable are stiffness of the neck and jaw (lockjaw). Within 24 to 48 hours, muscular rigidity of the trunk and extremities develops. The back becomes arched (opisthotonos), the abdominal muscles are stiff and boardlike, and the face assumes an unusual appearance, with wrinkling of the forehead and distortion of the corners of the mouth (a "sardonic grin" sign). Any stimulation, such as a sudden noise, a bright light, or a touch, causes painful, paroxysmal spasms. The sensorium is clear throughout the course of the disease, so the child is aware of the pain associated with muscle spasms. As these spasms begin to include laryngospasm, respiratory obstruction, and a collection of secretions in the respiratory tract, death by asphyxiation may occur.

Fever is an ominous sign accompanying tetanus. Children who survive the disease rarely have more than a low-grade fever.

Therapeutic Management. A child needs to be cared for in a quiet, stimulation-free room. If the wound has necrotic tissue, it may be débrided to ensure that no secondary infections arise. Enteral or total parenteral nutrition may be necessary to prevent aspiration from laryngeal spasm. Tetanus immune globulin (human) is administered to supply passive antitoxins to combat the growing organisms.

Parenteral penicillin G or erythromycin is administered to reduce the number of growing forms of the bacillus. Sedation and a muscle relaxant may be necessary to reduce the severity and pain of the muscle spasms. A child may need to be intubated and mechanical ventilation begun to maintain respiratory function.

Prevention. Tetanus is a serious disease, but it can be prevented through active immunization and suitable booster immunization. Children routinely receive tetanus immunization as part of routine DTaP immunization and a booster dose at school age; thereafter they should receive a booster dose every 10 years. At the time of a wound, the wound site should be cleaned well with soap and water and a suitable antiseptic. If the wound is deep, such as a knife stab, a nail puncture, or a dog bite, it should not be sutured but should be left open to heal by secondary intention. This reduces the possibility of an anaerobic pocket forming in the wound. If the child received basic immunization against tetanus and it has been fewer than 10 years since the last injection, no booster or antitoxin management is needed at the time of the wound.

If a child's immunization record cannot be obtained, or if it has been more than 10 years since the child received a booster injection or an initial injection for tetanus, a child will probably be treated with a booster injection and tetanus immune globulin. A booster injection provides tetanus antigen to the child. If the child received initial immunization for this disease, the booster will cause the body to "remember" how to make tetanus antibodies, and the body will begin to produce them rapidly. By the time the invading tetanus organisms from the wound have passed their long incubation period (3 days to 3 weeks), the child will have antibodies in the system prepared to eradicate the organisms. If the initial immunizations were incomplete or are unknown, in addition to tetanus antigen the child will also receive the passive antibodies included in tetanus immune globulin (Ogle & Anderson, 2008).

Lyme Disease

- Causative agent: *Borrelia burgdorferi,* a spirochete
- Incubation period: 3 to 30 days
- Period of communicability: Not communicable from one person to another
- Mode of transmission: Deer tick
- Active artificial immunity: Lyme disease vaccine

Lyme disease is caused by a spirochete, *Borrelia burgdorferi,* that is transmitted by a tick often carried on deer (Philip & Jacobs, 2009). The disease is the most frequently reported vector-borne infection in the United States, occurring most often in the summer and early fall. Almost immediately after the tick bite, an erythematous papule is noticeable at the site, which spreads over the next 3 to 30 days (the incubation period) to become a large, round ring with a raised swollen border (erythema chronicum migrans; Fig. 43.13). This is followed by systemic involvement that leads to cardiac, musculoskeletal, and neurologic symptoms. Cardiac involvement may be so severe that it includes heart block from atrioventricular conduction abnormalities. Neurologic symptoms commonly include stiff neck, headache, and cranial nerve palsy. Musculoskeletal symptoms occur in 50% of children and include painful swollen arthritic joints, particularly the knee.

Amoxicillin or penicillin V is administered at the time of the bite to young children. Doxycycline is given to those older than 8 years of age. A vaccine for the disease has been approved for use in adults who live or work in high-risk areas but not yet for children.

Parents should be cautioned to inspect the skin of children who have been playing in wooded areas for tick bites to help identify the disorder before debilitating symptoms occur. Other suggestions for avoiding Lyme disease are shown in Box 43.8.

FIGURE 43.13 The rash of Lyme disease. (© Larry Mulvehill/Science Source/Photo Researchers.)

BOX 43.8 * Focus on Family Teaching

Tips for Avoiding Exposure to Lyme Disease

Q. Marty's father tells you, "My children love to play in the woods, but I'm so afraid that they'll get Lyme disease. What can I do to protect them?"

A. Here are some suggestions for you and your children to help reduce the risk for exposure to Lyme disease:

- Wear protective clothing when hiking or playing in wooded areas: long sleeves, high necklines, long slacks. Tuck bottom of slacks into socks or boots.
- Wear light-colored clothing, so any tick present on clothing can be readily observed.
- Inspect skin for ticks thoroughly after hiking or playing in wooded areas. Remove any ticks found with tweezers.
- Report any area of inflammation that might be a tick bite to a health care provider for early diagnosis.
- Ask your primary care provider about the availability of Lyme disease vaccine. Currently, it is administered only to adults with high-risk occupations, but it is anticipated that the vaccine will soon be available for children living in high-risk areas.

OTHER INFECTIOUS PATHOGENS

Rickettsial Diseases

Rickettsiae are organisms that resemble viruses both in size and in their inability to reproduce except inside the cells of a host organism. They reproduce by fission, however, as bacteria do; like bacteria, they are complete organisms containing both RNA and DNA. They multiply inside ticks, lice, mites, or fleas (arthropods) without causing disease. They are transmitted to humans through the bite or feces of the infected arthropod. An exception is Q fever, which is spread by droplet infection. All rickettsial diseases include fever, and almost all include a rash caused by rickettsial multiplication in the endothelial cells of small blood vessels. Rickettsiae invasion triggers an immune response.

Rocky Mountain Spotted Fever

- Causative agent: *Rickettsia rickettsii*
- Incubation period: 3 to 12 days
- Period of communicability: Not communicable from one person to another
- Mode of transmission: Wood, dog, or rabbit tick
- Active artificial immunity: Rocky Mountain spotted fever vaccine

Rocky Mountain spotted fever is the second most common rickettsial disease seen in the United States. It is most prevalent in the western United States and is transmitted by a tick (Buckingham et al., 2007). It is seen most often during the spring and early summer, when ticks are most commonly seen. A reddened area develops at the site of the tick bite. In 2 to 8 days, a typical rash, persistent headache, fever (as high as 104° F [40° C]), and mental confusion begin. The rash is distinctive, beginning with reddened macules, then changing to petechiae. It begins on the wrists and ankles, then spreads up the arms and legs onto the trunk. Unlike most rashes, it can cover the palms and soles (Fig. 43.14).

FIGURE 43.14 Typical rash of Rocky Mountain spotted fever. (Courtesy of Stuart Starr, MD, The Children's Hospital of Philadelphia.)

In untreated children, symptoms worsen to include central nervous system involvement (stiff neck and seizures) and cardiac and pulmonary symptoms such as heart failure and pneumonia. Nitrogen loss in the urine becomes extreme. An accompanying hyponatremia may also be present.

Therapy is with tetracycline or erythromycin for 7 to 10 days. Caution parents to administer the drug for the full course of therapy to ensure disease eradication and prevent the risk of complications. Rocky Mountain spotted fever was a serious childhood illness before antibiotic therapy was available, and it still has the potential to be serious if the symptoms are not reported when they first occur.

Murine Typhus

Murine typhus is seen almost exclusively in the southern United States. It is transmitted by mites and fleas that live on rats. Its symptoms are almost identical to those of Rocky Mountain spotted fever. It responds to tetracycline or a third-generation antibiotic such as ciprofloxacin (Cipro).

Chlamydial Infections

Chlamydiae are gram-negative nonmotile organisms similar to rickettsiae. Chlamydial pneumonia or vaginitis may occur in children (see Chapters 40 and 47). Psittacosis is a chlamydial infection commonly found in children.

Psittacosis

Psittacosis, caused by *Chlamydia psittaci,* is a disease transmitted to children by birds, such as parakeets, lovebirds, parrots, chickens, turkeys, and pigeons (Ogle & Anderson, 2008). The bird has no apparent symptoms of illness. Children develop symptoms of an upper respiratory infection, possibly accompanied by a low-grade fever, a dry cough, weakness, and anorexia out of proportion to the fever. An enlarged spleen may also be present. Children may

TABLE 43.3 ✻ Common Parasitic Infections

Infection	Organism	Symptoms	Treatment
Pediculosis capitis	Head lice	Small, white flecks on hair shaft (nits or eggs of lice) Extreme pruritus	Wash hair with shampoo such as lindane (Kwell). Comb nits from hair with fine-toothed comb. Wash bed sheets, recently worn clothes. Vacuum pillows, mattresses, or other items unable to be washed. Teach children not to exchange combs, hair barrettes, or other personal items.
Pediculosis	Pubic lice	Same as for head lice except on pubic hair	Same as head lice
Scabies	Female mite (*Acarus scabiei*)	Black burrow filled with mite feces 1–2 inches long, usually between fingers and toes, on palms, or in axilla or groin	Caution adolescent that groin infestations might be spread by physical intimacy. Wash area with lindane (Kwell) lotion or permethrin (Elimite).

develop patchy bronchopneumonia. The course of the disease is as long as 3 to 4 weeks. Treatment is with erythromycin for young children and tetracycline for children over the age of 8 years.

Parasitic Infections

Parasites are organisms that live on and obtain their food supply from other organisms. Frequently seen parasites in children include head lice and scabies (Table 43.3). Parents are often embarrassed when they learn that their child has lice. Reassure them that this infestation can happen to any child (Box 43.9).

Helminthic Infections

Helminths are pathogenic or parasitic worms. They may be roundworms (nematodes), flukes (trematodes), or tapeworms (cestodes). Most helminths begin life when the eggs or larvae are eliminated in the feces or urine of humans. They are then transmitted to the oral cavity by contaminated foods or hands. Because children tend to be careless about washing their hands before eating or tend to suck their thumbs, they are prone to these infections (Wilson & Caumes, 2008).

Roundworms (Ascariasis)

The roundworm parasite lives in the intestinal tract. Eggs are excreted in the feces. Children typically ingest the eggs when they eat food with hands that are improperly washed. Larvae, which hatch from the ingested eggs, penetrate the intestinal wall and enter the circulation. From there, they may migrate to any body tissue. Children have a loss of appetite and perhaps nausea and vomiting. Intestinal obstruction may occur from a mass of roundworms in the intestinal tract. Ascariasis can be prevented by the sanitary disposal of feces to prevent contamination of the soil. A single dose of an anthelmintic such as pyrantel pamoate (Antiminth) controls the infection.

Hookworms

Hookworm eggs, like roundworm eggs, are found in human feces. They enter children's bodies through the skin and then

BOX 43.9 ✻ Focus on Communication

When Marty's 6-year-old brother Joshua visits him, you notice he has scratch marks on his neck and forehead. His hair shafts are covered by sandlike particles. You suspect he has pediculosis capitis or head lice.

Less Effective Communication

Nurse: Mrs. Ireland, I'm wondering if you've noticed these sandlike particles in your son's hair.
Mrs. Ireland: Well, you know boys. They don't always wash well.
Nurse: I'm concerned they may be the eggs of head lice.
Mrs. Ireland: We're not that poor. Don't insult us.
Nurse: I didn't mean to. Like you said, it's probably something else.

More Effective Communication

Nurse: Mrs. Ireland, I'm wondering if you've noticed these sandlike particles in your son's hair.
Mrs. Ireland: Well, you know boys. They don't always wash well.
Nurse: I'm concerned they may be the eggs of head lice.
Mrs. Ireland: We're not that poor. Don't insult us.
Nurse: Let's talk about head lice, and how easy it is for anyone to get them.

The above scenario is an example of what can happen if people believe one of the myths that circulate related to communicable diseases. Head lice can be spread easily in locker rooms or classrooms, so any child can contract them.

migrate to the intestinal tract, where they attach themselves onto the intestinal villi. They suck blood from the intestinal wall to sustain themselves. If a great number of hookworms are present, severe anemia may result. Treatment is with anthelmintics to destroy the worms. Children may also need therapy for the anemia.

Pinworms

Pinworms are small, white, threadlike worms that live in the cecum. At night, the female pinworm migrates down the intestinal tract and out the anus to deposit eggs on the skin in the anal and perianal region. The movement of the worms causes the anal area to itch, and the child awakens at night crying and scratching. Some of the eggs are then carried from the child's fingernails to the mouth. They hatch in the child's intestinal tract, and the cycle is repeated (Weinberg & Levin, 2008).

The worms are large enough that they can be seen if children's buttocks are separated when they are sleeping. Pressing a piece of cellophane tape against the anus and then looking at it under a microscope will generally reveal pinworm eggs.

Treatment is with a single dose of mebendazole (Vermox) or pyrantel pamoate (Antiminth). Both drugs destroy pinworms. All family members are treated for pinworm infestation because the worms are easily transmitted from person to person. Underclothing, bedding, towels, and nightclothes should be washed before reuse. Teach children to avoid nail-biting and to wash their hands before food preparation or eating to avoid transfer of pinworm eggs to the gastrointestinal tract.

Protozoan Infections

Protozoa are unicellular organisms. They absorb fluid through the cell membrane and can move from place to place by pseudopod, flagella, or cilia action. They are most pathogenic in the gastrointestinal, genitourinary, and circulatory systems. Some protozoa reproduce by simple binary fission; other forms have complex life cycles. Protozoa have the ability to form cysts or surround themselves with a membrane; this makes them resistant to destruction.

Giardiasis

Giardia lamblia is a protozoan infection that is responsible for epidemic outbreaks of diarrhea, particularly in travelers to Europe and in day care centers in the United States (Yoder et al., 2007).

Transmission occurs when the child ingests the cysts of the organism on unclean hands. In the intestine, the cysts develop into the mature form of the organism, causing symptoms such as diarrhea, weight loss, abdominal cramps, and nausea.

Diagnosis is made by history and recognition of the mature form of the organism in the stool or on duodenal aspiration. Therapy is with metronidazole (Flagyl) for 7 days (Escobedo & Cimerman, 2007).

Fungal Infections

Fungi are larger than bacteria; some are unicellular (yeasts), but generally they are multicellular (molds). Fungal infections are most often divided into groups according to the body tissue they infect. Deep mycoses invade internal organs. Transmission is by the inhalation of spores. Subcutaneous mycoses invade skin, subcutaneous tissue, and bone. Infections usually occur from introduction of the fungi into a wound. Superficial mycoses invade only the hair, skin, or nails.

Superficial Fungal Infections

Four superficial fungal infections are seen frequently in children: tinea cruris, pedis, capitis, and corporis.

Tinea Cruris. Tinea cruris (jock itch) occurs on the inner aspects of the thighs and scrotum. It is pruritic. Local application of clotrimazole (Lotrimin) or econazole (Spectazole) liquid or powder destroys the infection (Karch, 2009).

Tinea Pedis. Tinea pedis (athlete's foot) produces skin lesions between the toes and on the plantar surface of the foot. Pruritic, pinpoint vesicles and fissuring, especially between the toes, may occur. It is treated with liquid preparations of an antifungal agent such as clotrimazole (Lotrimin).

Tinea Capitis. Tinea capitis (ringworm) is a fungal infection that begins as an infection of a single hair follicle but spreads rapidly in a circular pattern to produce a lesion usually approximately 1 inch in diameter. The hairs involved in the lesion generally break off. The circle becomes filled with dirty-appearing scales. Some strains of tinea capitis may be detected because they glow green under a Wood's light. Newer strains of the organism do not do this, so the test is losing its accuracy.

Treatment is with griseofulvin given orally. Adolescents should be cautioned not to use alcohol while taking this drug; this may cause tachycardia. Safety during pregnancy is not established. Children need to avoid strong sunlight during therapy because photosensitivity may occur.

Tinea capitis is not as contagious as was once assumed. Children need not be kept home from school, although they should be cautioned not to exchange towels or combs or other potential fomites. The course of the disease may be long; it may be 3 months before all lesions have faded (Ali, Graham, & Forgie, 2007).

Tinea Corporis. Tinea corporis is fungal infection of the epidermal layer of the skin. It presents as a scaly ring of inflammation with a clear area in the center anywhere on the body (Fig. 43.15). Treatment is with a topical antifungal agent such as clotrimazole (Lotrimin).

Candidiasis

Candida albicans is the fungus responsible for candidal (monilial) infections. Candidal organisms grow in the vagina of many adult women and adolescents (candidal vaginitis) (see Chapter 47). Newborns born vaginally may develop an infection of the mucous membrane of the mouth (thrush or oral candidal infection). Thrush is characterized by white plaques on an erythematous base on the buccal membrane and the surface of the tongue. It resembles a milk curd left from a recent milk feeding. Thrush plaques do not scrape away, however, whereas milk curds do. The mouth is painful, and the child does not eat well due to the inflammation and local pain.

FIGURE 43.15 Ringworm. The fungus spreads rapidly, producing a circular, ringlike lesion. (© SPL/Science Source/Photo Researchers.)

C. albicans can also cause a severe, bright red, sharply circumscribed diaper-area rash (Fig. 43.16). Satellite lesions are usually also present. The rash is marked by its intense color, and it does not improve with the usual diaper rash measures, such as Desitin ointment, frequent changing of diapers, or exposure to air.

Nystatin is an example of an effective antifungal drug (Karch, 2009). For oral thrush, it is generally administered by mouth approximately four times a day. It should be dropped into the mouth after feedings so it will remain in contact with the lesions rather than being washed away immediately by a feeding. For diaper rash, a nystatin ointment is prescribed.

Candidiasis can become a generalized infection, especially in a newborn. It can spread easily through a newborn nursery (Mohan, Eddama, & Weisman, 2009). There is a tendency to think of thrush as a common, almost expected disease of infants. It needs treatment, however, to prevent it from becoming more serious or systemic or epidemic.

FIGURE 43.16 Monilial diaper rash. Note the intense red color of the rash. (© Custom Medical Stock Photograph.)

✔ Checkpoint Question 43.5

Marty had a pinworm infection last year. A typical symptom of this infection to assess for would be:

a. Nausea and vomiting.
b. Anal itching on awakening.
c. Loose, bloody stools.
d. Mild jaundice and itching.

Key Points for Review

- The incubation period of an infectious disease is the time between the invasion of an organism and the onset of symptoms. The prodromal period is the time between the beginning of nonspecific symptoms and specific symptoms. Children are infectious during the prodromal period. Illness is the stage during which specific symptoms are evident. The convalescent period is the interval between the time symptoms begin to fade and the time the child returns to full wellness.
- The chain of infection depends on the presence of a reservoir, a portal of exit, a means of transmission, a portal of entry, and a susceptible host. To reduce the spread of infection, use standard infection precautions. Transmission-based precautions—airborne, droplet, and contact—also may be necessary.
- Common viral infections of childhood include exanthem subitum (roseola), rubella (German measles), measles (rubeola), chickenpox (varicella), herpes zoster, erythema infectiosum (fifth disease), pityriasis rosea, mumps (epidemic parotitis), infectious mononucleosis, and cat-scratch disease. Other important viral infections include poliomyelitis (now almost extinct), herpesvirus infections, verrucae (warts), rabies, and West Nile virus disease.
- Streptococcal diseases include scarlet fever and impetigo. Staphylococcal infections include furunculosis (boils), cellulitis, and scalded skin disease. Outbreaks of diphtheria, whooping cough (pertussis), and tetanus (lockjaw) still occur.
- Important tick-borne diseases are Rocky Mountain spotted fever and Lyme disease. Parasitic infections are pediculosis capitis (head lice), pediculosis pubis, and scabies. Helminthic infections are roundworms, hookworms, and pinworms. Fungal infections are tinea capitis and tinea corporis (ringworm).
- Teaching parents and children about infection control measures and the need for keeping immunizations up to date is essential to reduce the risk of infectious disorders in children.

CRITICAL THINKING EXERCISES

1. Marty Ireland is the 10-year-old boy you met at the beginning of the chapter. He was diagnosed as having scarlet fever the morning after surgery for appendicitis. Is it likely that Marty contracted this infection while he was hospitalized, or is it more likely that the contact occurred before hospitalization? What is the typical pattern of scarlet fever lesions? What would you recommend to his parents to help reduce the itchiness of the rash?
2. Suppose Marty's mother tells you one disease she is not worried about is Lyme disease, as her children never eat limes. How would you respond to her?
3. Suppose Marty's mother tells you she doesn't intend to have her newborn immunized because she feels the risk of developing a complication from vaccine administration is higher than letting her child contract simple childhood illnesses. How would you counsel her?
4. Examine the National Health Goals related to infectious diseases in children. Most government-sponsored funds for nursing research are allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to the Ireland family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to infectious disorders in children. Confirm your answers are correct by reading the rationales.

Chapter 44

Nursing Care of a Family When a Child Has a Hematologic Disorder

KEY TERMS

- agranulocytes
- allogeneic transplantation
- autologous transplantation
- blood dyscrasias
- erythroblasts
- erythrocytes
- erythropoietin
- granulocytes
- hemochromatosis
- hemolysis
- hemosiderosis
- hypodermoclysis
- leukocytes
- leukopenia
- megakaryocytes
- normoblasts
- pancytopenia
- petechiae
- plethora
- poikilocytic
- priapism
- purpura
- reticulocytes
- synergeneic transplantation
- thrombocytes
- thrombocytopenia

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe the major hematologic disorders of childhood.
2. Identify National Health Goals related to children with hematologic disorders that nurses could help the nation achieve.
3. Use critical thinking to analyze ways that nursing care for a child with a hematologic disorder could be more family centered.
4. Assess a child with a hematologic disorder.
5. Formulate nursing diagnoses for a child with a hematologic disorder such as sickle-cell anemia.
6. Identify expected outcomes for a child with a hematologic disorder.
7. Plan nursing care for a child with a hematologic disorder.
8. Implement nursing care related to a child with a hematologic disorder, such as reducing the possibility of infection.
9. Evaluate expected outcomes for achievement and effectiveness of care.
10. Identify areas related to care of children with hematologic disorders that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of hematologic disorders in children with nursing process to achieve quality maternal and child health nursing care.

Lana is a 4-year-old girl diagnosed with thalassemia major. She has a prominent mandible and wide-spaced upper front teeth from overgrowth of bone marrow centers. Her skin is bronze from the number of transfusions (64) she has received in her short lifetime. Joey, a 7-year-old with sickle-cell anemia, is seen at the same clinic. His growth is only in the 5th percentile, and he's had two vaso-occlusive crises in the past year. "Why did this happen?" Lana's mother asks you. "Why were our two families so unlucky? What could we do to help our children have better lives?" Previous chapters described the growth and development of well children. This chapter adds information about the dramatic changes, both physical and psychosocial, that occur when children have a hematologic disorder.

What additional health teaching does Lana's mother need to help her better understand these hematologic diseases?

The blood and blood-forming tissues that make up the hematologic system play a vital role in body metabolism: transporting oxygen and nutrients to body cells, removing carbon dioxide from cells, and initiating blood coagulation when vessels are injured. As a result, any alteration in the substance or function of blood or its components can have immediate and life-threatening effects on the functioning of all body systems. For instance, an alteration in the process of coagulation can result in death from acute and uncontrollable blood loss. Inadequate red cell formation results in decreased oxygenation in tissues (Linker, 2009).

Hematologic disorders, often called **blood dyscrasias,** occur when components of the blood are formed incorrectly or either increase or decrease in amount beyond normal ranges. Most blood dyscrasias in children originate in the bone marrow, where blood cells are formed. National Health Goals related to blood disorders are shown in Box 44.1.

Blood dyscrasias do not occur at equal rates in all countries, because many of these disorders are inherited. Sickle-cell anemia, for example, occurs mainly in African Americans; thalassemia occurs in children from Mediterranean countries. Iron-deficiency anemia, an example of a noninherited disorder, tends to occur in children from lower socioeconomic areas of many countries, because iron-rich foods often are expensive. Being aware of the differences in the incidence of blood dyscrasias this way can be helpful in planning care and providing health care services for children and communities. Treatment for blood disorders can be culturally influenced as well. For example, families who are Jehovah's Witnesses may refuse blood transfusions, a common therapy for blood disorders, on religious grounds.

BOX 44.1 * Focus on National Health Goals

National Health Goals have been set to address both iron-deficiency anemia and sickle-cell anemia, two common blood disorders in children:

- Reduce the incidence of iron deficiency among children aged 1 to 2 years to less than 5% and among women of childbearing age to less than 7% from baselines of 9% and 11%.
- Reduce hospitalization for sickle-cell disease yearly among children aged 9 years and under from a baseline of 41.3 hospitalizations per 100,000 children to 33 per 100,000 (http://www.nih.gov).

Nurses can help the nation achieve these goals by educating parents about the importance of women taking an iron supplement during pregnancy and adding iron-rich cereal to their infants' diets. They could help reduce hospital admissions by being certain that parents are well informed about their child's sickle-cell disease and precautions they can take to help avoid disease crises. Nursing research questions that could add important information for prevention for iron-deficiency anemia include: what are ways of increasing adherence among pregnant women that would help ensure that all women take an iron supplement during pregnancy and do infants maintain higher iron levels when cereal is eaten with milk or orange juice?

Nursing Process Overview

For a Child With a Hematologic Disorder

Assessment

Many of the symptoms of hematologic disorders begin insidiously, with symptoms such as pallor, lethargy, and bruising. These are such minor symptoms that parents may not bring their child to a health care facility for some time. They are surprised to learn when they do that such subtle symptoms can signify the presence of a serious illness.

Many hematologic disorders are inherited. When a child is diagnosed with one, parents may feel guilty or blame themselves or their partner for their child's disease. It may be difficult for parents to support a child during an illness when they need intensive support themselves because they feel the illness is their fault. Be certain both parents and children receive the support and comfort that they need.

Asking at routine checkups about a child's dietary intake often reveals iron-deficiency anemia. Many infants with this problem have been drinking too much milk and not eating enough iron-containing foods. This makes them iron-deficient, but aside from paleness and irritability, they appear plump and "healthy." Their parents do not suspect their baby's appearance masks a nutritional deficiency.

Nursing Diagnosis

Nursing diagnoses commonly used with children who have hematologic disorders are:

- Deficient knowledge related to the cause of child's illness
- Imbalanced nutrition, less than body requirements, related to parental lack of knowledge of need for iron-rich foods
- Anxiety related to frequent blood-sampling procedures
- Pain related to tissue ischemia
- Compromised family coping related to long-term care needs of child with a chronic hematologic disorder

Outcome Identification and Planning

When helping parents plan outcomes, be certain that the outcomes are realistic for both the child and family. It may not be possible to reduce the number of blood-sampling procedures, for example, but a child can be helped, with distraction techniques, to deal with the pain and anxiety the procedures produce.

Children with hematologic disorders often are prescribed long-term medication such as a corticosteroid. When a child appears very ill, parents are usually very conscientious about giving such medicine. When a child has a disorder with few symptoms, however, like a blood dyscrasia, it is easy for parents to forget to give the medication. In addition, a child may refuse to take the medication for a long time because it tastes bad or upsets the stomach. Planning includes helping parents devise ways to

disguise the taste or remember to give the medication over the long term.

Nutritional planning is another area that needs consideration. Parents of children with iron-deficiency anemia, for example, may need to modify meal plans not only for the child but also for the entire family; this is not necessarily easy to do, because iron-rich foods are expensive. If children are "fussy eaters," parents may need a great deal of support to insist that children eat foods containing iron rather than giving them what they want to eat. If a child will be restricted in activity for long periods because the immune system is compromised as a part of the illness, planning must include ways to keep the child engaged with friends to promote development. Parents may need help investigating possible resources for education and support to do this.

Because of the chronicity of some of the hematologic disorders, parents and children often need the support of outside agencies. Some organizations helpful for referral are the Aplastic Anemia Foundation of America (http://www.aplastic.org), Sickle-cell Disease Association of America (http://www.sicklecelldisease.org), American Society of Pediatric Hematology and Oncology (http://www.aspho.org), and National Hemophilia Foundation (http://www.hemophilia.org).

Implementation

Nursing interventions for children with hematologic disorders include helping to obtain specimens for testing and assisting with blood or hematopoietic stem cell transfusions. Remember that a finger puncture for blood is often as painful as a venipuncture (and more painful afterward because the fingertip is irritated every time the child attempts to use it). Suggesting that blood be drawn by means of an intermittent device may reduce the number of times a child is subjected to venipuncture. Applying an anesthetic cream (mixtures of lidocaine and prilocaine) before finger punctures or venipunctures also helps to reduce pain and improve cooperation with these procedures. Even so, children may need some therapeutic playtime with a syringe and a doll to express their anger about constant invasion by needles.

Outcome Evaluation

Evaluation focuses on whether short-term outcomes such as moderation of pain or elimination of anxiety in a child undergoing diagnosis or treatment were achieved and progress is being made toward the achievement of long-term outcomes such as improving the ability of the family to manage the stress of raising a child with a chronic illness or deal with frequently occurring health crises.

Examples of expected outcomes that suggest goals were achieved are:

- Parents correctly state the most frequent causes of iron-deficiency anemia.
- Child states she feels better able to cope with blood-sampling procedures through the use of imagery.
- Parents describe realistic plans to ensure adherence to long-term medication administration.
- Parents voice they understand importance of preventing dehydration in school-age child with sickle-cell anemia.

ANATOMY AND PHYSIOLOGY OF THE HEMATOPOIETIC SYSTEM

Blood components originate in the bone marrow, circulate through blood vessels, and ultimately are destroyed by the spleen.

Blood Formation and Components

The formation of blood cells begins in the fetal yolk sac as early as week 2 of intrauterine life. By month 2 of intrauterine life, the liver and spleen begin forming blood components. At approximately month 4, the bone marrow becomes and remains the active center for the origination of blood cells. As in extrauterine life, the spleen serves as the organ for the destruction of blood cells once their normal life span has passed.

The total volume of blood in the body is roughly proportional to body weight: 85 mL/kg at birth, 75 mL/kg at 6 months of age, and 70 mL/kg after the first year. The *blood plasma* (the liquid portion containing proteins, hormones, enzymes, and electrolytes) is in equilibrium with the fluid of the interstitial tissue spaces. Although it is important in diseases causing vomiting and diarrhea (when this fluid may become depleted, leading to dehydration), plasma is not a major site of hematologic disease. The formed elements—the erythrocytes (red blood cells), leukocytes (white blood cells), and thrombocytes (platelets)—are the portions most affected by hematologic disorders in children.

Erythrocytes (Red Blood Cells)

Erythrocytes (red blood cells [RBCs]) function chiefly to transport oxygen to and carry carbon dioxide away from body cells. RBCs are formed under the stimulation of **erythropoietin,** a hormone produced by the kidneys that is stimulated whenever a child has tissue hypoxia. Children with kidney disease often have a low number of RBCs because erythropoietin secretion is inadequate in diseased kidneys. *Polycythemia*, or an overproduction of RBCs, can occur in children who experience prolonged systemic hypoxia because of erythropoietin overproduction.

RBCs form first as **erythroblasts** (large, nucleated cells), then mature through **normoblast** and **reticulocyte** stages to mature, nonnucleated erythrocytes. Approximately 1% of RBCs are in the reticulocyte stage at all times. An elevated reticulocyte count indicates that rapid production of new RBCs is occurring. This is seen in children with iron-deficiency anemia once iron therapy is begun and the body is again able to produce RBCs. The absence of a nucleus in the mature red blood cell allows for increased space for oxygen transport, but it also limits the life of cells because metabolic processes are limited. At the end of their life span (about 120 days), erythrocytes are destroyed through phagocytosis by reticuloendothelial cells, found in the highest proportion in the spleen.

In infants, the long bones of the body are filled with red marrow actively producing RBCs. In early childhood, yellow marrow begins to replace this in long bones, so blood element production is then carried out mainly in the ribs, scapulae, vertebrae, and skull bones. The yellow marrow remaining in the extremities can be activated if necessary to produce additional blood products.

At birth, an infant has approximately 5 million RBCs per cubic millimeter of blood. This concentration diminishes

rapidly in the first months, reaching a low of approximately 4.1 million per cubic millimeter at 3 to 4 months of age. The number then slowly increases until adolescence, when the adult value of approximately 4.9 million per cubic millimeter is reached.

Hemoglobin. The component of RBCs that allows them to carry out the transport of oxygen is *hemoglobin*, a complex protein. Hemoglobin is composed of globin, a protein (like all proteins) dependent on nitrogen metabolism for its formation, and heme, an iron-containing pigment. Deficiency of either iron stores or nitrogen, therefore, will interfere with the synthesis of hemoglobin. It is the heme portion that combines with oxygen and carbon dioxide for transport.

The hemoglobin in erythrocytes during fetal life is different from that formed after birth. Fetal hemoglobin has a special affinity for oxygen, so it can absorb oxygen at the low oxygen tension that exists in utero. It is composed of two alpha and two gamma polypeptide chains. At birth, 40% to 70% of the infant's hemoglobin is fetal hemoglobin (hemoglobin F). This is gradually replaced by adult hemoglobin (hemoglobin A) during the first 6 months of life. Hemoglobin A is composed of two alpha and two beta chains. For this reason, diseases such as sickle-cell anemia or the thalassemias, which are disorders of the beta chains, do not become apparent clinically until this hemoglobin change has occurred (at approximately 6 months of age). However, because some hemoglobin A is present even in early intrauterine life, they can be diagnosed prenatally by hemoglobin analysis or electrophoresis.

The hemoglobin amount in blood varies according to the number of RBCs present and the average amount of hemoglobin each cell contains. Hemoglobin levels are highest at birth (13.7 to 20.1 g/100 mL); they reach a low at approximately 3 months of age (9.5 to 14.5 g/100 mL), and then gradually rise again until adult values are reached at puberty (11 to 16 g/100 mL).

Bilirubin. After a RBC reaches its life span of approximately 120 days, it disintegrates and its protein component is preserved by specialized cells in the liver and spleen (reticuloendothelial cells) for further use. Iron is released for reuse by the bone marrow to construct new RBCs. As the heme portion is degraded, it is converted into protoporphyrin. Protoporphyrin is then further broken down into indirect bilirubin. Indirect bilirubin is fat soluble and cannot be excreted by the kidneys in this state. It is therefore converted by the liver enzyme glucuronyl transferase into *direct bilirubin*, which is water soluble. This is then excreted in bile.

In the newborn, generally liver function is so immature that the conversion from indirect to direct bilirubin cannot be made. Because of this, bilirubin remains in the indirect form. When the level of indirect bilirubin in the blood rises to more than 7 mg/100 mL, it permeates outside the circulatory system, and the infant shows signs of yellowing or jaundice. If excessive **hemolysis** (destruction) of RBCs occurs from other than natural causes, a child will also show signs of jaundice.

Leukocytes (White Blood Cells)

Leukocytes (white blood cells [WBCs]) are nucleated cells. They are few in number compared with RBCs, with approximately 1 WBC to every 500 RBCs. Their primary function is defense against antigen invasion. There are two main forms of WBCs: **granulocytes** (those with granules in the cell cytoplasm) and **agranulocytes** (those without granules in the cell cytoplasm). Granulocytes (often referred to as polymorphonuclear forms) are further differentiated as neutrophils, basophils, and eosinophils. The agranulocytic leukocytes are further differentiated as lymphocytes and monocytes.

A typical total white cell count is 5000 to 10,000 cells per cubic millimeter of blood. The WBC count in newborns is approximately 20,000 per cubic millimeter, a high level caused by the trauma of birth. In the newborn, granulocytes are the most common WBCs. By 14 to 30 days of life, the total WBC count falls to approximately 12,000 per cubic millimeter, and lymphocytes become the dominant type. By 4 years of age, the WBC count reaches an adult level (5000 to 10,000 cells/mm^3), and granulocytes are again the dominant type. Leukocytes are produced in response to need. Their life span varies from approximately 6 hours to unknown intervals.

Thrombocytes (Platelets)

When blood is centrifuged in a test tube, plasma rises to the top as a clear yellow fluid; red cells sink to the bottom as a dark-red paste. Between these two layers a thin white strip (often termed a buffy coat) forms that consists of the WBCs and thrombocytes. **Thrombocytes** are round, nonnucleated bodies formed by the bone marrow. Their function is capillary hemostasis and primary coagulation. The normal range is 150,000 to 300,000 per cubic millimeter after the first year. Immature thrombocytes are termed **megakaryocytes.** If large numbers of these are present in serum, it indicates that rapid production of platelets is occurring.

Blood Coagulation

Effective blood coagulation depends on a complex series of events including a combination of blood and tissue factors released from the plasma (the intrinsic pathway) and from injured tissue (the extrinsic pathway). The plasma-released factors are factors VIII, IX, and XII. Factors released from injured tissues are a tissue factor (an incomplete thromboplastin or factor III), plus factors VII and X. Together, these pathways form factor V. The names for coagulation factors are given in Box 44.2.

BOX 44.2 ✻ Blood Coagulation Factors

I	Fibrinogen
II	Prothrombin
III	Thromboplastin
IV	Calcium
V	Labile factor (platelet phospholipids)
VII	Stable factor
VIII	Antihemophilic factor
IX	Christmas factor; antihemophilic factor B; plasma thromboplastin component
X	Stuart factor
XI	Plasma thromboplastin antecedent (antihemophilic factor C)
XII	Hageman factor
XIII	Fibrin stabilizing factor

Numbers refer to the order in which factors were discovered, not to the order of action in coagulation.

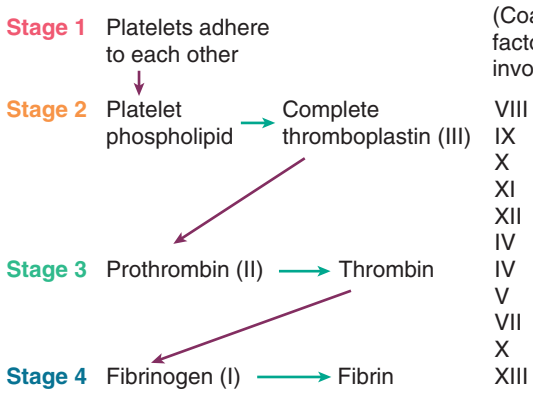

FIGURE 44.1 Steps in blood coagulation.

When a vessel is injured, vasoconstriction occurs in the area proximal to the injury, narrowing the vessel lumen and reducing the amount of blood to the injured area. Platelets begin to adhere to the damaged vessel site and to one another, forming a platelet plug. This is the first stage of clotting (Fig. 44.1).

In the second stage, factors from either the intrinsic or the extrinsic system combine with platelet phospholipid to form complete thromboplastin.

In the third stage, thromboplastin converts prothrombin (factor II) to thrombin if ionized calcium is present. The production of prothrombin and factors VII, IX, and X depends on the presence of vitamin K. This stage will be incomplete if levels of any of factors VIII through XII, vitamin K, or calcium are deficient.

In the fourth stage, thrombin converts fibrinogen (factor I) to fibrin. Fibrin strands form a mesh incorporating RBCs, WBCs, and platelets to form a permanent protective seal at the site of injury. Factor XIII (fibrin stabilizing factor) acts to make the fibrin clot insoluble and permanent.

To prevent too much coagulation after the seal is complete, plasminogen is then converted to plasmin (a fibrinolysin) near the injury to halt the clotting sequence. Blood coagulation problems will result if any step or factor in the process is inadequate. Common tests for blood coagulation are described in Table 44.1.

TABLE 44.1 ✻ Tests for Blood Coagulation

Test	Definition	Normal Value
Prothrombin time (PT)	Measures action of prothrombin after complete thromboplastin is added to the blood in a test tube; reveals deficiencies in prothrombin, factors V, VII, and X. International Normalized Ratio (INR) is a comparative rating of PT ratios that allows for more sensitive analysis.	11–13 seconds (PT) 2.0–3.0 (INR)
Partial thromboplastin time (PTT)	Measures activity of thromboplastin after incomplete thromboplastin is added to blood in a test tube; reveals deficiencies in thromboplastin, factors VIII–XII	30–45 seconds
Bleeding time	Measures the time required for bleeding at a stab wound on the earlobe to cease; reveals deficiencies in platelet formation and vasoconstrictive ability	3–10 minutes
Clot retraction	Measures platelet function; interval from placement of blood in a tube to the point clot shrinks and expels serum	Retraction at side of test tube in 1 hour; complete in 24 hours
Tourniquet	Measures capillary fragility and platelet function; response of tissue to application of tourniquet to forearm for 5–10 minutes	0–2 petechiae per 2-cm area
Prothrombin consumption time	Evaluates thromboplastin function; child's blood is allowed to clot and PT is then done on the serum; if clot formation used a great deal of prothrombin (as it should), serum prothrombin time will be brief; prolongation denotes defects in thromboplastin function	Approximately 20 seconds
Thromboplastin generation time	Tests basic ability to form thromboplastin; difficult test to do; ordered rarely to distinguish factor VIII from factor IX defects	12 seconds or less
Plasma fibrinogen	Measures stage 4 clotting process; level of fibrinogen in blood	200–400 mg/100 mL plasma
Venous clotting time (Lee-White)	Measures factor defects in stages 2 and 4; time it takes venous blood to clot in a test tube	9–12 minutes

ASSESSMENT OF AND THERAPEUTIC TECHNIQUES FOR HEMATOLOGIC DISORDERS

Assessment of children with hematologic disorders begins with a history to identify inherited disorders. For specific diagnosis, children generally require several diagnostic procedures such as blood cell or bone marrow analysis.

Bone Marrow Aspiration and Biopsy

Bone marrow aspiration provides samples of bone marrow so that the type and quantity of cells can be determined (Beattie, 2007). In children, the aspiration sites used are the iliac crests or spines (rather than the sternum, which is commonly used in adults; Fig. 44.2) because these sites have larger marrow compartments during childhood. Also, performing the test at these sites is usually less frightening for children. In neonates, the anterior tibia can be used.

For a bone marrow aspiration, a child lies prone on a treatment table. Use of a hard table rather than a bed is advantageous because pressure is needed to insert the needle through the surface of the bone into the marrow compartment. Conscious sedation may be used to help reduce the child's fear. Topical anesthesia helps reduce pain.

The area of the aspiration is cleaned with an antiseptic solution and draped. The overlying skin is infiltrated with a local anesthetic. After a few minutes, a large-bore needle and stylus is introduced through the overlying tissue into the bone. This involves considerable pressure. When the marrow cavity is reached, the stylus is removed, a syringe is attached to the needle, and bone marrow is aspirated (appears as thick blood in the syringe). The syringe is then removed, and marrow is expelled onto a slide and allowed to dry. After being sprayed with a preservative, it is taken to the laboratory for analysis. The aspiration needle is removed, and pressure is applied to the puncture site to prevent bleeding. After another few minutes, a pressure dressing is applied.

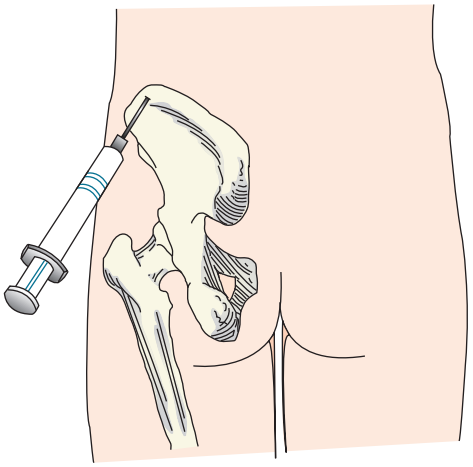

FIGURE 44.2 A common site used for bone marrow aspiration in children is the iliac crest. In neonates, the anterior tibia may be used.

A child feels pain from the local anesthetic injection and hard pressure while the needle is inserted. Some report a sharp pain when the marrow is actually aspirated. If conscious sedation is used, monitor vital signs until the child is fully awake. Monitor pulse and blood pressure and observe the dressing every 15 minutes for the first hour after the procedure to be certain that no bleeding is occurring. Keep the child fairly quiet for the first hour by playing a quiet game or other activity. Allow young children an opportunity for therapeutic play with a doll and syringe to help them express their feelings about such a painful, invasive procedure. If the procedure was done as an ambulatory procedure, instruct parents to take the child's temperature 12 and 24 hours after the procedure to detect infection.

Blood Transfusion

Transfusions of blood or its products are used in the treatment of many disorders, including the anemias and primary immunodeficiency disorders (see Chapter 42). A variety of forms of blood are available, including whole blood, packed RBCs, washed RBCs (as much "foreign" matter is removed as possible to reduce the possibility of blood reaction), plasma, plasma factors, platelets, WBCs, and albumin. No matter what is the blood product, it is important that it has been carefully matched with the child's blood type. Blood must be infused accompanied with a solution as nearly isotonic as possible (normal saline). If blood is given with a hypertonic solution, fluid will be drawn out of the RBCs, causing them to shrink; if infused with a hypotonic solution, fluid will be drawn into the cells, and they will burst. In both instances, they will be destroyed.

Packed RBCs is the most common form of transfusion used with children because they help minimize the risk of fluid overload. The usual amount of blood transfused to children is 15 mL/kg body weight. The commonly accepted rate for transfusions in a child is 10 mL/kg/hr unless the child has hypovolemic shock and volume equilibrium needs to be established. An infusion of packed RBCs at a proportion of 15 mL/kg can be expected to raise the hematocrit level 5 points. A transfusion of platelets will elevate the platelet count by approximately 10,000 cells. Platelets last only approximately 10 days, however, so transfusions of these must be repeated every 10 days.

Even if given slowly, a blood transfusion is always a strain on a child's circulation beyond that of a regular intravenous infusion, because the circulatory system must accommodate a thick, difficult-to-mobilize fluid.

Before any transfusion, ensure that a signed consent form is obtained to respect sociocultural or religious beliefs. Also obtain vital signs to establish a baseline. Monitor vital signs about every 15 minutes during the first hour and approximately every half hour for the remainder of the transfusion. Give the infusion slowly for the first 15 minutes; then increase the rate to 10 mL/kg/hr if no reaction occurs. Common symptoms of blood transfusion reactions are shown in Table 44.2.

Provide an enjoyable activity for children during transfusions. Without this, a child can become bored and could attempt to increase the infusion rate to speed up the process.

TABLE 44.2 ✻ Common Symptoms of Blood Transfusion Reactions

Symptoms	Cause	Time of Occurrence	Nursing Interventions
Headache, chills, back pain, dyspnea, hypotension, hemoglobinuria (blood in urine)	Anaphylactic reaction to incompatible blood; agglutination of red blood cells occurs; kidney tubules may become blocked, resulting in kidney failure	Immediately after start of transfusion	Discontinue transfusion. Maintain normal saline infusion for accessible intravenous line. Administer oxygen as necessary. Anticipate physician order for diuretic to increase renal tubule flow and reduce tubule plugging and/or heparin to reduce intravascular coagulation.
Pruritus, urticaria (hives), wheezing	Allergy to protein components of transfusion	Within first hour after start of transfusion	Discontinue transfusion temporarily. Give oxygen as needed. Anticipate physician order for antihistamine to reduce symptoms.
Increased temperature	Possible contaminant in transfused blood	Approximately 1 hour after start of transfusion	Discontinue transfusion. Obtain blood culture to rule out bacterial invasion as ordered.
Increased pulse, dyspnea	Circulatory overload	During course of transfusion	Discontinue transfusion. Give oxygen as needed. Provide supportive care for pulmonary edema and congestive heart failure. Anticipate physician order for diuretic to increase excretion of fluid.
Muscle cramping, twitching of extremities, convulsion	Acid-citrate-dextrose anticoagulant in transfusion is combining with serum calcium and causing hypocalcemia	During course of transfusion	Discontinue transfusion. Anticipate physician order for calcium gluconate intravenously to restore calcium level.
Fever, jaundice, lethargy, tenderness over liver	Hepatitis from contaminated transfusion	Weeks or months after transfusion	Obtain transfusion history of any child with hepatitis symptoms. Refer for care of hepatitis.
Bronze-colored skin	Hemosiderosis or deposition of iron from transfusion in skin	After repeated transfusions	Support self-esteem with altered body image. Administer iron-chelating agent (deferoxamine) as ordered to help reduce level of accumulating iron.

Hematopoietic Stem Cell Transplantation

Stem cell transplantation is the intravenous infusion of hematopoietic stem cells from bone marrow obtained by marrow aspiration or from peripheral or umbilical cord blood drawn from a donor to reestablish marrow function in a child with defective or nonfunctioning bone marrow. Donors are compatible when their human leukocyte antigen (HLA) system matches that of the recipient.

Hematopoietic stem cell transplantation has become a relatively common procedure for children with blood disorders such as acquired aplastic anemia, sickle-cell anemia, thalassemia, and leukemia and some forms of immune dysfunction diseases. Although a stressful procedure to undertake, it offers children the opportunity for a complete reversal of symptoms (Nuss & Wilson, 2007). There is no guarantee that the graft will be accepted by the recipient, or that improvement will occur. However, with good tissue

compatibility in the absence of infection, this can be effective in most children.

Hematopoietic stem cells can be recovered from circulating peripheral blood after the stimulation of stem cell production by a cytokine or stem cell colony-stimulating factor. Stem cell transplants are most successful when recipients have not already received multiple blood transfusions that have sensitized them to blood products. Success also depends on the HLA compatibility of donated stem cells to the child's blood. An identical twin is the ideal donor; a parent or sibling may be next best, although compatibility is not guaranteed. Siblings have about a 25% chance of being HLA compatible.

Stem cell transplants are allogeneic, synergeneic, or autologous. **Allogeneic transplantation** involves the transfer of stem cells from an immune-compatible (histocompatible) donor, usually a sibling, although a national registry allows compatible volunteer donors to be located. **Synergeneic transplantation** involves a donor and recipient who are genetically identical (are identical twins). **Autologous transplantation** involves use of the child's own stem cells. The source of most autologous transfusions is cord blood that was banked at the child's birth (Tse, Bunting, & Laughlin, 2008). If this is not available, stem cells are aspirated from the bone marrow or obtained from circulating blood, treated to remove abnormal cells, and then reinfused.

Parents who are found to be incompatible donors may feel guilty and frustrated they can not do more for their child. If the most compatible person for transplant is a young sibling, health care personnel and parents alike may have some reservations about submitting the young child to bone marrow aspiration (Weiner et al., 2007).

To prevent a child from rejecting newly transplanted donor stem cells by the T lymphocytes, a drug such as cyclophosphamide (Cytoxan) will be administered intravenously to the child before the procedure to suppress marrow and T-lymphocyte production. This may cause nausea and vomiting. Total body irradiation to destroy the child's marrow also may be done. This is a difficult time for the child because even with antiemetic therapy, total body irradiation causes extreme nausea, vomiting, and diarrhea.

To obtain hematopoietic stem cells from peripheral blood, donors receive 5 days of a colony-stimulating factor to promote the release of stem cells into the peripheral blood. Blood is then collected by a plasmapheresis technique. If umbilical cord blood is used, it is drained from the placenta immediately after birth. It is then cryopreserved in a cord blood bank and infused into the recipient by usual blood infusion technique.

If the marrow will be taken directly from a donor, on the day of the procedure, the donor is admitted to the hospital for a 1-day stay and receives epidural anesthesia or conscious sedation, as multiple bone marrow aspirations from the posterior iliac crests are necessary for retrieval. The marrow is strained to remove fat and bone particles and any other unwanted cells. An anticoagulant is added to prevent clotting. It is then infused intravenously into the recipient's bloodstream.

Because an infused hematopoietic stem cell solution is fairly thick, the infusion takes 60 to 90 minutes. Do not use a filter that is normally used for the infusion of blood products, because this would filter out marrow tissue. Monitor the child's cardiac rate and rhythm during the infusion to detect circulatory overload or pulmonary emboli from unfiltered particles.

Fever and chills are common reactions to a hematopoietic stem cell transplant infusion. Acetaminophen (Tylenol), diazepam (Valium), or diphenhydramine hydrochloride (Benadryl) may be prescribed to reduce this reaction.

After the infusion, take the child's temperature at 1 hour and then every 4 hours to detect infection that could occur because the child's WBCs are nonfunctional from radiation or immunosuppression. Reinforce strict handwashing and limit the child's diet to cooked foods to reduce exposure to bacteria.

Almost immediately after the infusion, stem cells begin to migrate from the child's bloodstream into the marrow. If engraftment occurs (the transplant is accepted), new RBCs can be detected in the peripheral blood in approximately 3 weeks. WBCs and platelet cells may not return to normal for up to 1 year after a transplant; weight gain may also be delayed (Box 44.3).

At first, the WBC count must be measured daily; bone marrow aspirations or venous blood samples are scheduled at regular intervals to assess the growth of the new marrow.

What if... Lana's 12-year-old sister donates hematopoietic stem cells to Lana, but the transplant does not "take"? How would you explain to the donor child that she did not fail?

BOX 44.3 ✻ Focus on Evidence-Based Practice

Do children continue to grow following hematopoietic stem cell transplantation?

To analyze the growth patterns of children following hematopoietic stem cell transplantation, researchers secured anthropometric measurements on 35 children who received a transplant in a tertiary children's hospital prior to their transplant and again at 2 and 4 months afterward. The results of the study showed that although height showed an increase, weight, skinfold triceps, and mid-arm circumference showed a decrease over the 4-month measurement period. Almost all children experienced gastrointestinal symptoms such as constipation, diarrhea, nausea, vomiting, change in taste, dry mouth, and loss of appetite that could have interfered with nutrition and be a cause of the delayed growth.

Based on the above study, would you be surprised if a child gained no weight in the 3 months since a hematopoietic stem cell transplant? Would it be important to assess gastrointestinal symptoms in all posttransplant children?

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Anxiety related to lack of knowledge about procedure and expected outcome of hematopoietic stem cell transplant

Outcome Evaluation: Parents state the reason for the transplant; state they are agreeable to the procedure even though they know the transplant may not be successful, depending on immunologic factors that are not totally known to science.

Hematopoietic stem cell transplantation is an emotional experience not only for the child but also for the parents and the marrow donor. Be certain that both the child who receives the transplant and the donor understand they are not responsible for the outcome of the transplant. Its success does not depend on their behavior or what kind of person they are but on immunologic factors over which they have no control. Be certain donors know that if bone marrow aspiration was done, the donor sites will feel tender afterward. Conscious sedation will leave them feeling exhausted for several days. Donors who have undergone bone marrow aspiration generally are asked to return to their primary care provider in 24 to 48 hours to be certain the aspiration sites are not infected (no local swelling, redness, intense pain, or fever).

Nursing Diagnosis: Risk for delayed growth and development related to extended restrictions and infection control precautions in hospital or at home

Outcome Evaluation: Parents express satisfaction with child's ongoing development. Objective tests of developmental stage show child within age-appropriate ranges.

Children may be restricted from interacting with other children to prevent them from contracting an infection following stem cell transplantation until the WBC count returns to a safe range. Because of this restriction, be certain they are not isolated from health care providers. Visit the room frequently; provide sterilized play materials as appropriate. Most children grow tired of a restricted diet and may crave fresh fruits and vegetables. Thick-skinned fruits such as bananas and oranges can be given soon after the procedure, but unwashed foods are avoided as they could carry bacteria.

Be certain children are well prepared for all procedures. Allow them to make as many choices as they can about their care to help them preserve a sense of control over their life. Children who receive a transplant need periods of therapeutic play incorporated into their care so they can begin to express their anger and frustration at the number of intravenous therapies or follow-up bone marrow aspirations they require. Measures to help children cope with pain, such as imagery, can help a child accept one more painful procedure. Encourage parents to spend time with their child during long periods of hospitalization for additional support.

Provisions for completing schoolwork need to be made as soon as a child has a return of RBCs in the peripheral blood (approximately 3 weeks). On the day of discharge, parents may be surprised that the child's blood replacement is not complete and that they will need to continue infection control measures and restrictions at home. Help them locate a support group in their community if possible. Be certain they feel free to call the transplant center after discharge if they have any problems. Once the danger of infection has passed and the restrictions can be discontinued, some parents may still be reluctant to allow their child outside, fearing that the child may still be susceptible to infection. Frequent follow-up for the next year not only is necessary to ensure that a child is free of infection but assesses whether the parents allow their child to pursue age-appropriate activities.

If children are prepared adequately for these painful or restrictive procedures and supported throughout, they should have no long-term consequences. Not all hematopoietic stem cell transplants are successful, however, and some children will die of the original disease that necessitated the transplant. A risk is that some children develop an infection despite all precautions and die of sepsis in the weeks immediately after the transplant.

Graft-Versus-Host Disease

Graft-versus-host disease (GVHD) is a potentially lethal immunologic response of donor T cells against the tissue of the bone marrow recipient (Saria & Gosselin-Acomb, 2007). The symptoms range from mild to severe and include a rash and general malaise beginning 7 to 14 days after the transplant. Latent virus infections may become active. Severe symptoms include high fever and diarrhea and liver and spleen enlargement as cells are destroyed.

Because there is no known cure for GVHD, prevention is essential. Careful tissue typing; intravenous administration of an immunosuppressant such as methotrexate, a corticosteroid, or cyclosporine before transplant; and irradiation of blood products (which helps to inactivate mature T lymphocytes) before stem cell infusion all can help reduce the incidence of this complication. Drugs such as methotrexate and cyclosporine kill all rapidly growing cells, including WBCs and T lymphocytes, so administration of these drugs after transplantation cannot be continued because they would also slow the growth of the host's new stem cells. Depletion of mature T lymphocytes from donor bone marrow before it is infused into the child offers good results, as does the administration of corticosteroids or antithymocyte globulin (ATG), an immune serum, to children after the transplant (Grosskreutz et al., 2007).

✔ Checkpoint Question 44.1

Lana, who has thalassemia major, is scheduled for a bone marrow transplant. Which is the best instruction for her regarding this?

a. She must not move while the bone marrow is infused into her.
b. She will not be allowed to eat raw fruit following the transplant.
c. Her hip bones will feel tender from the marrow transplantation.
d. She will not need any further bone marrow aspirations after this.

Splenectomy

One of the purposes of the spleen is to remove damaged or aged blood cells. This poses a problem with diseases such as sickle-cell anemia and the thalassemias because the spleen recognizes the typical cells of these diseases as damaged and destroys them. This causes children with these disorders to have a continuous anemia, with hemoglobin levels as low as 5 to 9 g/mL. In some children, therefore, removal of the spleen (splenectomy) will not cure the basic defect of the blood cells but will limit the degree of anemia (Owusu-Ofori & Hirst, 2009). Splenectomy formerly required a large abdominal incision but today it can be performed by laparoscopy.

A second function of the spleen is to strain the plasma for invading microorganisms so that phagocytes and lymphocytes can destroy them. This causes children who have had their spleen removed to be very susceptible to pneumococcal infections because this bacteria is no longer removed systematically from the body (Riddington & Owusu-Ofori, 2009). After surgery, oral penicillin is given as a prophylactic antibiotic for a year or two to guard against infection. The child should receive pneumococcal and meningococcal vaccines as well as routine immunizations, including influenza vaccine. Teach parents about signs of infection (cough, fever, general malaise), and encourage them to report any such signs immediately.

HEALTH PROMOTION AND RISK MANAGEMENT

Hematologic disorders cover a wide range of diseases and produce multiple symptoms in children (Box 44.4). Many disorders such as sickle-cell anemia and hemophilia are inherited. Health promotion and disease prevention, therefore, begins with ensuring that families have access to genetic counseling so they can be aware of the incidence of a disorder in their family and the potential for the disease to develop in their child.

The most frequently occurring anemia in children, iron-deficiency anemia, is preventable. This condition could be virtually eliminated if all infants were breastfed and those infants who are formula-fed were fed iron-fortified formula for the full first year. Also, when cereal is introduced, iron-fortified types should be used. The disorder occurs again with a high incidence in adolescents because adolescent diets tend to be low in meat and green vegetables, the chief dietary sources of iron. Adolescents who begin vegetarian diets become especially prone to developing the disorder. Counseling parents of young children to maintain well-child health care visits and urging adolescents to ingest iron-rich foods could have a major impact on decreasing the incidence of the disorder.

Aplastic anemia, or the inability to form blood elements, can be acquired if a child is exposed to a toxic drug or chemical. Educating parents about the importance of keeping poisons out of the reach of children could help decrease the incidence of this disorder.

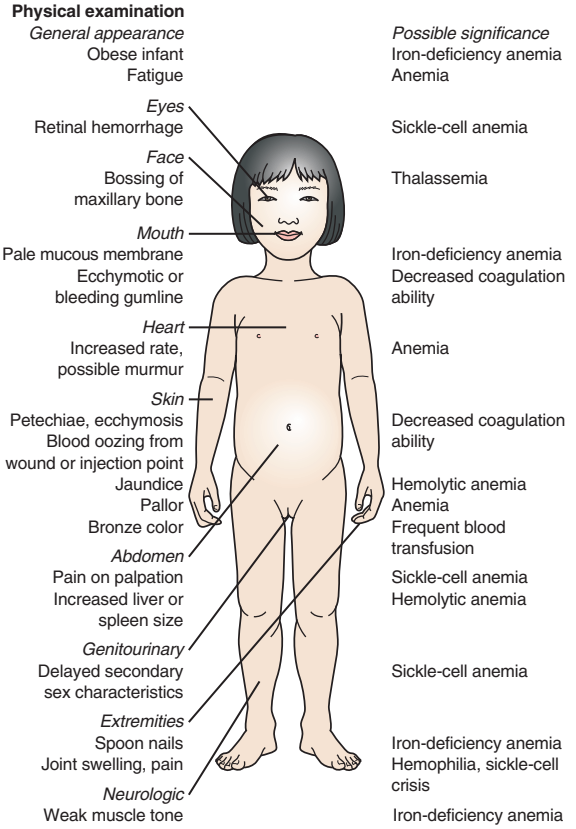
Nurses can also help make the therapy for these disorders much less painful and distressing than it was in the past. All hematologic disorders require obtaining blood specimens for diagnosis and continued testing for follow-up. Many therapies include blood product transfusion. The use of EMLA cream or topical lidocaine can greatly reduce the pain of venipuncture. Helping a child to use a distraction technique such as imagery can reduce apprehension or fear associated with the procedures or treatments.

Box 44.4 Assessment
Assessing a Child With a Hematologic Disorder

History

Chief concern: Fatigue, easy bruising, epistaxis.
Past medical history: Low birthweight; blood loss at birth; lack of vitamin K administration at birth.
Nutrition: "Picky eater" or presence of pica. Increasd milk intake.
Past illnesses: History of recent illness; history of recent medicine ingestion
Family history: Inherited blood disorder; parents known to have sickle-cell trait, thalassemia minor, or hemophilia in family.

Physical examination



DISORDERS OF THE RED BLOOD CELLS

Most RBC disorders fall into the category of the anemias, or a reduction in the number or function of erythrocytes. Polycythemia, or an increase in the number of RBCs, can also occur and may be as dangerous to a child as a reduction in RBC production.

Anemia occurs when the rate of RBC production falls below that of cell destruction, or when there is a loss of RBCs, causing their number and the hemoglobin level to fall below the normal value for a child's age. Anemias are classified according to the changes seen in RBC numbers or configuration, or according to the source of the problem.

Although any reduction in the amount of circulating hemoglobin lessens the oxygen-carrying capacity, clinical symptoms are not apparent until the hemoglobin level reaches 7 to 8 g/100 mL. Average values for hemoglobin and RBC number are shown in Appendix F.

Normochromic, Normocytic Anemias

Normochromic, normocytic anemias are marked by impaired production of erythrocytes by the bone marrow, or by abnormal or uncompensated loss of circulating RBCs, as with acute hemorrhage. The RBCs are normal in both color and size, but there are simply too few of them.

Acute Blood-Loss Anemia

Blood loss sufficient to cause anemia might occur from trauma such as an automobile accident with internal bleeding; from acute nephritis in which blood is lost in the urine; or in the newborn from disorders such as placenta previa, premature separation of the placenta, maternal–fetal or twin-to-twin transfusion, or trauma to the cord or placenta, as might occur with cesarean birth. It can also occur from intestinal parasites such as tapeworm (Barnett et al., 2007).

Children are in shock from acute blood loss and appear pale. As the heart attempts to push the reduced amount of blood through the body more rapidly, tachycardia will occur. Loss of RBCs needed for oxygen transport causes body cells to register an oxygen deficit, and children begin to breathe rapidly. Newborns may have gasping respirations, sternal retractions, and cyanosis. They will not respond to oxygen therapy because they lack RBCs to transport and use the oxygen. Such infants become listless and inactive.

This type of acute blood-loss anemia generally is transitory because the sudden reduction in available oxygen stimulates the release of erythropoietin from the kidney and a regeneration response in the bone marrow. The reticulocyte count becomes elevated, evidence the bone marrow is trying to increase production of erythrocytes to meet the sudden shortage.

Treatment involves control of bleeding by addressing its underlying cause. The child or infant should be placed in a supine position to provide as much circulation as possible to brain cells. Keep the child warm with blankets; place an infant in an incubator or under a radiant heat warmer. Blood transfusion may be necessary to provide an immediate increase in the number of erythrocytes. Until blood is available for transfusion, a blood expander such as plasma or intravenous fluid such as normal saline or Ringer's lactate may be given to expand blood volume and improve blood pressure.

Anemia of Acute Infection

Acute infection or inflammation, especially in infants, may lead to increased destruction or decreased production of erythrocytes. Common conditions include osteomyelitis, ulcerative colitis, and kidney infection. Management involves treatment of the underlying condition. When this is reversed, the blood values will return to normal.

Anemia of Renal Disease

Either acute or chronic renal disease can cause loss of function in kidney cells, and this causes an accompanying decrease in erythropoietin production. This decreases the stimulation for RBC production in the bone marrow, and a resultant normocytic, normochromic anemia occurs. Administration of recombinant human erythropoietin can increase RBC production and correct the anemia, but not the renal disease (Tse, Bunting, & Laughlin, 2008).

Anemia of Neoplastic Disease

Malignant growths such as leukemia or lymphosarcoma (common neoplasms of childhood) result in normochromic, normocytic anemias because invasion of bone marrow by proliferating neoplastic cells impairs RBC production. There may be accompanying blood loss if platelet formation also has decreased. The treatment of such an anemia involves measures designed to achieve remission of the neoplastic process and transfusion to increase the erythrocyte count.

Hypersplenism

Under normal conditions, blood is filtered rapidly through the spleen. If the spleen is enlarged and functioning abnormally, blood cells pass through more slowly, with more cells being destroyed in the process. This increased destruction of RBCs can cause anemia and may lead to pancytopenia (deficiency of all cell elements of blood). Virtually any underlying splenic condition can cause this syndrome.

Therapeutic management consists of treating the underlying splenic disorder, including possible splenectomy. Although the spleen's role in the body's defense mechanisms against infection is not well documented, the organ appears to be relatively important in early infancy. Its function decreases as a child grows older, and it may serve no immune function at all in adulthood. If the spleen is removed, there is no decrease in general immunity or in gamma globulin or antibody formation. With the removal of the spleen's filtering function, however, there seems to be an increased susceptibility to meningitis or pneumonia due to pneumococci. For this reason, a splenectomy may be delayed until after 2 years of age, when the risk of meningitis decreases. Such children should receive immunization against influenza, pneumococci, and *H. influenzae* in addition to prophylactic penicillin for 2 years after the splenectomy.

Aplastic Anemias

Aplastic anemias result from depression of hematopoietic activity in the bone marrow. The formation and development of WBCs, platelets, and RBCs can all be affected.

Congenital aplastic anemia (Fanconi syndrome) is inherited as an autosomal recessive trait. A child is born with several congenital anomalies, such as skeletal and renal abnormalities, hypogenitalism, and short stature. Between 4 and 12 years of age, a child begins to manifest symptoms of **pancytopenia,** or reduction of all blood cell components (Linker, 2009).

Acquired aplastic anemia is a decrease in bone marrow production that can occur if a child is exposed excessively to radiation, drugs, or chemicals known to cause bone marrow damage. Drugs that may cause this include chloramphenicol, sulfonamides, arsenic (contained in rat poison, sometimes eaten by children), hydantoin, benzene, or quinine. Exposure to insecticides also may cause severe bone marrow dysfunction. Chemotherapeutic drugs temporarily reduce bone marrow production. A serious infection such as meningococcal

pneumonia might cause autoimmunologic suppression of the bone marrow.

Assessment. When symptoms begin, a child appears pale, fatigues easily, and has anorexia. These symptoms reflect the lower RBC count (anemia) and tissue hypoxia. Because of reduced platelet formation **(thrombocytopenia),** the child bruises easily or has **petechiae** (pinpoint, macular, purplish-red spots caused by intradermal or submucous hemorrhage). A child may have excessive nosebleeds or gastrointestinal bleeding. As a result of a decrease in WBCs **(leukopenia),** a child may contract an increased number of infections and respond poorly to antibiotic therapy. Observe closely for signs of cardiac decompensation such as tachycardia, tachypnea, shortness of breath, or cyanosis from the long-term increased workload on the heart. Ask about any exposure to drugs or chemicals or recent infection. Bone marrow samples will show a reduced number of blood elements; blood-forming spaces become infiltrated by fatty tissue.

Therapeutic Management. The ultimate therapy for both congenital and acquired aplastic anemia is hemopoietic stem cell transplantation (Gluckman et al., 2007). If a donor cannot be located, the disease is managed by procedures to suppress T-lymphocyte–dependent autoimmune responses with antithymocyte globulin (ATG) or cyclosporine or transfusion of new blood elements (Ambruso, Hays, & Goldenberg, 2008). ATG, given intravenously, must always be administered cautiously because of the high risk for anaphylaxis. Packed RBCs and platelet transfusions are generally necessary to maintain adequate blood elements. Prophylactic platelet transfusions may be given (Ferrara et al., 2007). An RBC-stimulating factor (erythropoietin) may be helpful. Colony-stimulating factors may also improve bone marrow function. Some children show improvement with a course of an oral corticosteroid (prednisone). Testosterone to stimulate RBC growth may be tried.

For children who receive a hematopoietic stem cell transplant, chances of complete recovery are good. For others, the course is uncertain. A decreased platelet count may persist for years after other blood elements have returned to normal. Bleeding, therefore, especially petechiae or purpura, may be a long-term problem. Any drug or chemical suspected of causing the bone marrow dysfunction must be discontinued at once and the child must never be exposed to that substance again. Children with aplastic anemia are apt to be irritable because of their fatigue and recurring symptoms. Their parents may feel responsible for causing the illness if it originated from exposure to a chemical such as an insecticide. Many parents will have less confidence in health care personnel if the illness followed treatment with a drug such as chloramphenicol. They wonder how they can trust in a drug to cure the illness if they believe that one drug caused the illness. How can they trust that their child will not be harmed further?

When discussing with parents the outcome of this disease, be conservatively optimistic. It may be easier for parents to deal with this problem if they face only one day or one blood test at a time rather than trying to predict the outcomes of all the blood tests to come. They need to feel they can discuss their frustration and bitterness about continual abnormal results with health care personnel. Establishing good communication with these parents does much to establish their trust in everyone caring for their child.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for infection related to dramatic decrease in number of WBCs

Outcome Evaluation: Child's temperature remains below 100° F (38.0° C) axillary; symptoms of infection such as cough, vomiting, or diarrhea are absent.

Exposure to other children must be limited as long as WBC production is inadequate to prevent infection. Remind parents of the signs and symptoms of infection and advise them to come for treatment promptly if their child shows any of these signs. In the absence of granulocytes, however, antibiotic therapy may be ineffective, and severe septicemia can result. WBCs (granulocytes) may be transfused to counteract a severe infection.

Nursing Diagnosis: Risk for disturbed body image related to changed appearance occurring as medication side effect

Outcome Evaluation: Child views self as a worthwhile person; does not appear to be excessively shy or reluctant to interact with peers.

Children who receive corticosteroids such as prednisone to suppress the immune response almost always experience some of the drug's side effects, such as a cushingoid appearance, hirsutism, hypertension, and marked weight gain. Long-term therapy with testosterone can result in masculinizing effects, such as growth of facial and body hair, the development of acne, and deepening of the voice. Be sure both children and their parents know that these effects are related to the medication and that they will remain for an extended period but will fade when the medication is withdrawn.

Adolescents may have an especially difficult time accepting weight gain and increased acne. They need a chance to express their feelings about their changed appearance. Reinforce and emphasize positive attributes.

Nursing Diagnosis: Risk for injury related to ineffective blood clotting mechanisms secondary to inadequate platelet formation

Outcome Evaluation: Child exhibits no ecchymotic skin areas, gingival bleeding, or epistaxis; stools are negative for occult blood.

Inadequate platelet formation interferes with blood coagulation, placing a child at risk for bleeding (Box 44.5).

Hypoplastic Anemias

Hypoplastic anemias also result from depression of hematopoietic activity in bone marrow; they can be either congenital or acquired. Unlike aplastic anemias, in which WBCs, RBCs, and platelets are affected, in hypoplastic anemias only RBCs are affected.

Congenital hypoplastic anemia (Blackfan-Diamond syndrome) is a rare disorder that shows symptoms as early as

BOX 44.5 ✻ Techniques for Reducing Bleeding With Thrombocytopenia

Some techniques for reducing bleeding due to inadequate platelet formation include:

- Limit the number of blood-drawing procedures; combine samples whenever possible.
- Use a blood pressure cuff instead of a tourniquet to reduce the number of petechiae.
- Apply pressure to any puncture site for a full 5 minutes before applying a bandage.
- Minimize use of adhesive tape to the skin (pulling for removal may tear the skin and cause petechiae).
- Pad side and crib rails to prevent bruising.
- Protect intravenous sites to avoid numerous reinsertions.
- Administer medication orally or by intravenous infusion when appropriate to minimize the number of injection sites.
- Assess that the child is offered foods that can be chewed without irritation (avoid toast crusts, for example).
- Urge the child to use a soft toothbrush.
- Check toys for sharp corners, which may cause scratches. Urge the child to be careful with paper, because paper cuts can bleed out of proportion to their size.
- Assess the need for routine blood pressure determinations. Tight cuffs could lead to petechiae.
- Distract the child from rough play; suggest stimulating but quiet activities to minimize risk of injury.
- Keep a record of blood drawn; do not draw extra amounts "just in case" so children do not become more anemic.

the first 6 to 8 months of life. It affects both sexes and is apparently caused by an inherent defect in RBC formation. No changes in the leukocytes or platelets occur. An acquired form is caused by infection with parvovirus, the infectious agent of fifth disease (Servey, Reamy, & Hodge, 2007).

The onset of hypoplastic anemia is insidious, and at first it may be difficult to differentiate from iron-deficiency anemia. In iron-deficiency anemia, blood cells appear hypochromic and microcytic; in hypoplastic anemia, they are normochromic and normocytic but few in number.

With acquired hypoplastic anemia, the reduction of RBCs is transient, so no therapy is necessary. Children with the congenital form show increased erythropoiesis with corticosteroid therapy. Long-term transfusions of packed RBCs are needed to raise erythrocyte levels. As a result of the necessary number of transfusions, **hemosiderosis** (deposition of iron in body tissue) can occur. Therefore, an iron chelation program such as subcutaneous infusion **(hypodermoclysis)** of deferoxamine (Desferal) may be started concurrently with transfusions. Deferoxamine binds with iron and aids its excretion from the body in urine; it is given 5 or 6 days a week over an 8-hour period. This is one of the few times that an infusion is given subcutaneously. Parents can do this at home after careful instruction, often while their child is asleep at night. The parent must assess that voiding is present and specific gravity is normal (1.003 to 1.030) before drug administration.

For such an infusion, an area beside the scapula or on the thigh is cleaned with alcohol; a short 25-gauge needle is inserted at a low angle into only the subcutaneous tissue. The medication is then allowed to infuse slowly. Periodic slit-lamp eye examinations should be scheduled to check for cataract formation, a possible adverse effect of deferoxamine.

Congenital hypoplastic anemia is a chronic condition. However, approximately one fourth of affected children will undergo spontaneous permanent remission before age 13 years. If not, they are candidates for hematopoietic stem cell transplantation. Both the child and the parents need support from health care personnel to help them accept the many procedures and tests required.

✔ Checkpoint Question 44.2

Lana has received iron chelation therapy in the past. Iron chelation therapy is:

a. A procedure to remove excess iron from the child's body.
b. A procedure to help iron move effectively into hemoglobin.
c. A therapy to increase the iron level in bone and muscle cells.
d. A therapy to convert iron into calcium to increase heart action.

Hypochromic Anemias

When hemoglobin synthesis is inadequate, the erythrocytes appear pale (hypochromia). Hypochromia is generally accompanied by a reduction in the diameter of cells (RBCs are also microcytic).

Iron-Deficiency Anemia

Although the incidence of iron-deficiency anemia is decreasing in the United States due to improved infant nutrition, it is still the most common anemia of infancy and childhood, occurring when the intake of dietary iron is inadequate. Most iron in the body is incorporated in hemoglobin, but an additional amount is stored in the bone marrow to be available for hemoglobin production. Inadequate dietary iron prevents proper hemoglobin formation. With iron-deficiency anemia, RBCs are both small in size (hypocytic) and pale (hypochromic) due to the stunted hemoglobin.

Children are at high risk for iron-deficiency anemia because they need more daily iron in proportion to their body weight to maintain an adequate iron level than do adults. This results in a necessary daily intake of 6 to 15 mg of iron. Iron-deficiency anemia occurs most often between ages 9 months and 3 years; its frequency rises again in adolescence, when iron requirements increase for girls who are menstruating. It also is found in overweight teenagers if they ingest most of their calories from high-carbohydrate, not iron-rich, foods (Brotanek et al., 2007).

Causes in Infants. Several causes lead to iron-deficiency anemia. When an infant's diet lacks sufficient iron, the infant usually has enough in reserve to last for the first 6 months. After that, if the infant's diet continues to be iron deficient, there will be difficulty forming adequate RBCs. Infants of

low birth weight have fewer iron stores than those born at term because iron stores are laid down near the end of gestation. Because low-birth-weight infants also grow rapidly and their need for RBCs expands accordingly, they tend to develop iron-deficiency anemia before 5 to 6 months. As a preventive measure, they may be given an iron supplement beginning at about 2 months of age.

Women with iron deficiency during pregnancy tend to give birth to iron-deficient babies because the babies do not receive iron stores. Low hemoglobin levels from iron-deficiency anemia lead to diffusion of plasma proteins such as albumin and gamma globulin out of the bloodstream by osmosis. The loss of transferrin, a plasma protein responsible for binding iron to protein to facilitate its transportation to bone marrow after absorption from the gastrointestinal tract, further depletes this system of iron transport.

Infants born with structural defects of the gastrointestinal system, such as gastroesophageal reflux (chalasia—an immature valve between the esophagus and stomach, resulting in regurgitation) or pyloric stenosis (narrowing between the stomach and duodenum, resulting in vomiting), are particularly prone to iron-deficiency anemia. Although their diet is adequate, they cannot make use of the iron because it is never adequately digested. Infants with chronic diarrhea are also prone to this form of anemia due to inadequate absorption. Some infants develop minimal gastrointestinal bleeding if fed cow's milk; this is why breast milk or commercial formula is recommended for the full first year.

Iron-deficiency anemia can be prevented in formula-fed infants by giving them iron-fortified formula. If an infant is breastfed, iron-fortified cereal should be introduced when solid foods are introduced in the first year. Fortunately, these cost no more than nonfortified foods. Occasionally, an infant becomes constipated while ingesting iron-rich formula, but this is the exception rather than the rule.

Causes in Older Children. In children older than 2 years, chronic blood loss is the most frequent cause of iron-deficiency anemia. This is caused by gastrointestinal tract lesions such as polyps, ulcerative colitis, Crohn's disease, protein-induced enteropathies, parasitic infestation, or frequent epistaxis.

Adolescent girls can become iron deficient because of frequent attempts to diet and overconsumption of snack foods low in iron. Without sufficient iron, their body cannot compensate for the iron lost with menstrual flow.

Assessment. Common symptoms of iron-deficiency anemia are shown in Box 44.6. Children with iron-deficiency anemia appear pale. Because the pallor develops slowly, however, parents may not realize how extensive it is. They may describe their child as "fair-skinned" even though the child's pallor is so extreme the skin is transparent. In dark-skinned infants, pale mucous membranes may be the most significant finding.

Infants may show poor muscle tone and reduced activity. They are generally irritable from fatigue. Their heart may be enlarged, and there may be a soft systolic precordial murmur as the heart increases its action, attempting to supply body cells with more oxygen. The spleen may be slightly enlarged. Fingernails become typically spoon-shaped or depressed in contour.

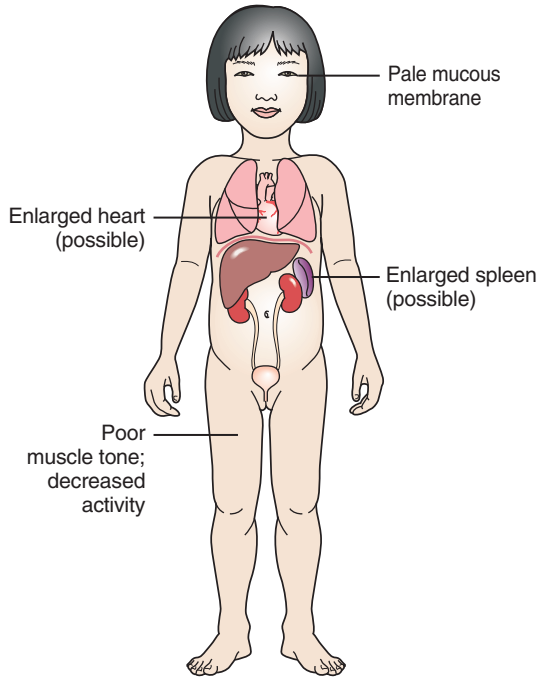
A 24-hour dietary history generally reveals an abnormally high milk intake. As a rule, infants should not ingest more than 32 oz of milk a day. Infants with iron-deficiency anemia may be drinking up to 50 oz a day. One quart of milk provides only approximately 0.5 mg of iron. In contrast, 1 tablespoon of iron-fortified baby cereal supplies 2.5 to 5.0 mg of iron.

As iron-deficiency anemia develops, laboratory studies will reveal a decreased hemoglobin level (a hemoglobin level less than 11 g/100 mL of blood) and reduced hematocrit level (below 33%). The RBCs are microcytic and hypochromic and possibly **poikilocytic** (irregular in shape). The mean corpuscular volume is low. The mean corpuscular hemoglobin may be reduced. Serum iron levels are normally 70 μg/100 mL; with iron-deficiency anemia the level is often as low as 30 μg/100 mL, with an increased iron-binding capacity (more than 350 μg/100 mL). The level of serum ferritin reflects the extent of iron stores so is less than 10 μg/100 mL (normal is 35 μg/mL). Without iron, heme precursors cannot be used, so free erythrocyte protoporphyrins increase to more than 10 μg/g from a normal of 1.9 μg/g.

Monoamine oxidase (MAO) is an enzyme important for central nervous system maturation. Iron is incorporated into MAO, so without iron this necessary enzyme is absent and central nervous system maturation may be affected.

There may be an association in school-age children between iron-deficiency anemia and poor school achievement, probably related to chronic fatigue. Iron-deficiency anemia is also associated with pica (the eating of inedible substances such as dirt and paper). Eating ice cubes is common in adolescents. Until the anemia is corrected, parents need to supervise the child's environment to keep inedible materials out of his or her reach.

Box 44.6 Assessment
Assessing a Child With Iron-Deficiency Anemia



BOX 44.7 ✻ Focus on Pharmacology

Ferrous Sulfate (Feosol)

Classification: Ferrous sulfate is an iron salt.
Action: Supplies iron for red cell production. It elevates the serum iron concentration and then is converted to hemoglobin or trapped in the reticuloendothelial cells for storage and eventual conversion to a usable form of iron (Karch, 2009).
Pregnancy risk category: A
Dosage: For severe iron-deficiency anemia: 4 to 6 mg/kg/day, in three divided doses. For mild iron-deficiency anemia: 3 mg/kg/day in two divided doses.
Possible adverse effects: Gastrointestinal upset, anorexia, nausea, vomiting, constipation, dark stools, stained teeth (liquid preparations)

Nursing Implications

- Instruct parents to administer the drug on an empty stomach with water to enhance absorption. If this causes gastrointestinal irritation, administer it after meals. Avoid giving it with milk, eggs, coffee, or tea.
- If the liquid preparation is ordered, advise parents to mix it with water or juice to mask the taste and prevent staining of teeth. Encourage the parents to have the child drink the medication through a straw to avoid staining of the teeth.
- Keep in mind that iron is absorbed best in the presence of vitamin C. Suggest parents give the iron with a citrus juice such as orange juice to help absorption. Some children may be prescribed vitamin C to take concurrently to increase absorption.
- Inform child and parents that iron may turn stools black.
- Encourage parents to include high-fiber foods in the child's diet to minimize the risk of constipation.
- Reinforce the need for thorough brushing of teeth to prevent staining.
- Remind parents about the need for follow-up blood studies to evaluate the effectiveness of the drug.

Therapeutic Management. Therapy for iron-deficiency anemia focuses on treatment of the underlying cause. Sources of gastrointestinal bleeding must be ruled out. The diet must be rich in iron and should contain extra vitamin C, as this enhances iron absorption. An iron compound such as ferrous sulfate for 4 to 6 weeks is the drug of choice to improve RBC formation and replace iron stores (Domellof, 2007) (Box 44.7).

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Imbalanced nutrition, less than body requirements, related to inadequate ingestion of iron

Outcome Evaluation: Parents report child's dietary intake includes iron-rich foods; parents administer ferrous sulfate as prescribed; serum iron levels increase to normal by 6 months.

When planning care for an infant with iron-deficiency anemia, it is helpful to minimize the child's activities to prevent fatigue, particularly at mealtime, as a fatigued child is more reluctant to eat any food, let alone eat iron-rich foods.

Counsel parents on measures to improve their infant's nutrition, such as adding iron-rich foods while decreasing formula or breast milk intake. If the child is not fond of meat, suggest parents substitute cheese, eggs, green vegetables, or fortified cereal. Because iron-rich foods are often expensive, remind parents that these items are important and that they should not substitute less expensive, high-carbohydrate foods. Before iron therapy is started, help parents create reminder sheets so they can manage to give the supplement over a long period of time. Alert parents to possible side effects, such as stomach irritation, constipation, and that liquid iron preparations can stain teeth if not taken through a straw. Iron is absorbed best with an accompanying acid medium so ascorbic acid may also be prescribed (or the parent be advised to give the iron medication with orange juice) to increase absorption. To avoid constipation, the child may need additional fiber like that supplied by green leafy vegetables. If oral iron is not tolerated or if there is a doubt the child will take it, an iron-dextran injection (Imferon) can be given intramuscularly. Imferon stains the skin and is extremely irritating unless it is given by deep Z-track intramuscular injection.

Of all age groups, adolescents tend to do the least well with taking medicine consistently. Help them plan a daily time for taking their iron supplement with a medication reminder chart. At first, they may reject this as childish, but assure them that everyone needs these charts. Review with them the iron-rich foods they will need to eat daily. An iron supplement is effective only if taken with iron-rich foods.

After 7 days of iron therapy, a reticulocyte count is usually obtained. If elevated, this means the child is now receiving adequate iron and the rapid proliferation of new erythrocytes is correcting the anemia. Iron medication must be taken for at least 4 to 6 weeks after the RBC count is normal to rebuild iron levels in the blood. In some children, maintenance therapy may continue for as long as a year.

Chronic Infection Anemia

Acute infection interferes with RBC production, producing a normochromic, normocytic anemia. When infections are chronic, anemia of a hypochromic, microcytic type occurs. This is probably caused by impaired iron metabolism as well as impaired RBC production.

The degree of anemia is rarely as severe as that occurring with iron deficiency. Administration of iron has little effect until the infection is controlled (Adamson & Longo, 2008).

Macrocytic (Megaloblastic) Anemias

A macrocytic anemia is one in which the RBCs are abnormally large (Primack & Mahaniah, 2008). These cells are actually immature erythrocytes or megaloblasts (nucleated immature red cells). For this reason, these anemias are often referred to as megaloblastic anemias. Because these anemias are caused by nutritional deficiencies, they occur less frequently in the United States than in developing countries.

Anemia of Folic Acid Deficiency

A deficiency of folic acid combined with vitamin C deficiency produces an anemia in which the erythrocytes are abnormally large. There is often accompanying neutropenia and thrombocytopenia. Mean corpuscular volume and mean corpuscular hemoglobin are increased, whereas mean corpuscular hemoglobin concentration is normal. Bone marrow will contain megaloblasts, indicating inhibition of the production of erythrocytes at an early stage. Megaloblastic arrest, or inability of RBCs to mature past an early stage, may occur in the first year of life from the continued use of infant food containing too little folic acid or from an infant drinking goat's milk, which tends to be deficient in folic acid. Treatment is daily oral administration of folic acid. Response to treatment is dramatic.

Pernicious Anemia (Vitamin B_{12} Deficiency)

Vitamin B_{12} is necessary for maturation of RBCs. Pernicious anemia results from deficiency or inability to use the vitamin (Waterbury, 2007). In children, the cause is more often lack of ingestion of vitamin B_{12}. The vitamin is found primarily in foods of animal origin, including both cow's milk and breast milk. Adolescents may be deficient in vitamin B_{12} if they are ingesting a long-term, poorly formulated vegetarian diet.

For absorption of vitamin B_{12} from the intestine, an intrinsic factor must be present in the gastric mucosa. In adults, lack of the intrinsic factor is the most frequent cause of the disorder. If a child has an intrinsic factor deficiency, symptoms can occur as early as the first 2 years of life (once the intrauterine stores of vitamin B_{12} have been exhausted). The child appears pale, anorexic, and irritable, with chronic diarrhea. The tongue appears smooth and beefy red due to papillary atrophy. In children, neuropathologic findings such as ataxia, hyporeflexia, paresthesia, and a positive Babinski reflex are less noticeable than in adults.

Laboratory findings reveal low serum levels of vitamin B_{12}. The rate and efficiency of absorption of vitamin B_{12} can be tested by the ingestion of the radioactively tagged vitamin. The dose absorbed in the presence and absence of a dose of intrinsic factor can be measured.

If the anemia is caused by a B_{12}-deficient diet, temporary injections of B_{12} will reverse the symptoms. If the anemia is caused by lack of the intrinsic factor, lifelong monthly intramuscular injections of B_{12} may be necessary. Parents and the child need to understand that lifelong therapy will be necessary.

Hemolytic Anemias

Hemolytic anemias are those in which the number of erythrocytes decreases due to increased destruction of erythrocytes. This may be caused by fundamental abnormalities of erythrocyte structure or by extracellular destruction forces.

Congenital Spherocytosis

Congenital spherocytosis is a hemolytic anemia that is inherited as an autosomal dominant trait. It occurs most frequently in the white Northern European population (Adamson & Longo, 2008). RBCs are small and defective, apparently due to abnormalities of the protein of the cell membrane that make them unusually permeable to sodium. The life span of erythrocytes is diminished.

The disease may be noticed shortly after birth, although symptoms may appear at any age. The hemolysis of RBCs appears to occur in the spleen, apparently from excessive absorption of sodium into the cell. The abnormal cell swells, ruptures, and is destroyed. Chronic jaundice and splenomegaly develop. The mean corpuscular hemoglobin concentration is increased because the cells are small. Gallstones may be present in the older school-age child and adolescent because of the continuous hemolysis, bilirubin release, and incorporation of bilirubin into gallstones.

Infections may precipitate a crisis or cause bone marrow failure. During such a period, the anemia increases rapidly as the hemolysis continues. Blood transfusion will be necessary to maintain a sufficient number of circulating erythrocytes until the crisis passes.

The diagnosis of the disease is based on family history, the obvious hemolysis, and the presence of the abnormal spherocytes. The treatment is generally splenectomy at approximately 5 to 6 years. This measure will increase the number of RBCs present but will not alter their abnormal structure.

Glucose-6-Phosphate Dehydrogenase Deficiency

The enzyme glucose-6-phosphate dehydrogenase (G6PD) is necessary for maintenance of RBC life. Lack of the enzyme results in premature destruction of RBCs. The disease is transmitted as a sex-linked recessive trait. It occurs most frequently in children of African American, Asian, Sephardic Jewish, and Mediterranean descent. Approximately 10% of African American males have the disorder (Waterbury, 2007). Because the disease is sex-linked, males of high-risk groups should be screened in infancy.

G6PD occurs in two identifiable forms. Children with congenital nonspherocytic hemolytic anemia have hemolysis, jaundice, and splenomegaly and may have aplastic crises. Other children have a drug-induced form in which the blood pattern is normal until the child is exposed to fava beans or drugs such as antipyretics, sulfonamides, antimalarials, and naphthaquinolones (the most common drug in these groups is acetylsalicylic acid [aspirin]). Approximately 2 days after ingestion of such an oxidant drug, the child begins to show evidence of hemolysis.

A blood smear will show *Heinz bodies* (oddly shaped particles in RBCs). The degree of RBC destruction depends on the drug and the extent of exposure to it. The child may have accompanying fever and back pain. Occasionally a newborn is seen with marked hemolysis because the mother ingested an initiating drug during pregnancy.

G6PD deficiency may be diagnosed by a rapid enzyme screening test or electrophoretic analysis of RBCs. Drug-induced hemolysis usually is self-limiting, and blood transfusions are rarely necessary. Both parents and children should be told of the abnormality in the child's metabolism so they can avoid common drugs such as acetylsalicylic acid.

Sickle-Cell Anemia

Sickle-cell anemia is the presence of abnormally shaped (elongated) RBCs. It is an autosomal recessive inherited disorder on the beta chain of hemoglobin; the amino acid valine takes the place of the normally appearing glutamic acid. The erythrocytes become characteristically elongated and crescent-shaped (sickled) when they are submitted to low oxygen tension (less than 60% to 70%), a low blood pH (acidosis), or increased blood viscosity, such as occurs with dehydration or hypoxia. When RBCs sickle, they can not move freely through vessels. Stasis and further sickling occur (a *sickle-cell crisis*). Blood flow halts and tissue distal to the blockage becomes ischemic, resulting in acute pain and cell destruction (Linker, 2009).

Because fetal hemoglobin contains a gamma, not a beta, chain, the disease usually will not result in clinical symptoms until a child's hemoglobin changes from the fetal to the adult form at approximately 6 months. However, the disease can be diagnosed prenatally by chorionic villi sampling or from cord blood during amniocentesis. If these were not done, it can be identified at birth by neonatal screening (Lees, Davies, & Dezateux, 2009). The abnormal form of hemoglobin in this disorder is designated hemoglobin S. A child with sickle-cell disease is said to have hemoglobin SS (homozygous involvement).

Sickle-cell disease occurs in about 1 of every 400 African American infants in the United States. Sickle-cell trait occurs in approximately 1 in 12 (Ambruso, Hayes, & Goldenberg, 2008).

Both parents of the child with the disease will have both normal adult and hemoglobin S or be carriers (heterozygous) of the *sickle-cell trait* (have hemoglobin AS). In people with the trait, approximately 25% to 50% of hemoglobin produced is abnormal. They produce enough normal hemoglobin to compensate for the hemoglobin that is sickled and therefore show no symptoms. A child with the disease (homozygous) produces no normal hemoglobin and so shows characteristic symptoms of sickle-cell anemia. A very few children have combinations of hemoglobin S and hemoglobin C or E, leading to mild anemia (Creary, Williamson, & Kulkarni, 2007).

Sickle-Cell Crisis. *Sickle-cell crisis* is the term used to denote a sudden, severe onset of sickling. Symptoms of crisis occur from pooling of many new sickled cells in vessels and consequent tissue hypoxia beyond the blockage (a *vaso-occlusive crisis*). A sickle-cell crisis can occur when a child has an illness causing dehydration or a respiratory infection that results in lowered oxygen exchange and a lowered arterial oxygen level, or after extremely strenuous exercise (enough to lead to tissue hypoxia). Sometimes no obvious cause of a crisis can be found (Box 44.8). Symptoms are sudden, severe, and painful (see Focus on Nursing Care Planning Box 44.9). Laboratory reports reveal a hemoglobin level of only 6 to 8 g/100 mL. A peripheral blood smear demonstrates sickled cells. The WBC count is often elevated to 12,000 to 20,000/mm^3. Bilirubin and reticulocyte levels are increased.

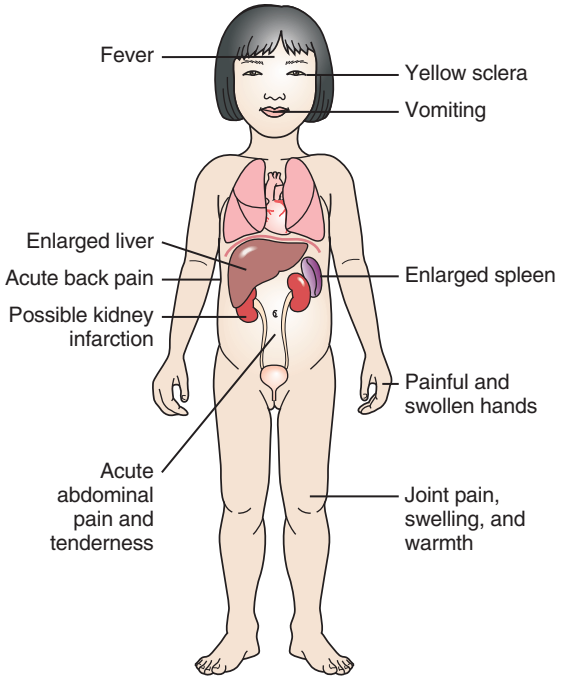
Further complications that may occur are aseptic necrosis of the head of the femur or humerus with increased joint pain or a cerebrovascular accident that occurs from a blocked artery, causing loss of motor function, coma, seizures, or even death (Owusu-Ofori & Hirst, 2009). If there is renal involvement, hematuria or flank pain may be present.

Additional types of crisis may occur.

- A *sequestration crisis* may occur when there is splenic sequestration of RBCs or severe anemia occurs due to pooling and increased destruction of sickled cells in the liver and spleen). This leads to shock from hypovolemia. The spleen is enlarged and tender.
- A *hyperhemolytic crisis* can occur when there is increased destruction of RBCs. A *megaloblastic crisis* may occur if the child has folic acid or vitamin B deficiency (new RBCs cannot be fully formed due to lack of these ingredients).
- An *aplastic crisis* is manifested by severe anemia due to a sudden decrease in RBC production. This form usually occurs with infection.

Assessment for Sickle-Cell Anemia. Hemoglobin electrophoresis is used to diagnose sickle-cell anemia at birth from the few red cells that have already converted to their adult form. At approximately 6 months of age, children with sickle-cell disease begin to show initial signs of fever and anemia. Stasis of blood and infarction may occur in any body part, leading to local pain. Some infants have swelling of the hands and feet (a hand–foot syndrome) probably caused by aseptic infarction of the bones of the hands and feet. Children with sickle-cell anemia tend to have a slight build and characteristically long arms and legs. They may have a protruding abdomen because of an enlarged spleen and liver. In adolescence, the spleen size may decrease from

Box 44.8 Assessment
Assessing a Child With Sickle-Cell Crisis



BOX 44.9 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Child With Sickle-Cell Anemia

Joey is a 7-year-old with sickle-cell anemia. He is seen in the emergency room for a vaso-occlusive crisis.

Family Assessment ✻ Child lives with two older brothers (10 and 12) and both parents in a 3-bedroom home. Father works as a distributor for a local water bottling company. Mother, an x-ray technician, is temporarily on duty with the National Guard in the Middle East. Father rates finances as, "Not good. Medical bills kill us."

Client Assessment ✻ Thin, black boy whose weight is at only 5th percentile for age. Was screened and diagnosed with sickle-cell anemia at birth. Described as "picky eater"; has eaten almost no meat since mother is not at home. Father states "I don't have time to fuss" over meals. Has a history of two former vaso-occlusive crises. Missed last regularly scheduled health assessment 2 weeks ago, as father had difficulty taking off from work for visit. Was playing "tag" with older brothers on local beach this afternoon. Sclera was jaundiced and child was crying from pain by time father returned from work. Hemoglobin 6 g/100 mL; hematocrit 31%.

Nursing Diagnosis ✻ Altered tissue perfusion related to vaso-occlusive crisis

Outcome Criteria ✻ Oxygen saturation level is maintained at 95% or higher; pain decreases to tolerable level; symptoms of hemolytic crisis decrease.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Assess if child understands he will need to remain in bed.	Admit child to hospital unit; restrict to bed rest.	Bedrest reduces the need for oxygen in body cells.	Child complies with bedrest; plays nonaction games with parent or health care personnel.
		Consultations		
Nurse practitioner/ physician	Assess if hematology service is needed for consult.	Meet with hematology service as needed for emergency and long-range consult.	Repeated vaso-occlusive crises suggest family needs better management strategies.	Hematology service meets with physician/nurse practitioner and parent and child as indicated.
		Procedures/Medications		
Nurse/nurse practitioner	Assess degree of child's pain by use of FACES pain scale.	Administer prescribed narcotic as required.	Vaso-occlusive crises can cause sharp pain that requires strong analgesia.	Child rates pain as no higher than 2 following analgesia administration.
Nurse	Assess O_2 saturation level by pulse oximetry.	Administer oxygen by face mask to keep O_2 saturation above 95% or as prescribed.	O_2 saturation decreases as sickled cells are unable to carry a full complement of oxygen.	Child cooperates with pulse oximetry and oxygen administration. SO_2 remains above 95%.
Nurse	Determine whether child has been taking folic acid at home.	Administer folic acid as prescribed.	Folic acid is necessary to build new red cells to replace those that have been hemolyzed.	Child takes folic acid cooperatively.
		Nutrition		
Nurse	Assess child's intake and output.	Begin IV therapy as prescribed.	IV therapy helps restore hydration and reduce sickle-cell clotting.	Child names best hand to start infusion; cooperates with arm board restriction.

Nurse/ nutritionist	Assess child's usual dietary intake by 24-hour dietary recall history.	Demonstrate child's reduced weight to parent using height/weight chart. Plan ways to increase calorie intake.	Even "picky eaters" need to take in enough food daily to meet growth and maintenance needs.	Parent states he will try harder to serve foods child likes; child voices intent to eat at least one meat helping daily.
		Patient/Family Education		
Nurse	Assess family members' understanding of the causes of sickle-cell vaso-occlusive crises.	Review with family members the importance of child avoiding dehydration and oxygen deficiency.	Dehydration leads to clumping of sickled cells, cutting off circulation in distant body parts.	Family members state they are aware they must be as responsible as child for avoiding sickling circumstances.
		Psychosocial/Spiritual/Emotional Needs		
Nurse	Assess the stress level of the family in light of absent mother and child with chronic illness.	Review with family ways to maintain a tight family unit (game night, common activities) to maintain family until mother returns.	When families miss a support person, they need to rally together to devise other support methods.	Father states he will try harder to meet children's needs although worrying about wife's safety is a major concern.
		Discharge Planning		
Nurse	Determine whether parent has any questions about care of a child with sickle-cell anemia.	Schedule a follow-up visit in 3 days for evaluation.	Care of a chronically ill child can be a major strain on a family. Follow-up visits help share responsibility for care.	Father states he understands importance of follow-up visit and will keep appointment with child.

repeated infarction and atrophy. An atropic spleen leaves a child more susceptible to infection than normal because the spleen can no longer filter bacteria. Pneumococcal meningitis and salmonella-induced osteomyelitis become frequent illnesses; prophylactic antibiotics and pneumococcal vaccine may be prescribed to prevent these infections (Davies et al., 2009).

An acute chest syndrome with symptoms of pulmonary infiltrates with chest pain, fever, tachypnea, wheezing, or cough that leads to pneumonia may also occur. Acute chest syndrome develops because, when areas of the lung become inflamed and hypoxic, sickle cells adhere to the activated endothelium and then fail to be reoxygenated (Adamson & Longo, 2008). Blood transfusion is used to increase the oxygen-carrying capacity of blood, and broad-spectrum antibiotics are given to resolve the pneumonia.

Another common complication occurs when the liver becomes enlarged from stasis of blood flow. Eventually, cirrhosis (fibrotic degeneration) will occur from infarcts and tissue scarring. The kidneys may have subsequent scarring also, so kidney function may be decreased. The sclerae are generally icteric (yellowed) from release of bilirubin from destruction of the sickled cells; small retinal occlusions may lead to decreased vision. Regular eye examinations are necessary in children with sickle-cell disease to detect this. Cell clusters in the blood vessels of the penis may cause **priapism,** or persistent, painful erection (Chinegwundoh & Anie, 2009).

Therapeutic Management. The child in sickle-cell crisis has three primary needs: pain relief and adequate hydration and oxygenation to prevent further sickling and halt the crisis.

Acetaminophen (Tylenol) may be adequate pain relief for some children; for others, a narcotic analgesic such as intravenous morphine may be needed. Once children are pain free, they are able to relax, reducing the metabolic demand for oxygen and helping to end the sickling. Hydration is generally accomplished with intensive intravenous fluid replacement therapy. Tissue hypoxia leads to acidosis. The acidosis must be corrected by electrolyte replacement. Some kidney infarction may have occurred, so do not administer potassium intravenously until kidney function has been determined (the child is voiding). Otherwise, excessive potassium levels may occur, possibly leading to cardiac arrhythmias. If infection appears to be the precipitator for a sickling crisis, blood and urine cultures, a chest radiograph, and a complete blood count will be taken and the infection will be treated by antibiotics. Blood transfusion (usually packed RBCs) may be necessary to maintain the hemoglobin above 12 g/dL (termed hypertransfusion).

Hydroxyurea, an antineoplastic agent that has the potential to increase the production of hemoglobin F (fetal hemo-

globin), can be used in children with sickle-cell disease to increase their overall hemoglobin level (Jones, Davies, & Olujohungbe, 2009). The drug, given orally, can cause anorexia. Therefore, monitor the child's nutrition intake during this drug therapy. If none of the above measures appears to be effective, children may be given an exchange transfusion to remove most of the sickled cells and replace them with normal cells. Exchange transfusion (see Chapter 26) must be done with small amounts of blood at each exchange. Otherwise, the pressure changes can cause such irregularities in blood volume that heart failure results. Hematopoietic stem cell transplantation is possible for the child who does not respond to usual therapies.

✔ Checkpoint Question 44.3

Joey, who has sickle-cell anemia, has had two vaso-occlusive crises in the past year. A vaso-occlusive crisis occurs because:

a. An enlarged spleen causes blood to pool there.
b. Dehydration leads to thrombosed sickle cells.
c. Hemorrhage reduces a child's total blood volume.
d. Decreased platelet number leads to poor coagulation.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Ineffective tissue perfusion related to generalized infarcts due to sickling

Outcome Evaluation: Child's respiratory rate is 16 to 20/min; cyanosis is absent; arterial blood gases within acceptable parameters including P_{CO_2} = 40 mm Hg; P_{O_2} = 80 to 90 mm Hg; oxygen saturation of 95%; urine output greater than 1 mL/kg/hr.

Oxygen may be administered by nasal cannula or mask if arterial blood gases reveal a low P_{O_2} level. Oxygen may not reach every distal body part effectively, however, if blood flowing to the part is obstructed by the sickled cells. When hemoglobin S is below 40%, there generally is adequate blood flow to body cells. High concentrations of oxygen are not used because hypoxia is a stimulant to erythrocyte production—production badly needed to replace damaged cells. Monitor the flow rate carefully and use pulse oximetry to evaluate oxygen saturation levels for changes. Encourage bed rest to relieve the pain and reduce oxygen expenditure (Box 44.10).

It is important to maintain accurate intake and output records and to test urine for specific gravity and hematuria to detect the extent or presence of kidney damage from infarcts.

Nursing Diagnosis: Ineffective health maintenance related to lack of knowledge regarding long-term needs of child with sickle-cell anemia

Outcome Evaluation: Parent accurately describes disease process and identifies special precautions necessary to prevent sickle-cell crisis.

In many children, episodes of sickling grow less severe as a child reaches adolescence. Such children will have a normal life expectancy but still experience the stresses of chronic illness. Other children experience such devastating episodes in early childhood that the disease becomes fatal at an early age. Parents need support to supervise children carefully day by day when they are aware that, due to the intense episodes, the child may die despite the precautions.

Between crises, care focuses on preventing recurring crises. Although the hemoglobin level of children may remain as low as 6 to 9 g/100 mL, children adjust well to this chronic state. Children who receive frequent blood transfusions should not be given supplementary iron or iron-fortified formula or vitamins or they may receive too much iron; high levels of excess iron are deposited in body tissues **(hemochromatosis)** to a point of staining body tissue or being incorporated into body tissue with fibrotic scarring (hemosiderosis). Oral folic

BOX 44.10 ✻ Focus on Communication

Joey, who has sickle-cell disease, is seen in the emergency department with a new vaso-occlusive crisis. His right knee is discolored by a large brush burn. He's crying from pain.

Less Effective Communication

Nurse: Hello, Mr. Harrow. I need to ask some questions to see if anything triggered this new crisis.
Mr. Harrow: He better not have been doing something he's not allowed to do.
Nurse: His knee looks like he fell. Were you running, Joey? So you got dehydrated?
Mr. Harrow: He better not say he was doing that!
Nurse: Joey, how did you hurt your knee?
Joey: I don't know.
Nurse: Okay. Let's get you better and not worry about what started this.

More Effective Communication

Nurse: Hello, Mr. Harrow. I need to ask some questions to see if anything triggered this new crisis.
Mr. Harrow: He better not have been doing something he's not allowed to do.
Nurse: His knee looks like he fell. Were you running, Joey? So you got dehydrated?
Mr. Harrow: He better not say he was doing that!
Nurse: Mr. Harrow, I need to get an accurate history of what happened. I'd like Joey to tell us how he thinks the accident happened. Then later on, we can talk about what are good rules for him to be following.

Children with blood disorders have to follow a great many rules to avoid clotting or bleeding episodes, such as not playing contact sports or playing too hard in the sun. Because these forbidden activities are appealing, children occasionally break the rules. In an emergency room, it is important that children and parents both recognize that the priority at the moment is obtaining an accurate history. Until they realize this, they may be so concerned with the broken rule that they are unable to move beyond that to secure adequate therapy.

acid may be prescribed to help rebuild hemolyzed RBCs.

Children with sickle-cell anemia need to be followed at regular health care visits. They must receive childhood immunizations so they are not vulnerable to common childhood infections such as measles or pertussis. They are also candidates for meningococcal, pneumococcal, and influenza vaccines to prevent infection. They may be prescribed oral penicillin as prophylaxis for the first 5 years. Puberty may be delayed, and both parents and children may need counseling to accept this. Once puberty changes do occur, they are adequate, just later than usual. Parents and children with sickle-cell disease also need support and positive reinforcement to enhance the child's self-esteem and to learn how to deal with problems that occur as a result of this chronic hematologic disorder (Box 44.11).

Caution parents to bring their child to a health care facility at the first indication of infection. Some parents are reluctant to do this, afraid that they will be labeled overprotective. Assure them that health care personnel are knowledgeable about sickle-cell anemia, and they know that a child with even a minor infection could become very ill.

Parents must make decisions regarding children's activity levels. Children should attend regular school and should be allowed to participate in all school activities except contact sports (such as football), which could result in rupture of an enlarged spleen or liver. Long-distance running is also inadvisable because it can lead to dehydration. During the summer, parents need to offer the child frequent drinks to prevent dehydration, especially on long hikes and at the beach. Caution parents against taking the child on board an unpressurized aircraft in which the oxygen concentration may fall during flight.

Some children who have had kidney infarcts and lessened ability to concentrate urine have chronic nocturnal enuresis (bedwetting).

Children with sickle-cell disease are at high risk if they need surgery. The hours of being held on nothing-by-mouth status, as well as being unable to eat afterward, may lead to dehydration. Anesthesia may cause a transient hypoxia leading to sickling. Parents must be cautioned that even for such a simple operation as tooth extraction, therefore, they must alert health care personnel about their child's condition.

BOX 44.11 * Focus on Family Teaching

School Safety Precautions for Children with Sickle-Cell Disease

Q. Joey's father says to you, "My son has sickle-cell disease. What can I do to help keep him safe at school?"

A. Use these guidelines to help ensure your son's safety at school:

- Be certain your child either takes fluid with him or buys adequate fluid for lunch. Children with sickle-cell anemia need to maintain a high fluid intake to prevent their blood from becoming thick.
- Provide additional fluid in the summer, when dehydration is more apt to happen. Anticipate ways to provide fluid during long hikes or school trips; time spent on a hot beach may need to be limited.
- Learn about sources high in folic acid, such as vegetables and fruit, and be certain these foods are included in your son's diet every day.
- Encourage the boy to get adequate sleep at night as a general measure to prevent illness.
- With the exception of contact sports (to avoid damage to an enlarged spleen) and long-distance running (to prevent dehydration), encourage your son to participate in normal school activities.
- Know that bedwetting may occur as part of the illness. Encourage your son to take baths in the morning if this occurs so his clothes don't smell of urine.
- Maintain routine health care such as immunizations to prevent common childhood illnesses such as measles and mumps, which cause fever and dehydration.
- Call your primary health care provider at the first sign of illness, such as an upper respiratory infection, so therapy can be begun immediately.

What if... Joey's parent tells you he restricts Joey, who has sickle-cell anemia, from drinking any fluid after 4 PM to prevent bedwetting? Is this a good solution to bedwetting for this child? How would you counsel this parent?

Thalassemias

The thalassemias are autosomal recessive anemias associated with abnormalities of the beta chain of adult hemoglobin (HgbA). Although these anemias occur most frequently in the Mediterranean population, they also occur in children of African and Asian heritage (Waterbury, 2007).

Thalassemia Minor (Heterozygous Beta-Thalassemia)

Children with thalassemia minor, a mild form of this anemia, produce both defective beta hemoglobin and normal hemoglobin. Because there is some normal production, the RBC count will be normal, but the hemoglobin concentration will be decreased 2 to 3 g/100 mL below normal levels. The blood cells are moderately hypochromic and microcytic because of the poor hemoglobin formation.

Children may have no symptoms other than pallor. They require no treatment, and life expectancy is normal. They should not receive a routine iron supplement because their inability to incorporate it well into hemoglobin may cause them to accumulate too much iron. The condition represents the heterozygous form of the disorder or can be compared with children having the sickle-cell trait.

Thalassemia Major (Homozygous Beta-Thalassemia)

Thalassemia major is also called Cooley's anemia or Mediterranean anemia. Because thalassemia is a beta chain

TABLE 44.3 ✻ Effects of Thalassemia Major

Body Organ or System	Effect of Abnormal Cell Production
Bone marrow	Overstimulation of bone marrow leads to increased facial-mandibular growth
Skin	Bronze-colored from hemosiderosis and jaundice
Spleen	Splenomegaly
Liver and gallbladder	Cirrhosis and cholelithiasis
Pancreas	Destruction of islet cells and diabetes mellitus
Heart	Failure from circulatory overload

hemoglobin defect, symptoms do not become apparent until a child's fetal hemoglobin has largely been replaced by adult hemoglobin during the second half of the first year of life. Effects of thalassemia major on body systems are summarized in Table 44.3. Unable to produce normal beta hemoglobin, the child shows symptoms of anemia: pallor, irritability, and anorexia (Muncie, 2008).

RBCs are hypochromic (pale) and microcytic (small). Fragmented poikilocytes and basophilic stippling (unevenness of hemoglobin concentration) are present. The hemoglobin level is less than 5 g/100 mL. The serum iron level is high because iron is not being incorporated into hemoglobin; iron saturation is 100%.

Assessment. To maintain a functional level of hemoglobin, the bone marrow hypertrophies in an attempt to produce more RBCs. This may cause bone pain; the ineffective attempt often leads to the formation of target cells or large macrocytes that are short-lived and nonfunctional. As bone marrow becomes hyperactive, this results in a characteristic change in the shape of the skull (parietal and frontal bossing) and protrusion of the upper teeth, with marked malocclusion. The base of the nose may be broad and flattened; the eyes may be slanted with an epicanthal fold, as in Down syndrome. A radiograph of bone shows marked osteoporotic (of lessened density) tissue, possibly resulting in fractures. The child may have hepatosplenomegaly due to excessive iron deposits and fibrotic scarring in the liver and the spleen's increased attempts to destroy defective RBCs. Abdominal pressure from the enlarged spleen may cause anorexia and vomiting. Epistaxis is common, as is diabetes mellitus due to pancreatic hemosiderosis (deposition of iron) and cardiac dilatation with an accompanying murmur. Arrhythmias and heart failure are frequent causes of death.

Therapeutic Management. Digitalis, diuretics, and a low-sodium diet may be prescribed to prevent heart failure, which could result from the decompensation that accompanies anemia, and from myocardial fibrosis caused by invasion of iron (hemosiderosis). Transfusion of packed RBCs every 2 to 4 weeks (hypertransfusion therapy) will maintain hemoglobin between 10 and 12 g/100 mL. With this level of hemoglobin, erythropoiesis is suppressed and cosmetic facial alterations, osteoporosis, and cardiac dilatation are minimized. Hypertransfusion therapy also reduces the possibility that splenectomy will be necessary. Frequent blood transfusions, unfortunately, increase the risk of blood-borne disease, such as hepatitis B, and hemosiderosis. Children may receive an oral iron-chelating agent to remove this excessive store of iron, such as deferasirox (Stumpf, 2007). Others receive deferoxamine given subcutaneously over 6 to 8 hours as they sleep at night (Karch, 2009).

Splenectomy may become necessary to reduce discomfort and also to reduce the rate of RBC hemolysis and the number of transfusions needed. Bone marrow stem cell transplantation can offer a cure. With treatment, the overall prognosis of thalassemia is improving but still grave. Most children with the disease die of cardiac failure during adolescence or as young adults if they do not receive a hematopoietic stem cell transplant (Muncie, 2008).

Nursing Diagnoses and Related Interventions ✻

Nursing Diagnosis: Risk for situational low self-esteem related to changed physical appearance

Outcome Evaluation: Child states he can accept altered appearance and interacts with peers.

Children with thalassemia major may have delayed growth and sexual maturation. They usually develop a marked change in facial appearance because of the overgrowth of marrow-producing centers of the facial bones. This can be demoralizing because these changes will be permanent. In addition, the child who receives frequent blood transfusions may develop such hemosiderosis that skin color appears bronze.

Children should be allowed as much activity as possible and should attend regular school, if possible, to maintain a nearly normal childhood. Discussions about other children's reactions to their changing facial appearance can be helpful.

Autoimmune Acquired Hemolytic Anemia

Occasionally, autoimmune antibodies (abnormal antibodies of the IgG class) attach themselves to RBCs, destroying them or causing hemolysis. This may occur at any age, and its origin is generally idiopathic, although the disorder may be associated with malignancy, viral infections, or collagen diseases such as rheumatoid arthritis or systemic lupus erythematosus. A child may recently have had an upper respiratory infection, measles, or varicella virus infection (chickenpox). Such hemolysis may occur after the administration of drugs such as quinine, phenacetin, sulfonamides, or penicillin.

The exact cause is unknown but appears to involve a change in the RBCs themselves, making them act as antigens, or a change in antibody production, making antibodies destructive to other substances.

Assessment. The onset is insidious. Children have a low-grade fever, anorexia, lethargy, pallor, and icterus from release of indirect bilirubin from the hemolyzed cells. Both

urine and stools appear dark because the excess bilirubin is being excreted. In some children, the illness begins abruptly with high fever, hemoglobinuria, marked jaundice, and pallor. The liver and spleen may be enlarged.

Laboratory findings reveal that the RBCs are extremely small and round (spherocytosis), resembling hereditary spherocytosis. The reticulocyte count is increased as the body attempts to form replacement RBCs. A direct Coombs' test result is positive, indicating the presence of antibodies attached to red cells. Hemoglobin levels may fall as low as 6 g/100 mL.

Therapeutic Management. In some children, the disease process runs a limited course and no treatment is necessary. In others, a single blood transfusion may correct the disturbance. For these children, it is difficult to cross-match blood for transfusion because the red cell antibody tends to clump or agglutinate all blood tested. If cross-matching is impossible, the child may be given type O Rh-negative blood. Observe the child carefully during any transfusion for signs of transfusion reaction.

If anemia is persistent, corticosteroid therapy (oral prednisone) to reduce the immune response is generally effective, increasing the RBC count and hemoglobin concentration in a short period. For some children, stronger immunosuppressive agents such as cyclophosphamide (Cytoxan) or azathioprine (Imuran) are necessary to reduce antibody formation. If these are ineffective, splenectomy may be necessary.

Often it is difficult for parents to understand the process causing their child's condition. How could a child's body turn on itself? How long will this last? What will stop it from happening again? There are no answers to these questions. Provide the parents and child with support as they wait for this unexplainable process to run its course and for their child to be well again.

✔ Checkpoint Question 44.4

Autoimmune acquired hemolytic anemia can occur in any child. The usual cause of this disorder is:

a. Allergy to the protein found in fish.
b. A mutant gene similar to sickle cell.
c. An elevated eosinophil cell count.
d. Antibody production against red cells.

Polycythemia

Polycythemia is an increase in the number of RBCs (Zull, 2007). The condition results from increased erythropoiesis, which occurs as a compensatory response to insufficient oxygenation of the blood in order to help supply more oxygen to body cells. Chronic pulmonary disease and congenital heart disease are the usual causes of polycythemia in childhood. Also, it may occur from the lower oxygen level maintained during intrauterine life in newborns or with twin transfusion at birth (one twin receives excess blood while a second twin is anemic).

Plethora (marked reddened appearance of the skin) occurs because of the increase in total RBC volume. Erythrocytes are usually macrocytic (large) and the hemoglobin content is high. This means that the mean corpuscular hemoglobin will be elevated; the mean corpuscular hemoglobin concentration, however, will be normal, indicating that, although many in number, each erythrocyte is normally saturated with hemoglobin. The RBC count may be as high as 7 million/mm^3. Hemoglobin levels may be as high as 23 g/100 mL.

Treatment of polycythemia involves treatment of the underlying cause. Because of the high blood viscosity from so many crowded blood cells, cerebrovascular accident or emboli may occur. The risk increases particularly if the child becomes dehydrated, such as with fever or during surgery. Exchange transfusion or phlebotomy to reduce the RBC count may be necessary.

DISORDERS OF THE WHITE BLOOD CELLS

Most disorders characterized by a decrease or increase in the number of WBCs or specific WBC components occur in response to another disease (often infection or an allergic reaction) in the body (Table 44.4). Laboratory values of WBCs, therefore, provide one of the first objective indicators of infectious disease, often aiding in specific diagnoses. These diseases are discussed in Chapter 43. Leukemia, overproduction of WBCs, is discussed with other malignant conditions in Chapter 53.

DISORDERS OF BLOOD COAGULATION

Platelets are necessary for blood coagulation, so disorders that limit the number of platelets limit the effectiveness of this process. A normal platelet level is 150,000/mm^3. Thrombocytopenia (decreased platelet count) is defined as a platelet count of less than 40,000/mm^3. Thrombocytopenia often leads to purpura, or blood seeping from vessels into the skin. In one rare disorder, children are born with thrombocytopenia and are also missing the radius bone in the forearm (TAR [thrombocytopenia/absent radius] syndrome).

Purpuras

Purpura refers to a hemorrhagic rash or small hemorrhages in the superficial layer of skin. Two main types of purpura occur in children: idiopathic thrombocytopenia purpura and Henoch-Schönlein syndrome.

Idiopathic Thrombocytopenic Purpura

Idiopathic thrombocytopenic purpura (ITP) is the result of a decrease in the number of circulating platelets in the presence of adequate megakaryocytes (precursors to platelets). The cause is unknown, but it is thought to result from an increased rate of platelet destruction due to an antiplatelet antibody that destroys platelets making this an autoimmune illness (Schmidt & Aldeen, 2007).

In most instances, ITP occurs approximately 2 weeks after a viral infection such as rubella, rubeola, varicella, or an upper respiratory tract infection. Congenital ITP may occur in the newborn of a woman who has had ITP during pregnancy. An antiplatelet factor apparently crosses the placenta and causes platelet destruction in the newborn in the same way that Rh incompatibility or hemolytic disease of the newborn develops (see Chapter 26). However, in ITP, the platelets, not the RBCs, are sensitized.

TABLE 44.4 ✻ Disorders of White Blood Cells

Disorder	Description	Causes/Treatment
Neutropenia	Reduced number of white blood cells	Transient phenomenon with nonpyrogenic infections such as viral disease Response to therapy with some drugs, such as 6-mercaptopurine or nitrogen mustard Possible side effect from drugs such as phenytoin sodium (Dilantin), chloramphenicol, or chlorpromazine Treatments: Possibly white blood cell transfusion; prophylactic antibiotics
Neutrophilia	Increased number of circulating white blood cells, primarily neutrophils (total number of cells increases and the proportion of mature neutrophils changes, with an increase in immature cells)	Usually in response to infection or inflammation (see Chapter 43) Treatment: antibiotic therapy to eliminate infectious organisms
Leukemia	Uncontrolled proliferation of white blood cells	Neoplastic disorder (see Chapter 53)
Eosinophilia	Increased number of eosinophils	Associated with many allergic disorders, such as atopic dermatitis, and with parasitic invasion (see Chapters 42 and 43)
Lymphocytosis	Increased number of lymphocytes	Normally occurs in the preschool period, when there is a marked predominance of lymphocytes in relation to neutrophils Abnormally elevated in childhood illnesses such as pertussis, infectious mononucleosis, and lymphocytic leukemia Treatment: Therapy for the underlying condition

Assessment. Manifestations often begin abruptly, first evidenced as miniature petechiae or as large areas of asymmetric ecchymosis most prominent over the legs, although they may occur anywhere on the body (Fig. 44.3). Epistaxis or bleeding into joints may be present.

Laboratory studies reveal marked thrombocytopenia. The platelet count may be as low as 20,000/mm^3. Bone marrow examination reveals a normal number of megakaryocytes.

Therapeutic Management. Oral prednisone to reduce the immune response and intravenous immunoglobulin (IVIG) or, in Rh-positive children, anti-D immunoglobulin to supply anti-ITP antibodies are used to treat ITP (Giulino, Bussel, & Neufeld, 2007). Platelet transfusion will temporarily increase the platelet count, but because the life span of platelets is relatively short, a platelet transfusion has only limited effect. Children with central nervous system bleeding may require a splenectomy although this is rarely necessary.

If the child experiences joint pain from bleeding, acetaminophen (Tylenol) rather than salicylates or ibuprofen is prescribed for pain. Both salicylates and ibuprofen increase the chance for bleeding as they prevent the aggregation of platelets at wound sites.

In most children, ITP runs a limited, 1- to 3-month course. A few children develop chronic ITP. A course of immunosuppressive drugs may be attempted if the chronic state persists.

All children need to be vaccinated against the viral diseases of childhood so that diseases such as rubella, rubeola, and varicella are eradicated and can no longer lead to this defective coagulation process.

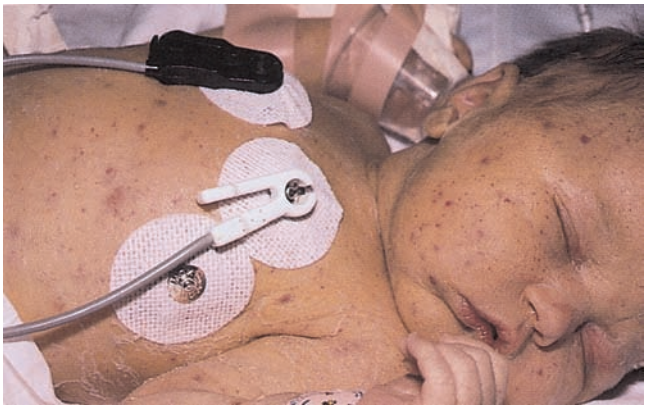


FIGURE 44.3 An infant with ITP. Notice the tiny petechiae and larger ecchymotic areas. (From Zitelli, B. J., & Davis, H. W. [1997]. *Atlas of pediatric physical diagnosis* [3rd ed.]. St. Louis: Mosby–Year Book, Inc.)

Nursing Diagnoses and Related Interventions ✻

Nursing Diagnosis: Health-seeking behaviors related to injury-prevention measures

Outcome Evaluation: Parents state precautions they will take to reduce possibility of bleeding; repeat correct dose and timing of medication therapy; child's

skin is free of ecchymotic areas; platelet count rises to normal values.

The techniques for reducing bleeding described earlier in the chapter such as padding surfaces where the child plays (see Box 44.5) can be used to reduce the possibility of bleeding for the child with ITP. Parents cannot eliminate the possibility of a serious bleeding injury, however, until the platelet count returns to normal. The chief danger to the child from ITP, aside from the psychological stress of a perplexing illness, is intracranial hemorrhage. Although this is rare, be alert for signs such as persistent headache, nuchal rigidity, and lethargy.

Nursing Diagnosis: Risk for compromised family coping related to diagnosis of child's illness

Outcome Evaluation: Parents state they understand the nature of their child's illness and have identified ways to carry out daily activities despite the illness.

Because symptoms such as the easy bruising of ITP mimics the beginning ones of leukemia, parents may be extremely frightened when symptoms first occur. You can assure them after the diagnosis is made that this bruising is not leukemia. If the ITP follows a long course (2 or 3 months), reassure them that this process will not later become leukemia. A child may have so many bruises that the parents are initially suspected of child abuse. This can cause them to become very defensive and angry at health care personnel. Allow them time to express their anger and regain confidence in their health care team.

It is always bewildering for parents to be told that no one knows exactly what is causing their child's illness. To feel comfortable that health care personnel can manage their child's care without knowing the exact cause, they need careful explanations of all procedures.

Henoch-Schönlein Syndrome

Henoch-Schönlein purpura (also called anaphylactoid purpura) is caused by increased vessel permeability. Although no definite allergic correlation can be identified, it is generally considered to be a hypersensitivity reaction to an invading allergen. It occurs most frequently in children between 2 and 8 years of age, and more frequently in boys than girls (Hellmann & Imboden, 2009). Usually, there is a history of a mild infection before the outbreak of symptoms. The syndrome presents (because of the purpura) as a possible platelet disorder until a differential diagnosis is made.

Assessment. The purpural rash occurs typically on the buttocks, posterior thighs, and extensor surface of the arms and legs (Fig. 44.4). The tips of the ears may be involved. The rash begins as a crop of urticarial lesions that change to pink maculopapules. These become hemorrhagic (bright red) and then fade, leaving brown macular spots that remain for several weeks. The child's joints are tender and swollen. The child may have gastrointestinal symptoms such as abdominal pain, vomiting, or blood in stools. Gross or microscopic hematuria may be present from kidney involvement. A biopsy shows granulocytes in the walls of small arterioles.

FIGURE 44.4 The distinctive purpural rash of Henoch-Schönlein syndrome appearing on the buttocks of a young child. (From Zitelli, B. J., & Davis, H. W. [1997]. *Atlas of pediatric physical diagnosis* [3rd ed.]. St. Louis: Mosby–Year Book, Inc.)

Laboratory studies show a normal platelet count. Sedimentation rate, WBC count, and eosinophil count are elevated.

Therapeutic Management. Treatment involves oral corticosteroid therapy (prednisone) and mild analgesics for a short period. Nose and throat cultures rule out continuing bacterial involvement. Urine should be assessed for protein and glucose to detect kidney involvement. Typically the disease runs a course of 4 to 6 weeks. A few children develop chronic nephritis as a complication (Butani & Morgenstern, 2007).

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) is an acquired disorder of blood clotting that results from excessive trauma or some similar underlying stimulus (Bowman, 2007). Normal blood clotting is a balance between the hemostatic (clotting) system and the fibrinolytic (dissolving) system of the bloodstream. After a blood vessel injury, local vasoconstriction rapidly prevents additional blood loss at the site. With the tear in the vessel wall, the underlying collagen is exposed. This causes platelets to swell and become adherent and irregular in shape. They release adenosine diphosphate, which attracts additional platelets and binds them together (platelet aggregation). This phenomenon results in a platelet plug to seal the vessel. The plug is strengthened by fibrin threads that form as a result of an intrinsic and extrinsic coagulation process into a firm, fixed structure. To prevent too much clotting from occurring, plasmin or fibrinolysin, a proteolytic enzyme formed from plasminogen, digests fibrin threads and causes lysis of the clot along with consumption of blood clotting factors. As plasmin, fibrinogen, and fibrin are lysed, fibrin degradation products are formed. These products prevent the laying down of further fibrin and platelet aggregation.

With DIC, an imbalance occurs between clotting activity and fibrinolysis. Extreme clotting due to endothelial damage begins at one point in the circulatory system, depleting the

availability of clotting factors such as platelets and fibrin from the general circulation. A secondary initiation of fibrinolysis begins as well. A paradox exists: the child has both increased coagulation and a bleeding defect at the same time. Many of the complications of pregnancy (abruptio placentae or death of a fetus) initiate DIC, so this is a common complication seen accompanying bleeding during pregnancy (see Chapter 21). DIC also tends to occur in children with acute infections or trauma.

Assessment

A child begins to have uncontrolled bleeding from puncture sites from injections or intravenous therapy. Ecchymoses and petechiae form on the skin. The toes and fingers may appear pale, cyanotic, or mottled and feel cold because small blood vessels are so filled with coagulated blood that circulation to the extremities is impaired. If coagulation is acute, neurologic or renal symptoms may occur from occlusion of vessels supplying the brain and kidneys. Observe all children with a serious illness carefully for signs of increased bleeding such as petechiae or oozing from blood-sampling sites to help identify that this is happening.

With DIC, laboratory tests usually reveal:

- Thrombocytopenia (level depends on the rate at which bone marrow can replace platelets)
- Large platelets on blood smear, possibly fragmented (from passing through meshes of collecting fibrin)
- Prolonged prothrombin and partial thromboplastin times
- Markedly low serum fibrinogen levels (less than 100 mg/100 mL)
- Elevated fibrin split products

Therapeutic Management

To halt the process of DIC, the underlying insult that began the phenomenon must be halted. Intravenous heparin administration helps to interfere with the marked coagulation. Although blood transfusion may be necessary to correct blood loss, it may be delayed until after heparin has been administered so that the new blood factors are not also consumed by the coagulation process. Fresh-frozen plasma, platelets, or fibrinogen may be administered.

With adequate therapy, the results of blood coagulation studies will return to normal. If renal or brain cells were damaged from occluded capillaries, permanent injury to these areas can result.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Deficient knowledge about blood clotting disorder related to its paradoxical nature

Outcome Evaluation: Client or parents accurately state nature of illness and proposed therapy; state signs and symptoms of disease; verbalize understanding of treatments.

Parents may be bewildered by the paradoxical problems of bleeding on the one hand and clotting on the other. If they understand the action of heparin—to discourage blood coagulation—their child's need and the medication seem directly contradictory. Be certain that both children and parents are given a full explanation. The child has an increased risk of hemorrhage because part of the coagulation system has used up coagulation factors; heparin is acting to stop this coagulation. This explanation will help parents understand what is happening and foster trust and confidence in caregivers.

Hemophilias

Hemophilia is an inherited disorder of blood coagulation. There are numerous hemophilia types, each involving deficiency of a different blood coagulation factor.

Hemophilia A (Factor VIII Deficiency)

The classic form of hemophilia is caused by deficiency of the coagulation component factor VIII, the antihemophilic factor. It is transmitted as a sex-linked recessive trait. In the United States, the incidence is approximately 1 in 10,000 white males. The female carrier may have slightly lowered but sufficient levels of the factor VIII component so that she does not manifest a bleeding disorder. Males with the disease also have varying levels of factor VIII, and their bleeding tendency varies accordingly, from mild to severe (Ambruso, Hays, & Goldenberg, 2008).

Factor VIII is an intrinsic factor of coagulation, so the intrinsic system for manufacturing thromboplastin is incomplete. The child's coagulation ability is not absent because the extrinsic or tissue system remains intact. Because of this system, the child's blood will eventually coagulate after an injury.

Assessment. Hemophilia often is recognized first in the infant who bleeds excessively after circumcision. If the disease has not shown itself for several generations in a family, the parents may be unaware of its existence. For this reason, all infants need careful and thoughtful observation after circumcision.

Because infants do not receive many injuries, children's bleeding tendencies may not become apparent until they become active (crawling, climbing, or walking).

Suddenly the lower extremities (where the child bumps things) become heavily bruised. There is soft tissue bleeding and painful hemorrhage into the joints, which become swollen and warm. The child holds the injured joint stiffly. Repeated bleeding into a joint causes damage to the synovial membrane (hemarthrosis), possibly resulting in severe loss of joint mobility.

Severe bleeding may also occur into the gastrointestinal tract, peritoneal cavity, or central nervous system. Interestingly, nosebleeds are common but are not as severe as with the platelet deficiency syndromes. The child must be identified as having hemophilia before surgery is performed for any reason; otherwise, fatal bleeding could occur.

With hemophilia, the platelet count and prothrombin time are normal. The whole blood clotting time is markedly prolonged or normal, depending on the level of factor VIII present. A thromboplastin generation test is abnormal. Partial thromboplastin time (PTT) is the test that best reveals the low levels of factor VIII.

Therapeutic Management. With even minor abrasions, bleeding must be controlled by the administration of factor VIII. This may be supplied by fresh whole blood or by fresh or frozen plasma, but it is best supplied by a concentrate of factor VIII. One bag of concentrate per 5 kg body weight is usually sufficient. This provides protection for approximately 12 hours; another transfusion may be necessary after that time. Powdered forms of factor VIII that can be stored at home and reconstituted as needed are available. In some children, administration of desmopressin (DDAVP), which stimulates the release of factor VIII, may be helpful. Prophylactic administration, although expensive, may best reduce bleeding episodes.

In a few children, antibodies (termed inhibitors) to factor VIII develop, rendering the factor ineffective. If this happens, epsilon-aminocaproic acid, a fibrinolytic enzyme that helps to stabilize clot formation and promote wound healing, can be self-administered every 6 hours if needed. Children with inhibitors to factor VIII can also be given a factor IX concentrate (Proplex or Konyne). This concentrate enters the coagulation cascade after factor VIII and halts bleeding.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Parental health-seeking behaviors related to strategies for protecting child from injury

Outcome Evaluation: Child's skin is free of ecchymotic areas; frequent epistaxis is absent; blood pressure is within age-appropriate parameters; swelling or warmth at joints is absent.

Parents need information about how to prevent bleeding episodes and also how to respond when one occurs. Prevention of injury is the most important intervention with these children. Help parents to set appropriate limits. An active infant may need to have crib sides padded; all toys need to be inspected for sharp edges or parts.

Parents (and the child as soon as approximately 10 years of age) can be taught to administer a replacement factor intravenously to prevent bleeding immediately after an injury. Although the child needs to be assessed by a health care provider, this action, combined with immobilization of the injured extremity and an ice pack applied locally, almost always eliminates the need for hospital admission. Pressure should be applied to a laceration to halt bleeding directly. "Butterfly bandages" are used in place of suturing for lacerations whenever possible, because sutures make additional puncture sites that could bleed.

Nursing Diagnosis: Pain related to joint infiltration by blood

Outcome Evaluation: Child states that pain is at a tolerable level.

The child with hemophiliac bleeding experiences discomfort because of the bleeding into joints and may be frightened because his parents are so frightened. Immobilization of the affected joint helps to decrease bleeding and also helps provide relief. Be certain that immobilized joints are in good alignment. As soon as the acute bleeding episode has halted (approximately 48 hours), perform passive range of motion as ordered to maintain function. Acetaminophen (Tylenol) rather than ibuprofen is ordered as an analgesic because ibuprofen may prolong bleeding. As soon as effective levels of factor VIII have been provided, the pain in the bleeding joint is generally relieved, despite the continued heat or swelling.

Nursing Diagnosis: Risk for interrupted family processes related to fears regarding child's prognosis and long-term nature of illness

Outcome Evaluation: Family members voice their fear regarding illness; state that they can cope despite stress level; demonstrate positive coping responses.

Parents of children with hemophilia are frightened during a time of acute bleeding, not just because of what is currently happening but also because they may have seen other family members or even a previous child die of the disease. Be certain to give them a chance to talk about how the bleeding began ("I should have noticed that toy had a sharp edge," "He fell from his bike. I should have watched him more closely"). It is extremely important for parents to allow the child to lead a normal life. Remind them that it is impossible to prevent all injuries. Assist them with measures that offer them a sense of control over the situation. As children reach school age, they must learn to monitor their own activities to prevent bleeding episodes.

von Willebrand's Disease

von Willebrand's disease, an inherited autosomal dominant disorder affecting both sexes, is often referred to as angiohemophilia. Along with a factor VIII defect, there is also an inability of the platelets to aggregate. In addition, the blood vessels cannot constrict to aid in coagulation. Bleeding time is prolonged, with most hemorrhages occurring from mucous membrane sites.

Epistaxis is a major problem, because all children tend to rub or pick at their nose as a nervous mechanism. In girls, menstrual flow is unusually heavy and may cause embarrassment from stained clothing. Childbirth is obviously a risk for women with von Willebrand's disease (James & Jamison, 2007). Bleeding is controlled with factor VIII replenishment as with hemophilia, or by administration of DDAVP, which stimulates factor VIII release.

Christmas Disease (Hemophilia B, Factor IX Deficiency)

Christmas disease, caused by factor IX deficiency, is transmitted as a sex-linked recessive trait. Only approximately 15% of people with hemophilia have this form. Treatment is with a concentrate of factor IX, available for home administration (Linker, 2009).

Hemophilia C (Factor XI deficiency)

Hemophilia C or plasma thromboplastin antecedent deficiency, caused by factor XI deficiency, is transmitted as an autosomal recessive trait occurring in both sexes. The symptoms

are generally mild compared with those in children with factor VIII or factor IX deficiencies. Bleeding episodes are treated with administration of DDAVP or transfusion of fresh blood or plasma (Ambruso, Hays, & Goldenberg, 2008).

✔ Checkpoint Question 44.5

Disseminated intravascular coagulation can occur in any child with a critical illness. The drug of choice you would expect to administer for this condition is:

a. Erythropoietin, to stimulate new red cells.
b. Methotrexate, to decrease red cell number.
c. Heparin, to halt abnormal coagulation.
d. Prednisone, to decrease the immune reaction.

Key Points for Review

- Hematopoietic stem cell transplantation is the main therapy for numerous blood dyscrasias. Transplantation can be allogeneic (from a histocompatible donor) or autologous (using the child's own marrow or umbilical cord blood) or synergeneic (the donor and recipient are identical twins).
- Splenectomy, another possible treatment, may increase a child's susceptibility to pneumococcal infections. Assess whether a child has received pneumococcal vaccine after a splenectomy.
- Disorders of the red blood cells that commonly occur in children include acute blood-loss anemia and anemia of acute infection. Aplastic and hypoplastic anemias occur from depression of hematopoietic activity in bone marrow. These anemias can be congenital or acquired.
- A major hypochromic anemia that develops in children is iron-deficiency anemia. Children invariably fatigue easily because they cannot oxygenate body cells well. Their care must include measures to keep them from tiring; oxygen administration may be necessary.
- Macrocytic anemias occur from folic acid deficiency and pernicious anemia (vitamin B_{12} deficiency).
- Hemolytic anemias include congenital spherocytosis, glucose-6-dehydrogenase deficiency, sickle-cell anemia, thalassemia, and autoimmune acquired hemolytic anemia. Sickle-cell anemia occurs most often in African American children.
- Disorders of white blood cells that occur include neutropenia (reduced number of white blood cells) and neutrophilia (increased number). Neutropenia makes children susceptible to infection.
- Disorders of blood coagulation include the purpuras (idiopathic thrombocytopenic purpura and Henoch-Schönlein syndrome), disseminated intravascular coagulation, and the hemophilias.
- Children with blood coagulation disorders must carefully guard against injury. This includes monitoring types of toys and activities. It may include padding a crib or side rail.
- Disorders of the blood tend to be long-term illnesses. Education of the parents and child is important to promote adaptation to the condition and enhance long-term medication therapy.

CRITICAL THINKING EXERCISES

1. Lana is the 4-year-old girl diagnosed with thalassemia major whom you met at the beginning of the chapter. She has a prominent mandible and wide-spaced upper front teeth from overgrowth of bone marrow centers. Her skin is bronze from the number of transfusions (64) she has received in her short lifetime. "Why is my daughter starting to look different?" Lana's mother asks you. What additional health teaching does Lana's mother need to help her better understand her daughter's disease? How would you explain why skin color changes have happened to her daughter?
2. Joey, a 7-year-old with sickle-cell anemia, is seen at the same clinic as Lana. His growth is only in the fifth percentile, and he has had two vaso-occlusive crises in the past year. Every summer for the past 2 years, while he has been home from school on summer vacation, he has had an acute episode of his illness. What assessments would you want to make of his family before this summer? What precautions would you want to discuss with them?
3. Justin is a 5-year-old boy with hemophilia who wants to join a preschool soccer program. How would you counsel his family regarding this plan?
4. Examine the National Health Goals related to hematologic disorders in children. Most government-sponsored funds for nursing research are allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to Lana's family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to hematologic disorders in children. Confirm your answers are correct by reading the rationales.

Chapter 45

Nursing Care of a Family When a Child Has a Gastrointestinal Disorder

KEY TERMS

- beriberi
- celiac disease
- dehydration
- gastroesophageal reflux
- hiatal hernia
- inguinal hernia
- insensible loss
- intussusception
- irritable bowel syndrome
- keratomalacia
- kwashiorkor
- liver transplantation
- McBurney's point
- Meckel's diverticulum
- necrotizing enterocolitis
- nutritional marasmus
- overhydration
- pellagra
- rickets
- scurvy
- steatorrhea
- volvulus
- xerophthalmia

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe common gastrointestinal disorders seen in children.
2. Identify National Health Goals related to gastrointestinal disorders and children that nurses could help the nation achieve.
3. Analyze ways that nursing care of a child with a gastrointestinal disorder could be more family centered.
4. Assess a child with a gastrointestinal disorder.
5. Formulate nursing diagnoses for a child with a gastrointestinal disorder.
6. Develop expected outcomes for a child with a gastrointestinal disorder.
7. Plan nursing care for a child with a gastrointestinal disorder.
8. Implement nursing care for a child with a gastrointestinal disorder, such as preparing the child for surgery.
9. Evaluate expected outcomes for achievement and effectiveness of care.
10. Identify areas of care related to gastrointestinal disorders and children that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of gastrointestinal disorders with nursing process to achieve quality maternal and child health nursing care.

Barry Abraham is a 2-year-old boy diagnosed with celiac disease whom you see at a birthday party. His abdomen is protuberant, yet his arms and legs seem thin and wasted. He refuses to eat a piece of birthday cake even though his mother sits beside him insisting on it. "See the problem I have with him?" she asks you. "He eats nothing. When he does, he gets diarrhea."

Previous chapters described the growth and development of well children and the nursing care for children with disorders of other systems. This chapter adds information about the dramatic changes, both physical and psychosocial, that can occur when children develop gastrointestinal disorders. Such information builds a base for care and health teaching for children with these disorders.

Does Barry's mother understand her son's disease? Is she choosing wise food selections for him?

The gastrointestinal (GI) system involves a long body tract and numerous organs. Because it is so long and diverse, a multitude of possible disorders can occur along it, including both congenital disorders and acquired illnesses. Because the GI system is responsible for taking in and processing nutrients for all parts of the body, any problem with the system can quickly affect other body systems and, if not adequately treated, can affect overall health, growth, and development.

Health education is extremely important for children with GI disorders and their families because it can be difficult to appreciate the seriousness of GI illness. Often, parents are surprised to find that what they thought was a simple "stomach flu" has caused serious electrolyte imbalances and possibly a life-threatening state for their child. Some GI disorders require both parents and child to learn new nutritional patterns. When children are young, the parents need education concerning this topic. As children grow older, counseling to help them maintain self-esteem and learn nutritional requirements so they can become independent become important.

Food poisoning and hepatitis are examples of GI illnesses that are so pervasive that national health goals have been set to limit their incidence (see Box 45.1).

Nursing Process Overview

For a Child With a Gastrointestinal Disorder

Assessment

Children with GI disorders quickly become dehydrated, especially if vomiting or diarrhea is a symptom. This means they need to be assessed for signs of fluid loss, such as poor skin turgor, dry mucous membranes, or lack of tearing. When talking to parents about a child's symptoms, ask exactly what they mean when they say "spitting up" or "a little vomiting." Also ask how many times a child has voided or how many diapers have been wet in the past 24 hours, and whether this is less than usual. Compare the child's current weight with past weight measurements, if available. Unless the child is an adolescent who has been actively dieting, there is never a normal reason for weight loss in children.

Ask parents to describe what they mean by diarrhea as some parents mistakenly confuse normal newborn or infant stools with diarrhea. As a rule, all children with diarrhea, especially small children, need to be seen by a health care provider because fluid and electrolyte changes occur rapidly in children because of the greater percentage of fluid held extracellularly rather than intracellularly.

For many children, a GI tract disorder is diagnosed largely by presenting symptoms such as those just described. In other instances, x-ray studies with a contrast medium (barium) or an endoscopic examination may be needed to confirm the presence of an anomaly. Ultrasound or magnetic resonance imaging (MRI) also may be helpful. Another important assessment area is laboratory testing for electrolyte balance through serum analysis or fluid concentration through urinalysis.

Nursing Diagnosis

Nursing diagnoses relevant to children with GI disorders invariably center on imbalanced nutrition, because most GI diseases alter the kind and amount of nutrients ingested or absorbed into the body in some way. However,

BOX 45.1 ✻ Focus on National Health Goals

Nutrition deficiencies, unsafe food preparation, and hepatitis are three areas that could be reduced in incidence if people knew more about them and took active interventions to reduce their occurrence or spread. National Health Goals addressing these include:

- Reduce infections caused by key food-borne pathogens such as *Salmonella* infection from 13.6 per 100,000 to 6.8 per 100,000, *Listeria* infection from 0.47 per 100,000 to 0.24 per 100,000, and *E. coli* infection from 22 per 100,000 to 11 per 100,000.
- Increase the proportion of persons 2 years of age and older who meet the daily recommendation of calcium from 45% to 74%.
- Reduce the incidence of chronic hepatitis B viral infections in infants and young children (perinatal infections) from a baseline of 1682 instances per year to a target level of 400 instances per year.
- Reduce the rate of hepatitis B infections in adolescents 19 to 24 years of age from 24 per 100,000 population to 2.4 per 100,000 population.
- Reduce the incidence of hepatitis C from a baseline of 2.4 new cases per 100,000 population to 1 new case per 100,000 population.
- Reduce the rate of hepatitis A infection from a baseline of 11.3 per 100,000 to 4.5 per 100,000 (http://www.nih.gov).

Nurses can help the nation achieve these goals by counseling parents about safe food preparation and the need for children to ingest adequate calcium for sound bone growth, by serving as consultants to day care providers to reduce the spread of stool contamination in these settings, and by actively administering hepatitis A and B vaccines to infants and adolescents to eradicate these forms of the illness in another generation. Nursing research in several areas could be helpful: What is the best media to use to educate parents about safe food preparation? Does the brand of diapers used by children in day care influence the spread of infectious stool? How many infants are not being brought for follow-up care and so do not receive all three immunizations against hepatitis B? Do most parents appreciate the devastating outcome that can result from hepatitis?

GI disorders also take an emotional toll on the ill child and family. Feeding is one of the primary ways mothers bond with their newborns, so bonding can be seriously threatened when a newborn develops a GI disorder, especially when hospitalization is required. The process of eating and the types of food eaten are also integral components of family life and culture, so any disruption caused by illness can place a strain on the entire family. Examples of nursing diagnoses are:

- Impaired parenting related to interference with establishing parent–infant bond
- Interrupted family processes related to chronic illness in child
- Risk for deficient fluid volume related to chronic diarrhea
- Imbalanced nutrition, less than body requirements, related to malabsorption of necessary nutrients
- Situational low self-esteem related to feelings of being different resulting from special dietary restrictions

Outcome Identification and Planning

Planning care for a child with a GI disorder often includes nutritional planning with the child and parents. Be certain when helping to plan a new nutritional pattern that the person who actually prepares or supervises the child's nutrition is included. In many instances, some of the foods that a child eats may be prepared by a babysitter, day care center staff, the child's other parent, or a grandparent. Many children eat breakfast and lunch at school cafeterias. That means it may be necessary to contact school staff to ask them to make meal exceptions for a child or to supervise a choice of foods (or to see that a child eats only the packaged lunch brought to school, not extra items the child trades for with friends).

Some parents are unfamiliar with basic food categories and the importance of providing food from the food pyramid in children's diets. When a special diet is requested, they may have little understanding of which foods have high or low fiber content, or which foods are "bland" or "clear." Many parents have difficulty keeping children restricted to "nothing by mouth" (NPO) for tests or to rest the GI tract as they have been told that dehydration happens quickly in infants (which it does). They need support to follow the necessary restrictions when those restrictions are so opposed to basic parenting, which involves giving food.

If feedings will be given by nasogastric or gastrostomy tube, parents need enough practice time to be comfortable with the equipment and the technique before they are given the responsibility of doing it alone at home. If a child is going to gag or become distressed when a new tube is passed, parents need to have this happen where there are calm, supportive people nearby, not when they are by themselves at home.

Anticipate the need for additional support for the family and child with a chronic GI disorder. Agencies that might be helpful for referral are the Celiac Disease Foundation (http://www.celiac.org), Crohn's and Colitis Foundation of America (http://www.ccfa.org), International Foundation for Functional Gastrointestinal Disorders (http://www.iffgd.org), and North American Society for Pediatric Gastroenterology, Hepatology and Nutrition (http://www.naspgn.org).

Implementation

Never underestimate the difficulty family members may experience adapting to alternative nutrition methods such as total parenteral nutrition or enteric or gastrostomy feedings, or caring for a child with a colostomy. Parents need a great deal of support to adapt their busy life to these alternative methods of feeding or care.

GI disorders that occur at birth are discussed in Chapter 27. Insertion of a nasogastric tube, enteral and parenteral nutrition, and administration of an enema are discussed in Chapter 37. Be certain to give clear, simple explanations, and praise both parents and child after they demonstrate these procedures. Children can easily interpret enemas as punishment because of the extreme intrusiveness. Provide therapeutic play before and after these procedures to reduce children's anxiety.

Outcome Evaluation

Recording children's height and weight is a primary method to evaluate nutritional outcomes. Even if a diet is limited in a special way, if it is adequate, children should gain weight and maintain growth.

Because children will ultimately be responsible for their own nutrition, expected outcomes should include making certain that children gradually learn more about their specific nutritional measures so they can become increasingly responsible for their own intake. Often, only when they are at this stage can their parents feel secure enough to let them stay overnight with a friend, visit a relative in a distant city, go to summer camp—activities that become important to children as they reach school age.

The saying "people are what they eat" has some relevance. Children who require special nutritional plans need to be evaluated for self-esteem at periodic health visits. Do children think of themselves as inferior to or different from others because of food restrictions? What kind of positive experiences can be offered to such children, or what can parents do to provide children with experiences that would improve self-esteem?

Some examples of expected outcomes are:

- Child lists examples of bland foods to select for lunch from school cafeteria menu.
- Parent states steps she will take to seek medical care if child has a second episode of severe diarrhea.
- Family members state they have adjusted to care of a child with celiac disease.

ANATOMY AND PHYSIOLOGY OF THE GASTROINTESTINAL SYSTEM

Embryonic development of the GI tract is discussed in Chapter 9. Digestion begins in the mouth, where food is broken down into small particles and mixed with saliva from the sublingual, submandibular, and parotid glands. Both gagging and swallowing reflexes are present even in newborns to prevent aspiration with swallowing. Digestion continues in the stomach and small intestine, the same as in adults.

The esophagus pierces the diaphragm to serve as a passageway to the stomach (Fig. 45.1). Occasionally, an infant is born with a portion of the bowel or stomach protruding

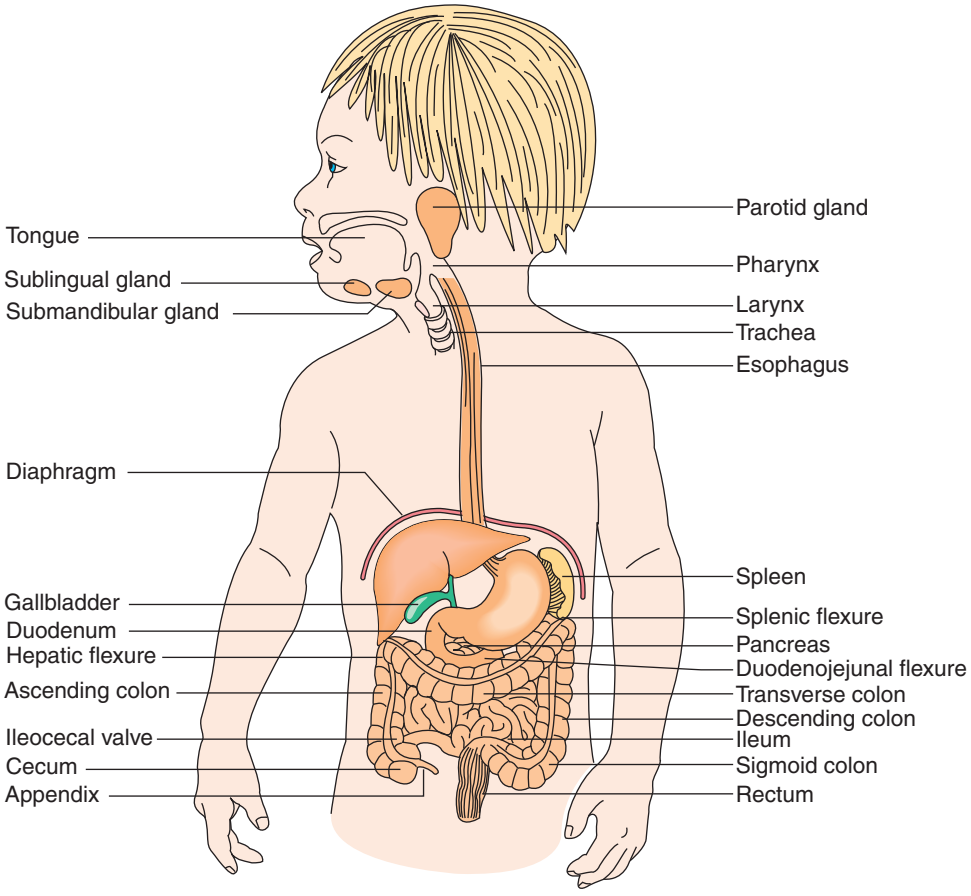

FIGURE 45.1 The gastrointestinal tract.

through the diaphragm's esophageal opening (hiatal or diaphragmatic hernia). At the junction of the esophagus and the stomach is the gastroesophageal (cardiac) sphincter. In some newborns, this sphincter is so lax that fluid regurgitates into the esophagus (gastroesophageal reflux). At the distal end of the stomach is the pyloric sphincter. In some infants, this valve is narrowed (stenosed), preventing food from flowing out of the stomach freely (pyloric stenosis). Originally, it was believed that the stomach was sterile because the action of hydrochloric acid could easily kill invading organisms and limit infections. However, since the discovery that a bacterium, *Helicobacter pylori,* is the cause of peptic ulcer disease, it is obvious that organisms can and do survive in the stomach. Vomiting and diarrhea are symptoms that arise because of stomach or intestinal infections (McQuaid, 2009).

The small intestine is divided into three sections: duodenum, jejunum, and ileum. The large intestine is divided into the cecum, ascending colon, transverse colon, descending colon, sigmoid colon, and rectum. The appendix, which frequently becomes diseased in children, is attached to the cecum.

DIAGNOSTIC AND THERAPEUTIC TECHNIQUES

Several typical procedures are used in the diagnosis and therapy of GI disorders. Common diagnostic procedures include fiberoptic endoscopy, colonoscopy, and barium enema. Children need good preparation for these procedures because they are potentially frightening. If children receive conscious sedation for a procedure, they need preparation for this as well as the actual procedure.

Therapy may include alternative methods of feeding such as enteral (nasogastric or gastrostomy tube feedings) or nutrition sources such as total parenteral nutrition and intravenous (IV) therapy to rest the GI tract. A colostomy or ileostomy may be created to further rest the GI tract. As these are used for other disorders as well, these procedures, their meaning, their impact on children, and nursing responsibilities are discussed in Chapters 37 and 38.

HEALTH PROMOTION AND RISK MANAGEMENT

Health promotion related to GI disorders focuses on a wide area because the causes of these disorders cover a wide range. Some disorders, such as appendicitis, cannot be prevented because they occur for unpredictable causes. Some, such as celiac disease (sensitivity or abnormal immunologic response to protein), involve genetic aspects that cannot be changed. Some, such as Crohn's disease and ulcerative colitis, are associated with an autoimmune response. Other conditions, such as vomiting and diarrhea, are often caused by foods that were

refrigerated improperly or spread through improper handwashing and thus can be prevented. A vaccine to prevent rotavirus infections is recommended for infants (Soares-Weiser et al., 2009). Hepatitis can be prevented through good handwashing (hepatitis A) and immunization (hepatitis A and B). Vitamin and protein deficiency disorders can be prevented by educating parents about the food pyramid and how to select foods that fit each of the sections.

The incidence of GI illnesses varies among communities. Vomiting and diarrhea, for example, tend to occur because of food poisoning in communities where refrigeration is less than optimal, and people eat raw meat or unprocessed cheese. Celiac disease occurs most frequently in children of Northern European ancestry. Because constipation, vomiting, and diarrhea are so common, every culture has home remedies for these symptoms: cascara for constipation; psyllium for diarrhea; ginger, peppermint, licorice, or chamomile tea for nausea or vomiting. To be certain that a child seen in a health care facility does not receive two forms of the same drug (one prescribed and one given in an herb form by a parent), always ask what home remedies have been given and document these on the child's plan of care.

Because any interference in nutrition pervades many aspects of children's lives, families often need help with planning care. Help families plan the necessary adaptations to their lifestyle to prevent the disease from interfering with family functioning (Will day care center personnel do gastrostomy feedings? Will a nursery school accept a child with a colostomy? Can a child select a gluten-free diet at the school cafeteria?). All families should be encouraged to eat at least one meal a day together so they can have time to share experiences and "touch base" with each other. For the family with a child who has a feeding problem such as a gastrostomy feeding or total parenteral nutrition, this can be difficult. Urge such families to bring the child to the table for a social time even if the child cannot eat with the family. If watching family members eat while the child cannot is too difficult, urge the family to provide a "together" time in some other way so they do not miss out on this valuable family activity.

Some GI disorders in children, such as aganglionic megacolon, are diagnosed late because parents think the child's refusal to eat is just the sign of being a "picky eater" or a manifestation of 2-year-old autonomy. Educating parents about normal nutrition and how to distinguish things such as vomiting from illness from normal "spitting up" or severe diarrhea from a simple GI upset helps parents bring their children for care at the earliest possible time. Early intervention prevents the child from becoming dehydrated and seriously ill.

FLUID, ELECTROLYTE, AND ACID–BASE IMBALANCES

The GI system plays a major role in maintaining fluid, electrolyte, and acid–base balance. It is the main route by which substances are taken into the body and can be a major source of loss if vomiting or diarrhea occurs (Holliday, Ray, & Friedman, 2007).

Fluid Balance

Retaining fluid is of greater importance in the body chemistry of infants than that of adults because fluid constitutes a greater fraction of the infant's total weight. In adults, body water accounts for approximately 60% of total weight. In infants, it accounts for as much as 75% to 80% of total weight; in children, it averages approximately 65% to 70%.

Fluid is distributed in three body compartments: (a) intracellular (within cells), 35% to 40% of body weight; (b) interstitial (surrounding cells and bloodstream), 20% of body weight; and (c) intravascular (blood plasma), 5% of body weight. The interstitial and the intravascular fluid together are often referred to as the *extracellular fluid* (ECF), totaling 25% of body weight. In infants, the extracellular portion is much greater, totaling up to 45% of total body weight (Fig. 45.2). In young children, this amount is 30%; in adolescents, it is 25%.

Fluid is normally obtained by the body through oral ingestion of fluid and by the water formed in the metabolic breakdown of food. Primarily, fluid is lost from the body in urine and feces. Minor losses, **insensible losses,** occur from evaporation from skin and lungs and from saliva (of little importance except in children with tracheostomies or those requiring nasopharyngeal suction). Infants do not concentrate urine as well as adults because their kidneys are immature. As a result, they have a proportionally greater loss of fluid in their urine. In infants, the relatively greater surface area to body mass also causes a greater insensible loss. Fluid intake is altered when a child is nauseated and unable to ingest fluid

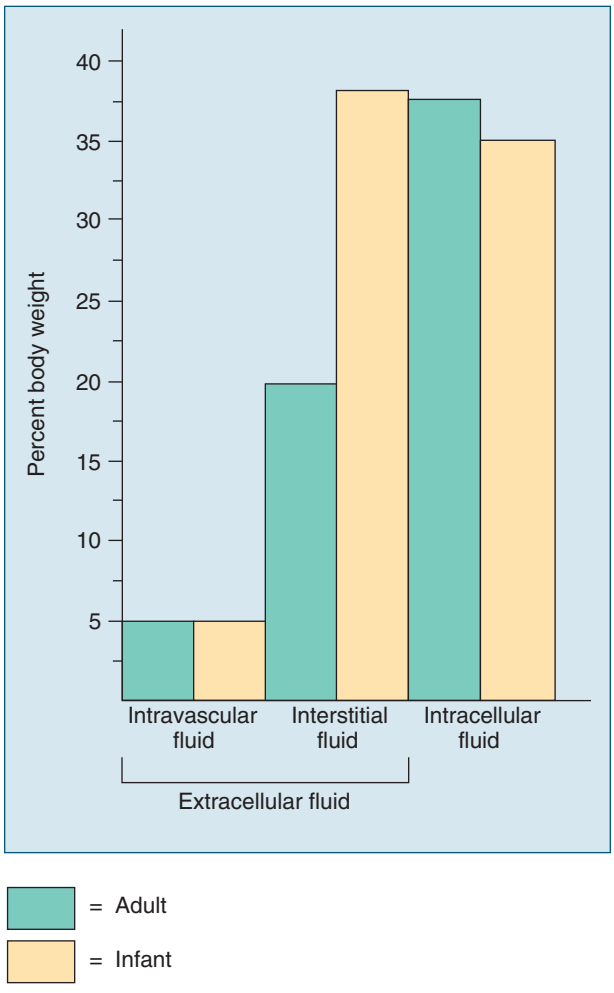

FIGURE 45.2 Distribution of fluid in body compartments.

TABLE 45.1 ✻ A Method to Calculate Fluid Requirement

Body Weight	Fluid Requirement per 24 h
Up to 10 kg	100 ml/kg
11–20 kg	1000 ml + 50 ml/kg for each additional kg over 10 kg
More than 20 kg	1500 ml + 20 ml/kg for each additional kg over 20 kg

or is vomiting and losing fluid ingested. When diarrhea occurs, or when a child becomes diaphoretic because of fever, the fluid output can be markedly increased. **Dehydration** occurs when there is an excessive loss of body water (Scherb, Stevens, & Busman, 2007).

In an adult's weighing 70 kg, the extracellular fluid volume is approximately 14,000 mL. Each day, the well adult's ingests approximately 2000 mL of fluid and excretes approximately 2000 mL as urine. This means that approximately 14% of the adult's total ECF (2000 mL of 14,000 mL) is exchanged each day. In contrast to this, 7-kg infants have an ECF volume of only 1750 mL. They ingest approximately 700 mL daily and excrete approximately 700 mL daily. Therefore, they exchange approximately 40% of their volume daily. As a result of this increased exchange rate, infants' fluid balance may be more critically affected when they are ill. Adults, when they do not eat for a day because of a GI upset, and whose kidneys continue to excrete at the normal rate, will have 14% less fluid in the extracellular space by the end of the day. Infants who do not eat for a day (providing kidney function remains constant) will be 40% short of ECF by the end of the day. This is obviously a more important loss of fluid than the same loss would be in an adult; therefore, dehydration is always a more serious problem in infants than in older children and adults. Requirements of fluid for infants and children are shown in Table 45.1.

Fluid Imbalances

Under most circumstances, water and salt are lost in proportion to each other (*isotonic dehydration*). Occasionally, water is lost out of proportion to salt or water depletion or *hypertonic dehydration* occurs. Occasionally, electrolytes are lost out of proportion to water (*hypotonic dehydration*). Each of these abnormal states produces specific symptoms.

Isotonic Dehydration

When a child's body loses more water than it absorbs (as with diarrhea) or absorbs less fluid than it excretes (as with nausea and vomiting), the first result will be a decrease in the volume of blood plasma. The body compensates for this rapidly by shifting interstitial fluid into the blood vessels. The composition of fluid in these two spaces is similar, so the replacement by this fluid does not change plasma composition. However, this replacement phenomenon can proceed only until the interstitial fluid reserve is depleted—a danger point for a child because it is difficult for the body to replace interstitial fluid from the intracellular fluid (the fluids in these two compartments have different electrolyte contents). If an infant continues to lose fluid after this point, the volume of the plasma will continue to fall rapidly, resulting ultimately in cardiovascular collapse. Typical signs and symptoms of isotonic dehydration are summarized in Table 45.2.

Hypertonic Dehydration

Water is apt to be lost in a greater proportion than electrolytes when fluid intake decreases in conjunction with a fluid loss increase, as might occur in a child with nausea (preventing fluid intake) and fever (increased fluid loss through perspiration); profuse diarrhea, where there is a greater loss of fluid than salt; or renal disease associated with polyuria such as nephrosis with diuresis. In these instances, fluid loss is out of proportion to the loss of electrolytes, and, with such an increased loss of fluid, electrolytes concentrate in the blood. Fluid shifts from the interstitial and intracellular spaces into the bloodstream (from areas of less osmotic pressure to areas of greater pressure). Dehydration occurs in the interstitial and intracellular compartments. The red blood cell count and hematocrit will be elevated because the blood is more concentrated than usual. Levels of electrolytes such as sodium, chloride, and bicarbonate will also likely be increased. Additional signs and symptoms are summarized in Table 45.2.

Hypotonic Dehydration

With hypotonic dehydration, there is a disproportionately high loss of electrolytes relative to fluid lost. The plasma concentration of sodium and chloride will be low. This could result from excessive loss of electrolytes by vomiting or from low intake of salt associated with extreme losses through diuresis. It also occurs when there is extreme loss of electrolytes in diseases such as adrenocortical insufficiency or diabetic acidosis. When low levels of electrolytes occur, the osmotic pressure in

TABLE 45.2 ✻ Signs and Symptoms of Dehydration

	Isotonic	Hypotonic	Hypertonic
Thirst	Mild	Moderate	Extreme
Skin turgor	Poor	Very poor	Moderate
Skin consistency	Dry	Clammy	Moderate
Skin temperature	Cool	Cool	Warm
Urine output	Decreased	Decreased	Decreased
Activity	Irritable	Lethargic	Very lethargic
Serum sodium level	Normal	Reduced	Increased

extracellular spaces decreases. The kidneys begin to excrete more fluid to decrease ECF volume and bring the proportion of electrolytes and fluid back into line. This may lead to a secondary extracellular dehydration (see Table 45.2).

Overhydration

Overhydration may be as serious as dehydration. It generally occurs in children who are receiving IV fluid. The excess fluid in these instances is usually extracellular. The condition is serious because the ECF overload can lead to cardiovascular overload and cardiac failure.

When large quantities of salt-poor fluid (hypotonic solutions) such as tapwater are ingested or are given by enema, the body transfers water from the extracellular space into the intracellular space to restore normal osmotic relationships. This transfer results in intracellular edema manifested by headache, nausea, vomiting, dimness and blurring of vision, cramps, muscle twitching, and seizures. A situation in which intracellular edema may occur is when tap water enemas are given to a child with aganglionic disease of the intestine.

Acid–Base Imbalance

The GI system often is involved with two severe acid–base imbalances: metabolic acidosis and metabolic alkalosis. These imbalances occur with severe diarrhea or vomiting.

When dealing with acid–base balance, a key component is pH. The abbreviation "pH" refers to two French words that mean the "power of hydrogen." pH denotes whether a solution is acid or alkaline, determined by the proportion of hydrogen (H^+) ions in relation to hydroxide (OH^-) ions—the two substances that disassociate when water is broken down into its basic components ($H_2O = H^+$ and OH^-). A solution is acid (pH below 7.0) if it contains proportionately more H^+ ions than OH^- ions. It is alkaline (pH above 7.0) if the proportion of OH^- ions exceeds that of H^+ ions.

Whether body serum is becoming acidotic is determined by analyzing a sample of arterial blood for blood gases. The pH of blood is normally slightly alkaline, ranging from 7.35 to 7.45. P_{CO_2} (the amount of dissolved carbon dioxide in arterial blood) is normally 35 to 45 mm Hg. The level of bicarbonate (HCO_3) in arterial blood is normally 22 to 26 mEq/L.

Metabolic Acidosis

Metabolic acidosis may result from diarrhea. When diarrhea occurs, a great deal of sodium is lost with stool. This excessive loss of Na^+, in turn, causes the body to conserve H^+ ions in an attempt to keep the total number of positive and negative ions in serum balanced. As a result, a child becomes acidotic as the number of H^+ ions in the blood increases proportionately over the number of OH^- ions present. With metabolic acidosis, arterial blood gas analysis will reveal a decreased pH (under 7.35) and a low HCO_3 value (near or below 22 mEq/L). The lower the HCO_3 value is, presumably the more Na^+ ions that have been lost or the more extensive the diarrhea has been.

To correct this problem (a pH too low is incompatible with life), the body uses both its kidney and respiratory buffering systems. The respiratory buffering system attempts to correct the imbalance quickly. H^+ ions combine with HCO_3^- ions to form carbonic acid. This, in turn, is broken down into CO_2 and water, which is then eliminated by the lungs during expiration. This process works immediately, and, as it continues for a time, the bicarbonate level in the serum falls lower and lower as the body uses up its bicarbonate store.

In the kidneys, H^+ ions are excreted directly or combine with other substances, such as phosphate and ammonia, to form a weak acid, which is excreted. Unfortunately, this process is slow, taking up to 24 hours.

The child breathes rapidly (hyperpnea) to "blow off" CO_2 to prevent it from combining with H_2O and reforming HCO_3. Urine becomes more acid as ammonia formation in the urine is increased.

Metabolic Alkalosis

With vomiting, a great deal of hydrochloric acid is lost. When Cl^- ions are lost this way, the body has to decrease the number of H^+ ions present so the number of positive and negative charges remains balanced. This causes the child to become alkalotic as the number of H^+ ions becomes proportionately lower than the number of OH^- ions present. To further reduce the number of H^+ ions, the lungs conserve CO_2 and water by slowing respirations (hypopnea). The excessive CO_2 retained by this maneuver dissolves in the blood as carbonic acid and then is converted into excessive H^+ and HCO_3^-. With metabolic alkalosis, therefore, the serum HCO_3 invariably will be high. The higher the value, presumably the more Cl^- ions have been lost or the more extensive the vomiting has been.

The child will breathe slowly and shallowly; pH will be elevated (near or above 7.45), and HCO_3 level will be near or above 28 mEq/L.

When alkalosis occurs from vomiting, a secondary electrolyte problem often occurs. As the kidneys begin to help conserve H^+ ions, K^+ ions are exchanged for H^+ ions—that is, K^+ ions are excreted in order to retain H^+ ions. As a result of this loss of K^+ into the urine, low K^+ levels (hypokalemia) invariably accompany metabolic alkalosis.

✔ Checkpoint Question 45.1

Barry has frequent bouts of vomiting. What secondary electrolyte problem often occurs when metabolic alkalosis results from vomiting?

a. Acidosis.
b. Hyponatremia.
c. Hypokalemia.
d. Hyperchlorosis.

COMMON GASTROINTESTINAL SYMPTOMS OF ILLNESS IN CHILDREN

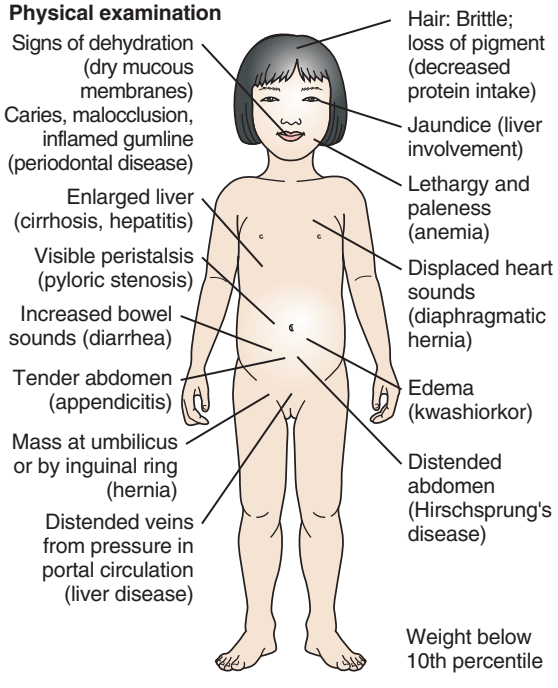
Vomiting and diarrhea in children commonly occur as symptoms of disease of the GI tract as well as symptoms of disease in other body systems (Box 45.2). Pneumonia or otitis media, for example, may present first with vomiting or diarrhea. The danger is that either can lead to a disturbance in hydration, electrolyte, or acid–base balance. In many infants, these secondary disturbances can be more threatening to the child than the primary disease.

Box 45.2 Assessment
Assessing a Child With Altered GI Function

History

Chief concern: Vomiting, diarrhea, constipation, abdominal pain, abdominal distention, weight below normal standard, lethargy, paleness.
Past medical history: History of past vomiting or diarrhea or abdominal pain; hydramnios in pregnancy.
Family history: Relatives have a similar disorder; high stress level because of home or school environment.

Physical examination



Vomiting

Many children with vomiting are suffering from a mild gastroenteritis (infection) caused by a viral or bacterial organism. The adolescent who is pregnant may also experience vomiting. Some children develop persistent or cyclic vomiting (Fitzpatrick et al., 2007). In all forms, vomiting is always potentially serious because a metabolic alkalosis and dehydration may result.

Assessment

In describing symptoms of vomiting, be certain to differentiate between the various terms that are used (Table 45.3). It is important that vomiting be described correctly this way because different conditions are marked by different forms of vomiting, and a correct description of the child's actions can aid greatly in diagnosis.

Therapeutic Management

The treatment for vomiting is to withhold food from the stomach for a time as if there is nothing in the stomach, vomiting cannot occur. Most parents treat vomiting in the opposite way. Every time a child vomits, they attempt to feed the child again. The child vomits again and they feed again, and so on. This prolongs the vomiting and intensifies the potential for electrolyte imbalance.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for deficient fluid volume related to vomiting

Outcome Evaluation: Skin turgor remains good; specific gravity of urine is 1.003 to 1.030; urine output is more than 1 mL/kg/hr; episodes of vomiting decrease in frequency and amount.

TABLE 45.3 Differentiation Between Regurgitation and Vomiting

Characteristic	Regurgitation	Vomiting
Timing	Occurs with feeding	Timing unrelated to feeding
Forcefulness	Runs out of mouth with *little force*	Forceful; often projected 1 ft away from the infant; *projectile vomiting*—projected as much as 4 ft (most often related to increased intracranial pressure in newborns; in infants age 4–6 wk, possibly because of pyloric stenosis)
Description	Smells barely sour; only slightly curdled	Extremely sour smelling, appearing curdled, yellow, green, clear or watery, or black; perhaps fresh blood or old blood staining from swallowed maternal blood (in newborns)
Distress	Nonpainful; child does not appear to be in distress and may even smile as if sensation is enjoyable	Possible crying just before vomiting as if abdominal pain is present, and after vomiting as if the force of action is frightening
Duration	Occurs once per feeding	Continuing until stomach is empty; followed by dry retching
Amount	1–2 tsp	Full stomach contents

To decrease vomiting, withhold food and fluid for a time (nothing by mouth [NPO]), depending on the age of the child. On the average, a period of 3 to 6 hours is usually sufficient. In the older child, after this period of fasting, offer a few ice chips, then water in small amounts—approximately 1 tbsp every 15 minutes, four times; then 2 tbsp every half-hour, four times. Popsicles can be substituted for water. If this is retained, children can be given small sips of clear liquids, such as tea, ginger ale, or a rehydration fluid such as Pedialyte. The World Health Organization provides a home recipe for fluid rehydration of 2 tablespoons of sugar (or honey) with ¼ teaspoon of table salt and ¼ teaspoon of baking soda dissolved in 1 liter (1 qt) of water.

Children may become hungry and want whole glasses of fluid, but keeping the quantity to small sips prevents vomiting. Once the child is able to retain sips of clear liquids, the child can be offered portions of broth, clear soup, and skim milk in addition to clear liquids. Dry crackers or toast will help assuage hunger. By the second day, children can take a soft diet; by the third day, they should be back to their regular diet.

For the infant, introduce fluid after a fasting period of approximately 3 hours in the same slow manner: 1 tbsp every 15 minutes for 2 hours, then 1 oz every 2 hours for the next 12 to 18 hours. Glucose water or a commercial hydration solution such as Pedialyte may be given as fluid during this time to help the infant maintain electrolyte balance. Infants progress, as do older children, gradually to clear liquids or breast milk, then a soft diet, then a regular diet. If vomiting is prolonged, infants may need IV therapy or an antiemetic to restore hydration (Leung et al., 2007).

Teach parents the importance of following these routines of gradually increasing fluid at intervals. Assure them that if children receive a small amount of fluid and do not vomit it, they will ultimately receive more fluid than if they take a large amount but, because of gastroenteritis, vomit that amount. Parents are capable of understanding that stomach secretions are lost along with vomitus each time, and the preservation of these stomach secretions is important to keep their child well. Antiemetic medicine is rarely necessary for children because acute gastroenteritis is a self-limiting condition and vomiting may actually be helpful if it rids the child's body of toxic substances. If vomiting is severe, however, an antiemetic such as promethazine (Phenergan) or Ondansetron (Zofran) may be prescribed. Always ask parents if they have used an herbal remedy, to be certain that any medication prescribed will be safe with the alternative treatment.

Diarrhea

Diarrhea caused by a virus is the major cause of infant gastroenteritis in developing countries. The most common viral pathogens that invade the GI tract include rotaviruses and adenoviruses (Bass, Pappano, & Humiston, 2007). The most common bacterial pathogens include *Campylobacter jejuni, Salmonella, Giardia lamblia,* and *Clostridium difficile.* Diarrhea may also be caused by *Escherichia coli* infection (Cennimo et al., 2007). It can be easily spread by common diaper changing areas in day care centers or airport restrooms (Kotch et al., 2007). Diarrhea that is acute is usually associated with infection; chronic diarrhea is more likely related to a malabsorption or inflammatory cause.

Diarrhea in infants is always serious because infants have such a small ECF reserve that sudden losses of water exhaust the supply quickly. Breastfeeding may actively prevent diarrhea by providing more antibodies and possibly an intestinal environment less friendly to invading organisms and so should be advocated.

Mild Diarrhea

Assessment. Normal and diarrheal stool characteristics are compared in Table 45.4. If diarrhea is mild, fever of 101° to 102° F (38.4° to 39.0° C) may be present. Children usually are anorectic and irritable and appear unwell. The episodes of diarrhea consist of 2 to 10 loose, watery bowel movements per day.

The mucous membrane of the mouth appears dry and the skin feels warm although skin turgor will not yet be decreased. The pulse will be rapid and out of proportion to the low-grade fever. Urine output is usually normal.

Therapeutic Management. At this stage, diarrhea is not yet serious, and children can be cared for at home. As with vomiting, treatment for diarrhea must involve resting the GI tract, but this is necessary for only a short time. At the end of approximately 1 hour, parents can begin to offer an oral rehydration solution such as Pedialyte in small amounts on a

TABLE 45.4 ✻ Differentiation Between Infant Normal Stool and Diarrheal Stool

Characteristic	Infant Normal Stool	Diarrheal Stool
Frequency	1–3 daily	Unlimited number
Color	Yellow	Green
Effort of expulsion	Some pushing effort	Effortless; may be explosive
pH	More than 7.0 (alkaline)	Less than 7.0 (acidic)
Odor	Odorless	Sweet or foul smelling
Occult blood	Negative	Positive; blood may be overt
Reducing substances	Negative	Positive

regimen similar to that for vomiting (Freedman, 2007). For breastfed infants, breastfeeding should continue. Again, it may be difficult for parents to restrict fluid for a short time if they think they should overfeed children to make up for the fluid loss. Children also need measures to reduce the elevated temperature. In developing countries, where children may be zinc deficient, zinc may be administered. Probiotics (dietary supplements containing potentially beneficial bacteria or yeasts) to change the bacterial flora of the intestine may be administered (Walter & Isolauri, 2007).

Caution parents to contact their health care provider rather than use over-the-counter drugs such as loperamide (Imodium) or kaolin and pectin (Kaopectate) to halt diarrhea because, as a rule, these are too strong for young children (Karch, 2009). Also caution parents to wash their hands after changing diapers to prevent the spread of infection to themselves and to notify their health care provider if fever, pain, or diarrhea worsens.

Infants may develop a lactase deficiency after diarrhea that leads to lactose intolerance. With lactose intolerance, a child cannot take formula or breast milk or new diarrhea will begin. Such an infant will need to be introduced to a lactose-free formula initially before being returned to the usual formula or to breast milk.

Severe Diarrhea

Assessment. Severe diarrhea may result from progressive mild diarrhea, or it may begin in a severe form. Infants with severe diarrhea are obviously ill. Rectal temperature is often as high as 103° to 104° F (39.5° to 40.0° C). Both pulse and respirations are weak and rapid. The skin is pale and cool. Infants may appear apprehensive, listless, and lethargic. They have obvious signs of dehydration such as a depressed fontanelle, sunken eyes, and poor skin turgor. The episodes of diarrhea usually consist of a bowel movement every few minutes. The stool is liquid green, perhaps mixed with mucus and blood, and it may be passed with explosive force. Urine output will be scanty and concentrated. Laboratory findings will show elevated hematocrit, hemoglobin, and serum protein levels because of the dehydration. Electrolyte determinations will indicate a metabolic acidosis (Sondheimer, 2008).

It is difficult to measure the amount of fluid a child has lost, but an estimate can be derived from the loss in body weight, if known. For example, if a child weighed 10.4 kg yesterday at a health maintenance visit and today weighs 8.9 kg, the child has lost more than 10% of body weight. Mild dehydration occurs with a loss of 2.5% to 5% of body weight. In contrast, severe diarrhea quickly causes a 5% to 15% loss. Any infant who has lost 10% or more of body weight requires immediate treatment.

Therapeutic Management. Treatment focuses on regulating electrolyte and fluid balance by oral or IV rehydration therapy, initiating rest for the GI tract, and discovering the organism responsible for the diarrhea.

All children with severe diarrhea or diarrhea that persists longer than 24 hours should have a stool culture taken so definite antibiotic therapy can be prescribed. Stool cultures may be taken from the rectum or from stool in a diaper or a bedpan. Blood specimens need to be drawn for a hemoglobin level (an estimation of hydration as well as anemia); white blood cell and differential counts (to attempt to establish whether infection is present); and determinations of P_{CO_2}, Cl^-, Na^+, K^+, and pH (to establish electrolyte needs). If a child can drink, the most effective way to replace fluid is by offering oral rehydration therapy. For a child who will not drink, an IV solution such as normal saline or 5% glucose in normal saline is begun. The solution will provide replacement of fluid, sodium, and calories. Although infants usually have a potassium depletion, potassium cannot be given until it is established that they are not in renal failure. Giving potassium IV when the body has no outlet for excessive potassium can lead to excessively high potassium levels and heart block. *Before this initial IV fluid is changed to a potassium solution, therefore, be certain that the infant or child has voided—proof that the kidneys are functioning.*

Fluid must be given to replace the deficit that has occurred, for maintenance therapy, and to replace the continuing loss until the diarrhea improves. If infants have lost less than 5% of total body weight, their fluid deficit is approximately 50 mL/kg of body weight. If infants have lost 10% of body weight, they need approximately 100 mL/kg of body weight to replace their fluid deficit. If the weight loss suggests a 12% to 15% loss of body fluid, they require 125 mL/kg of body weight to replace the fluid lost. This fluid will be given rapidly in the first 3 to 6 hours, and then it will be slowed to a maintenance rate. Once infants void, a potassium additive can be ordered to restore serum potassium.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Deficient fluid volume related to loss of fluid through diarrhea

Outcome Evaluation: Skin turgor remains good; specific gravity of urine is 1.003 to 1.030; urine output is more than 1 mL/kg/hr; bowel movements are formed and fewer than four per day. Stool tests negative for reducing substances and blood pH is more than 7.

Promote Hydration and Comfort. During the time infants are NPO, wet infants' lips with a moisturizing cream or jelly such as Vaseline if they appear to be dry. Offer them a pacifier to suck if this seems to comfort them. (They want to suck because they are very thirsty, and, if they have intestinal cramping with the diarrhea, they interpret this as hunger.)

As the infant's condition improves, oral intake can be increased, changing to a soft then a regular diet. Some children become lactose intolerant after diarrhea and will need a lactose-free formula for rehydration (Misra et al., 2007).

If the child with severe diarrhea also has a fever, measures to reduce the fever will be necessary (see Chapter 37). Do not obtain rectal temperatures to assess fever, because stimulating the anal sphincter could initiate more diarrhea. Assess perianal skin for irritation from liquid stools, and keep the skin clean and dry.

Record Fluid Intake and Output. Much of the nursing care of children with diarrhea focuses on careful

recording of fluid intake and output. Because children have dehydration when first seen, oral rehydration or IV therapy serves as their lifeline. Be sure to maintain proper functioning of an IV infusion and site if this is used. An arm board may be necessary to prevent catheter dislodgment or interference with the infusion. Soft restraints applied to the affected and unaffected extremities may be necessary to prevent a child from pulling, playing with, or poking at the tubing or site. If soft restraints are used, be sure to release them every hour and passively exercise the child's extremities. Give parents an explanation of why the IV infusion is important so they will understand the need for the soft restraints.

In children who are not toilet trained, apply a disposable urine collection bag to help separate urine from feces. This makes it obvious that the child is voiding, confirming kidney function. Confirmation of adequate kidney function is necessary for IV K^+ replacement therapy, if ordered.

Separating urine from stools also helps to judge the appearance of stools or their water content. For each stool passed, record its color, consistency, odor, size, and the presence of any blood or mucus. Weigh soiled diapers to reveal the number of grams of stool in the diaper (1 g = 1 mL fluid). Testing the stool for acidity and for reducing substances (sugars) indicates how quickly the stool has passed through the irritated tract. A stool positive for sugar indicates that little absorption occurred, because sugar is normally absorbed rapidly from ingested food. Acid stool (pH less than 7.0) shows the presence of unabsorbed sugar also (a process occurs similar to the process that causes acid to invade tooth enamel in the presence of glucose on teeth). Diarrheal stools are green from lack of time for bile to be modified in the intestine. As diarrhea improves and stool remains in the intestine for a longer period, the stool deepens in color and the acid and sugar contents fade. Testing stools for occult blood shows the extent of bowel irritation that is occurring from the acid stool. As the diarrhea improves and the irritation to the bowel lessens, the finding of occult blood disappears.

Nursing Diagnosis: Risk for impaired skin integrity related to presence of diarrheal stool on skin

Outcome Evaluation: Skin in diaper area is not erythematous or ulcerated.

Because diarrheal stool is extremely irritating to the skin, change diapers immediately after infants pass any stool. Wash the skin of the diaper area well after each stool, and cover it with an ointment such as Vaseline or A&D to protect it from further irritation. If the child is older, caution the child to wipe away stool thoroughly.

If infants already have skin excoriation from the number of stools they have had at home, an ointment such as Desitin may help soothe the irritated skin. Exposing infants' buttocks to air is generally helpful in healing irritation. Assure older children that loss of stool by diarrhea is not "shameful" or "babyish" but to be expected because they are ill.

Nursing Diagnosis: Anxiety related to traumatic experience

Outcome Evaluation: Child interacts with parents in age-appropriate way; can be comforted after painful procedures.

All children with diarrhea are assumed to have an infectious form of gastroenteritis and therefore need contact and standard infection precautions. Children usually are uncomfortable from the diarrhea, exhausted, and confused with these new body sensations. They need the security of someone to stay with them. When a child with severe diarrhea is admitted to the hospital, many emergency procedures must be performed, such as collecting specimens, reducing temperature, and beginning rehydration. During all of these procedures, try to remember how all of this must seem to the child in the bed. Be sure to take time during initial procedures to touch and soothe children and talk to them; once the initial admission procedures are done, sit by the bed and hold a child or gently stroke a child's head. Teach parents how to adhere to standard infection precautions and follow contact precautions if necessary. Encourage them to give any care possible. Children need this support to counteract the strange world into which they have suddenly been plunged.

What if... Barry's mother tells you her doctor has told her to "force fluids" for Barry whenever he has diarrhea? She asks how much she should force the child to drink. How would you answer her?

Bacterial Infectious Diseases That Cause Diarrhea and Vomiting

Several common microorganisms are responsible for diarrhea in children.

Salmonella

- Causative agent: One of the *Salmonella* bacteria
- Incubation period: 6 to 72 hours for intraluminal type; 7 to 14 days for extraluminal type
- Period of communicability: As long as organisms are being excreted (may be as long as 3 months)
- Mode of transmission: Ingestion of contaminated food, especially chicken and raw eggs

Salmonella is the most common type of food poisoning in the United States and a major cause of diarrhea in children. The diagnosis of the infection can be made from stool culture. Children develop diarrhea, abdominal pain, vomiting, high temperature, and headache. They are listless and drowsy. The diarrhea is severe and may contain blood and mucus (Chambers, 2009). *Salmonella* infection may remain in the bowel as an intraluminal disease. When it does, it is treated, like severe diarrhea, with fluid and electrolyte replacement. Antibiotics are rarely prescribed as they may actually prolong the length of the infection (Sirinavin & Garner, 2009). If the infection becomes systemic (extraluminal disease), it is treated with the addition of an antibiotic such as ampicillin or a third-generation cephalosporin (Ogle & Anderson, 2008).

Complications such as meningitis, bronchitis, and osteomyelitis may occur. Because the source of *Salmonella* generally is infected food (contaminated chicken and eggs are common sources), caution parents to wash utensils used to prepare raw chicken such as cutting boards well and to cook eggs thoroughly. Although rare, *Salmonella* also may be transmitted to children by infected turtles (Box 45.3).

Listeriosis

- Causative agent: *Listeria monocytogenes*
- Incubation period: Variable, ranging from 1 day to more than 3 weeks
- Mode of transmission: Ingestion of unpasteurized milk or cheeses or vegetables grown in contaminated soil

Listeriosis is a serious infection caused by eating food contaminated with the gram-positive bacterium *Listeria monocytogenes*. The cause of the infection may be difficult to locate as the incubation period can last for almost a month. After this time, however, a child develops fever, muscle aches, nausea, and diarrhea. If infection spreads to the nervous system, symptoms such as headache, stiff neck, confusion, loss of balance, or convulsions can occur. The infection is particularly important to avoid during pregnancy as infections during pregnancy can lead to miscarriage or stillbirth, prematurity, or infection of the newborn. The bacteria is found in soil and water. Vegetables can become contaminated by being grown in contaminated soil. The most frequent source, however, is unpasteurized (raw) milk or foods made from unpasteurized milk such as soft cheese. Therapy is intravenous ampicillin and an aminoglycoside such as gentamicin. If a child is hospitalized, standard infection precautions should be instituted. Measures to avoid the infection are shown in Box 45.3.

BOX 45.3 ❊ Focus on Family Teaching

Preventing *Salmonella*- or *Listeria*-Caused Gastroenteritis

Q. Barry's mother says to you, "Our son had severe diarrhea from food poisoning. How can we make sure he doesn't get that again?"

A. Anyone can get food poisoning. However, it can be prevented by using the following measures:

- Wash your hands well before preparing any foods, but especially chicken and eggs.
- Remember that chicken may become contaminated with *Salmonella* at the factory where it was prepared. Wash your hands well after handling raw chicken to prevent the spread of infection to other foods being prepared.
- Clean cutting boards or food preparation surfaces with hot, soapy water and dry thoroughly after use to prevent them from becoming reservoirs of infection.
- Make a habit of preparing chicken last, after other foods are prepared.
- Cook eggs well (do not use raw eggs in milkshakes; cook soft-boiled or poached eggs at least 3 min).
- Refrigerate chicken and eggs after preparation.
- Wash hands well after playing with or feeding a pet turtle or changing the turtle's water.
- Wash raw vegetables thoroughly before eating.
- Avoid soft cheeses such as feta, Brie, Camembert, blue-veined, and Mexican queso fresco cheese. Hard cheeses; processed cheeses, including sliced cheese, cream cheese, cheese spreads, and cottage cheese; and yogurt need not be avoided.
- Cook leftover foods or ready-to-eat foods such as hot dogs until steaming hot before eating.
- Avoid foods from delicatessen counters such as prepared salads, meats, and cheeses or heat/reheat these foods until steaming before eating.
- Avoid refrigerated pates and other meat spreads or heat/reheat these foods before eating; canned or shelf-stable pate and meat spreads need not be avoided.
- Avoid raw or unpasteurized milk, including goat's milk, or milk products or foods that contain unpasteurized milk or milk products.

Shigellosis (Dysentery)

- Causative agent: Organisms of the genus *Shigella*
- Incubation period: 1 to 7 days
- Period of communicability: Approximately 1 to 4 weeks
- Mode of transmission: Contaminated food, water, or milk products

Shigella organisms, like the *Salmonella* group, cause extremely severe diarrhea that contains blood and mucus. As the organism becomes more resistant, ampicillin or trimethoprim–sulfamethoxazole, typical drugs used for therapy in the past, are being replaced by cephalosporins. The child needs intense fluid and electrolyte replacement. *Shigella* infection can be prevented by safe food handling and cautioning families to drink only from safe water sources (Ogle & Anderson, 2008).

Staphylococcal Food Poisoning

- Causative agent: Staphylococcal enterotoxin produced by some strains of *Staphylococcus aureus*
- Incubation period: 1 to 7 hours
- Period of communicability: Carriers may contaminate food as long as they harbor the organism
- Mode of transmission: Ingestion of contaminated food

With staphylococcal food poisoning, a child has severe vomiting and diarrhea, abdominal cramping, excessive salivation, and nausea within 2 to 6 hours of eating (Ogle & Anderson, 2008). Organisms are most often spread through creamed foods such as potato salad. It is often difficult to culture the causative organism from the contaminated food because although the staphylococci may have been destroyed by cooking, the enterotoxin that actually causes the disorder will not have been destroyed. The child needs intensive supportive therapy with fluid and electrolyte replacement and perhaps administration of a drug effective against *Staphylococcus,* such as cefotaxime. Food poisoning from this source can be prevented by proper refrigeration of food.

✔ Checkpoint Question 45.2

Barry's mother tells you she often makes milkshakes with raw eggs. What infectious organism is easily spread this way?

a. Pneumococcus.
b. *Salmonella*.
c. Streptococcus A.
d. *H. pylori*.

COMMON DISORDERS OF THE STOMACH AND DUODENUM

Disorders of the upper GI tract in children tend to involve inadequate valve function or infection.

Gastroesophageal Reflux

Gastrointestinal reflux or the regurgitation of stomach secretions into the esophagus through the gastroesophageal (cardiac) valve occurs mainly in infants and adolescents.

Gastroesophageal Reflux in Infants

Gastroesophageal reflux in infants occurs from a neuromuscular disturbance in which the gastroesophageal (cardiac) sphincter and the lower portion of the esophagus spasm and allow easy regurgitation of gastric contents into the esophagus. It usually starts within 1 week after birth and may be associated with a hiatal hernia (see later discussion). Children with cerebral palsy or other neurologic involvement are at particular risk. The regurgitation occurs almost immediately after feeding or when the infant is laid down after a feeding. If the amount of the reflux is large or constant, an infant does not retain sufficient calories and will fail to thrive. In addition, aspiration pneumonia or esophageal stricture from the constant reflux of hydrochloric acid into the esophagus can occur (Sondheimer & Sundaram, 2008).

Assessment. The diagnosis is suggested by the history. Vomiting appears effortless and is not projectile; it begins much earlier in life than the vomiting associated with pyloric stenosis. The child may be irritable and may experience periods of apnea. Inserting a probe or catheter through the nose into the distal esophagus and determining the pH from secretions can show whether gastric secretions are entering the esophagus (if the pH is less than 7.0, then acid is present). Esophageal manometry is used to measure the strength of the esophageal sphincter. Fiberoptic endoscopy or esophagography (barium swallow) will further show the involved sphincter and the reflux of stomach contents into the esophagus, especially if the infant's head is tilted downward.

Therapeutic Management. The traditional treatment of GI reflux is to feed infants a formula thickened with rice cereal (1 tbsp of cereal per 1 oz of formula or breast milk) while holding them in an upright position and then keeping them upright in an infant chair for 1 hour after feeding so gravity can help prevent reflux (Craig et al., 2009). An H_2 receptor antagonist such as ranitidine (Zantac) or a proton pump inhibitor such as omeprazole (Prilosec) may be prescribed daily to reduce the possibility of the stomach acid contents irritating the esophagus.

Gastroesophageal reflux is usually a self-limiting condition. As the esophageal sphincter matures and the child begins to eat solid food and is maintained in a more upright position, the problem disappears. If not, botulinum toxin may be injected into the lower esophageal sphincter to temporarily relieve symptoms of obstruction. If medical therapy this way is ineffective, a laparoscopic or surgical myotomy procedure (narrowing of the esophageal sphincter) may be performed. After this procedure, the child will temporarily have a nasogastric tube in place that is attached to intermittent low suction. It is usually irrigated with normal saline every 2 hours to ensure patency. Assess nasogastric tube drainage and any vomitus for coffee-colored drainage (although this is normal for the first 24 hours) that would indicate bleeding from the surgical site. When infants are first fed after surgery, they may display signs of abdominal discomfort and distention because food can no longer reflux into the esophagus as readily as it could before surgery. As their stomach adjusts to this, symptoms fade. Before this happens, however, the distention may be so extreme that it leads to bradycardia and dyspnea. Be alert for the development of these important signs and symptoms.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for imbalanced nutrition, less than body requirements, related to regurgitation of food with esophageal reflux

Outcome Evaluation: Skin fold returns to place quickly when turgor is assessed; specific gravity of urine is 1.003 to 1.030; intake is 50 cal/lb/24 hr.

Teach parents the importance of monitoring intake, output (urination), and weight. Also reinforce the need to keep the infant upright, such as in an infant seat, after a feeding. Be certain parents understand how much cereal to mix with formula or breast milk. Encourage parents to feed the infant during the short time that the infant remains in the hospital after surgery so that they can regain their confidence as parents.

Gastrointestinal Reflux in Adolescents

Gastroesophageal reflux disease (GERD) affects about 20% of adults; symptoms frequently begin in adolescence. Irritation to the esophagus occurs when stomach contents, including hydrochloric acid, reflux through the lower esophageal sphincter and irritate the esophageal lining. Reflux occurs because of an incompetent sphincter especially when the adolescent lies supine or when intra-abdominal pressure is increased by a full stomach, lifting or bending, or tight clothing. It is potentially dangerous because it can lead to erosion of the esophagus with perforation or stricture of the esophagus. It may be associated with the development of esophageal cancer in later life (Zagaria, 2008).

The typical symptom is heartburn that occurs 30–60 minutes after a meal. Diagnosis is based on history (typical symptoms of heartburn) and, if symptoms are severe, endoscopy to reveal the irritated esophagus (esophagitis). The goal of

treatment is to provide symptomatic relief and to heal any esophagitis identified.

Adolescents should avoid lying down until 3 hours after a meal and should sleep at night with their upper body elevated on a foam wedge. They should avoid acidic foods such as tomato products, citrus fruits, or spicy foods. Avoiding foods that delay gastric emptying such as fatty foods, chocolate, or alcohol and eating smaller portions may also be helpful. Weight loss, avoiding bending after meals, and removing tight belts are also recommended steps.

Antacids relieve pain immediately by decreasing the concentration of the stomach acid and are sold over the counter. H_2-receptor antagonists such as cimetidine (Pepcid) or ranitidine (Zantac) are also available over the counter and can be taken before meals to prevent heartburn symptoms. Proton pump inhibitors such as omeprazole (Prilosec) or rabeprazole (Aciphex), drugs that halt the release of stomach acids, are prescription drugs that offer the best long-term relief. Adolescents generally take these for 6 to 8 months until esophageal healing is complete.

As adults, esophageal reflux may return. Some adults require surgery in later life to relieve esophageal strictures or recurring ulcers from returning irritation.

Pyloric Stenosis

The pyloric sphincter is the opening between the lower portion of the stomach and the beginning portion of the intestine, the duodenum. If hypertrophy or hyperplasia of the muscle surrounding the sphincter occurs, it is difficult for the stomach to empty, a condition called *pyloric stenosis* (Fig. 45.3). With this condition, at 4 to 6 weeks of age, infants begin to vomit almost immediately after each feeding. The vomiting grows increasingly forceful until it is projectile, possibly projecting as much as 3 to 4 feet. The incidence is high, approximately 1:150 in males and 1:750 in females. It tends to occur most frequently in first-born white male infants. The exact cause is unknown, but multifactorial inheritance is the likely cause. It occurs less frequently in breastfed infants than in formula-fed infants. Formula-fed infants typically begin having symptoms at approximately 4 weeks of age. Breastfed infants begin having symptoms at 6 weeks because the curd of breast milk is smaller than that of cow's milk, and it passes through a hypertrophied muscle more easily. For unknown reasons, an increased incidence is seen in infants who receive a macrolide antibiotic such as erythromycin (Maheshwai, 2007).

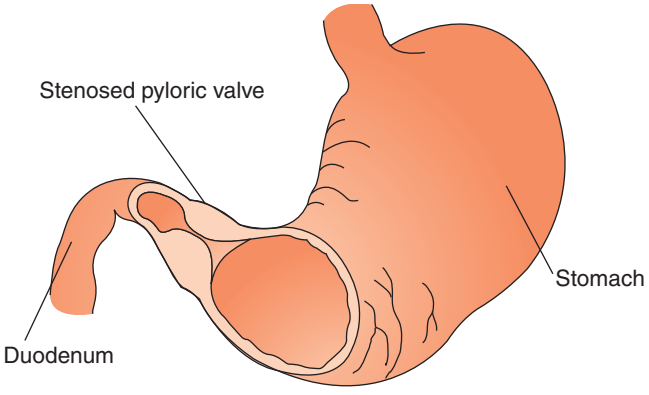


FIGURE 45.3 Pyloric stenosis. Fluid is unable to pass easily through the stenosed and hypertrophied pyloric valve.

Vomitus usually smells sour because it has reached the stomach and has been in contact with stomach enzymes. There is never bile in the vomiting of pyloric stenosis because the feeding does not reach the duodenum to become mixed with bile. Infants are usually hungry immediately after vomiting because they are not nauseated. Although it is difficult to assess whether nausea is present in infants, signs such as a disinterest in eating, excessive drooling, or chewing on the tongue may suggest this.

Assessment

The diagnosis of pyloric stenosis is made primarily from the history. Whenever parents say that their baby is vomiting or spitting up, be certain to get a full description:

- What is the duration? *Begins at 6 weeks of age*
- What is the intensity? *Projectile vomiting*
- What is the frequency? *Immediately after eating*
- What is the description of the vomitus? *Sour but contains no bile*
- Is the infant ill in any other way? *No.*

Many infants have signs of dehydration from the vomiting when they are first seen. Lack of tears (many infants younger than age 6 weeks do not tear), dry mucous membrane of the mouth, sunken fontanelles, fever, decreased urine output, poor skin turgor, and weight loss are common signs seen. Alkalosis also may be present because of the excessive loss of Cl^- ions from stomach fluid, along with accompanying hypochloremia, hypokalemia, and starvation. Hypopnea (slowed respirations) occurs as the body attempts to compensate for the alkalosis. This will cause the HCO_3 content of plasma generally to be above 30 mEq/L (normal is 22 to 28 mEq/L). Tetany may occur with alkalosis because the increased HCO_3^- ions may combine with Ca^{2+} ions, trying to effect homeostasis and thereby lowering the level of ionized calcium. Low serum calcium levels lead to tetany.

A definitive diagnosis is made by watching the infant drink. Before the child drinks, attempt to palpate the right upper quadrant of the abdomen for a pyloric mass. If one is present, it feels round and firm, approximately the size of an olive. As the infant drinks, observe for gastric peristaltic waves passing from left to right across the abdomen. The olive-size lump becomes more prominent. The infant vomits with projectile emesis. If the diagnosis is still in doubt, an ultrasound will show the hypertrophied sphincter (Oldham & Aiken, 2007). Endoscopy also may be used for diagnosis by directly visualizing the hypertrophied sphincter.

Therapeutic Management

Treatment is surgical or laparoscopic correction (a pyloromyotomy), performed before electrolyte imbalance from the vomiting or hypoglycemia from the lack of food occurs. Before surgery, if electrolyte imbalance, dehydration, and starvation have already occurred, these must be corrected by administration of IV fluid, usually isotonic saline or 5% glucose in saline. Oral feedings are withheld to prevent further electrolyte depletion. An infant who is receiving only IV fluid generally needs a pacifier to meet nonnutritive sucking needs

and be comfortable. If tetany is present, verified by a low calcium level on blood analysis, IV calcium also must be administered. The infant usually needs additional potassium, but as a rule this can not be administered until it is determined that the child's kidneys are functioning (the child is voiding). Otherwise, the potassium buildup could cause cardiac arrhythmias.

For surgical correction, the muscle of the pylorus is split down to the mucosa, allowing for a larger lumen. Although the procedure sounds simple, it is technically difficult to perform, and there is a high risk for infection afterward because the abdominal incision is near the diaper area.

The prognosis for infants with pyloric stenosis is excellent if the condition is discovered before an electrolyte imbalance occurs.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for deficient fluid volume related to inability to retain food

Outcome Evaluation: Skin turgor remains good; specific gravity of urine is 1.003 to 1.030; vomiting episodes have ceased; weight is within acceptable age-appropriate parameters.

Preoperative Care. Preoperative management consists of fluid and electrolyte replacement based on laboratory determinations. A baseline weight is essential for establishing the extent of dehydration. Note carefully the frequency of urination, the specific gravity of the urine, and the number of stools passed to help assess dehydration and starvation. Parents may be impatient with preoperative management because it may take 24 hours or more to restore a severe fluid imbalance. They need an explanation that infants cannot go to surgery with an electrolyte imbalance; these hours before surgery are as important to the welfare of their child as the operation itself.

Postoperative Care. Infants will return from surgery or laparoscopy with an IV line in place. The postoperative feeding regimen differs from one surgeon to another but usually involves frequent feedings of small amounts of fluid. Approximately 4 to 6 hours after surgery, infants are started on a small amount of an oral rehydrating solution by bottle. If no vomiting occurs, the amount is increased or half-strength formula or breastfeeding is begun. Finally, by 24 to 48 hours, infants are taking their full formula diet or being fully breastfed. They are usually discharged from the hospital at the end of 48 hours.

Postoperatively, it is important that infants be given no more than the amount of fluid ordered at a time so the surgical repair site is not overwhelmed. Infants need to ingest these small amounts because a small quantity of fluid passing through the sphincter in the immediate postoperative days helps to keep adhesions of the sphincter from forming. As the amount taken orally increases, the IV fluid will be decreased and then discontinued. Infants should be bubbled well after a feeding so there is no pressure from air in the stomach. Lay them on their side after feeding so that if vomiting does occur, there is little chance of aspiration. Laying them on their right side may aid the flow of fluid through the pyloric valve by gravity. Continue to monitor daily weights to confirm that the child is receiving adequate intake. Usually no vomiting occurs postoperatively, but if it does occur, report it immediately. The feeding regimen may need to be adjusted accordingly, and the infant may require a longer hospital stay. Some infants have a short-term diarrhea (dumping syndrome) after surgery because of rapid functioning of the pyloric sphincter, but this tends to resolve without additional therapy.

Nursing Diagnosis: Risk for infection at site of surgical incision related to danger of contamination from feces because of proximity of incision to diaper area

Outcome Evaluation: Infant's temperature is below 98.6° F (37.0° C) axillary; incision is clean, dry, and intact without erythema or drainage.

The surgical incision for pyloric stenosis may be covered with collodion, a solution similar to clear nail polish, or a similar commercial compound to help keep urine and feces from touching it. Keep diapers folded low to prevent the incision from being contaminated, and change diapers frequently. If the incision should be exposed to feces, wash the collodion well with soap and water.

Nursing Diagnosis: Risk for impaired parenting related to infant's feeding difficulty and illness

Outcome Evaluation: Parents hold and feed infant; express positive characteristics about infant.

Encourage the parents to "room in" with their child so they can grow comfortable and confident in caring for the child again. When the child first began vomiting so forcefully, parents may have felt they were doing something wrong and so may have lost confidence in themselves as parents. Explain to them that the vomiting was caused by a physical problem and not by anything they did.

Hospitalization often occurs near the infant's second month, when the child would normally receive diphtheria-tetanus-pertussis, rotavirus, pneumococcal, oral poliomyelitis, and *Haemophilus influenzae* immunizations. Ask if they could be administered before discharge so the child's immunization status remains current. This also might serve to remind parents that getting back to normal means regular health care visits for vaccines and checkups.

Hiatal Hernia

Hiatal hernia is the intermittent protrusion of the stomach up through the esophageal opening in the diaphragm. When this occurs, the volume of the stomach is suddenly restricted, leading to periodic vomiting similar to that of gastroesophageal reflux. With a hiatal hernia, however, pain usually accompanies the vomiting. Shortness of breath may occur from compression of the lung space by the stomach (Skandalakis, 2007).

Hiatal hernia is diagnosed by history and an ultrasound or barium swallow. Keeping a baby in an upright position helps prevent the condition from recurring. Medication to reduce acid secretions may also be helpful. If the condition has not corrected itself by the time the infant is 6 months old, even with maintaining an upright position most of the day, laparoscopic surgery may be performed to reduce the stomach's ability to protrude through the diaphragm.

Peptic Ulcer Disease

A *peptic ulcer* is a shallow excavation formed in the mucosal wall of the stomach, the pylorus, or the duodenum. In infants, ulcers tend to be gastric; in adolescents, they are usually duodenal. Such ulcers occur in a primary form caused by infection of *H. pylori* bacteria and a secondary form that follows severe stress such as burns or chronic ingestion of medications such as acetylsalicylic acid or prednisone (Lebwohl, 2007).

Peptic ulcer disease occurs in only 1% to 2% of children. It occurs more frequently in males than in females. In addition to infection from *H. pylori,* associated factors in adolescents may include a genetic tendency and use of nonsteroidal anti-inflammatory drugs (NSAIDs), alcohol, caffeine, and cigarettes (Barba, Fitzgerald, & Wood, 2007).

The small ulceration of the gastric or duodenal lining leads to pain, blood in the stool, and vomiting (with blood). If left uncorrected, peptic ulcer disease can lead to bowel or stomach perforation with acute hemorrhage or pyloric obstruction (Hua et al., 2007). A chronic ulcer condition may lead to anemia from the constant, gradual blood loss.

Assessment

An ulcer occurring in a neonate usually presents with hematemesis (blood in vomitus) or melena (blood in the stool). Such ulcers are usually superficial and heal rapidly, although they can lead to rupture, with symptoms of respiratory distress, abdominal distention, vomiting, and, if extensive, cardiovascular collapse. If an ulcer occurs in a toddler, the first symptoms are usually anorexia or vomiting. Bleeding follows in several weeks. If an ulcer begins when children are of preschool or early school age, pain may be the presenting symptom. The child may report pain as mild, severe, colicky, or continuous. It is often poorly localized, although it may be in the epigastric area as in adults. If the pain occurs in the right lower quadrant, it can be confused with appendicitis.

In older, school-age children and adolescents, symptoms are generally those of the adult: a gnawing or aching pain in the epigastric area before meals that is relieved by eating. Vomiting (because of spasm and edema of the pylorus) occurs in a small number of children. On abdominal palpation, epigastric tenderness is noted.

Fiberoptic endoscopy is the most reliable diagnostic test to confirm the diagnosis of peptic ulcer disease; it allows for visual inspection and cultures for *H. pylori*. Because childhood ulcers are shallow, they may not show up well on radiography. In many children, little increase in gastric activity can be demonstrated by gastric analysis. Children with this condition must have blood tests done periodically to be monitored for blood loss anemia.

Therapeutic Management

Children with peptic ulcer disease are treated with a combination of medications to reduce the bacteria count and suppress gastric acidity. Adolescents are prescribed an antibiotic such as amoxicillin or clarithromycin (Biaxin) and a proton pump inhibitor such as omeprazole (Prilosec). Bismuth subsalicylate (Pepto-Bismol) is soothing and mildly antibiotic and so may be prescribed concurrently. Younger children are prescribed cimetidine (Tagamet) because safe levels of omeprazole have yet to be established for this age group. With current therapy, only a few children experience the potential complications of perforation, blood loss anemia, and intestinal obstruction, although some school-age children and adolescents will have recurring symptoms as they grow older. Most important to prevent an ulcer reoccurring seems to be evacuation of *H. pylori* from the child's stomach or intestine (Bose et al., 2007).

Nursing Diagnoses and Related Interventions

Having peptic ulcer disease can be difficult for children because it is painful, and remembering to take medicine daily may be a problem.

Nursing Diagnosis: Pain related to ulceration in intestinal tract

Outcome Evaluation: Child exhibits verbal and nonverbal signs of decreased pain; the infant appears comfortable without excessive crying.

Children with peptic ulcer disease should be able to eat a normal diet, avoiding heavily spiced food such as pizza or sausage if such food causes discomfort. Work with them to devise a schedule so they can remember to take their medications.

Be certain that the outcomes planned are realistic. It may not be possible to relieve symptoms of peptic ulcer immediately. However, children can be helped immediately to understand why the pain occurs and what they can do to help relieve it.

✔ Checkpoint Question 45.3

Barry's older sister had pyloric stenosis as an infant. Vomiting with pyloric stenosis typically occurs:

a. Immediately after feeding.
b. An hour after feeding.
c. On arising in the morning.
d. When the infant cries.

HEPATIC DISORDERS

Hepatic disorders include both acquired disorders, such as hepatitis or cirrhosis, and congenital disorders, such as obstruction or atresia of the biliary duct.

Liver Function

The liver lies immediately under the diaphragm on the right side. In infants, 1 or 2 cm of liver is readily and normally

palpable. The organ is essential for the normal metabolism of carbohydrates, proteins, and fats. It plays a role in the maintenance of normal blood sugar level by changing glucose to glycogen and storing it until needed by body cells. It then reverses the process and changes glycogen back to glucose and releases it into the blood when cells need it (Jonas & Perez-Atayde, 2007).

The liver assists in the catabolism of fatty acids and protein and serves as a temporary storage space for both fat and protein. The liver, by the means of the enzyme glucuronosyltransferase, converts indirect (or unconjugated) bilirubin into direct (or conjugated) bilirubin so it can be excreted in bile and eliminated from the body. This is an important function in the newborn, and jaundice can result if the level of glucuronosyltransferase is low because of immaturity.

The liver manufactures bile, a secretion necessary for the digestion of fat; fibrinogen and prothrombin, substances essential for blood clotting; heparin, a substance necessary to keep blood from clotting in intact vessels; and blood proteins. It produces large amounts of body heat. It destroys red blood cells and detoxifies many harmful absorbed substances, such as drugs. Because the liver, a life-sustaining organ, performs all of these functions, any disorder involving the liver is always serious. Several common liver function tests are used to diagnose the nature of liver pathology (Table 45.5).

Hepatitis

Hepatitis (inflammation and infection of the liver) is caused by invasion by hepatitis A, B, C, D, or E virus (Tan & Lok, 2007).

Hepatitis A

- Causative agent: A picornavirus, hepatitis A virus (HAV)
- Incubation period: 25 days on average
- Period of communicability: Highest during 2 weeks preceding onset of symptoms
- Mode of transmission: In children, ingestion of fecally contaminated water or shellfish; day care center spread from contaminated changing tables
- Immunity: Natural; one episode induces immunity for the specific type of virus
- Active artificial immunity: HAV vaccine (recommended for all children 12 to 23 months of age and workers in day care centers) (AAP, 2009)
- Passive artificial immunity: Immune globulin

Hepatitis B

- Causative agent: A hepadnavirus; hepatitis B virus (HBV)
- Incubation period: 120 days on average
- Period of communicability: Later part of incubation period and during the acute stage
- Mode of transmission: Transfusion of contaminated blood and plasma or semen; inoculation by a contaminated syringe or needle through IV drug use; may be spread to fetus if mother has infection in third trimester of pregnancy
- Immunity: Natural; one episode induces immunity for the specific type of virus
- Active artificial immunity: Vaccine for the HBV virus recommended for routine immunization beginning at birth and also to all health care providers (AAP, 2009)

TABLE 45.5 ✻ Liver Function Tests

Test	Description
Serum bilirubin	Indirect bilirubin found in large quantities in bloodstream indicates that the child is not converting it to direct bilirubin; hence, liver cell function may be impaired; the normal value of total bilirubin in serum is 1.5 mg per 100 mL; if large amounts of direct bilirubin are found in serum, it implies obstruction of the bile duct, preventing the excretion of the converted substance.
Stool and urine bilirubin	If bile pigments can be obtained from stool (excreted as urobilinogen in stool and urine), it is evidence that bile is being manufactured and excreted from the liver; without the presence of bile pigment, stool appears light in color (clay colored). Even trace amounts of bilirubin in urine are abnormal, possibly indicating liver dysfunction.
Alkaline phosphatase	Alkaline phosphatase is an enzyme produced by the liver and bone and excreted in the bile; with bile duct obstruction, increased levels of alkaline phosphatase will be in the blood.
Prothrombin time	This test is associated with blood coagulation. In chronic liver disease, the level of prothrombin produced by the liver may fall so severely that the prothrombin time is increased; there is little change in prothrombin time in mild or short-term liver disease.
Aspartate transaminase (AST; serum glutamic-oxaloacetic transaminase [SGOT])	AST (SGOT) is an enzyme found in the heart and liver; when there is acute cellular destruction in either organ, the enzyme is released into the bloodstream from the damaged cells; the blood levels are increased by 8 hours after injury; the level reaches a peak in 24 or 36 hours and then falls to normal in 4 to 6 days.
Alanine transaminase (ALT; serum glutamate pyruvate transaminase [SGPT])	ALT (SGPT) is an enzyme found mostly in the liver; it rises for the same reasons as AST (SGOT) but is not as sensitive an indicator of liver damage.
Lactic dehydrogenase (LDH)	LDH is another enzyme found in the heart and liver; it is a relatively insensitive indicator of liver destruction, however; infectious mononucleosis is the one disease in which increased levels of LDH are seen frequently.
Serum albumin	Albumin, a serum protein, is chiefly synthesized in the liver; most acute or chronic liver disease will cause decreased serum albumin.

- Passive artificial immunity: Specific hepatitis B immune serum globulin

Hepatitis C, D, and E

Although hepatitis A and B are the viruses that most frequently cause hepatitis, hepatitis C, D, and E viruses may also be involved. Hepatitis C (HCV) is a single-strand RNA virus. Transmission, as with HBV, is primarily by blood or blood products, IV drug use, or sexual contact. The virus produces mild symptoms of disease, but there is a high incidence of chronic infection with the virus.

Hepatitis D (HDV) or the delta form is similar to HBV in transmission, although it apparently requires a coexisting HBV infection to be activated. Disease symptoms are mild, but there is a high incidence of fulminant hepatitis after the initial infection.

The E form of hepatitis is enterically transmitted similarly to hepatitis A (fecally contaminated water). Disease symptoms from the E virus are usually mild, except in pregnant women, in whom they tend to be severe (Patra et al., 2007).

Assessment. No matter which virus is involved, hepatitis is a generalized body infection with specific intense liver effects. Type A occurs in children of all ages and accounts for approximately 30% of instances. Hepatitis B tends to occur in newborns from placental-fetal transfer and in adolescents after intimate contact or the use of contaminated syringes for drug injection.

Clinically, it is impossible to differentiate the type of hepatitis from the signs that are present. All hepatitis viruses cause liver cell destruction, leading to increased serum aspartate amino transaminase (AST), alanine aminotransaminase (ALT), and alkaline phosphatase levels. Albumin synthesis decreases, and bile formation and excretion are impaired. The type of virus causing the disease can be determined by the recognition of a specific antibody against the virus (anti-HAV IgM, anti-HBV IgM, and so forth).

Children notice headache, fever, and anorexia. Symptoms with hepatitis A are generally mild. Jaundice occurs as liver function slows. This lasts for approximately a week, and then symptoms fade with full recovery. Symptoms of hepatitis B are more marked. Children report generalized aching, right upper quadrant pain, and headache. They may have a low-grade fever. They feel ill; they are irritable and fretful from pruritus (itching). After 3 to 7 days of such symptoms, the color of the urine becomes darker (brown) because of the excretion of bilirubin. In another 2 days, the sclerae of the eyes become jaundiced; soon a child has generalized jaundice. With the generalized jaundice, there is little excretion of bilirubin into the stool, so the stools become white or gray. This icteric (jaundiced) phase lasts for a few days to 2 weeks. Some children have an anicteric form of infection, in which they develop the beginning symptoms but then never develop the jaundice. They are as infectious, however, as children with overt jaundice.

Laboratory studies will show elevations of the liver enzymes AST (SGOT) and serum alanine transaminase (ALT; serum glutamate pyruvate transaminase [SGPT]). Levels of bilirubin are increased in the urine. Bile pigments in the stool are decreased. Serum bilirubin levels are increased.

Therapeutic Management. All health care providers should receive prophylaxis against hepatitis with the hepatitis vaccine. Infants should also receive routine immunization against HBV. All women should be screened during pregnancy for hepatitis B surface antigen (HBsAg). Infants born to hepatitis-positive mothers receive both HBIG and active immunization at birth to prevent them from contracting the disease (Lee et al., 2009). Hepatitis A vaccine is available for health care providers and included in routine immunization programs for infants beginning at one year of age (AAP, 2009).

Strict handwashing and infection control precautions are mandatory when caring for children with hepatitis. Feces must be disposed of carefully because the type A virus can be cultured from feces. Syringes and needles must be disposed of with caution because the type B virus can be transmitted by blood. Contacts should receive immune globulin (hepatitis A) or hepatitis B immune globulin (HBIG) as appropriate.

The treatment for hepatitis A is increased rest and maintenance of a good caloric intake. A low-fat diet, once recommended, is not required and, in any event, is difficult to enforce. Children are generally hungrier at breakfast than later in the day, so encourage them to eat a healthy breakfast. Children can be cared for at home. They should not return to school or a day care center until 2 weeks after the onset of symptoms.

Lamivudine (Epivir), an antiviral agent, may be effective in reducing viral replication with hepatitis B. Interferon also may be prescribed. Of those with type B, 90% will recover completely, but 10% will develop chronic hepatitis and become hepatitis carriers. Hepatitis B is always potentially serious because newborns who contract the disease at birth have an increased risk for liver carcinoma later in life (Perrillo & Jacobson, 2007). As hepatitis B is a sexually transmitted disease, preadolescent children with the infection need to be screened for the possibility of sexual abuse (Lewin, 2007).

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Pain related to pruritus of jaundice and liver inflammation

Outcome Evaluation: Child states level of itching is tolerable; no scratch marks on skin; reports right upper quadrant pain is minimal.

Pruritus from jaundice results in extreme discomfort for some children (Cies & Giamalis, 2007). Being certain that a child is not overheated and not perspiring reduces the itching. A cool bath is often comforting. Skin moisturizers such as Eucerin or an antihistamine may be prescribed. Cholestyramine (Questran) is a bile acid sequestrant, which binds bile in the GI tract to prevent its reabsorption so helps prevent pruritus. Teaching a child distraction techniques such as putting pressure on a pruritic area or trying imagery to lessen the urge to scratch can also be helpful.

Chronic Hepatitis

Hepatitis is considered chronic when it persists for longer than 6 months. This is most often the result of hepatitis B,

D, or C infection. Abnormal liver enzyme levels and a liver biopsy establish the diagnosis and can also predict the severity. With chronic hepatitis, fatty infiltration and bile duct damage can occur. The disease may progress to cirrhosis and eventually liver failure. Therapy is supportive to compensate for decreased liver function (Friedman, 2009).

Fulminant Hepatic Failure

Fulminant hepatic failure is present when acute, massive necrosis or sudden, severe impairment of liver function occurs, leading to hepatic encephalopathy. Hepatic encephalopathy is the result of ammonia intoxication caused by the inability of the liver to detoxify the ammonia being constantly produced by the intestine in the process of digestion (Cochran & Losek, 2007).

Children show mental aberrations such as confusion, drowsiness, or disorientation. Treatment involves reducing protein intake and administering lactulose to prevent absorption of ammonia in the colon or administering nonabsorbable antibiotics such as neomycin to decrease the production of ammonia by the intestinal bacteria. Liver transplantation (surgical replacement of a malfunctioning liver by a donor liver) may be necessary. As adults have excess liver tissue, a donor liver may be provided by a living donor. Otherwise, many children cannot survive the long wait for a cadaver donor organ.

Obstruction of the Bile Ducts

Obstruction of the bile ducts in children generally occurs from congenital atresia, stenosis, or absence of the duct. It also can occur from the plugging of biliary secretions, though this is rare. When the bile duct is obstructed, bile, unable to enter the intestinal tract, accumulates in the liver. Bile pigments (direct bilirubin) enter the bloodstream and jaundice occurs, increasing in intensity daily.

Assessment

Although bile duct obstruction is a congenital disorder, the chief sign (jaundice) does not develop until approximately 2 weeks of age. This delay differentiates it clinically from physiologic jaundice, which occurs in almost all newborns on the third day of life, or the jaundice of Rh or ABO isoimmunization, which typically occurs during the first 24 hours of life. Laboratory findings will also distinguish this type of jaundice from other types. Physiologic jaundice and isoimmunization jaundice occur from a rise in indirect bilirubin, whereas the jaundice of bile duct obstruction is a result of a rise in direct bilirubin. Alkaline phosphatase levels are also elevated. The AST (SGOT) level is normal in the early phase but later becomes abnormal, when prolonged obstruction and back-pressure cause liver cell damage. In addition, because bile salts (necessary for fat absorption) are not reaching the intestine, absorption of fat and fat-soluble vitamins (vitamins A, D, E, and K) is poor. Calcium absorption, which depends on vitamin D absorption, also is poor. The infant's stools appear light in color from lack of bile pigments. The pressure on the liver from the obstruction becomes so acute with time that cell destruction or cirrhosis occurs. Ultimately, without liver transplantation, death from liver failure will result (Kamath, 2008).

Therapeutic Management

Before treatment is begun, appropriate blood work and a liver biopsy under local anesthesia may be obtained to rule out hepatitis. Duodenal secretions may be collected by endoscopy to assess for bile. Radionuclide imaging may also be performed. For this, the infant is given an IV radioactive isotope that when taken up by the liver would normally be seen flowing through the bile ducts. If the problem appears to only be a mucus plug in the duct, children may be given magnesium sulfate (installed into the duodenum to relax the bile duct) or dehydrocholic acid (Decholin) IV to stimulate the flow of bile. If atresia of the bile duct is the problem, surgical correction is the treatment (a Kasai procedure). With this surgery, a loop of bowel is sutured next to the liver to create a fistula for bile flow between the liver and intestine. A double-barreled colostomy is then created (enterostomy). Bile flows out of the proximal loop into a collecting bag. It is periodically returned to the distal loop of intestine by injection. After 6 to 12 weeks, the colostomy is closed when a normal bile flow has been established. However, surgical correction is impossible in all infants with atresia because the atresia tends to occur too far back in the liver to be in an operable area. Liver transplantation is needed for children with extensive involvement or in whom a Kasai procedure is not successful.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for imbalanced nutrition, less than body requirements, related to inability to digest fat

Outcome Evaluation: Infant's weight remains in same percentile on standardized growth curve; absence of signs of vitamin deficiency such as cracked lips or altered bone growth; dietary record reflects intake of adequate nutrients.

Preoperative Care. Infants who are admitted for surgery for bile duct obstruction are placed on a low-fat, high-carbohydrate diet preoperatively. They are given water-soluble forms of vitamins A, D, and K to improve vitamin levels. If the vitamin K level is too low, coagulation may be affected, increasing surgical risk. Vitamin K may be administered parenterally until prothrombin levels rise to normal limits. Infants will also be well hydrated with parenteral fluids.

Postoperative Care. Following surgery, infants return with a nasogastric tube in place attached to low intermittent suction. Observe carefully for abdominal distention because paralytic ileus is a frequent complication of this type of surgery. The nasogastric tube will be left in place until peristalsis has returned. Gradually, children will be introduced to oral fluids and eventually to a normal diet. If the repair is successful, the child's stools change to a yellow and then brown (normal stool) color after surgery. Description of stools is, therefore, an important postoperative observation.

If bile flow is inadequate after surgery, infants will remain on a medium-fat, high-carbohydrate diet or receive total parenteral nutrition while they await transplantation surgery.

Cirrhosis

Cirrhosis is fibrotic scarring of the liver. Cirrhosis means "yellow," or the typical color of hepatic scar tissue. It occurs rarely in children, although it may be seen as a result of congenital biliary atresia or as a complication of chronic illnesses such as protracted hepatitis, sickle-cell anemia, or cystic fibrosis.

When fibrotic infiltrates replace normal liver cells, liver function is impaired, resulting in a decreased ability to detoxify toxic substances, decreased protein synthesis, inability to produce prothrombin, decreased ability to produce bile, and, possibly, hypoglycemia. Children will have large, fatty stools resulting from the decrease in bile production; avitaminosis of fat-soluble vitamins; symptoms of hemorrhage from decreased clotting ability; and anemia.

Fibrotic infiltration interferes not only with the function of liver cells but also with blood flow through the liver. This leads to portal hypertension from the back-pressure of blood that cannot flow readily through the scarred organ (Fig. 45.4). This leads to compromised heart action, *ascites* (an exudate of fluid into the abdomen), possibly esophageal varices (back-pressure causes them to dilate), and hypersplenism.

Once fibrotic infiltration begins, there is no way to reverse the changes. Nursing care focuses on promoting comfort, providing adequate nutrition by a high-carbohydrate, medium-chain–triglyceride diet, and preventing further involvement until liver transplantation can be scheduled.

FIGURE 45.4 A child with cirrhosis of the liver. Note the abdominal distention and development of prominent, tortuous veins secondary to portal hypertension. (From Zitelli, B. J., & Davis, H. W. [1997]. *Atlas of pediatric physical diagnosis* [3rd ed.]. St. Louis: Mosby–Year Book, Inc.)

Cholestyramine (Questran) may be prescribed to stimulate bile flow and reduce reabsorption of bile into the circulation to minimize jaundice.

Esophageal Varices

Esophageal varices (distended veins) is a frequent complication of liver disorders such as cirrhosis (McQuaid, 2009). They generally form at the distal end of the esophagus near the stomach because of back-pressure on the veins there because of increased blood pressure in the portal circulation. Varices may bleed if children cough vigorously or strain to pass stool. Gastric reflux into the distal esophagus may irritate and erode the fine covering of the distended vessels, causing rupture.

Rupture of esophageal varices is an emergency because children can lose a large quantity of blood quickly from the engorged vessels. Vasopressin or nitroglycerin may be given IV to lessen hypertension and reduce the hemorrhage. Injection of a sclerosing agent into veins may be attempted to decrease their size. Iced saline nasogastric lavage may be instituted to promote vasoconstriction. A Sengstaken-Blakemore tube or Linton-Nachlas catheter may be passed into the stomach. After insertion, balloons on the sides of the catheter are inflated to apply pressure against the bleeding vessels. As with an external tourniquet, the compression must be reduced for 5 to 10 minutes every 6 to 8 hours, or tissue necrosis can result.

Children must be monitored for future bleeding episodes. Frequent vital sign measurements and testing of stool and any vomitus for the presence of blood will indicate new esophageal bleeding.

Liver Transplantation

Liver transplantation is the surgical replacement of a malfunctioning liver by a donor liver (Bueno et al., 2007). Donor livers are not readily available, so the waiting time for surgery may be months. Finding an acceptable, child-sized liver may be especially difficult, so adult livers can be reduced in size for transplantation. A lobe of a liver from a living donor is frequently used today. Often, the child is extremely ill with ascites, GI bleeding, extreme pruritus, hepatic encephalopathy, or renal dysfunction before the surgery can be performed. This makes nursing care after liver transplantation in a child complex because it involves taking care of a child who has had major surgery, and also one who normally would be categorized as too ill to undergo surgery.

Despite the severity of illness and the length of surgery, however, children tend to recover quickly after liver transplantation (Treem, 2007). Both children and parents must have thorough preoperative preparation so they understand the seriousness of the surgery and the possibility that the graft will be rejected. It helps to introduce the parents to others whose children have successfully undergone the procedure so they have support people available.

Preoperative Management

Preoperative management consists of keeping the child in the best physical condition possible so that, when a liver is available, transplantation can be performed. For many children, this includes dialysis and severe nutritional restrictions.

Surgical Procedure

Liver transplantation requires a wide subcostal incision. The vena cava is temporarily clamped during the removal of the natural liver to prevent bleeding, which means that all IV lines must be placed in the upper extremities (if placed in lower extremities, fluid could not return through the clamped venous circulation to the upper body). The total operation takes 10 to 14 hours to complete.

Postoperative Management

Rejection of a liver transplant is most often because of the function of T lymphocytes. Careful tissue matching (HLA matching) is necessary to reduce the possibility of stimulating T-cell rejection. To further reduce the action of T lymphocytes, children are given an immunosuppressive drug such as mycophenolate mofetil (CellCept), cyclosporine (Sandimmune), or tacrolimus (Prograf) before the transplantation.

Nursing care after liver transplantation surgery focuses on preventing complications that may arise from the surgery and the continued immunosuppression. Children may need assisted ventilation for approximately 24 hours postoperatively to prevent pulmonary complications such as atelectasis and pneumonia because the large abdominal incision makes coughing and deep breathing difficult. In addition, ascites has placed pressure against the diaphragm, interfering with lung expansion, and preoperative pulmonary edema may be present. After discontinuation of mechanical ventilation and extubation, chest physiotherapy may be started to mobilize lung secretions.

Advocate for adequate pain control. Assess blood pressure, capillary refill, peripheral pulses, and skin color frequently to ensure adequate cardiovascular function, which is important for good tissue perfusion of the transplanted liver. The child may have a central venous pressure line or an arterial line such as a Swan-Ganz catheter inserted to assess hemodynamic status. Assess neurologic status hourly using a modified Glasgow Coma Scale (see Chapter 52).

Usually, a child is positioned flat for the first 24 hours to prevent cerebral air emboli, which may result from any air remaining in the transplanted liver. Typically, children have a nasogastric tube inserted during surgery attached to low intermittent suction postoperatively. Irrigate the tube according to agency policy to maintain patency. Assess the gastric pH by aspirating stomach contents every 4 hours; based on this assessment, administer antacids or H_2 receptor antagonists such as cimetidine or mucosal protectants as prescribed to help prevent stress ulcer. If preoperative esophageal varices are present, assess nasogastric drainage carefully for frank or occult blood.

A T-tube inserted into the bile duct for drainage allows the amount of bile being produced by the new liver to be evaluated. Once bowel sounds become active, nasogastric suction and the T-tube are usually discontinued and liquids and then solid foods are introduced gradually. If vomiting occurs and is persistent, total parenteral nutrition may be used for 3 or 4 days to rest the intestinal tract before fluid is reintroduced.

Hypoglycemia is a danger postoperatively because glucose levels are regulated by the liver, and the transplanted organ may not function efficiently at first. Assess serum glucose levels hourly by fingerstick puncture. A 10% solution of dextrose IV may be necessary to prevent hypoglycemia.

Sodium, potassium, chloride, and calcium levels are evaluated approximately every 6 to 8 hours to be certain that an electrolyte balance is maintained. Even if a low potassium level is detected, potassium is rarely added to IV solutions because of the risk that renal failure has occurred because of the stress of surgery. Plus, if the graft begins to necrose, the breakdown of cells will release potassium, elevating the level even more. Continuous cardiac monitoring is usually necessary to detect hyperkalemia (hyperkalemia causes elevation of T waves or ventricular fibrillation), hypokalemia (causes small T waves and a U wave), or other arrhythmias.

Many children develop hypertension within 72 hours after surgery. This occurs because of alterations in the renin–angiotensin system because of the not yet fully functioning transplanted liver or as a side effect of cyclosporine, tacrolimus, and steroid therapy, which is continued postoperatively to guard against transplant rejection. IV therapy with hypotensive agents such as hydralazine (Apresoline) and nitroprusside may be needed to reduce hypertension. Hypotension will occur if the transplanted liver becomes dysfunctional or if there is bleeding caused by poor blood coagulation. To help detect bleeding, observe and record abdominal girth, the incision line, and drainage from any catheters or tubes placed in the incision to allow peritoneal secretions to drain.

A warming blanket may be required postoperatively to maintain normal body temperature after the long exposure of surgery. Take axillary or tympanic, not rectal, temperatures, because many children with liver damage have hemorrhoids that could rupture from the trauma of a thermometer insertion. Prevent the child from unnecessary exposure during procedures and care to help maintain normal body temperature.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for infection related to administration of immunosuppressive medication

Outcome Evaluation: Temperature remains within normal range; no presence of exudate or inflammation around abdominal incision.

Liver transplantation is possible because of the preoperative administration of an immunosuppressive agent that suppresses T lymphocytes, the lymphocytes responsible for rejecting transplanted organs. Immunosuppressive agents must be continued postoperatively to prevent graft rejection. Because children are prone to infection while receiving immunosuppressive therapy, be sure to use strict aseptic technique, standard infection precautions, and careful handwashing. Clean the skin around any abdominal drains every 4 hours to avoid skin breakdown and prevent a portal of entry for microorganisms.

Serum transaminases (AST [SGOT] and ALT [SGPT]), alkaline phosphatase, serum bilirubin, and ammonia levels are assessed at least daily to detect rejection although children usually do not show signs of liver rejection until 5 to 7 days after surgery. In addition to changes in these laboratory values, with liver rejection the child also may develop fever and

increasing abdominal girth. Also, the urine turns orange from increased urobilinogen excretion. If signs of rejection appear to be occurring, doses of cyclosporine, tacrolimus, and a corticosteroid such as methylprednisolone are increased to maximum levels.

Nursing Diagnosis: Interrupted family processes related to stress of surgery and uncertainty of transplantation outcome

Outcome Evaluation: Child and family state that although waiting is difficult, they are able to do so; family identifies ways they have changed family life at home to accommodate child's illness and surgery.

Children and parents need continued support during the postoperative period while they wait to see if the graft will be rejected. They need continued contact with health care personnel through telephone calls and clinic visits.

After successful liver transplantation, a child should be able to function normally, attending school and enjoying age-appropriate activities. Be certain by hospital discharge that parents have a return appointment for evaluation and are aware of the symptoms of graft rejection, such as jaundice, lethargy, and fever. Contact sports may be limited to prevent injury to the new liver and adolescents need to be cautioned to avoid alcohol to prevent liver damage from this source.

✔ Checkpoint Question 45.4

Barry's family likes to eat shellfish. What form of hepatitis is most apt to be contracted by eating contaminated shellfish?

a. Hepatitis B.
b. Hepatitis A.
c. Hepatitis E.
d. Hepatitis C.

INTESTINAL DISORDERS

Because the intestines form a long body system, several either congenital or acquired disorders can occur.

Intussusception

Intussusception, the invagination of one portion of the intestine into another (Fig. 45.5), usually occurs in the second half of the first year of life (Kaiser, Applegate, & Ladd, 2007).

In infants younger than 1 year, intussusception generally occurs for idiopathic reasons. In infants older than 1 year, a "lead point" on the intestine likely cues the invagination. Such a point might be a Meckel's diverticulum, a polyp, hypertrophy of *Peyer's patches* (lymphatic tissue of the bowel that increases in size with viral diseases), or bowel tumors. The point of the invagination is generally at the juncture of the distal ileum and proximal colon.

Assessment

Children with this disorder suddenly draw up their legs and cry as if they are in severe pain; they may vomit. After the peristaltic wave that caused the discomfort passes, they are symptom-free and play happily. In approximately 15 minutes, the same phenomenon of intense abdominal pain strikes again. Vomitus will begin to contain bile because the obstruction is invariably below the ampulla of Vater, the point in the intestine where bile empties into the duodenum. After approximately 12 hours, blood appears in the stool and possibly in vomitus, described as a "currant jelly" appearance. The abdomen becomes distended as the bowel above the intussusception distends.

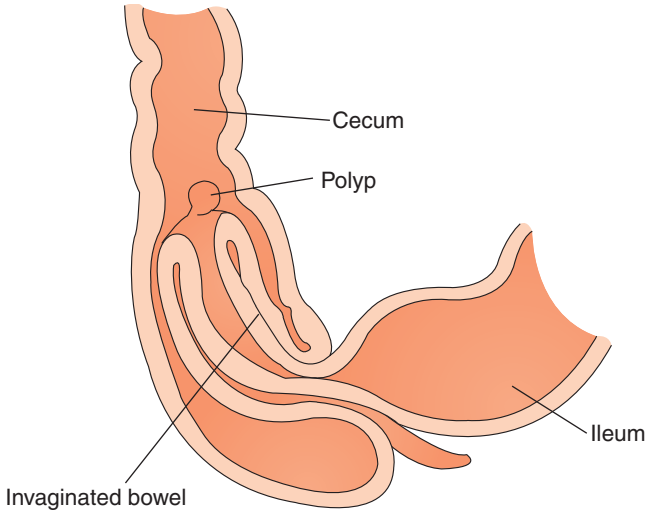

FIGURE 45.5 Intussusception. The distal ileal segment of bowel has invaginated into the cecum. A polyp serves as a lead point.

If necrosis occurs, children generally have an elevated temperature, peritoneal irritation (their abdomen feels tender; they may "guard" it by tightening their abdominal muscles), an increased white blood cell count, and often a rapid pulse.

Diagnosis is suggested by the history. Any time a parent is describing a child who is crying, be certain to ask enough questions to recognize the possibility of intussusception:

- What is the duration of the pain? *It lasts a short time, with intervals of no crying in between.*
- What is the intensity? *Severe*
- What is the frequency? *Approximately every 15 to 20 minutes*
- What is the description? *The child pulls up legs with crying.*
- Is the child ill in any other way? Yes. *Vomits; refuses food; states stomach feels "full."*

The presence of the intussusception is confirmed by ultrasound or a CT scan (Applegate, 2008).

Therapeutic Management

The condition is a surgical emergency. Reduction of the intussusception must be done promptly by either instillation of a water-soluble solution, barium enema, or air (pneumatic insufflation) into the bowel or surgery to reduce the invagination before necrosis of the effected portion of the bowel occurs. If there is no lead point, just the pressure of these nonsurgical techniques may reduce the intussusception. After this type of reduction, children are observed for 24 hours because some children will have a recurrence of the intussusception within this time. If this occurs, children will be scheduled for an additional reduction or surgery.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Pain related to abnormal abdominal peristalsis

Outcome Evaluation: Child can be comforted between spasms of pain, demonstrates interest in toys or social interactions.

Infants with intussusception are bewildered by this type of episodic pain because it is so different from any pain they have experienced before. Ordinarily, if they pinch a finger on a toy and it hurts, a parent picks them up, kisses their fingers, and the pain goes away. A parent picks them up now and the pain goes away, but it returns repeatedly. Infants need to be held and rocked and comforted in an attempt to relieve their fright at this strange happening.

Nursing Diagnosis: Risk for deficient fluid volume related to bowel obstruction

Outcome Evaluation: Infant's skin turgor is good; pulse is 90 to 100 beats/min. Amount of diarrhea and blood loss in stool is minimal. Episodes of vomiting decrease in frequency.

Infants are kept on NPO status before surgery or nonsurgical reduction. Because they have abdominal pain, they may find comfort in sucking a pacifier. Because they have been vomiting, IV fluid therapy may be started to re-establish their electrolyte balance and to supply adequate fluid to hydrate them.

Following a nonsurgical reduction, infants are kept NPO for a few hours and then introduced gradually to regular feedings. Infants who have surgery will return with a nasogastric tube attached to low intermittent suction and an IV infusion in place. The nasogastric tube will remain in place until the suture line is healing and peristaltic function has returned. Once bowel sounds are present, oral feedings can be started gradually.

Nursing Diagnosis: Risk for impaired parenting related to infant's illness

Outcome Evaluation: Parents hold and talk to infant; express positive characteristics about infant.

Parents need to hold infants after intussusception reduction or postoperatively to promote bonding and also to comfort the infant. Provide guidance and support as needed. When oral feeding is resumed, encourage the parents to participate with this aspect of care, as it provides them with an opportunity to regain confidence in themselves as parents. Reassure them that this did not occur because of anything they did or anything they fed their child. Urge them to continue to hold and be with the child as recovery proceeds to reassure themselves that the child is now once again well.

Volvulus

A **volvulus** is a twisting of the intestine (Fig. 45.6). The twist leads to obstruction of the passage of feces and compromise of the blood supply to the loop of intestine involved. This occurs most often because, in fetal life, a portion of the intestine first protrudes into the base of the umbilical cord at approximately 6 weeks of intrauterine life. At approximately 10 weeks of intrauterine life, it returns to the abdominal cavity. As the intestine returns to the abdominal cavity, it rotates to its permanent position. After the rotation, the mesentery becomes fixed in this position. In volvulus, this action is incomplete and the mesentery does not attach in a normal position. The bowel is left free to move and twist (Ingoe & Lange, 2007).

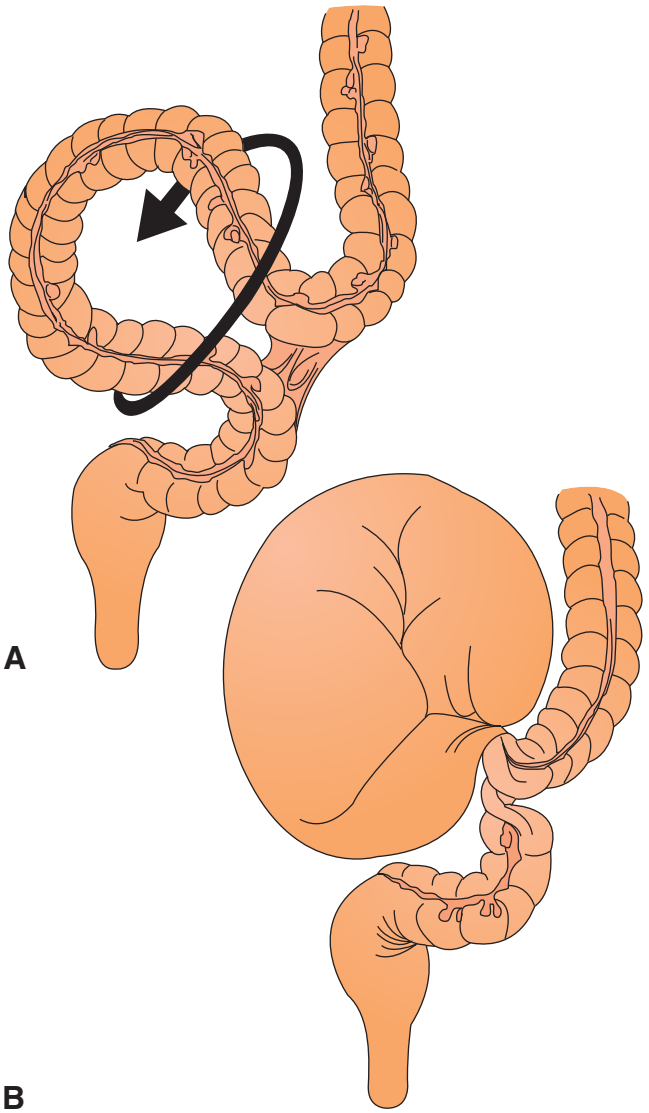

FIGURE 45.6 Volvulus of the sigmoid colon. (**A**) The unattached loop of bowel twists. (**B**) The bowel lumen is obstructed, leading to inability of stool to pass and compression of the blood supply to the looped bowel segment.

Usually, the symptoms are those of intestinal obstruction and occur during the first 6 months of life. Symptoms may include intense crying and pain, pulling up the legs, abdominal distention, and vomiting. The diagnosis is made based on the history and an abdominal examination, which reveals an abdominal mass. An ultrasound or lower barium x-ray also will show the obstruction. Surgery is used to relieve the volvulus and reattach the bowel so it no longer is so

free moving. This must be done promptly before necrosis of the intestine occurs from a lack of blood supply to the involved loop of bowel. Preoperative and postoperative care will be the same as for infants with intussusception.

Necrotizing Enterocolitis

Necrotizing enterocolitis (NEC) is a condition that develops in approximately 5% of all infants in intensive care nurseries. The bowel develops necrotic patches, interfering with digestion and possibly leading to a paralytic ileus. Perforation and peritonitis may follow (Carter, 2007).

The necrosis appears to result from ischemia or poor perfusion of blood vessels in sections of the bowel. The ischemic process may occur when, owing to shock or hypoxia, there is vasoconstriction of blood vessels to organs such as the bowel. The entire bowel may be involved, or it may be a localized phenomenon. The incidence of NEC is highest in immature infants, those who have suffered anoxia or shock, and those fed by enteral feedings. Infants with infections may develop it as a further complication of their already stressed state.

Assessment

There is a lower incidence of the condition in infants who are fed breast milk than in those who are fed formula because intestinal organisms grow more profusely with cow's milk than breast milk (cow's milk lacks antibodies). A response to the foreign protein in cow's milk may also be a mechanism that starts the necrotic process. Therefore, encouraging breastfeeding may help prevent this disorder (Grave et al., 2007).

Signs of NEC usually appear in the first week of life. The infant's abdomen becomes distended and tense. The stomach does not fully empty by the next feeding time because of poor intestinal action; if the stomach contents are aspirated before a feeding, a return of undigested milk of more than 2 mL will be obtained. Stool may be positive for occult blood. Periods of apnea may begin or increase in number. Signs of blood loss because of intestinal bleeding, such as lowered blood pressure and inability to stabilize temperature, also may be present.

Abdominal x-ray films show a characteristic picture of air invading the intestinal wall; if perforation has occurred, there will be air in the abdominal cavity. Abdominal girth measurements made just above the umbilicus every 4 to 8 hours increase.

Therapeutic Management

As soon as the condition is recognized, usual breast or formula feedings are discontinued, and the infant is maintained on IV or total parenteral nutrition solutions to rest the GI tract with the additional supplement of enteral probiotics (Al Faleh & Bassler, 2009). An antibiotic may be given to limit secondary infection. Handle the abdomen gently to lessen the possibility of bowel perforation.

If the area of necrosis appears to be localized, surgery to remove that portion of the bowel may be successful. If a large portion of the bowel is removed, the infant may be prone to "short-bowel" syndrome or may have a problem with digestion of nutrients in the future. If the bowel perforates, peritoneal drainage or a laparotomy will be necessary to help remove fecal secretions from the abdomen. An infant may need a temporary colostomy performed to allow for bowel function.

NEC is a grave insult to an infant already stressed by immaturity. The prognosis is guarded until the infant can again take oral feedings without bowel complications.

Appendicitis

Appendicitis (inflammation of the appendix) is the most common cause of abdominal surgery in children. It occurs most frequently in school-age children and adolescents, although it can occur in preschoolers and even in newborns (Della Rocca, 2007). The *appendix*, a blind-ended pouch attached to the cecum, may become inflamed because of an upper respiratory or other body infection, but the cause of appendicitis is generally obscure. In most instances, fecal material apparently enters the appendix, hardens, and obstructs the appendiceal lumen. Inflammation and edema develop, leading to compression of blood vessels and cellular malnutrition. Necrosis and pain result. If the condition is not discovered early enough, the necrotic area will rupture and fecal material will spill into the abdomen, causing peritonitis—a potentially fatal condition.

Assessment

Most parents assume that appendicitis begins with sharp pain, so they may dismiss a child's early symptoms for some time as simple gastroenteritis. Actually, pain is a late symptom. Diagnosis is made on a cluster of symptoms: anorexia, pain or tenderness in the right lower quadrant, nausea or vomiting, elevation of temperature, and leukocytosis (Ebell, 2008). The history typically begins with anorexia for 12 to 24 hours. Children do not eat and do not act like their usual selves. Nausea and vomiting may then occur. The abdominal pain, when it does start, is at first diffuse. Gradually, it becomes localized to the right lower quadrant. The point of sharpest pain is often one third of the way between the anterior superior iliac crest and the umbilicus **(McBurney's point).** If the child's appendix is displaced from this usual position, the pain will not be at this typical point, so pain at any other point does not rule out appendicitis. Pregnant adolescents are apt to have displaced pain. Fever is a late symptom.

It is important in history taking to document the progress of the disease, for example:

- How was the child on Monday? *Not herself. She was not eating.*
- How was she Monday night? *She had generalized abdominal pain.*
- Tuesday morning? *She had sharp localized pain.*
- Now? *She has localized pain, vomiting, and fever.*

Until the pain becomes localized, appendicitis is difficult to distinguish from acute gastroenteritis. Often, it is difficult to palpate children's abdomens because they guard their abdomen or make abdominal muscles stiff and hard by tensing them. Although this interferes with abdominal examination, it is in itself an important sign that children have abdominal pain. To assist in a diagnosis of a painful abdomen, always palpate the anticipated tender area last.

Rebound tenderness is a phenomenon in which a child feels relatively mild pain when the area over the appendix is

palpated, but, once an examiner's hand is withdrawn, the child experiences acute pain caused by the shifting of the abdominal contents. This is diagnostic for appendicitis, but it should be done with children only when necessary because it does cause acute pain. Caution children that the maneuver may cause pain. On auscultation, bowel sounds will be reduced: only one or two are heard in the same length of time that 30 are normally heard. Absence of bowel sounds on auscultation suggests peritonitis or an appendix that has already ruptured.

Laboratory findings usually indicate leukocytosis (white blood cell count between 10,000 and 18,000/mm^3), which is actually low for the extent of the infection that may be present. Ketone levels in the urine are inordinately elevated as a symptom of starvation from poor intestinal absorption.

An ultrasound reveals the swollen appendix. It can also be confirmed by a CT scan. Pain in the right lower quadrant may also occur as a manifestation of right lower lobe pneumonia. Therefore, children may have a chest x-ray taken to rule this out as the source of pain. Because, in the past, assessment of appendicitis depended on being able to detect abdominal pain, both parents and health care providers may be reluctant to administer analgesia to children with abdominal pain. Because ultrasound can successfully reveal appendicitis, however, analgesia to make the child comfortable can be given (Bromberg & Goldman, 2007).

Therapeutic Management

Therapy for appendicitis is surgical removal of the appendix by laparoscopy before it ruptures (Sauerland, Lefering, & Neugebauer, 2009). Achieving surgery before rupture occurs is easier in older children, who are more capable of relating the progression of symptoms. It is more difficult in young children, whose history is not as accurate, who do not have the words to describe their symptoms, or who will not relax their abdominal muscles enough to allow for manual examination. Also, the wall of the appendix is thinner and perforates more readily in young children.

Nursing Diagnoses and Related Interventions

Priorities for nursing care must be established quickly because this is an emergency, and the child must be prepared immediately for surgery (see Focus on Nursing Care Planning Box 45.4).

Nursing Diagnosis: Pain related to inflamed appendix

Outcome Evaluation: Child states that level of pain is tolerable.

Once a diagnosis is made by ultrasound, a child needs an analgesic for pain. Cathartics and heat to the abdomen are contraindicated, because these increase the possibility of rupture of the appendix. The abdomen will be shaved and washed with an antiseptic solution immediately before surgery. If you are assisting with the procedure, be gentle because the abdomen is tender, and compression could cause the appendix to rupture. Use lukewarm, not hot water, because heat can increase the possibility of appendix rupture by increasing edema in the appendix. Urge the child to find the best position of comfort, and assure both parents and the child that surgery is being scheduled as soon as possible.

Nursing Diagnosis: Fear related to emergency nature of disorder and immediate surgery

Outcome Evaluation: Parents and child state that they understand what interventions are necessary and cooperate as necessary.

Admission for appendicitis often occurs rapidly. A parent telephones a primary care provider, who recommends the child be seen in an emergency room. Surgery is scheduled as soon as it can be arranged. A mere 30 minutes may pass from the time of the first phone call until the child is wheeled into surgery. During this time, the parent and child both need to be told exactly what is happening ("I'm going to take some blood; I'm putting your name tag on your arm") and who the people are who are caring for them ("This is Dr. Brown, the anesthesiologist. I'm Ms. Henry, a registered nurse."). Parents do not think clearly in this type of emergency, and their reactions to situations may not be their usual ones. Explain that the procedures being done for the child such as blood studies or a short wait while an operating room is prepared are necessary for safe surgery and that the danger of the appendix rupturing is not as acute a danger as they may have believed under these controlled circumstances.

Remember that these children have had no preparation for hospitalization. The axiom "What they don't know won't hurt them" is not true. Lack of knowledge can make appendicitis a harrowing experience for parents as well as children. Praise them for the things they did well, such as recognizing the child was ill and bringing the child immediately for care, to help offer a sense of control.

Nursing Diagnosis: Risk for deficient fluid volume related to NPO status

Outcome Evaluation: Child's skin fold returns to place quickly when turgor is assessed; pulse and blood pressure are within normal age limits; weight is maintained.

Preoperatively, obtain a urine sample for urinalysis and blood for a complete blood count. IV fluid therapy may be initiated to hydrate a child who has been vomiting a great deal. Postoperatively, children may have a nasogastric tube in place; they will be maintained on IV fluids until they can take adequate oral feedings (approximately 24 hours). With unruptured appendicitis, the postoperative course is uneventful; children are up a few hours after surgery and are discharged within several days. They generally return to school in another week.

Ruptured Appendix

If a child's appendix has already ruptured when the child is seen in the emergency department, the potential for peritonitis increases greatly. Children generally appear severely ill.

BOX 45.4 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Child With Appendicitis

Barry's parents bring his older sister, 10-year-old Leann, to the emergency department because of nausea, vomiting, and abdominal pain since yesterday. Father states, "We thought it was just an upset stomach, but it isn't getting any better, and the pain is much worse now."

Family Assessment ✻ Child lives with 2 younger siblings and both parents on a rural horse farm. Father works as a newspaper printer in town; mother cares for horses and stable. Mother reports finances as, "Good. We're enjoying this time of life."

Client Assessment ✻ Well-nourished, 10-year-old female with a history of no major medical problems. Temperature 101.2° F; pulse 100; respirations 24. Mother reports that yesterday the child stated she was not feeling well. "She wasn't eating, and she had pains in her stomach. Last night, the pain got worse and she started vomiting." Pain now localized in right lower quadrant. Legs drawn up against abdomen. Bowel sounds sluggish. Rebound tenderness present. White blood cell count of 17,000/mm^3. Ultrasound confirms appendicitis. Child is scheduled for emergency appendectomy.

Nursing Diagnosis ✻ Pain related to presence of appendicitis

Outcome Criteria ✻ Child states pain is not above a 2 on 1–10 pain scale.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Assess what is child's most comfortable position.	Do not palpate child's abdomen.	Palpating could rupture inflamed appendix.	Child states she knows not to put pressure on abdomen.
		Consultations		
Physician	Assess what anesthetist is available for emergency surgery.	Consult with anesthetist about emergency surgery.	Emergency surgery has added risks because of lack of preparation.	Anesthesiology service consults and readies for surgery.
		Procedures/Medications		
Nurse	Assess if child has ever had surgery before.	Wash abdomen and shave from nipple line to groin.	Removing abdominal hair helps prevent infection.	Abdominal preparation is completed prior to surgery.
Nurse	Assess if child's armband is in place.	Complete preoperative checklist.	Safety precautions are important to prevent misidentification during surgery.	Child's armband is in place; preoperative checklist completed and signed.
		Nutrition		
Nurse	Assess when was the last time child ate or drank. Assess skin turgor.	Keep child NPO while awaiting surgery.	Eating could evoke vomiting with aspiration during surgery.	Child cooperates to remain NPO until surgery.
Nurse	Assess if child has had prior experience with IV fluid administration.	Begin IV fluid as prescribed.	IV fluid can help prevent dehydration from previous vomiting while NPO.	Child states she understands why IV is prescribed; protects infusion site from trauma.

(continued)

BOX 45.4 ✻ Focus on Nursing Care Planning (continued)

		Patient/Family Education		
Nurse	Assess what child/parents understand about appendicitis.	Teach child and parents as needed about cause and course of appendicitis.	Better understanding of a child's condition can help child and parents accept the necessary procedures.	Child and parents state they have no questions about cause or course of appendicitis.
		Psychosocial/Spiritual/Emotional Needs		
Nurse	Assess child's level of pain using a 1-to-10 pain scale.	Discuss surgeon's preference to not prescribe analgesic as child will soon be anesthetized in O.R.	Pain relief may be delayed until appendicitis is diagnosed.	Child states she understands her pain will be relieved as soon as anesthesia is begun.
Nurse	Assess if child has experience with nonpharmacologic pain relief measures.	Teach child a nonpharmacologic pain relief method such as imagery.	Nonpharmacologic pain relief can be very effective for abdominal pain in children.	Child uses imagery as nonpharmacologic pain relief technique.
Nurse	Assess child and parents' level of apprehension about emergency situation.	Discuss positive aspects of parents' actions.	Reinforcing that parents acted with good judgment can increase self-esteem and ability to accept new developments.	Child and parents state that although their stress level is high, they are able to cope with new developments.
		Discharge Planning		
Nurse	Assess if child and parents have any questions prior to leaving for operating room.	Review what will happen in O.R. and immediate postoperative course.	The better informed child and parents are of happenings, the better they will be able to cooperate.	Child and parents state they feel prepared for next step in treatment for child's condition.

The white blood cell count rises to more than 20,000/mm^3. Position the child in a semi-Fowler's position, if possible, so that infected drainage from the cecum drains downward into the pelvis rather than upward toward the lungs. The child needs an IV fluid line inserted for hydration. Antibiotics will be begun preoperatively or as soon as the ruptured appendix is confirmed (Goldin et al., 2007).

During surgery, the child will have drains placed beside the surgery incision so any infectious material in the abdomen can continue to drain. Warm soaks to the incision line may be ordered three or four times a day to encourage drainage. Examine the wound carefully at each dressing change. Be certain not to dislodge drains while removing soiled dressings. Report immediately any drain that is expelled; the surgeon may want to replace it to ensure a patent drainage route. Often, drains are shortened with each dressing change to encourage initially deep areas, then areas closer to the skin to drain. IV fluid and antibiotic therapy are continued until full bowel function is restored.

Also assess for signs of peritonitis with dressing changes. These signs may include a boardlike (rigid) abdomen, generally shallow respirations (because deep breathing puts pressure on the abdomen and causes pain), and increased temperature. Although the postoperative course is slower (approximately 3 weeks) after a ruptured appendix, the prognosis is still good. A local abscess or intestinal adhesions may result. Adhesion formation, a long-term effect, could interfere with fertility in girls or cause bowel obstruction in both sexes later in life.

What if... Barry's older sister had appendicitis. What if her parent tells you she "dropped everything" to rush a child to the emergency department because of appendicitis? What questions would you want to ask to see if she has thought through the situation?

Meckel's Diverticulum

In embryonic life, the intestine is attached to the umbilicus by the omphalomesenteric (vitelline) duct. This duct becomes a vestigial ligament as infants reach term. In 2% or 3% of all infants, a small pouch of this duct remains, located off the ileum, approximately 18 inches from the ileum–colon junction: a **Meckel's diverticulum** (Nandish, Weston, & Wolstenhulme, 2007). In this structure, there may be some misplaced gastric mucosa, which secretes gastric acids that flow into the intestine and irritate the bowel wall. This can lead to ulceration and bleeding. Infants will have painless, tarry (black) stools or grossly bloody stools. On occasion, the diverticulum may serve as the lead point causing an intussusception. In some instances, a fibrous band extending from

the diverticulum pouch to the umbilicus acts as a constricting band, causing bowel obstruction.

The history of the child suggests the diagnosis. Because the pouch is small, it does not fill, and therefore it may not be evident on x-ray or ultrasound. Treatment is laparoscopy exploration and removal of the vestigial structure.

Celiac Disease (Malabsorption Syndrome; Gluten-Induced Enteropathy)

The basic problem in **celiac disease** is a sensitivity or abnormal immunologic response to protein, particularly the gluten factor of protein found in grains—wheat, rye, oats, and barley. When children with the disorder ingest gluten, changes occur in their intestinal mucosa or villi that prevent the absorption of foods, especially fat, across the intestinal villi into the bloodstream. As a result, children develop **steatorrhea** (bulky, foul-smelling, fatty stools); deficiency of fat-soluble vitamins A, D, K, and E (the vitamins are not absorbed because the fat is not absorbed); malnutrition; and a distended abdomen from the fat, bulky stools. Because vitamin D is one of the fat-soluble vitamins, rickets or loss of calcium from bones may occur. Hypoprothrombinemia may occur from loss of vitamin K. In addition, children may have hypochromic anemia (iron-deficiency anemia) and hypoalbuminemia from poor protein absorption (Tully, 2008).

Although gluten-induced enteropathy is a relatively rare condition, early recognition is essential so that treatment can be provided, along with early support and nutritional guidance for the parents. The illness occurs most frequently in children of a northern European background. It is apparently a dominantly inherited illness although children have different degrees of involvement. There is also an increased incidence in children of type 1 diabetes mellitus, IgA deficiency, and Down syndrome, suggesting an associated immune response etiology (Sondheimer & Sundaram, 2008).

Assessment

Children with the syndrome tend to be anorectic and irritable. They gradually fall behind other children their age in height and weight. They appear skinny, with spindly extremities and wasted buttocks. The face, however, in contrast to children with true starvation, may be plump and well-rounded (Fig. 45.7).

The diagnosis is based on the history; clinical symptoms such as bulky stools, malnutrition, distended abdomen, and anemia which become noticeable between 6 and 18 months of age; serum analysis of antibodies against gluten (IgA antigliadin antibodies); and a biopsy of the intestinal mucosa (done by endoscopy), which establishes the typical changes in intestinal villi. Children may have an oral glucose tolerance test, which will reveal poor absorption, and their stool may be collected to test for fat content, which will be increased.

In addition, the child's response to gluten is observed by placing the child on a gluten-free diet. In most instances, the response to this diet is dramatic: the child begins to gain weight, steatorrhea improves, and the irritability fades.

Therapeutic Management

Treatment is to continue the gluten-free diet for life, because there is some suggestion that these children are more prone to GI carcinoma later in life if they do not continue the diet into adulthood. In addition to this, children need to have water-soluble forms of vitamins A and D administered. Both iron and folate may be necessary as well to correct any anemia present.

FIGURE 45.7 A child with celiac disease. Typically, the child's abdomen will be distended from the fat, bulky stools. Note the wasted appearance of the buttocks. (From *Essentials of Pediatric Nursing*. Philadelphia: Lippincott Williams & Wilkins.)

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Imbalanced nutrition, less than body requirements, related to malabsorption of food

Outcome Evaluation: Child's weight is maintained on a percentile curve on a growth chart; skin turgor is good; steatorrhea is minimal; parents verbalize appropriate gluten-free food choices.

Parents need to record the consistency, appearance, size, and number of stools that the child passes. The disappearance of steatorrhea is a good indicator that the child's ability to absorb nutrients is improving.

Parents need a great deal of nutritional counseling when their child is first placed on a gluten-free diet so they can recognize foods that contain gluten (wheat, rye, oats, and barley products). Gluten is a part of wheat flour, gravy, soups, and sauces. Packaged and frozen foods usually contain gluten as fillers. Teach parents to be careful shoppers and read food labels carefully. Because children are anorectic when they are first introduced to the new diet, getting them to eat it may be a problem. Remember that toddlers often eat small servings better than larger ones. Help parents create incentives to eat, such as inviting dolls to "tea" or eating a picnic outside in nice weather.

As children reach school age, preparing a gluten-free diet grows more and more difficult, because favorite school-age foods such as spaghetti, pizza, hot dogs, cake, and cookies are not allowed. Selecting a diet in a school cafeteria may be impossible. Holidays pose additional problems—birthday cake, turkey stuffing, and holiday cookies are prohibited. Until children can recognize which foods they can or cannot eat, parents often find it difficult to let them stay at friends' houses or go to summer camp—activities important to children's learning independence.

Celiac Crisis

When children with celiac disease develop any type of infection, a crisis of extreme symptoms may occur. Both vomiting and diarrhea become acute. Children can quickly experience electrolyte and fluid imbalances and need intensive therapy to correct them (see the section on nursing care for children with vomiting and diarrhea earlier in the chapter). Gradually, after such an episode, they are placed back on a gluten-free diet.

DISORDERS OF THE LOWER BOWEL

In children, disorders of the lower bowel mainly create problems with evacuation.

Constipation

Constipation, or difficulty passing hardened stools, may occur in children of any age (Philichi, 2008). Constipation is distressing to children because passing hardened stool is painful and may cause anal fissures. A child then represses the next urge to defecate because of pain. The rectum gradually becomes distended and adjusts to the ever-present bulk of stool. The urge to defecate becomes less frequent. When the child does pass stool, it is larger and firmer than before and causes even more anal pain. This vicious cycle continues until the child becomes severely constipated. Children may have episodes of diarrhea or *encopresis* (involuntary release of stool) when their rectum can hold no more (see Chapter 54). They may experience abdominal pain from forceful intestinal contractions.

Some children begin holding stool for psychological reasons. Once the process begins, however, the hardened stool, the anal fissures, and the pain on defecation soon occur, and what began for an emotional reason becomes a physical ailment. This is important to understand, because with these children, therapy involves both counseling to correct the initial problem and treatment of the physical symptoms (McQuaid, 2009).

Assessment

When taking a history, be certain to have parents describe what they mean by constipation. Some children normally pass stool only every other day or every 3 days. As long as the stool is not hard and there is no discomfort associated with passing stool, this is not constipation. Examine the circumstances that may have led to constipation (diet low in fiber; little privacy in bathroom; family stress).

Children with constipation should be examined carefully to see if they have anal fissures. If these are present, sexual abuse must be ruled out. Constipation must be differentiated from aganglionic disease of the intestine. In constipation, on rectal examination, hard stool is found in the rectum; in aganglionic disease of the intestine, no stool is normally present.

Therapeutic Management

Treatment of chronic constipation is aimed at softening stool so it will pass painlessly. Children also need help to form good bowel habits so that stools are passed before they become large and hardened (Reading, 2007).

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Constipation related to pain from anal fissure and hardened stool

Outcome Evaluation: Child has a soft bowel movement without pain every other day.

For initial therapy, an enema may be administered to loosen hard stool. After this, a stool softener such as docusate sodium (Colace) is prescribed. In addition, children need to ingest a high-fiber, high-fluid diet and be urged to evacuate their bowels at the same time every day to form a habit.

Inguinal Hernia

Inguinal hernia is a protrusion of a section of the bowel into the inguinal ring. It occurs usually in boys (9:1) because, as the testes descend from the abdominal cavity into the scrotum late in fetal life, a fold of parietal peritoneum also descends, forming a tube from the abdomen to the scrotum (Brandt, 2008). In most infants, this tube closes completely. If it fails to close, intestinal descent into it (hernia) may occur at any time when there is an increase in intra-abdominal pressure. In girls, the round ligament extends from the uterus into the inguinal canal to its attachment on the abdominal wall. In girls, an inguinal hernia may occur because of a weakness of the muscle surrounding the round ligament.

Assessment

A hernia appears as a lump in the left or right groin. In some instances, the hernia is apparent only on crying (when abdominal pressure increases) and not when children are less active. Inguinal hernias are painless. Pain at the site implies that the bowel has become incarcerated in the sac, an emergency that requires immediate action to prevent bowel obstruction and ischemia.

The diagnosis is established by history and physical appearance. When taking a history of a well child, be certain to ask parents whether they have ever noticed any lumps in the child's groin area. The hernia may not be noticeable at the time of a health care visit, so, unless asked specifically, parents may not mention it. If present, the herniated intestine can be palpated in the inguinal ring on physical examination.

Therapeutic Management

Treatment of inguinal hernia is laparoscopy surgery. The bowel is returned to the abdominal cavity and retained there by sealing the inguinal ring. Pneumoperitoneum (instillation of carbon dioxide into the perineal cavity) during surgery may be performed to reveal the presence of an enlarged inguinal ring on the opposite side. If this is present, both sides may be repaired, and the child will return from surgery with dressings on both groins.

Formerly, surgery for inguinal hernia was delayed until the child was 3 or 4 years of age. Today, to prevent the complication of bowel strangulation—a surgical emergency—infants with inguinal hernia may have surgery before 1 year of age. If surgery is proposed as a prophylactic measure, setting outcomes may be difficult for parents as they weigh the value of surgical repair against the risk of anesthesia and surgery.

After surgery, keep the suture line dry and free of urine or feces to prevent infection. Most incisions in this area are closed by a tissue adhesive, which is waterproof and seals the incision from urine and feces. Even so, the infant will need frequent diaper changes and good diaper-area care. Assess circulation in the leg on the side of the surgical repair to be certain that edema of the groin is not compressing blood vessels and obstructing blood flow to the leg.

Hirschsprung's Disease (Aganglionic Megacolon)

Hirschsprung's disease, or *aganglionic megacolon*, is absence of ganglionic innervation to the muscle of a section of the bowel—in most instances, the lower portion of the sigmoid colon just above the anus (Dasgupta & Langer, 2008). The absence of nerve cells means there are no peristaltic waves in this section to move fecal material through the segment of intestine. This results in chronic constipation or ribbonlike stools (stools passing through such a small, narrow segment look like ribbons). The portion of the bowel proximal to the obstruction dilates, distending the abdomen (Fig. 45.8).

The incidence of aganglionic disease is higher in the siblings of a child with the disorder than in other children. It also occurs more often in males than in females. It is caused by an abnormal gene on chromosome 10. The incidence is approximately 1 in 5000 live births (Sondheimer, 2008).

Assessment

Occasionally, infants are born with such an extensive section of bowel involved that even meconium cannot pass. This is suggested if infants fail to pass meconium by 24 hours of age and have increasing abdominal distention (Hartman et al., 2007).

Because newborn stools are normally soft, however, symptoms of aganglionic megacolon generally do not become apparent until 6 to 12 months of age. By the time children are seen by a health care provider, they generally have a history of constipation or intermittent constipation and diarrhea. A careful history helps to document the illness:

- What is the duration of the constipation? *It may have been a problem from birth.*
- What do parents mean by constipation? *Children do not have a bowel movement more than once a week.*

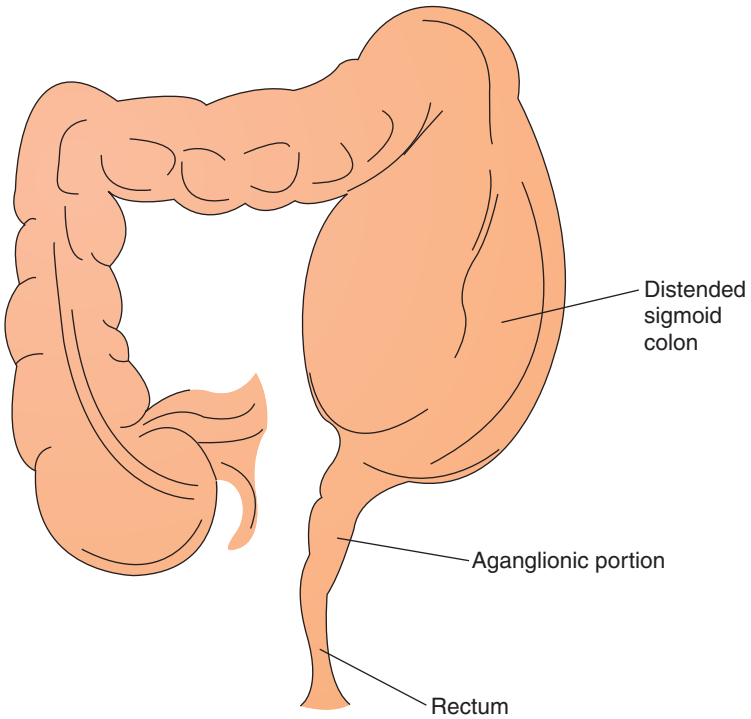

FIGURE 45.8 Aganglionic megacolon (Hirschsprung's disease). The distal portion of the bowel lacks nerve innervation. Because there is no peristalsis in this narrowed segment, the bowel proximal to it distends markedly.

- What is the consistency of the stool? *Ribbonlike or watery*
- Is the child ill in any other way? *Children with aganglionic disease of the intestine tend to be thin and undernourished, sometimes deceptively so because their abdomen is large and distended.*

If a gloved finger is inserted into the rectum of a child with true constipation, the examining finger will touch hard, caked stool. With aganglionic colon disease, the rectum is empty because fecal material cannot pass into the rectum through the obstructed portion. A barium enema is generally ordered to substantiate the diagnosis. The barium will outline on x-ray film the narrow, nerveless portion and the proximal distended portion of the bowel. A barium enema must be used cautiously, however, because children cannot expel this afterward any more effectively than they can stool. The definitive diagnosis is by a biopsy of the affected segment to show the lack of innervation or by anorectal manometry, a technique to test the strength or innervation of the internal rectal sphincter by inserting a balloon catheter into the rectum and measuring the pressure exerted against it.

Therapeutic Management

Repair of aganglionic megacolon involves dissection and removal of the affected section, with anastomosis of the intestine (termed a pull-through operation). Because this is a technically difficult operation to perform in a small abdomen, the condition is generally treated in the newborn by two-stage surgery: first a temporary colostomy is established, followed by bowel repair at 12 to 18 months of age. After the final surgery, children should have a functioning, normal bowel (Box 45.5). In the few instances in which the anus is deprived of nerve endings, a permanent colostomy will be established.

BOX 45.5 ✻ Focus on Evidence-Based Practice

What is the quality of life of children who have surgery for Hirschsprung's disease?

To answer this question, researchers asked 178 patients who had undergone pull-through operations for Hirschsprung's disease at least 5 years earlier to answer a questionnaire about their present state of health. Results showed that 50% of patients who had surgery 5 to 10 years earlier (67 patients) rated the result of their surgery as excellent. Sixty-eight percent of patients (75) who had surgery 10 to 15 years earlier rated their surgical outcome as excellent. Eighty-eight percent of those patients who had surgery 15 to 20 years earlier rated their surgical outcome as excellent. Patients who stated that their outcome was not excellent listed conditions such as constant soiling and an inability to hold back defecation. This created marked limitations in their social life because of their dependence on diapers and frustration because of teasing by their friends.

Based on the above, would you feel confident advising parents of a child about to have surgery for Hirschsprung's disease that their child will have normal fecal continance and a normal social life in the future?

Source: Niramis, R., et al. (2008). Quality of life of patients with Hirschsprung's disease at 5–20 years post pull-through operations. *European Journal of Pediatric Surgery, 18*(1), 38–43.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Constipation related to reduced bowel function

Outcome Evaluation: Child has a daily bowel movement through either a colostomy or by enema.

Before surgery, the child may be prescribed daily enemas to achieve bowel movements. The fluid used for enemas must be normal saline (0.9% NaCl) and not tap water. Tap water is hypotonic. If it is instilled into the bowel, it moves rapidly across the intestinal wall into interstitial and intravascular fluid compartments to equalize osmotic pressure (by the laws of osmosis, fluid moves from an area of less to greater concentration). This has led to death of infants from cardiac congestion or cerebral edema (water intoxication). Teach parents how to prepare and administer saline enemas at home. Parents can buy a ready-made saline preparation at a pharmacy, or they can prepare their own by mixing 2 tsp of noniodized salt to 1 quart of water. Although adding salt to water does not seem important, be certain that the parents understand the rationale for doing so and can demonstrate the proper technique and the proportion of salt to water for the enema.

Caring for a child with a colostomy is discussed in Chapter 37. An antibiotic solution or saline may be prescribed for daily infusion into the distal bowel to reduce the possibility of infection.

Nursing Diagnosis: Imbalanced nutrition, less than body requirements, related to reduced bowel function

Outcome Evaluation: Child ingests a low-residue diet; weight follows a percentile curve on a growth chart.

Preoperatively, older children may be in poor health from poor food intake over a long period. If this is so, they may be returned home on a minimal-residue diet, stool softeners, vitamin supplements, and perhaps daily enemas until their condition improves. Total parenteral nutrition can offer another source of nutrition. If a child is to be cared for at home, help the parents learn about a minimal-residue diet or one that is low in undigestible fiber, connective fiber, and residue. Fried foods and highly seasoned foods are omitted to eliminate chemical irritants in the intestinal tract.

Help parents to make out a reminder sheet for the stool softener so it is given daily. When children are beginning a special diet, it may be advisable to have parents refrain from introducing new feeding methods, such as a cup or spoon, unless children are at that developmental point where they will quickly adapt to the new procedure and are, in fact, so eager to feed themselves that they will actually eat better this way.

Postoperatively, after removal of the aganglionic portion and anastomosis of the colon at the second

step of the repair, infants will return with a nasogastric tube in place attached to low suction, an IV infusion, and probably an indwelling urinary (Foley) catheter. Observe the infant for abdominal distention. Assess bowel sounds and observe also for passage of flatus and stools. As soon as peristalsis has returned (approximately 24 hours after surgery), the nasogastric tube can be removed and the child will be offered small, frequent feedings of fluids, such as water or gelatin. The child is then introduced gradually to full fluids, a soft diet, a minimal-residue diet, and, finally, a normal diet for age.

Nursing Diagnosis: Risk for compromised family coping related to chronic illness in child

Outcome Evaluation: Parents state they are able to cope with the level of stress present from their child's condition.

Most parents feel tremendous relief after the second-stage surgery is complete. Caution parents that the child may still remain a "fussy eater" for a few months, because feeding problems that begin for physical reasons can continue for emotional or psychological reasons. Help parents to diminish the importance of meals gradually; to schedule periods during the day when they give their full and positive attention to the child, such as reading a story or putting a puzzle together; and to offer praise for pleasant, not difficult, behavior. These measures will help mealtime problems gradually diminish.

Inflammatory Bowel Disease: Ulcerative Colitis and Crohn's Disease

Two conditions are categorized as inflammatory bowel disease: *ulcerative colitis* and *Crohn's disease* (Merchant, 2007). Both involve the development of ulcers of the mucosa or submucosa layers of the colon and rectum. They both occur most frequently in young adults and adolescents, although, more and more frequently, symptoms first appear during school age. Both diseases occur more frequently in males than in females and show familial tendencies.

The cause of these disorders is obscure, but they probably represent an alteration in immune system response or are autoimmune processes. There is an increased number of immunoglobulins IgA and IgG present on intestinal mucosa. IgE immunoglobulins and the eosinophil count also may be elevated. Psychological factors have not been supported as a primary contributory factor to inflammatory bowel disease, but psychological problems often occur secondary to the disease, possibly intensifying symptoms. Smoking and frequent use of antibiotics or aspirin are correlated with the occurrence of Crohn's disease (Barter & Dunne, 2008).

Crohn's disease is an inflammation of segments of the intestine; it may affect any part of the GI tract but most commonly involves the terminal ileum. Inflamed segments are separated by normal bowel tissue. The wall of the colon becomes thickened and the surface is inflamed, leading to a "cobblestone" appearance of mucosa.

In ulcerative colitis, typically the colon and rectum are involved, with the distal colon and rectum most severely affected, and inflammation involves continuous segments.

As inflammation becomes acute with these disorders, children develop abdominal pain from contractions of the irritated portions. These areas do not absorb nutrients or fluid well, so diarrhea and malnutrition develop. To reduce abdominal pain (which is most acute after eating, when the bowel becomes active), children begin to skip meals. They may be malnourished and have a vitamin or iron deficiency at the time the condition is diagnosed.

Several complications may occur. Hemorrhage from bowel perforation during the active disease is possible. Perforation can lead to peritonitis or the formation of fistulas between bowel loops. Rectal fistula is present in as many as 20% of children. A relapse is apt to occur 6 to 12 months after therapy. With ulcerative colitis, there is an association between the disease and bowel carcinoma if the disease persists over 10 years (McQuaid, 2009).

Assessment

In both conditions, diarrhea and steatorrhea develop from the irritation and the unabsorbed fluid. If inflamed portions ulcerate, there will be blood in the stool. Weight loss occurs; growth failure occurs in prepubertal children. A recurring fever may be present (Table 45.6).

Diagnosis is established by colonoscopy and barium enema. On colonoscopy, the shallow ulcerations along the bowel can be seen; the mucosa is friable (easily irritated) and bleeds easily from inflammation. A biopsy may be performed for definite diagnosis. Observe children carefully after a bowel biopsy to detect rectal bleeding from an internal bleeding point (take blood pressure and pulse, and assess stool for occult blood).

Therapeutic Management

The child's bowel heals best if it is allowed to rest for a time. Enteral or total parenteral nutrition is usually provided for nutrition during the resting period (Wiskin, Wootton, &

TABLE 45.6 ✻ Comparison of Crohn's Disease and Ulcerative Colitis

Comparison Factor	Crohn's Disease	Ulcerative Colitis
Part of bowel affected	Ileum	Colon and rectum
Nature of lesions	Intermittent	Continuous
Diarrhea	Moderate	Severe and bloody
Anorexia	Severe	Mild
Weight loss	Severe	Mild
Growth retardation	Marked	Mild
Anal and perianal lesions	Common	Rare
Association with carcinoma	Rare	Common

BOX 45.6 ✻ Focus on Pharmacology

Sulfasalazine (Azulfidine)

Classification: Sulfasalazine is a combination anti-inflammatory agent and antibiotic.

Action: Reduces the inflammation of ulcerative colitis and Crohn's disease (Karch, 2009).

Pregnancy risk category: C (D at term)

Dosage: Varied, based on severity of illness, 20 to 75 mg/kg/day. Initially, 40 to 60 mg/kg/24 hr orally in four to six divided doses in children older than age 2 years. Maintenance therapy usually 20 to 30 mg/kg/day in four equally divided doses.

Possible adverse effects: Sensitivity to sunlight; dizziness; drowsiness, nausea, abdominal pains, crystalluria, and hematuria

Nursing Implications

- Caution the parents and child that the drug may turn urine orange-red and soft contact lenses yellow.
- Advise children to take with or just after meals to avoid GI irritation.
- Ensure adequate fluid intake to avoid crystallization of sulfa component in urine.
- Anticipate prescription for folic acid concurrently. Drug decreases folic acid absorption.
- Instruct the child and parents about the need to use sunscreens and protective clothing while outside.

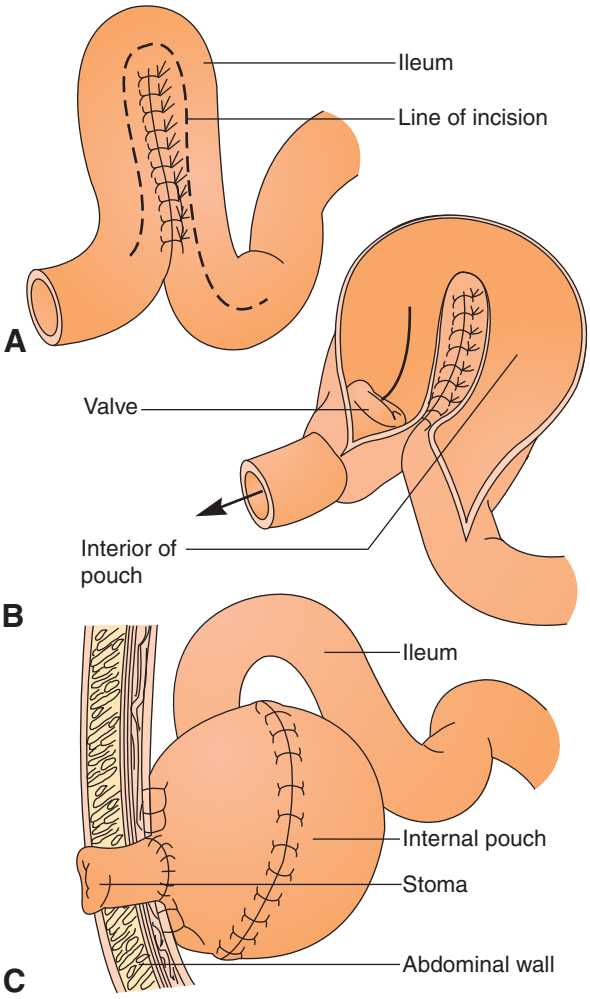

FIGURE 45.9 A continent ileostomy. (**A**) Segment of bowel is anastomosed. (**B**) Pouch for stool collection is formed. (**C**) Liquid stool is contained in pouch until drained by catheter.

Beattie, 2007). A child can remain home during this period as long as parents have thorough education about the child's nutritional needs (see Chapter 37).

When food is reintroduced after the resting period, a high-protein, high-carbohydrate, high-vitamin diet is prescribed to replace nutrients. Children may eat cautiously at first to avoid reintroducing diarrhea so assess intake and output. A combination of an anti-inflammatory drug such as prednisone (a corticosteroid), sulfasalazine (Azulfidine; a sulfonamide and salicylic acid), azathioprine (Imuran; an immunosuppressive agent), or monoclonal antibodies (infliximab) generally bring about a great improvement in symptoms (Box 45.6). For ulcerative colitis, cyclosporine may be used. If medical therapy is ineffective, bowel resection to remove a portion of the bowel (colectomy) followed by an ileoanal pull-through may be necessary. In some children, such a large portion of the bowel may be removed that a colostomy or a continent ileostomy needs to be constructed (for continent ileostomy, an internal reservoir is created using a section of bowel and emptied by insertion of a catheter; Fig. 45.9).

Bowel surgery is a serious step. Because it reduces the possibility of the child's developing intestinal cancer in association with ulcerative colitis, it may be necessary in children whose disease is running a long-term, debilitating course that does not improve (Ba'ath et al., 2007). Children who recover from inflammatory bowel disease should have a colonoscopy yearly for the rest of their lives.

Nursing Diagnoses and Related Interventions ✻

Nursing Diagnosis: Imbalanced nutrition related to poor absorption because of disease process

Outcome Evaluation: Child's weight follows a percentile growth curve; urine specific gravity is 1.003 to 1.030. Child states that alternative feeding method is tolerable.

Nutrition is a priority concern for children with both Crohn's disease and ulcerative colitis because malnutrition can occur from the combination of poor intestinal absorption and chronic diarrhea. Unless active steps are taken to supplement nutrition, children with inflammatory bowel disease can be left both short in stature and light in weight. Anorexia with protein, vitamin, fat, and mineral deficiencies all may occur.

When nutrition is supplied by enteral or total parenteral nutrition solutions, allowing the enteral infusion to flow during the night and removing the tube during the

day can make feedings more tolerable. Remember that food provides social experiences as well as nutrition. Help parents provide opportunities for usual mealtime stimulation in other ways.

Nursing Diagnosis: Risk for ineffective coping related to chronic illness

Outcome Evaluation: Child expresses feelings, states that she understands the disease and therapy, and suggests ways to minimize stress.

Caution children about the possible side effects, such as excessive weight gain, a round facial appearance, and facial acne, that may occur if corticosteroid therapy, such as prednisone, is used so they are not surprised by this. Assess blood pressure, intake and output, weight, and sleep patterns for any child taking steroids. Caution children that sulfasalazine (Azulfidine) turns urine an orange-yellow so they do not mistake this color change as bleeding.

Provide time to listen so children have someone outside their family to talk to about their symptoms and family or stress problems (Box 45.7). The disorder follows a chronic course and can involve embarrassing episodes of diarrhea or acute abdominal pain.

Irritable Bowel Syndrome (Chronic Nonspecific Diarrhea)

Irritable bowel syndrome involves intermittent episodes of loose and normal stools or recurrent abdominal pain. It appears slightly more often in girls than in boys. It is most often seen in infants 6 to 36 months of age. Most children outgrow the symptoms by 3 years of age. The cause is unknown, but it is associated with low fat intake (without fat slowing absorption, stool passes rapidly through the bowel). Excessive fluid intake also may play a role.

The symptoms are usually vague. The episodes of diarrhea may occur several times a week or as frequently as twice a day. There seems to be no relationship to meals.

Children are encouraged to eat a regular diet. Psyllium bulk agents will almost always reduce the frequency of symptoms. Probiotics or foods supplemented with lactic acid-producing bacteria may improve symptoms (Walter & Isolauri, 2007).

Chronic Recurrent Abdominal Pain

Some children develop episodes of recurring abdominal pain. Although such episodes can occur for reasons such as lactose intolerance or muscle strain from sports activities, in most instances the cause is unknown (Sondheimer, 2008). Children who experience this are commonly 6 or 7 years of age or in prepuberty (11 to 12 years of age). The pain is not accompanied by a change in bowel habits. There is no association with meals. Episodes of pain can last for only a few minutes or for hours. The intensity of the pain is mild or "annoying" rather than severe. It is generally poorly localized, although children may point to the umbilicus as the primary site. On physical examination, there is no abdominal tenderness, distention, guarding, or muscle spasm.

Symptoms of stress such as sleep disturbances, fears, or eating problems may be present. A family history may indicate problems in the family such as marital discord, financial problems, or physical illness in parents or siblings.

Although the cause of the pain cannot be identified, the pain is real. For some children, just having the opportunity to talk to an understanding person about the problem is all that is necessary to stop the attacks of pain. Other families need counseling regarding the underlying problem, such as allowing children to express their anger, reducing excessive demands on them, or giving them more attention by spending more time with them. The family may need to be referred to a family service agency for counseling (Huertas-Ceballos et al., 2009).

BOX 45.7 ✻ Focus on Communication

Barry's older sister Addie has Crohn's disease. Her doctor has told her parents she won't need surgery but will need long-term therapy. You see Mrs. Abraham filling out forms by Addie's bedside.

Less Effective Communication

Nurse: Mrs. Abraham, can I help you with anything?
Mrs. Abraham: No. With Addie well again in a short time, I'm going to start back to college. I'm filling out the forms.
Nurse: Do you mean Addie doesn't need parenteral nutrition?
Mrs. Abraham: She doesn't need anything. Not even surgery.
Nurse: That's wonderful. She's very lucky.

More Effective Communication

Nurse: Mrs. Abraham, can I help you with anything?
Mrs. Abraham: No. With Addie well again in a short time, I'm going to start back to college. I'm filling out the forms.
Nurse: Do you mean Addie doesn't need parenteral nutrition?
Mrs. Abraham: She doesn't need anything. Not even surgery.
Nurse: Let's review exactly what the doctor has told you.

People under stress often do not hear instructions well. When this happens, they may need them repeated several times before they truly comprehend what was said. An easy solution when you are aware that a parent has not heard potentially bad news is to ignore the loss of information, as in the first scenario above. A better solution is to explore with the parents what they did hear and help them receive more accurate information.

DISORDERS CAUSED BY FOOD, VITAMIN, AND MINERAL DEFICIENCIES

There are many underfed and malnourished children in every part of the world. Although extreme diseases of food or vitamin deprivation are rare in the United States, they do exist. Such children need early identification so they

can receive better nutrition before permanent damage occurs.

The average child does not develop a deficient intake of essential nutrients because, even if the child is occasionally a fussy eater, over the space of a week, a child does ingest foods containing the necessary nutrients. Carefully assess any child who has an interference in nutrition such as a GI illness or a child is receiving enteric feedings or total parenteral nutrition to make sure that nutrient deficiencies do not exist. Assess abused or neglected children closely for nutritional deficiencies, because they may not have been given adequate food.

Kwashiorkor

Kwashiorkor, a disease caused by protein deficiency, occurs most frequently in children ages 1 to 3 years, because this age group requires a high protein intake. It is a disease found almost exclusively in developing countries in Africa, Asia, and Latin America, although it does occur in the United States (Baron, 2009). It tends to occur after weaning, when children change from breast milk to a diet consisting mainly of carbohydrates. Growth failure is a major symptom. Because edema is also a symptom, however, children may not appear light in weight until the edema is relieved. There is a severe wasting of muscles, but, again, this is masked by the edema.

Edema results from hypoproteinemia, which causes a shift of body fluid from the intravascular compartments to the interstitial space, causing ascites (Fig. 45.10). This is the same phenomenon that causes extensive edema in children with nephrosis. The edema tends to be dependent, so it is first noted in the lower extremities. Children are generally irritable and uninterested in their surroundings. They fall behind other children of the same age in motor development.

If the child had a period of good protein intake, then poor protein intake, then good intake again, hair shafts develop a striped appearance of brown, then white, and so on—a "zebra sign." Children also have diarrhea, iron-deficiency anemia, and enlarged livers.

Without treatment, kwashiorkor is fatal. For therapy, a diet rich in protein is essential. Even so, there is evidence to suggest that protein malnutrition early in life, even if corrected later, may result in failure of children to reach their full potential of intellectual and psychological development.

FIGURE 45.10 A child with kwashiorkor. Here the extensive generalized edema masks the severe muscle wasting. Notice the severe abdominal distention from ascites.

Nutritional Marasmus

Nutritional marasmus is caused by a deficiency of all food groups, basically a form of starvation. Although it is seen most commonly in developing countries where food supplies are short, it can be seen in grossly neglected children or those with failure to thrive in the United States (see Chapter 55). These children are most commonly younger than 1 year of age. They have many of the same symptoms as children with kwashiorkor, including growth failure, muscle wasting, irritability, iron-deficiency anemia, and diarrhea. Whereas children with kwashiorkor are anorectic, children with nutritional marasmus are invariably hungry (starving) and will suck at any object offered them, such as a finger or their clothing. Treatment is a diet rich in all nutrients.

Vitamin and Mineral Deficiencies

Both vitamin and mineral deficiencies occur at a low rate in children of the United States because so many foods are enriched (restoration of ingredients removed by processing) or fortified (additional vitamins and minerals not normally present have been added). Milk, for example, is fortified with vitamins D and A. Orange juice is fortified with calcium. White bread is enriched with B vitamins. Vitamin deficiency diseases are summarized in Table 45.7.

Iodine Deficiency

Because iodine is not supplemented in food except as iodized salt, a diet deficient in iodine may lead to either hypothyroidism or overgrowth (*goiter*) of the thyroid gland as the gland struggles to produce thyroxine in the face of deficient iodine. Goiter tends to occur most commonly in girls at puberty and during pregnancy. It is potentially dangerous as an enlarged thyroid gland may lead to difficulty breathing. In the United States, areas where goiter is endemic are mainly the states bordering Canada, especially the Great Lakes area, and the states between the Rocky Mountains and the Appalachians (Rolfes, Pinna, & Whitney, 2009).

Supplemental iodine or synthetic thyroxine (Synthroid) is needed to correct the deficiency. Children must also be maintained on a diet adequate in iodine, found most abundantly in seafood (Rolfes, Pinna, & Whitney, 2009).

✔ Checkpoint Question 45.5

Kwashiorkor is a disorder common in developing countries. This disorder occurs because of lack of which nutrient?

a. Water-soluble vitamins.
b. Fats and triglycerides.
c. Quality protein.
d. Vitamin K.

TABLE 45.7 ✻ Vitamin Deficiency Disorders

Vitamin	Cause of Deficiency	Signs and Symptoms
Vitamin A	Lack of yellow vegetables in diet	Tender tongue; cracks at corners of mouth Night blindness **Xerophthalmia** (dry and lusterless conjunctivae) **Keratomalacia** (necrosis of the cornea with perforation, loss of ocular fluid, and blindness)
Vitamin B_1	Most common in children who eat polished rice as dietary staple, because B_1 is contained in hull of rice	**Beriberi** (tingling and numbness of extremities; heart palpitations; exhaustion) Diarrhea and vomiting Aphonia (cry without sound) Anesthesia of feet
Niacin	Common in children who eat corn as dietary staple, because corn is low in niacin	**Pellagra** (dermatitis; resembles a sunburn) Diarrhea Mental confusion (dementia)
Vitamin C	Lack of fresh fruits in diet	**Scurvy** (muscle tenderness; petechiae)
Vitamin D	Lack of sunlight	Poor muscle tone; delayed tooth formation **Rickets** (poor bone formation) Craniotabes (softening of the skull) Swelling at joints, particularly of wrists and cartilage of ribs Bowed legs Tetany (muscle spasms)

Key Points for Review

- Children with gastrointestinal disorders need to join the family for mealtime if possible. Even if they cannot eat the same foods as other family members, they benefit from the social interaction.
- Some gastrointestinal disorders lead to long-term therapies such as colostomy or gastrostomy feedings. Because these disorders interfere with common body functions such as eating and elimination, they are difficult for children to accept without the support of concerned health care providers.
- Children lose proportionately more fluid with vomiting and diarrhea than adults, so they need rapid assessment and interventions to avoid dehydration.
- Fluid, electrolyte, and acid–base imbalances tend to occur rapidly with vomiting and diarrhea. Vomiting leads to alkalosis. Diarrhea leads to acidosis.
- Gastrointestinal disorders almost always interfere with nutrition to some degree. This is a greater problem in children than adults because children need to ingest adequate nutrients and fluid daily for growth as well as body maintenance.
- Gastroesophageal reflux is a neuromuscular disturbance in which the cardiac sphincter is lax, allowing for easy regurgitation of gastric contents into the esophagus. It is treated by feeding a thickened formula and keeping an infant upright after feedings.
- Pyloric stenosis is hypertrophy of the valve between the stomach and duodenum. It impedes the passage of feedings, leading to vomiting.
- Peptic ulcer disease may occur in children of all ages. The disorder causes a shallow excavation to form in the mucosal wall of the stomach. It is treated, like adult ulcers, with antibiotics and agents to suppress gastric acidity.
- Forms of hepatitis seen in children include hepatitis A and C (caused usually by eating contaminated shellfish) and hepatitis B, D, and E (caused by contaminated blood or placental transfer).
- Congenital obstruction of the bile ducts occurs from failure of the bile duct to recanalize in utero. This can lead to fibrotic scarring of the liver (cirrhosis). Most of these children need a liver transplant to restore liver function.
- Intussusception is the invagination of one portion of the intestine into another. Volvulus is twisting of intestine. Both may lead to bowel obstruction.
- Necrotizing enterocolitis is the development of necrotic patches on the intestine. It occurs almost exclusively in immature infants.
- Appendicitis is inflammation of the appendix. It is always an emergency and is the most common reason for abdominal surgery in children. Laparoscopy is done to remove the appendix, ideally before it ruptures.
- Celiac disease (gluten-induced enteropathy) is a change in the ability of the intestinal villi to absorb. It is a dominantly inherited illness.
- Both inguinal and hiatal hernia can occur in children. These are surgically corrected when recognized.
- Hirschsprung's disease (aganglionic megacolon) is absence of ganglionic innervation in a section of the lower bowel. Therapy may involve a temporary colostomy followed by surgery in 6 to 12 months to remove the affected bowel portion.

- Inflammatory bowel disease can occur as either ulcerative colitis or Crohn's disease. Therapy is long-term. If medical therapy is unsuccessful, portions of the bowel may be surgically removed. Ulcerative colitis is associated with the development of colon cancer later in life.
- Kwashiorkor (protein deficiency), nutritional marasmus (starvation), vitamins A and D (rickets), B_1 (beriberi), and C (scurvy) deficiencies, or iodine deficiencies occur in children when they are not provided or cannot absorb adequate nutrients. Although more common in developing countries, they can occur in a child in any community.

CRITICAL THINKING EXERCISES

1. Barry is the 2-year-old boy you met at the beginning of the chapter. He was diagnosed with celiac disease. When you met him, his mother was insisting that he eat a piece of birthday cake. What health education does his mother need to help her choose a better diet for her son? What would have been a better food, probably available at a birthday party, that he could have eaten?
2. Suppose Barry is seen in a hospital emergency department with severe diarrhea. What emergency interventions does he need to prevent an electrolyte or fluid imbalance? What measures could you take to reduce his fear of the strange hospital environment?
3. Barry's older sister, who has Crohn's disease, is being cared for at home with total parenteral nutrition. How can you help her keep pace with her friends at school? How can you help her maintain a sense of high self-esteem in light of her many hospitalizations and home care?
4. Examine the National Health Goals related to gastrointestinal disorders in children. Most government-sponsored funds for nursing research are allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to the Abraham family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to gastrointestinal disorders in children. Confirm your answers are correct by reading the rationales.

Chapter 46

Nursing Care of a Family When a Child Has a Renal or Urinary Tract Disorder

KEY TERMS

- Alport's syndrome
- azotemia
- Bowman's capsule
- dialysis
- enuresis
- epispadias
- exstrophy of the bladder
- glomerular filtration rate
- glomerulonephritis
- hydronephrosis
- hypospadias
- nephrosis
- patent urachus
- polycystic kidney
- postural proteinuria
- prune belly syndrome
- vesicoureteral reflux

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe common renal and urinary disorders that occur in children.
2. Identify National Health Goals related to renal or urinary tract disorders in children that nurses can help the nation achieve.
3. Analyze methods for making nursing care of the child with a renal or urinary disorder more family centered.
4. Assess a child for a renal or urinary tract disorder.
5. Formulate nursing diagnoses related to renal or urinary disorders in children.
6. Establish expected outcomes for a child with a renal or urinary disorder.
7. Plan nursing care related to urinary or renal disorders in children.
8. Implement nursing care for a child with a renal or urinary disorder such as preparing a child for peritoneal dialysis.
9. Evaluate expected outcomes for achievement and effectiveness of care.
10. Identify areas related to care of the child with a renal or urinary disorder that would benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of renal and urinary tract disorders with the nursing process to achieve quality maternal and child health nursing care.

Carol Hendricks is a 4-year-old girl admitted to the hospital with nephrotic syndrome. She has marked ascites and edema. "I kept asking everyone why she was gaining so much weight when she doesn't eat anything," her grandmother tells you. "My daughter said this happened because she drank part of a beer I left on the coffee table. Do you think that's what caused it? What if she needs a kidney transplant? Will I be allowed to give a kidney to her?" Previous chapters described the growth and development of well children and the nursing care of children with disorders of other systems. This chapter adds information about the dramatic changes, both physical and psychosocial, that occur when children develop urinary tract or renal disorders. This information builds a base for assessment, care, and health teaching.

How would you answer Carol's grandmother? What information does she need to better understand her grandchild's condition?

Normally, the urinary system maintains the proper balance of fluid (water) and electrolytes in the blood. When disease occurs, such as with structural abnormalities or kidney malfunction, children may be left with excessive amounts of fluid in the body or with an imbalance of electrolytes essential to their body's functioning. Disorders involving the kidneys and urinary tract often are long term. Urinary tract disorders can ultimately (if not originally) affect the kidneys, resulting in kidney dysfunction, with potentially fatal consequences (Watnick & Morrison, 2009).

Unfortunately, because symptoms may be vague, or because a child or parents do not realize the seriousness of urinary disease or are embarrassed to discuss it, children may not be evaluated at the first sign of illness. Health education to increase the awareness of the symptoms of urinary tract and kidney disorders is an important area of family health teaching. National Health Goals related to renal or urinary tract disorders and children are shown in Box 46.1.

Nursing Process Overview

For Care of a Child With a Renal or Urinary Tract Disorder

Assessment

Because the symptoms of many urinary tract and renal disorders such as mild abdominal pain, slowly increasing edema, or low-grade fever are subtle, parents may not bring their child for evaluation as early in the disease as they might if symptoms were more definite. School nurses can play an important role in recognizing the seriousness of minor symptoms and making proper referrals for care.

The ease with which parents and children can discuss illnesses of the kidneys or urinary tract is culturally influenced. As a general rule, because elimination functions are typically regarded as private, this is not a body system that people discuss as comfortably as they do illnesses of other body systems. The more that modesty is stressed in a culture, the more difficult it may be for people to ask questions about this system's disorders. By being aware that this is a difficult area for parents to discuss, health care personnel can better observe whether added health education is needed when caring for a child with one of these disorders.

A hallmark of kidney or bladder infection is pain. If children have had bladder surgery, they also may experience pain on urination or pain from bladder spasms. Be sure to assess the degree of any pain, including its location and intensity, before administering an analgesic or antispasmodic. Urine specimens also provide valuable assessment information. Techniques for obtaining urine samples such as clean-catch, catheterization, 24-hour collections, suprapubic aspiration, and urinalysis are described in Chapter 37.

Nursing Diagnosis

Nursing diagnoses used with children with urinary tract or renal disorders are related to the symptoms these disorders cause. Some examples are:

- Pain related to bladder irritation from urinary tract infection
- Excess fluid volume related to decreased kidney function and fluid accumulation
- Fear related to as yet unknown outcome of kidney transplantation
- Imbalanced nutrition, less than body requirements, related to effects of dietary restrictions
- Social isolation related to immunosuppressant therapy
- Risk for injury related to body's inability to excrete waste products properly

Because the entire family becomes involved in long-term renal disease, other appropriate nursing diagnoses might include:

- Interrupted family processes related to the effects and stresses of child's chronic illness
- Compromised family coping related to the chronic nature of child's illness

Outcome Identification and Planning

Be certain that outcomes established for care are relevant to a child's age and condition. Because renal disease may become chronic, expected outcomes may need to be modified frequently to meet changing needs.

Planning for a child with a urinary tract or renal disorder often involves helping parents remember to give medicine. A child with nephrotic syndrome or a renal transplant, for example, may take three or four different types of medicine every day at home. Be certain parents understand

BOX 46.1 ✻ Focus on National Health Goals

Renal disease can lead to long-term illness, so preventing it is important to improving the health of the nation. The following National Health Goals address this concern:

- Reduce the rate of new cases of end-stage renal disease from a baseline of 300 per 1 million population to a target rate of 221 per 1 million population.
- Increase the proportion of patients with treated chronic kidney failure who receive a transplant within 3 years of end-stage renal disease (ESRD) from a baseline of 23.1 per 1000 to 30.5 per 1000 (http://www.nih.gov).

Nurses can help the nation achieve these goals by educating parents to give antibiotics conscientiously for streptococcal throat infections and being active advocates for organ transplant procedures.

Areas that would benefit from nursing research include: determining parents' or children's ability to accurately self-assess for proteinuria after streptococcal infections, identifying the specific needs of children on ambulatory peritoneal dialysis, designing ways to make low-potassium diets more appealing to children with end-stage renal disease, or designing ways that organ donation can be presented to make it more appealing to potential donors.

the types of medicine prescribed and the expected action of each. If school-age children cannot take medicine in school, they need a schedule that allows them to take medicine before they leave home in the morning or after they return in the afternoon. If a child's school allows medication to be given during school hours, an order from the prescriber and the reason for the medication is usually required.

If a child has severe renal impairment, parents may be asked to make decisions regarding kidney removal and transplantation. Provide them with ample time for discussion. If a kidney donor is sought among relatives, the parents must help decide whether the person whose tissue matches the child's really wants to donate a kidney or is being pressured to do so. Helping parents to schedule times for hemodialysis or peritoneal dialysis or to supervise continuous cycling peritoneal dialysis (CCPD), to care for their other children, and to provide a life apart from their child requires nursing planning. Referrals to support organizations such as the following may be helpful: National Kidney Foundation (http://www.kidney.org) and Kidney Dialysis Foundation (http://www.kdf.org.sg/).

Implementation

Parents may or may not understand the function of the urinary system because it is not a system that receives much discussion. For example, they may confuse the words "ureter" and "urethra." A nurse can play a major role as a resource person, explaining anatomy and the tests and procedures and why they are being done.

Many children with kidney disease take a corticosteroid for immunosuppression and so develop a typical cushingoid appearance. They may have edema or ascites, which makes them appear obese. A child may be teased or criticized by classmates because of this "different" appearance. Contacting the school nurse or making the reason for the child's appearance known to the child's teacher may be necessary to help minimize this. Frequent contact and discussion with the child's siblings are also important to help them understand the reason for so many tests and health care visits and why their sibling is receiving so much attention. Discussion also helps open up channels of communication with all members of the family.

If kidney damage is extensive and the child's kidneys fail or a transplant is rejected, nursing care needs to be refocused on helping the family to face the possibility of the child's death. Nursing interventions can begin to prepare the child, parents, and family for this event (see Chapter 56).

Outcome Evaluation

Children with urinary or renal disease often need follow-up care after their acute illness. Because they are followed by a specialty renal group or clinic, parents may assume that routine health maintenance care is being given as well. Check to see that children are receiving routine childhood immunizations (remember that children taking steroid or other immunosuppressive therapy should not receive live virus immunizations) and that parents have their questions about day-to-day childrearing concerns answered.

Children returning to health care agencies for re-evaluation usually need as much preparation for procedures as those having them for the first time. Memory blurs events and sometimes confuses children. For example, they may recall that a particular test involved an injection when it did not, making them worry needlessly unless their memories are refreshed. Parents wait anxiously for the results of re-evaluation studies. Ensure they are given test results as soon as a comprehensive opinion of the child's progress is available. Be sure that all involved are aware of how anxious a particular parent is to hear the results of the re-evaluation.

Examples suggesting achievement of outcomes are:

- Child reports pain is at a tolerable level and decreasing in intensity after treatment.
- Family members state they are able to cope with long-term illness in child.
- Child states the purpose of a low-sodium diet and lists the ingredients of a low-sodium meal.
- Child states she can accept the need for kidney transplantation.
- Child states the precautions he must follow to reduce possibility of infection while on immunosuppressive therapy.
- Child remains free of any signs and symptoms of complications related to accumulated waste products.

ANATOMY AND PHYSIOLOGY OF THE KIDNEYS

Embryonic development of the urinary tract is discussed in Chapter 9. Figure 46.1 identifies the structures of the tract. Kidneys are located slightly lower in relation to the ribs than in adults. They also do not have as much perinephric fat to pad them. This makes them more susceptible to trauma.

Nephron

A *nephron,* the functioning unit of the kidney, consists of a glomerulus (a filtrating unit) and a complex set of tubules with accompanying blood supply (Fig. 46.2). Enclosed by a

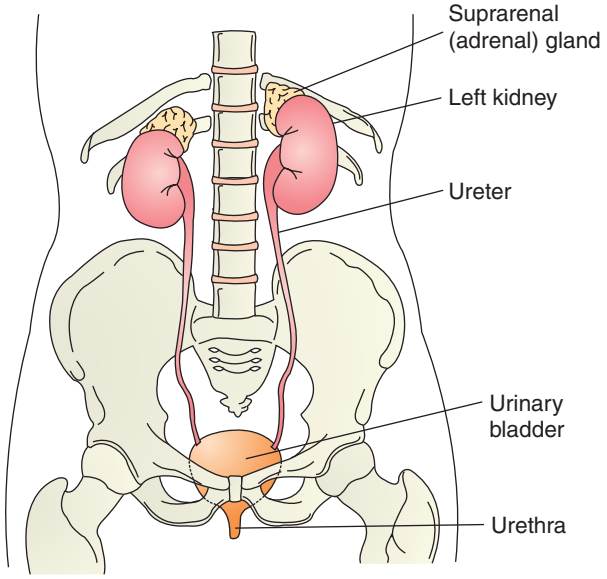

FIGURE 46.1 The urinary system.

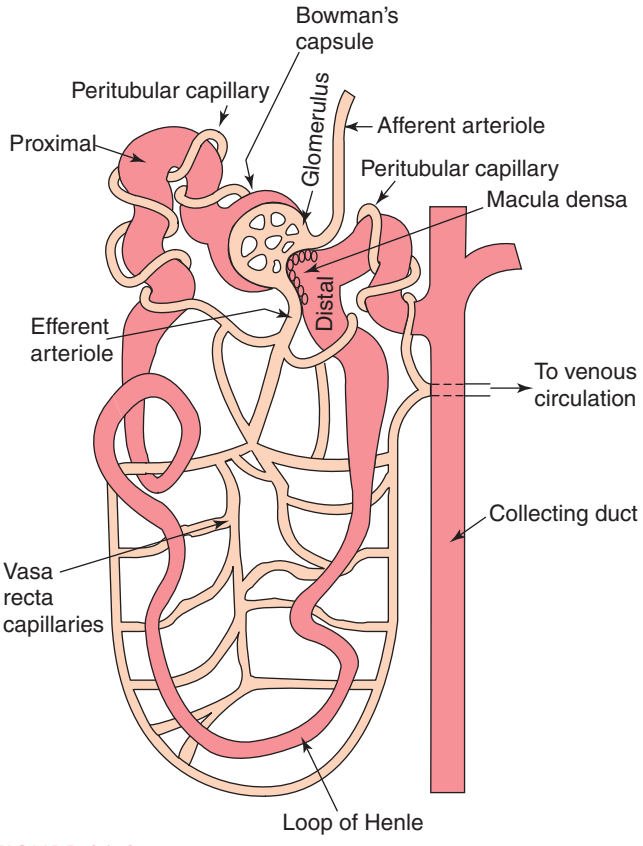

FIGURE 46.2 Basic structure of a nephron with its accompanying blood vessels.

TABLE 46.1 ✻ Functions of the Nephron

Site	Activity
Glomerulus	Secretion of water and all solutes except protein from blood
Proximal convoluted tubule	Reabsorption of 80% of glomerular filtrated water, all of glucose, amino acids, vitamins, and proteins; most of sodium, chloride, and ascorbic acid; secretion of creatinine
Descending and ascending loop of Henle	Reabsorption of additional water; fluid becomes neutral in reaction; specific gravity 1.010; additional reabsorption of sodium and chloride
Distal convoluted tubule	Reabsorption of water, sodium, chloride, phosphate, and sulfate as needed; secretion of potassium, H^+ ions, and ammonia (secretion of $NH4^+$ and H^+ ions conserves base because H^+ ions are substituted for sodium ions; sodium is reabsorbed as sodium bicarbonate)

double-walled chamber called a **Bowman's capsule,** the *glomerulus* is a capillary tuft supplied by a large afferent (ingoing) and a small efferent (outgoing) arteriole. It is invaginated within a tubule with a proximal and distal portion. In the glomerulus, water and solutes are filtered from the blood. This passage of water and solutes from the blood into the glomeruli is effective only as long as the blood pressure in glomerular arteries exceeds that in the tubule. The smaller efferent arteriole normally causes back-pressure in the glomerular arterioles, increasing the existing pressure and allowing filtration to occur readily. If blood pressure in these arterioles should fall below the tubular pressure or the tubular pressure should rise above that of the arterioles, little or no filtration will occur. For this reason, renal function must be assessed carefully in children who are hemorrhaging or are in shock with lowered blood pressure for any reason.

The solution that filtered into the tubule from afferent arterioles passes through the proximal portion, the loop of Henle, and then the distal portion. Beginning with the loop of Henle, water and electrolytes diffuse back into blood capillaries, reducing the volume of the filtrate by approximately 90%.

The glomerular filtrate enters the proximal tubule at a rate of approximately 120 mL/min. So much water is reabsorbed that the final end product (urine) left in the tubule is excreted at a rate of only approximately 1 mL/min. The proximal portion of the tubules reabsorbs most of the water, glucose, sodium chloride, phosphate (PO_4^-), sulfate (SO_4^-), and some bicarbonate (HCO_3) ions. This is a passive process, not particularly affected by body needs. In contrast, the distal portion of the tubule responds selectively to body needs. If necessary, Na^+ and HCO_3^- ions and additional water can be reabsorbed. The functions of nephron structures are summarized in Table 46.1.

Urine

The amount of urine excreted in a 24-hour period depends on fluid intake, kidney health, and age. Approximate urine output from different age groups is shown in Table 46.2. A significant decrease in urine production is *oliguria;* absence of urine production is *anuria.*

When renal disease occurs and glomerular or tubular function becomes impaired, nonprotein nitrogenous substances such as creatinine, urea, ammonia, and purine bodies are retained in the blood rather than being excreted. Urea is

TABLE 46.2 ✻ Child's Average Urine Output in 24 Hours

Age	Amount of Urine (mL)
6 mo–2 yr	540–600
2–5 yr	500–780
5–8 yr	600–1200
8–14 yr	1000–1500
Over 14 yr	1500

TABLE 46.3 ✻ Characteristics of Urine

Assessment	Normal Finding	Description/Implications
Color	Pale yellow	Color is influenced by urine concentration and ingredients; if fresh blood is present, urine may be red; if old blood, it may be brown or black.
Appearance	Clear	Bacteria, excessive crystals, or cells cause cloudiness; if protein content is high, it foams like beer when it is poured.
pH	4.6–8.0	Urine becomes alkaline (pH more than 7) with urinary tract infection or severe alkalosis; urine left at room temperature also becomes alkaline.
Specific gravity	1.003–1.030	Specific gravity is elevated in dehydration as kidneys try to conserve fluid, and decreased in overhydration as they try to rid the body of fluid.
Protein	0	Due to inflammation, protein molecules pass into urine; in adolescent girls, protein in urine may occur as a result of pregnancy; some children have *orthostatic proteinuria,* slight to mild proteinuria occurring only when they are standing.
Ketones	0	Ketones are released after breakdown of body protein, because of starvation.
Glucose	0	Glucose in urine occurs most frequently as a symptom of diabetes mellitus; in adolescent girls, glucosuria may occur with pregnancy.
Red blood cells	Less than 1 per high-power field Negative on dipstick	Blood may be present in urine as a result of such diseases as glomerulonephritis, urinary tract infection, or trauma; may also suggest systemic diseases such as leukemia or blood dyscrasias.
White blood cells	Less than 5 per high-power field	White blood cells are round, small configurations on a microscopic slide; they are present with bacteriuria.
Casts	0	Casts (protein configurations) are found most often in concentrated urine specimens; with cast formation, there is invariably proteinuria; casts comprise red blood cells, white blood cells, or desquamated renal epithelium; as an epithelial cast moves along the nephron, the cells begin to disintegrate, leaving a coarse granular cast; some disintegrate still further to become fine granular casts. The last stage of the process is a configuration in the shape of the tubule, termed a *waxy cast* (translucent and may be shiny and reflect light). The stage of the cast is important in indicating the flow of urine through the kidney. Hyaline casts are formations of protein appearing dull and reflecting light poorly; fatty casts are casts caused by the degeneration of tubular epithelial cells and are found in children with nephrosis. Red blood cells, white blood cells, and fatty casts are evidence of disease; other casts suggest urine stasis and probably proteinuria.
Crystals	Possibly present or not	Crystal formation is possibly indication of urine pH; uric acid, cystine, and calcium oxalate crystals are examples of crystals found in acid urine; phosphate crystals tend to be present in alkaline urine. Infection (particularly *Proteus* infection) is the most usual cause of alkaline urine. Sulfur crystals may be present if the child is receiving a sulfa drug (such as sulfamethoxazole [Gantanol]).

formed from the breakdown of amino acids by the liver. The amount of urea in urine is an indirect indication of kidney and liver function.

Creatinine is a product released during muscle cell metabolism. The amount excreted in urine normally remains constant, regardless of the amount of protein in the diet or body processes. When it is less in amount, therefore, it means that kidneys are not functioning as well as usual. When kidney function is impaired, not only is creatinine level reduced, but also some constituents that normally are retained such as albumin, glucose, blood, bile pigments, and casts will be allowed to enter the urine. Bile pigments that stain urine a green/yellow/brown color appear in the urine when the child has elevated levels of indirect or direct bilirubin in the blood plasma (hemolysis of red blood cells or jaundice will cause this). Casts are formed when there is an abnormal condition that causes the kidney tubule to become lined with protein formed from red and white blood cells, epithelial cells, or fatty cells that harden into the shape of the tubule. After urine washes the casts out, they can be detected by microscopic examination of urine. As protein deposits in this way only when fluid is slow-moving, their presence suggests slow filtration. Normal constituents of urine are shown in Table 46.3.

ASSESSMENT OF RENAL AND URINARY TRACT DYSFUNCTION

Assessment of urinary or renal tract disorders is based on the history, physical examination, and laboratory/diagnostic tests (Box 46.2).

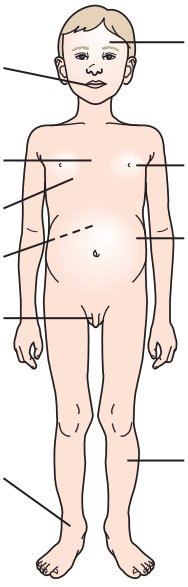
Box 46.2 Assessment
Assessing a Child for Renal and Urinary Tract Dysfunction

History

Chief concern: Child reports burning or cries on urination; bloody or "dark" urine, frequency of urination; abdominal pain, flank pain, enuresis. Parents report increase in size of abdomen, periorbital edema, poor appetite, frequent thirst, weight gain, strong odor to urine; diaper rash in infants. A school-age child may be described as a behavior problem because he or she frequently asks to use the bathroom.
Family history: History of renal disease, such as polycystic kidney, enuresis; hypertension.
Pregnancy history: Exposure to nephrotoxic drugs (antibiotics) during pregnancy. Oligohydramnios at birth.
Past illness history: Child recently had a throat or skin infection.

Physical assessment

General appearance
Fatigue, paleness
Growth restriction
Low-grade temperature



Head
Swelling around eyes
Odd facies; beaklike nose, small chin, prominent epicanthal folds, low-set ears

Mouth
Pale mucous membrane, caries

Cardiovascular
Hypertension

Chest
Gynecomastia

Respiratory
Rapid respirations

Back
Pain over kidney area

Abdomen
Tenderness over bladder area
Abdominal mass
Slack abdominal muscles
Protuberant abdomen

Genitals
Reddened urethra
Diaper area rash in infants
Round urethra in males
Constant dripping of urine
A stronger than usual arc of urine in males
Displaced urethral opening

Extremities
Bowed legs

Skin
Poor skin turgor
White crystals on skin
Edema

Neurologic
Confusion, muscle twitching

Laboratory/Diagnostic Tests

A variety of diagnostic tests may be performed, either in an ambulatory department or on an inpatient basis, to document renal or urinary tract disease.

Urinalysis

One of the most revealing tests of kidney function is also one of the simplest: urinalysis. For best results, specimens collected should be fresh because urine that stands at room temperature for any length of time changes composition. Devices used to collect urine specimens and the method for obtaining urine specimens from diapers are described in Chapter 37. A chemical reagent strip can be used to detect glucose, protein, and occult blood and to measure pH. Specific gravity is best determined by use of a refractometer (requires only a single drop [see Chapter 37]).

Creatinine Clearance Rate

Glomerular filtration rate is the rate at which substances are filtered from the blood to the urine. It is measured by the amount of creatinine (the breakdown product of creatine from muscle contraction) excreted in 24 hours as determined by a 24-hour urine sample. A venous blood sample is taken during the 24-hour period and compared with the urine findings (if urine creatinine is decreased, this will be increased). A normal creatinine clearance rate is 100 mL/min. A normal urine creatinine level is 0.7 to 1.5 mg/100 mL; creatinine in blood serum rarely exceeds 1 mg/dL (Watnick & Morrison, 2009).

Radioisotope Scanning

The administration of radioisotopes (a technetium scan) is a second way to assess glomeruli filtration ability. Radioactively tagged substances are given intravenously (IV); the rate at which these substances can be observed flowing through the kidney and excreted in urine is then determined. The level of radioisotopes used in these studies is small, and urinating removes the substance from the body immediately afterward. Children do not remain radioactive, so parents should not be afraid to stay near them or to hold them after such a study.

Urine Culture

A urinary tract infection (UTI), the presence of bacteria in urine, is diagnosed by a urine culture. Because bladder catheterization can introduce bacteria into the bladder and also is painful and intrusive, most urine specimens in children are obtained by a clean-catch procedure or sterile suprapubic aspiration (see Chapter 37). Several instant-read commercial kits for culturing urine are available for use in ambulatory settings.

Blood Studies

A blood urea nitrogen (BUN) test measures the level of urea in blood and is used to assess glomerular function, or how well the kidneys can clear this from the bloodstream. However, this level may not increase until approximately 50% of glomeruli are destroyed, because the remaining glomeruli can increase in size and function to accommodate urine production. A normal value is 5 to 20 mg/100 mL.

Ultrasonography and Magnetic Resonance Imaging

An *ultrasound* or *magnetic resonance imaging* (MRI) can detect differing sizes of kidneys or ureters and can differentiate between solid or cystic kidney masses. They do not involve x-rays and so may be repeated at frequent intervals for follow-up without danger of radiation exposure (Riccabona, 2007).

X-Ray Studies

A plain flat-plate abdominal x-ray film can provide information about the size and contour of the kidneys. This radiograph may be referred to as a *KUB* (*k*idney, *u*reters, and *b*ladder). A small kidney shown this way is generally a hypoplastic or an underdeveloped organ. A large kidney may indicate hydronephrosis or a polycystic kidney.

Computed Tomography

Computed tomography (CT) scans of the kidneys are used to show the size and density of kidney structures and adequacy of urine flow. Conscious sedation may be given before a CT

scan because a child must lie still for an extended time during the procedure, and the size of a CT scanner and the fact that it surrounds the child may be frightening. Be sure to prepare the child for this. A contrast medium may be injected before the procedure to better outline urine flow. If this medium is iodine based, be certain to ask about allergy to iodine before the study. Because a support person is not allowed to remain in the room during the procedure, thoroughly prepare children so they can comfortably remain still for the procedure.

Intravenous Pyelogram. An *intravenous pyelogram* (IVP) is an x-ray study of the upper urinary tract. It used to be a mainstay of diagnosis for kidney disorders but now is used less frequently because ultrasounds, MRIs, or CT scans reveal so much information. For an IVP, a radiopaque dye is injected into a peripheral vein, circulates through the bloodstream, and is almost immediately identified as a foreign substance by the kidney and filtered out into the urine by the glomeruli. X-ray films taken at frequent intervals show the outline of collecting systems in the kidney and of the ureters as the radiopaque dye passes through them.

In preparing children for an IVP, tell them that they will receive an injection. Say "medicine," not "dye" (or compare coloring kidneys to coloring with crayons or coloring Easter eggs), because the child may mistake "dye" for "die." Be sure children know that, after this injection, they must lie still in whatever position they are placed until all films are taken. This may be difficult for young children because x-ray tables are hard and cold and the x-ray camera overhead can be frightening. When explaining the test, compare the x-ray machine to a camera. Caution children that they may experience flushing of the face, warmth, and a salty taste in their mouth after the injection of medicine. Because the dye used is iodine based, ask the parents if the child has a known allergy to iodine. This is rarely known in children because they may have had no previous studies of this kind.

Voiding Cystourethrogram. A *voiding cystourethrogram* (VCUG), a study of the lower urinary tract, reveals the structure of the urethra and bladder and the presence of reflux into the ureters (Gomella & Haist, 2007). After bladder catheterization, a radiopaque dye is injected into the bladder, and the catheter is then removed. The child is asked to void into a bedpan while serial x-ray films are taken. Although the catheterization is unpleasant, being asked to void while they are observed on an x-ray table may be the most stressful part of the procedure for most children because they have been taught that voiding is a private act. Be sure that children are told in advance that they will be asked to do this. Caution a child that a first voiding this way after catheterization may be painful. A few children have difficulty voiding a second time later in the day because they worry that the second voiding will also sting. Pouring warm water over the perineal area while sitting on a toilet or sitting in a bathtub of warm water and voiding into the water may help relieve pain. Most children, once they void this second time and realize that it is not painful, usually have no further difficulty.

A VCUG should not be done if a child has an active UTI because there is danger that the radiopaque material injected into the bladder could spread, carrying bacteria from the infection into the ureters and kidneys. Report any symptoms of UTI such as frequency, pain on voiding, or low back pain to the radiologic physician. A clean-catch urine specimen for culture may be ordered before the VCUG to rule out infection.

✔ Checkpoint Question 46.1

Carol had a voiding cystourethrogram last year to help diagnose a urinary tract infection. Why is a voiding cystourethrogram a difficult test for preschool children?

a. Reading the instructions for the test is difficult.
b. Lying in an MRI machine is dark and scary.
c. They feel uncomfortable voiding in public.
d. The dye capsules may be too large to swallow.

Cystoscopy

Cystoscopy, examination of the bladder and ureter openings by direct examination with a cystoscope introduced through the urethra, is done to evaluate for possible vesicoureteral reflux or urethral stenosis. Radiopaque dye may be introduced into the bladder at the time of cystoscopy so the bladder can be visualized on radiography (cystography). Small catheters also can be threaded into the ureters for the introduction of dye to outline them (retrograde pyelography). Because the procedure is painful and requires a child to lie still, it is usually done under conscious sedation. After the procedure, the first voiding may be painful. Once allowed, urge children to drink plenty of fluids so they urinate frequently to flush out any pathogens introduced at the time of the procedure.

Renal Biopsy

Renal biopsy involves passing a thin biopsy needle into the kidney through the skin over the kidney. The procedure is used to diagnose the extent of renal disease and thereby predict disease outcome or progress or reveal beginning rejection of a transplanted kidney (Croker & Tisher, 2007). Renal biopsy may be done in an older child under only simple local anesthesia, but conscious sedation may be necessary for a younger child who cannot cooperate easily. The kidney is located first by ultrasound to accurately locate the place of the biopsy. The child lies prone with a sandbag under the abdomen for firmness. If the procedure is done under a local anesthetic, prepare children for the feel of a pinprick as the local anesthetic is injected; after this, they should not feel any further pain. What they will feel is pressure as the biopsy needle is inserted. Caution children that they need to lie still while the biopsy specimen is taken (if the child moved suddenly, the needle might puncture a renal artery or vein or tear vital glomeruli). Be certain children have support people to accompany them for this procedure so that they have someone to hold their hand or comfort them when they feel the pressure of the needle.

After the biopsy, press a sterile gauze square against the biopsy site for approximately 15 minutes to halt bleeding, and then apply a pressure dressing. Caution parents that a large dressing will be used and that the size of this dressing does not reflect the size of the specimen taken (the amount of tissue removed is no more than the lumen of the needle used, or approximately the size of a pencil lead).

If the procedure was done on an ambulatory basis, children can be discharged 2 to 4 hours after the procedure if vital signs are stable and they have voided. Measure vital signs and observe the biopsy site every 15 minutes for at least

the first hour. Do not lift the dressing to assess bleeding, because doing so destroys the protective function of the pressure dressing. Encourage children to drink a considerable amount of fluid (a glass every hour while awake) during the first 24 hours to keep urine flowing freely and prevent blood from clotting in the kidney tubules and blocking urine flow. Play games with the child, if necessary, to encourage a high fluid intake (the child must take a drink each time before a turn at a game; play "Simon Says" and have Simon frequently say, "Drink").

The first voiding after renal biopsy is invariably blood-tinged. Advise parents to keep children on restricted activity for 24 hours or until no more hematuria is present. Instruct parents how to keep serial urine samples, comparing each specimen with the previous one, to detect whether hematuria is becoming more or less marked. When urine no longer appears bloody, they can test it for occult blood to confirm that bleeding has stopped. A hematocrit may be ordered 24 hours after the procedure to ensure that no bleeding is continuing.

What if... Carol's grandmother telephones you after a kidney biopsy and says Carol is voiding black urine? Is there a possibility this is blood? What questions would you ask to elicit additional information? What recommendations would you make to the grandmother?

THERAPEUTIC MEASURES FOR THE MANAGEMENT OF RENAL DISEASE

As kidney function is necessary for life, if it deteriorates, some method to replace function must be instituted.

Peritoneal Dialysis

Dialysis is the separation and removal of solutes from body fluid by diffusion through a semipermeable membrane. *Peritoneal dialysis* uses the membrane of the peritoneal cavity to do this. Hemodialysis uses an outside synthetic membrane to do this. Unlike hemodialysis, peritoneal dialysis does not require elaborate equipment or expense, but it does take more time.

Peritoneal dialysis may be used as a temporary measure for children who experience sudden renal failure caused by trauma or shock. It is used for fairly long periods with children with chronic renal disease both in the hospital or at home to allow them to live until a kidney transplantation can be arranged (Coe & Lail, 2007). It is usually begun when the serum creatinine level reaches 10 mg/100 mL. Other indications are congestive heart failure, BUN of more than 100 mg/100 mL, hyperkalemia (potassium level of more than 6 mEq/L), and uremic encephalopathy (confusion or coma). CCPD allows the procedure to be done at home because less rigorous monitoring of the procedure is necessary.

Method for Performing Peritoneal Dialysis

Before peritoneal dialysis begins, a child's weight and vital signs are obtained to provide baseline information. Ask the child to void to reduce bladder size so that the bladder occupies as little anterior space as possible. If a child cannot void,

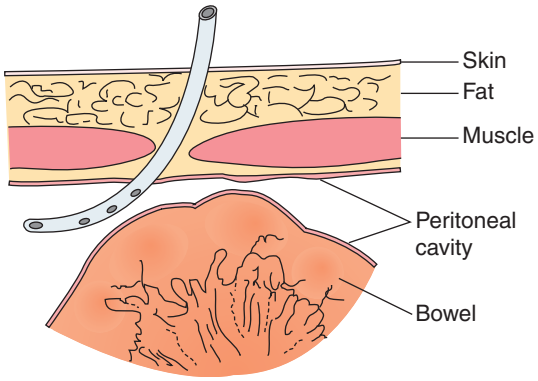


FIGURE 46.3 Insertion site for peritoneal dialysis catheter.

catheterization may be necessary. Following this, the child's abdomen is cleaned just below the umbilicus with an antiseptic solution and covered with a sterile drape; a local anesthetic is injected into the abdominal wall, and a large-bore needle is inserted into the peritoneal cavity. If ascites fluid is present, a quantity of this fluid is removed and then a warmed hypertonic glucose solution (approximately 50 to 100 mL/kg of body weight) or a commercial dialysis solution is infused by gravity flow into the peritoneal cavity. This distends the abdominal wall and allows safe insertion of a peritoneal catheter, which is sutured in place and covered with a sterile dressing (Fig. 46.3). This catheter will remain in place for the duration of dialysis.

As for any procedure, children need to be well prepared for peritoneal dialysis but if the procedure is presented in a matter-of-fact way, children usually accept it with no more apprehension than IV therapy. Both procedures involve a needle penetration. You can assure children that they will feel the initial prick of the needle that administers the local anesthetic but will feel only pressure after that as the peritoneal needle or catheter is inserted. The procedure is intrusive, however, and frightening. Provide opportunities for therapeutic play such as letting the child handle a cloth doll, a dialysis tube, IV tubing, a doll's bed, or syringes and needles.

With the dialysis tube in place, a prescribed amount of dialysis solution is then infused into the peritoneal cavity by gravity drainage. This takes approximately 10 minutes and is recorded as inflow time. Be certain that the infusion fluid is warmed to room temperature to prevent the child from becoming chilled; warming the solution to near body temperature also appears to improve diffusion efficiency. It can be warmed in a basin of warm water or with the use of commercial warm packs at the child's bedside. Heparin is generally added at least to the first infusion to keep any initial bleeding from the abdominal puncture from plugging the tube.

Infused fluid is allowed to remain in the child's peritoneal cavity for 15 to 60 minutes (called the *equilibrium* or *dwell time*). Because the infused solution is hypertonic, fluid from extracellular spaces diffuses across the semipermeable peritoneal membrane to dilute the hypertonic solution (the law of osmosis). Urea and electrolytes diffuse with this fluid. After this designated equilibrium time, drain the fluid from the peritoneal catheter into a collecting bottle (this takes approximately 10 minutes and is recorded as outflow time). More fluid generally drains from the peritoneal cavity than was infused, because excessive fluid has diffused across the

peritoneum, reducing peritoneal or ascitic fluid. After a cycle of inflow, equilibrium, and outflow time, a new cycle is begun. Peritoneal dialysis may be conducted continuously for periods of 12 to 72 hours, depending on the effectiveness of the procedure in restoring serum creatinine and BUN levels to normal.

Monitor vital signs at least every hour while children are undergoing peritoneal dialysis. During each new infusion period and while the solution is in the abdomen, carefully observe for shortness of breath, because the fluid exerts upward pressure on the diaphragm. Elevating the head of the bed helps to increase breathing space and ease respirations. If tachycardia or hypotension occurs, this suggests that hypovolemia is occurring. An increasing temperature (after 24 hours) may indicate peritoneal infection, a serious complication (Auron et al., 2007). Frequent blood studies are necessary during periods of peritoneal dialysis to determine electrolyte concentrations. If electrolyte imbalances occur, electrolytes may be added to the infusion solution or administered IV.

The longer the peritoneal catheter remains in place, the greater the risk of peritoneal infection at the catheter insertion site. Assess the insertion site daily for signs of infection, such as redness or drainage. Obtain temperature about every 4 hours. Ask children to report any abdominal pain or diarrhea. Assess for abdominal guarding or tenderness once daily by palpating the abdomen; a rigid abdomen suggest peritonitis or infection. Follow the agency's policy for cleaning and covering the end of the peritoneal catheter if there are periods when dialysis is halted (Fig. 46.4).

Once cycles of dialysis begin, children often grow bored lying in bed waiting for this procedure to be finished. They need planned interaction for these times—perhaps a toy or game that is allowed only during the procedure, so that it remains special. Children generally do not feel hungry while having peritoneal dialysis, because the bulk of peritoneal fluid causes pressure on the stomach and makes them feel uncomfortably full. They do well on a liquid diet or small frequent feedings during this time. So that children can feel that they have a sense of control over what is happening, let them help with the procedure by doing such things as recording the amount of solution infused and drained, and allowing them to select liquids they like for meals.

Peritoneal dialysis is a simple yet important concept. Help parents understand its importance so they can demonstrate a positive attitude toward it. The parents' acceptance of the procedure helps the child accept it as well.

FIGURE 46.4 Peritoneal catheter inserted into a child's abdomen. A secure dressing surrounds the insertion site to prevent infection. (Courtesy of Karen M. Polise, MSN, RN, Division of Nephrology, The Children's Hospital of Philadelphia.)

Continuous Cycling Peritoneal Dialysis

CCPD allows a child to go to school or participate in other activities while receiving dialysis. With CCPD, a permanent dialysis catheter is inserted and sutured into place at the abdomen. Each day, the child or parent attaches a bag of dialysis fluid and tubing to this and infuses a prescribed dialysis solution by gravity drainage; the bag and tubing are then rolled into a compact square under the child's clothes. The infused solution remains in the child for 4 to 6 hours during the day (8 hours at night); the dialysate bag is then lowered and the solution drains from the peritoneal cavity into it. The bag and fluid are then discarded and a new bag of dialysate solution is attached and raised, and new solution is infused.

CCPD requires careful monitoring and attention by the child or family. They must keep accurate records of infusions. Children can participate in gym programs but should not participate in contact sports or swimming. Teach parents to think ahead for holidays or family trips so they do not run short of supplies.

Because CCPD is continuous, electrolytes in the bloodstream are maintained at more constant levels than when intermittent dialysis is used although because a great deal of potassium is removed, children may become hypokalemic (Factor, 2007). CCPD also allows greater freedom because children can return home and go back to school. There are disadvantages, however. Infection can occur because of the long-term placement of the catheter. Dehydration or hypernatremia may occur because of excess fluid removal. Because the tube remains in place at all times and the peritoneal solution constantly distends the abdomen, the child appears obese and clothing is difficult to fit, the child is frequently reminded of the illness and may have difficulty accepting this change in body image. Possible complications of CCPD are summarized in Table 46.4.

Hemodialysis

Hemodialysis removes body wastes by using an external membrane as the diffusion surface. For hemodialysis, a catheter is inserted into an artery and blood is removed from the child and circulated through a dialysis coil. Urea and electrolytes in the blood diffuse into the surrounding fluid bath as the blood passes through the coil (Ahmad et al., 2007). After diffusion is complete, the blood is returned to the child's venous circulation (Fig. 46.5).

Hemodialysis can be done as a continuous process, but it is so effective that 3 hours of hemodialysis accomplishes as much as 12 hours of peritoneal dialysis. Children who have renal failure or whose kidneys have been removed while they await a kidney transplant can be maintained almost indefinitely by hemodialysis sessions two or three times a week or by continuous ultrafiltration or continuous arteriovenous hemofiltration (Schon et al., 2007). It can be used in infants as well as older children (Sousa et al., 2008).

TABLE 46.4 ✻ Possible Complications of Continuous Ambulatory Peritoneal Dialysis

Assessment	Problem	Interventions
Redness or pain or swelling at tube insertion site	Infection	Take culture at site; administer antibiotics as prescribed; continue site care as ordered; notify physician.
Abdominal pain, increased temperature, nausea and vomiting, cloudy return in drainage solution	Peritonitis	Notify physician; administer antibiotics as prescribed; auscultate for bowel sounds.
Cramps as fluid is infused	Irritation of peritoneal cavity	Infuse solutions more slowly; warm temperature of solution to body temperature.
Difficulty with infusion or drainage of fluid	Kinked or clotted tubing; malpositioned catheter	Assess tubing for kinking; change position of child; ask child to cough to increase abdominal pressure; add prescribed amount of heparin to dialysate bag (prevents clotting).
Weight increase; moist cough, shortness of breath	Fluid overload	Decrease sodium and fluid oral intake; assess blood pressure and weight; use 4.25% exchange solution until weight is again decreased.
Weight loss, hypotension, poor skin turgor, tachycardia	Fluid loss	Increase fluid and sodium intake; assess blood pressure and weight; do not use 4.25% solution.
Blood-tinged dialysis return	Ruptured blood vessel	Assess pulse and blood pressure; observe for further bleeding in drainage; flush catheter with prescribed amount of heparin to keep clots from forming.

To establish a site for initial blood removal, children may have a double-lumen central catheter inserted into a central vein, such as the subclavian or internal jugular vein.

A permanent technique is subcutaneous anastomosis of a vein and artery, creating an arteriovenous fistula (usually the brachial artery and brachiocephalic vein; Fig. 46.6A) or internal anastomosis of the artery and vein using a subcutaneous graft (see Fig. 46.6B). The possibility of infection is reduced with internal anastomosis, although, unfortunately, two venipunctures, one from a low point in the shunt to remove blood and one high in the shunt to return it, are necessary for dialysis (use lidocaine or EMLA cream to reduce pain). The ability to feel a thrill (vibration) or hear a bruit over the fistula or graft site is proof that it is open.

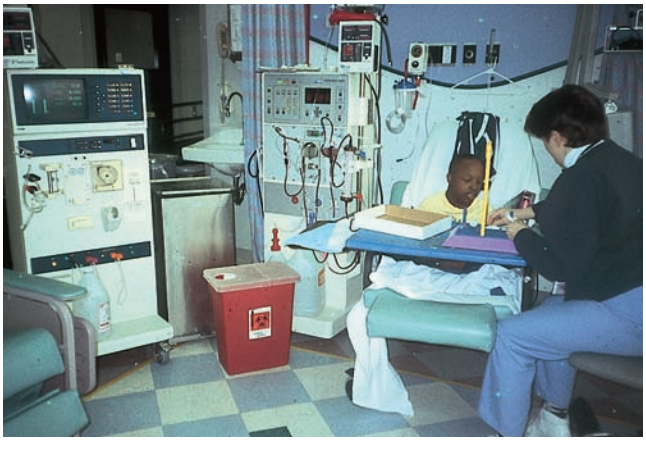

FIGURE 46.5 An adolescent receiving hemodialysis. A catheter from the child is connected to the hemodialysis equipment (in the background). Blood flows from the child through the catheter to the hemodialysis equipment for waste removal and is then returned to the child's venous circulation. (Courtesy of Karen M. Polise, MSN, RN, Division of Nephrology, The Children's Hospital of Philadelphia.)

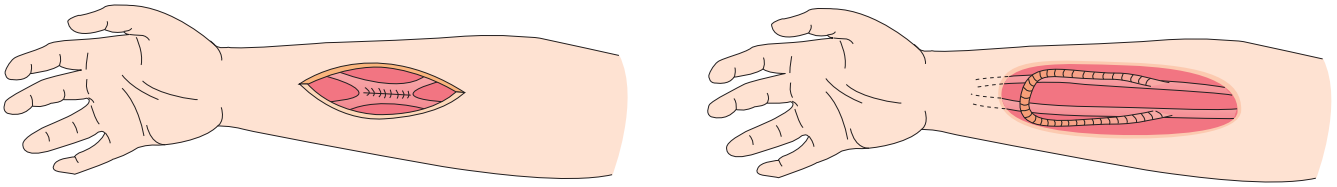
The risks of hemodialysis include infection introduced with venipuncture (severe because the infection automatically is septicemia) and clotting of the access site, which can lead to emboli. During hemodialysis, children may begin to show signs of confusion, vomiting, visual blurring, or hallucinations from a *dialysis disequilibrium syndrome.* This occurs because the hemodialysis is removing urea from the blood at too rapid a rate—faster than urea can be shifted from the brain to the blood. This causes fluid to shift into the brain, resulting in cerebral edema. The procedure must be temporarily halted to allow equalization to return. Muscle cramping may occur from sodium depletion. A "first use" syndrome or symptoms such as dizziness or muscle cramping may occur from a reaction to the fibers in the dialysis machine coil.

Children grow bored during hemodialysis as they do during peritoneal dialysis. They need entertainment so the procedure remains acceptable. Help parents provide stimulating activities such as a play board, a ball to throw, or rings to stack for the infant. Parents may envision the infant as so ill that lying still without an activity would be best. Children need stimulation and play to avoid missing normal developmental milestones, however, even during a long therapy such as dialysis.

When children's kidneys are removed prior to transplantation so they must remain on a continuous program of hemodialysis, they may come to resent a machine as "owning" or "controlling" them. They become aware that they cannot exist apart from it. Allowing them to plan special activities to



A B

do during hemodialysis time can help to give them a feeling of control.

HEALTH PROMOTION AND RISK MANAGEMENT

Several important interventions can help prevent urinary and renal disease in children. The first intervention is to educate parents and caregivers about wiping from front to back when changing diapers of female infants. The second intervention is to prevent urinary tract infection in girls by beginning education about perineal hygiene measures from the time they are first toilet-trained. Remind parents of simple ways to prevent UTI, such as not allowing children to bathe with bubble bath. Teach parents to recognize the normal appearance of urine (clear and yellow) so that they can recognize abnormalities, such as red, black, or cloudy urine and the signs and symptoms of UTI, such as urgency, frequency, and pain.

Educating parents about the importance of giving the full course of antibiotics prescribed for UTI can help prevent reinfection. Also important is educating parents about the importance of giving the full course of antibiotics after a streptococcal infection to prevent acute glomerulonephritis.

STRUCTURAL ABNORMALITIES OF THE URINARY TRACT

Because the urinary tract is a system of hollow tubes, congenital disorders can rise from faulty recanalization in intrauterine life.

Patent Urachus

When the bladder first forms in utero, it is joined to the umbilicus by a narrow tube, the *urachus.* When this fails to close properly during embryologic development, a fistula is left between the bladder and umbilicus **(patent urachus).** This occurs more commonly in males than in females. Nurses are frequently the ones to discover this condition as they notice clear fluid draining from the base of the umbilical cord while changing a newborn's diaper. If you test the fluid with Nitrazine paper for pH, its acid content will identify it as urine. An ultrasound will confirm the patent connection.

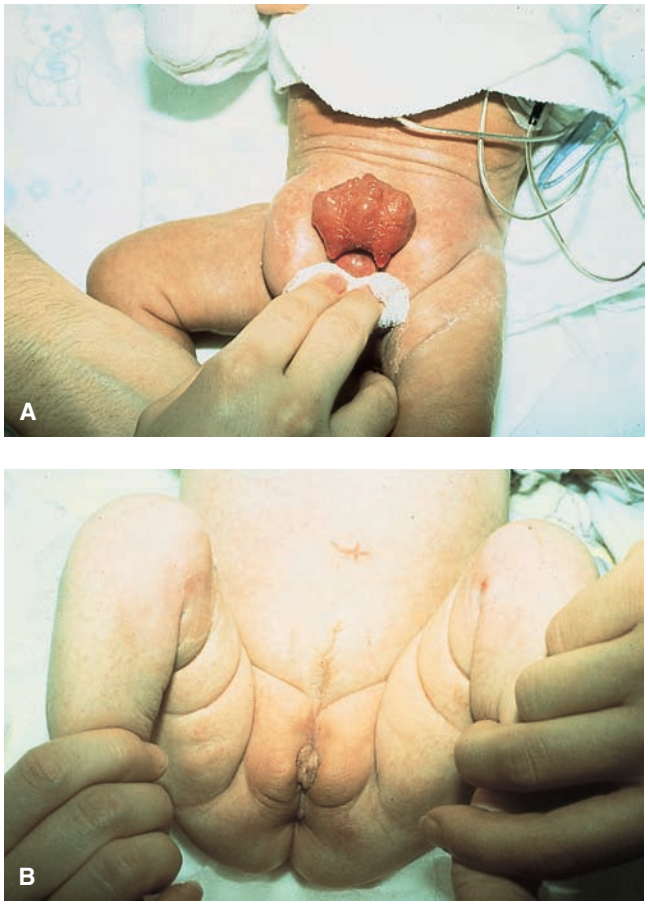
A few patent urachus abnormalities heal spontaneously, but most require surgical correction to prevent pathogens from entering the fistula site and causing persistent bladder infection. This can be done in the immediate neonatal period using only a small subumbilical incision (Ashley, 2007).

Exstrophy of the Bladder

Exstrophy of the bladder is a midline closure defect that occurs during the embryonic period of gestation (first 8 weeks). As a result, the bladder lies open and exposed on the abdomen. It occurs more frequently in males than females at a ratio of 2:1 (Atala, 2007).

Assessment

Exstrophy is often revealed by fetal ultrasound as there is no anterior wall of the bladder and no anterior skin covering on the lower anterior abdomen (Fig. 46.7A). The bladder appears bright red and continually drains urine from the open



A

B

FIGURE 46.7 Bladder exstrophy. (**A**) Prior to surgical reconstruction. Note the bright-red color of the bladder. (**B**) Following surgical reconstruction. (Courtesy of Karen M. Polise, MSN, RN, Division of Nephrology, The Children's Hospital of Philadelphia.)

surface. In males, the penis is often unformed or malformed. In females, the urethra may also be abnormally formed. Pelvic bone defects, particularly nonclosure of the pubic arch, and urethral defects such as epispadias—opening of the urinary meatus on the dorsal or superior surface of the penis—may be present. The skin around the bladder quickly becomes excoriated because of constant exposure to acid urine. Untreated bladder exstrophy leads to kidney infection from ascending organisms. When children with this disorder begin to walk, they may demonstrate a "waddling" gait from the effect of the nonfused pubic arch.

Therapeutic Management

The treatment of bladder exstrophy begins with surgical closure of the bladder and, if necessary, the anterior abdominal wall and construction of a urethra (Gearhart, Baird, & Nelson, 2007; see Fig. 46.7B).

Preoperative Interventions. To minimize the possibility of infection in the bladder while the infant is waiting for initial surgery, keep the exposed bladder covered by a sterile plastic bowel bag. This prevents the bladder surface from adhering to bedclothes or diapers and the mucosal surface from being injured. To prevent the skin of the abdomen from excoriation due to the constant irritation of urine, protect it with a substance such as A&D ointment, Karaya Gum, or Maalox. Consult a wound, ostomy, continence nurse for the best approach. To reduce pressure and prevent further separation of the symphysis, the orthopedic physician may ask that the infant's legs be flexed, brought together, and wrapped in Ace bandages to hold them in that position. If this is done, do not separate the infant's legs to apply diapers; just place them under the child instead. Be certain to change diapers promptly after defecation so feces are not brought forward to the open bladder. Position the infant on the back, the same as for all infants, so urine drains freely. Sponge bathe rather than tub bathe the infant to prevent water from entering the ureters and becoming a source of infection.

Parents often need support to view their child as normal in all other ways but the unusual bladder formation. In some instances, the bladder repair will not be done immediately, so parents will need instructions on how to care for the child at home while waiting for surgery.

Postoperative Interventions. Surgery may be completed either as a one-step or two-step procedure. In the first step, the bladder tissue is reconstructed; in the second, a urethra is created. After bladder construction, the surgical incision over the bladder area must be kept free of infection. Position the infant on the back or in an infant chair to prevent feces from coming forward and contaminating the incision line. A suprapubic or indwelling urethral catheter for urine drainage will be in place to allow the newly constructed bladder to rest. Immediately after surgery, urine draining from the catheter may be blood-stained, but this should clear after the first few hours. Children may notice sharp painful bladder contractions for the first few days after surgery. Analgesics and antispasmodics may be needed to keep the child comfortable. To prevent the nonfused pubic bone from separating and putting stress on the suture line, at the time of surgery, the child may be fitted with an external fixation device after an osteotomy to hold the pubic bones in approximation until they fuse (4 to 6 weeks).

After the second-stage urethra repair, children can be expected to experience some stress incontinence (loss of urine on physical exertion) from the constructed urethra. When they are older, Kegel exercises can help strengthen the perineal muscles.

Surgical repair may be limited if inadequate bladder tissue is present. For this reason, in some instances, the bladder is surgically removed and a ureterocecal implantation (ureters directed into the small intestine) or a *continent urinary reservoir* (an artificial bladder) is constructed (Fig. 46.8).

To construct a continent urinary reservoir, a small segment of the intestine, usually the cecum, is separated from the intestinal tract. The intestinal tract is then anastomosed so that a normal gastrointestinal (GI) tract is maintained. The separated segment is attached to the internal abdominal wall using the appendix to create an artificial urethra. The ureters are anastomosed to this segment.

Urine drains from the kidneys into the ureters, and then into the collecting bowel segment. The parent or child catheterizes the abdominal urethra three or four times daily to empty urine. The procedure is theoretically simple, but it is technically difficult to accomplish. Parents need a good review of anatomy to aid their understanding of the procedure. As the child reaches school age and begins school activities, such as showering, that exposes the condition to others, adjusting to a continent urinary reservoir can be difficult. Ensure that the child has a plan for follow-up care during the school years and in adolescence so the function of the reservoir and also the child's adjustment can continue to be assessed.

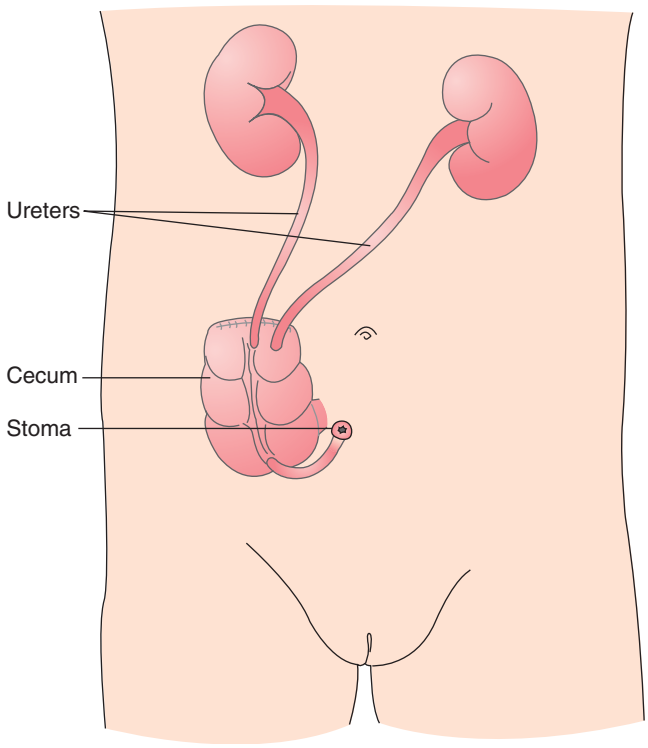


FIGURE 46.8 A continent urine reservoir. A portion of intestine is isolated; the attached ureters drain into it. The appendix creates an abdominal stoma for catheterization.

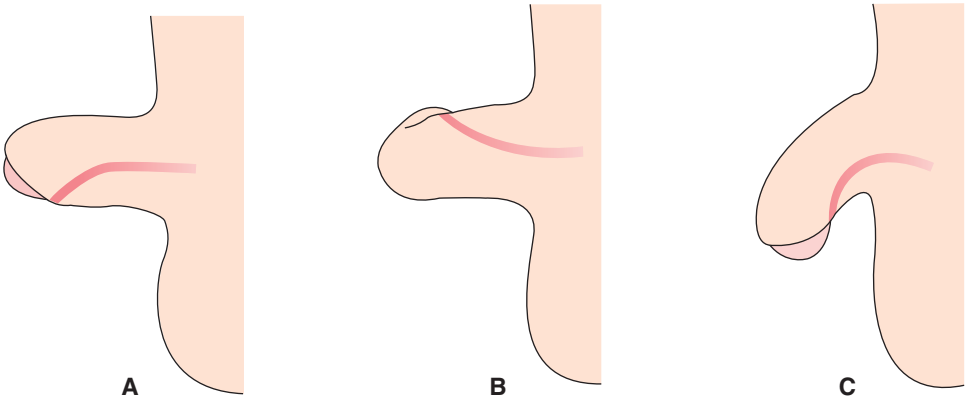

FIGURE 46.9 Urethral defects. (**A**) Hypospadias. (**B**) Epispadias. (**C**) Hypospadias with chordee.

Hypospadias

Hypospadias is a urethral defect in which the urethral opening is not at the end of the penis but on the ventral (lower) aspect of the penis (Fig. 46.9A). The meatus may be near the glans, midway back, or at the base of the penis (Hutton & Babu, 2007). This anomaly is fairly common, occurring in approximately 1 in 300 male newborns. It tends to be familial or may occur from a multifactorial genetic focus. **Epispadias** is a similar defect in which the opening is on the dorsal surface of the penis (Fig. 46.9B); this is corrected the same way.

Assessment

Be certain to inspect all male newborns at birth for hypospadias or epispadias as part of the routine physical examination. The degree of hypospadias may be minimal (on the glans but inferior in site) or maximal (at the midshaft or at the penalscrotal junction). Many newborns with hypospadias have an accompanying short *chordee*—a fibrous band that causes the penis to curve downward (often called a cobra-head appearance; Fig. 46.9C). Also inspect carefully for *cryptorchidism* (undescended testes), often found in conjunction with hypospadias.

If the penis defect is so extensive that sex determination is unclear, sex cell karyotyping (see Chapter 7) will be done. Hypospadias can be a difficult medical diagnosis for parents to accept because they may view it as a threat to the child's masculinity. This may cause them to have difficulty discussing this defect with relatives or health care personnel. Help parents work through these feelings by allowing them to talk about the disorder and by answering their questions honestly and openly.

Therapeutic Management

Children with hypospadias should not be circumcised because, at the time of the repair, the surgeon may wish to use a portion of the foreskin for the repair. In the newborn, a *meatotomy*—a surgical procedure in which the urethra is extended to a normal position—may initially be performed to establish better urinary function. When the child is older (age 12 to 18 months), adherent chordee may be released. If the repair will be extensive, all surgery may be delayed until the child is 3 to 4 years of age. To encourage penis growth and make the procedure easier, the child may have testosterone cream applied to the penis or receive daily injections of testosterone. It is important that hypospadias be corrected before school age so the child looks and feels like other children (Dodson et al., 2007). If left uncorrected, in later years, a meatal opening at an inferior penile site may interfere with fertility, because it does not allow sperm to be deposited close to the female cervix during coitus. Repair must be made before this time to prevent subfertility.

After surgical repair, a urethral urinary drainage catheter will be inserted to allow urine output without putting tension against the urethral sutures. The child may notice painful bladder spasms as long as the catheter is in place (3 to 7 days). An analgesic such as acetaminophen (Tylenol) and an antispasmodic medication such as oxybutynin (Ditropan) may be prescribed for pain relief.

After hypospadias repair, children can be expected to have usual urinary and reproductive function unless accompanying anomalies of the penis were present.

✔ Checkpoint Question 46.2

The appearance of a child with hypospadias is:

a. The urethra opens on the underside of the penis.
b. The bladder opens on the surface of the abdomen.
c. Urine drains into the rectum and is excreted with stool.
d. The child is unable to void, as there is no urethral meatus.

INFECTIONS OF THE URINARY SYSTEM AND RELATED DISORDERS

As the urinary system drains to the outside of the body, infection can easily spread to the bladder or kidneys.

Urinary Tract Infection

UTI occurs more often in females than in males at a rate of about 8% to 2% (Lum, 2008). Pathogens appear to enter the urinary tract most often as an ascending infection from the perineum. Most urinary pathogens are gram-negative rods. *E. coli* is a frequent offender. UTIs also are a common cause of nosocomial or health care–acquired infections in children with urinary catheters.

UTIs tend to occur more often in girls than in boys because the urethra is shorter in girls and because it is located close to the vagina (allowing the spread of vulvovaginitis) and close to the anus, from which *E. coli* spread. Changing diapers frequently can help reduce the risk for infection in infants. Girls should be taught early (when they are toilet-trained) to wipe themselves from front to back after voiding and defecating to avoid contaminating the urethra. There is a suggested correlation between the use of products such as bubble bath, feminine hygiene sprays, and hot tubs and UTI in girls so use of these should be discouraged or minimized (Schilling McCann et al., 2007). Infection also often occurs after sexual intercourse. Teach both adolescent males and females to void after sexual intercourse. Additional measures to prevent UTIs are summarized in Box 46.3.

UTIs need vigorous treatment in childhood so they do not spread to involve the kidneys (pyelonephritis). Girls who have more than three UTIs or boys with their first UTI should be referred to a urologist to determine whether they have a congenital anomaly such as urethral stenosis or bladder–ureter reflux that causes recurrent urinary stasis. A secondary problem is more likely in boys with a UTI.

BOX 46.3 ✻ Focus on Family Teaching

Preventing Urinary Tract Infection (UTI) in Females

Q. Carol's grandmother tells you, "Carol had a urinary tract infection last year. How can we prevent that from happening again?"

A. Here are some important tips to help prevent UTI:

- Encourage your granddaughter to drink periodically during the day, especially in warm weather or during exercise, to keep urine flowing freely and prevent stasis of urine in ureters.
- Urge her to urinate at least every 4 hours to prevent stasis of urine in the bladder.
- Teach her not to bathe with bubble bath; this can cause vulvar and urethral irritation.
- Help your granddaughter learn to wipe from front to back after moving her bowels or urinating, to prevent moving rectal contamination forward to the urethra.
- Have your granddaughter wear cotton, not synthetic, underwear to decrease perineal irritation.
- Instruct your granddaughter to wash her vulva daily to lower the bacterial count on the perineum.
- When your granddaughter begins menstruating, encourage her to change sanitary pads at least every 4 hours to reduce the possible growth of bacteria near the urethra.
- If symptoms of UTI should occur (pain on urination, frequency, blood in urine), call your primary health care provider. If an antibiotic is prescribed, make sure that your granddaughter takes it for the full prescribed course, so all bacteria are completely eradicated. Otherwise, after a short time, bacteria will proliferate, and the infection will recur.
- When your granddaughter becomes sexually active, teach her to urinate immediately after intercourse to remove any bacteria forced into the urethra by pressure.

Assessment

Although it may be possible to locate a UTI precisely as urethritis, cystitis, ureteritis, or pyelonephritis, the signs and symptoms in young children often are not clear-cut. When the exact location or extent of the infection is unknown, it is referred to simply as a UTI. The typical symptoms that occur in older children or in adults—pain on urination, frequency, burning, and hematuria—may not be present. If the infection is confined to the bladder (cystitis), the child may have a low-grade fever, mild abdominal pain, and enuresis (bedwetting). If the infection is a pyelonephritis, the symptoms generally are more acute, with high fever, abdominal or flank pain, vomiting, and malaise. Any child with a fever and no demonstrable cause on physical examination should be evaluated for UTI (Wan, Liu, & Chen, 2007).

Urine for culture can be collected by a clean-catch technique, suprapubic aspiration, or catheterization, so that bacteria from the vulva or foreskin do not contaminate the sample and give a false reading. Suprapubic aspiration is generally limited to infants because the sight of the syringe is so frightening to older children; plus, the procedure can introduce infection. The use of catheterization, also frightening and a potential source of infection, is limited in children of all ages.

Urine obtained from suprapubic aspiration is generally sterile, so any growth from this source is significant. A clean-catch urine specimen is said to be positive for bacteriuria if the bacterial colony count is more than 100,000/mL. A count of less than 10,000/mL is considered a negative culture. Counts between 10,000 and 100,000/mL are repeated. Usually, the urine also is positive for proteinuria (because of the presence of bacteria). Microscopic examination may indicate the presence of red blood cells (hematuria) because of mucosal irritation. The presence of red or white blood cells and bacteria tends to make urine more alkaline, so the pH will be elevated (greater than 7).

Therapeutic Management

The medical treatment for UTI is the oral administration of an antibiotic specific to the causative organism that is cultured (Lum, 2008).

In addition to the antibiotic, a child needs to drink a large quantity of fluid to "flush" the infection out of the urinary tract. Cranberry juice is often recommended as being highly effective in acidifying urine and making it more resistant to bacterial growth. In actual practice, there is little proof of its effectiveness, so offer any fluid the child drinks readily. If the child experiences moderate to severe pain on urination that interferes with the ability to void, suggest that the child sit in a bathtub of warm water and void into the water. A mild analgesic, such as acetaminophen (Tylenol), may help reduce pain enough to allow voiding.

With a UTI, treatment with antibiotics must be continued for the full prescription or the infection will return. Create a reminder sheet for parents to post in a readily visible location, such as on the refrigerator door, to help ensure adherence. A repeat clean-catch urine sample is usually obtained at 72 hours to assess the effectiveness of the antibiotic treatment.

After antibiotic therapy is stopped, it is helpful if parents obtain another clean catch urine specimen to be tested to prove that bacteria are not still present. After recurrent UTIs, children may be prescribed a prophylactic antibiotic for 6 months. At periodic health checkups for the next few years, a child should void a clean-catch specimen for culture or microscopic analysis.

"Honeymoon" Cystitis

Honeymoon cystitis refers to lower UTI seen in young women shortly after they initiate a first sexual relationship. Such infections occur in connection with the local irritation and inflammation caused by initial coitus.

Like most UTIs, these respond quickly to antibiotic therapy. Voiding as soon as possible after coitus may help to flush pathogenic organisms from the urethra and prevent such infections. When cystitis is seen in adolescent girls, it should alert health care providers to the possibility that a girl may be sexually active. In addition to needing counseling about personal hygiene measures to prevent UTI, the girl may need information on sexually transmitted infections, reproductive planning, and her responsibility for her maturing body. Recurrent UTIs in a school-age or preschool girl may suggest sexual abuse.

Vesicoureteral Reflux

Normally, urine flows from the ureters into the bladder, with almost no flow re-entering the ureters from the bladder. This is because the ureters enter the bladder obliquely, and a bladder skin flap or "valve" obscures the end of the ureter, preventing backflow. **Vesicoureteral reflux** refers to retrograde flow of urine from the bladder into the ureters (Watnick & Morrison, 2009). This reflux occurs because the valve that guards the entrance from the bladder to the ureter is defective, either from birth or because of scarring from repeated UTIs, bladder pressure that is stronger than usual, or ureters that are implanted at abnormal sites or angles. This backflow of urine happens at micturition (voiding) when the bladder contracts (Fig. 46.10).

Reflux leads to bladder infection because urine is retained in the ureters after voiding, and stasis of any fluid is subject to infection. It also appears that the capacity for normal bladder tissue to lyse bacteria becomes reduced due to the large residual urine volume that is always present. In addition, reflux is a potentially serious condition because it can lead to back-pressure on the kidneys, possibly leading to nephron destruction and, subsequently, hydronephrosis or dilatation of the renal pelvis. As it is prone to appear in families, it is most likely a heterogeneous disorder (Kelly et al., 2007).

Assessment

A child with reflux is usually first seen by health care personnel because of a history of repeated UTI. A voiding cystourethrogram, CT scan, cystoscopy, or cystography with contrast material will show the ureteral reflux. Based on diagnostic studies, reflux is graded from I to V by degree of reflux, with V being the most serious.

Therapeutic Management

The majority of instances of vesicoureteral reflux resolve with maturity without a need for surgery. Until this normal

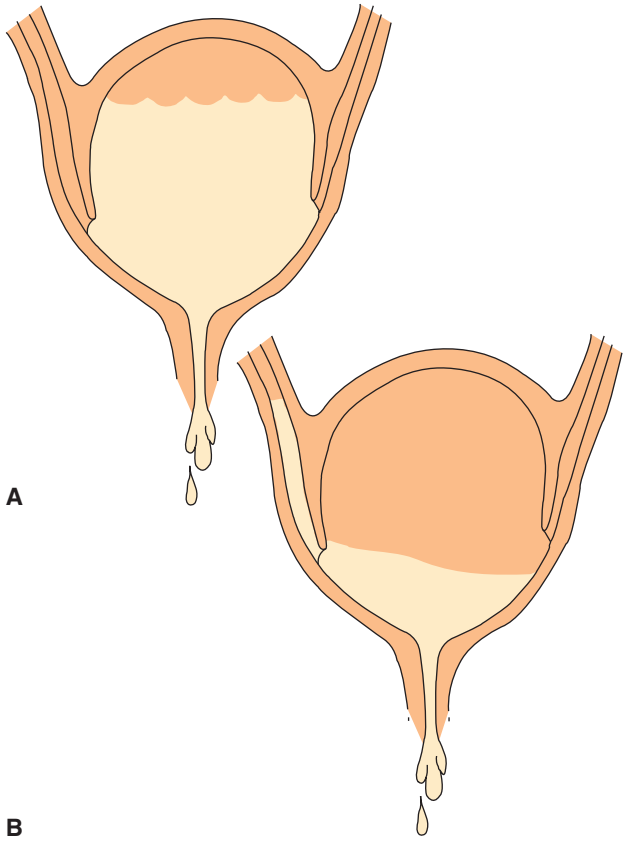

FIGURE 46.10 Vesicoureteral reflux. (**A**) Normal voiding pattern. (**B**) Reflux into ureters with voiding.

growth occurs, however, the condition must be rigorously treated to decrease the possibility of glomerular scarring from infection or back-pressure. Teaching double voiding (having the child void, then in a few minutes attempt to void again) may help to empty the bladder and prevent recurrent infection from urinary stasis. Some girls need to remain on prophylactic antibiotics to prevent bladder infection. Long-term maintenance with antibiotics may be as effective as surgery in reducing renal scarring from recurrent urinary tract infection in lower grades of reflux (Hensle, Grogg, & Eaddy, 2007).

If continuous antibiotic therapy does not prevent recurrent UTIs, reflux can be corrected by cystoscopy. Under general anesthesia or conscious sedation, a cystoscope is passed, and an agent such as Deflux (dextranomer–hyaluronic acid) is injected to stabilize the ureter valves (Sutherland et al., 2007). Laparoscopic surgery to correct the placement of ureters may be scheduled to reinsert the ureters at a more oblique angle, creating the usual valve effect.

After surgery, a suprapubic catheter remains in place to keep the bladder empty and prevent pressure against the surgical area. Two ureteral catheters (stents), threaded into the ureters to drain urine directly from the kidney pelvis, also exit at the suprapubic tube site. Tubes are attached as a closed drainage system to collecting bags. Sterile gauze dressings and antibiotic cream are placed around the tube insertion sites.

In preparing children for this type of surgery, be certain to prepare them for the number of tubes that will be inserted. Explain that even with the tubes in place, the child will be allowed to walk and move about soon after the operation (and

should do this). Be sure that the child and parents understand the importance of keeping the urine collection bags below the level of the child's bladder to prevent urine from flowing back into the bladder. Caution them not to raise the bags above the child's bladder level when helping the child out of bed.

Observe the catheter drainage tubes closely, every hour for the first 24 hours and then at least every 4 hours. Note the color and the amount of drainage (urine), and carefully measure and record it. Initially, drainage will be bloody, but this should clear in 1 or 2 days. Assess drainage for clots (should not be over pinpoint in size). The stents should drain an equal amount, to ensure that kidney production is equal on both sides. Urine will drain primarily from the stents for approximately the first 3 days after surgery; thereafter, drainage will flow around the stents and will be mainly from the suprapubic tube.

Be sure that the ends of the catheters do not become contaminated, because then infection can spread to the surgical area or the kidneys. An antiseptic solution may be ordered placed in the drainage bags to limit the growth of bacteria in the collecting urine. Be certain any amount added is subtracted from the output amount. As soon as urine drainage from the stent catheters has decreased and blood has cleared, the stent catheters will be removed. To show that urine is clearing of blood, obtain serial urine specimens each time collecting bags are emptied and label it with the time of removal. Comparing the color of these samples will show that urine is clearing of blood. School-age children can help label the containers, which can help to add to their sense of accomplishment and control over the situation. Many children become frightened when they learn the stent catheters will be removed. Assure them that this will not be painful and can be done at an ambulatory visit without anesthesia.

Incisional pain and painful bladder spasms may occur for the first 3 days after surgery, so antispasmodics may be prescribed to reduce bladder spasm. Also, not touching or not moving the suprapubic tube helps to reduce spasms because this limits bladder irritation. The suprapubic tube is removed between 4 and 7 days after surgery (again, a nearly painless procedure). There may be slight urine leakage from the puncture site of the tube for 1 or 2 days after removal of the tube. Keep a sterile dressing in place to absorb the leaking urine. Remind the child and parents to avoid tub baths until the suprapubic tube site has closed completely.

A few children continue to have bladder reflux after ureter reimplantation. All children need follow-up care such as repeated urine cultures or perhaps an IVP or ultrasound at a later date to establish that surgery was effective in halting the reflux.

Hydronephrosis

Hydronephrosis is enlargement of the pelvis of the kidney with urine as a result of back-pressure in the ureter (Watnick & Morrison, 2009). The back-pressure is generally caused by obstruction, either of the ureter or of the point where the ureter joins the bladder, as with vesicoureteral reflux. Although this may occur at any age, it occurs most often in the first 6 months of life. If it occurs during intrauterine life, it will be revealed by fetal ultrasound (Hubert & Palmer, 2007).

Children with hydronephrosis are usually asymptomatic. They may have repeated UTIs from urinary stasis (difficult to detect in a child this age except as general irritability or crying on voiding). Elevated blood pressure caused by increasing tubular pressure (which activates the renin-angiotensin system) may be detected on a routine health assessment, although blood pressure is not taken routinely in a child of this age. With severe back-pressure, the infant experiences flank or abdominal pain. Abdominal palpation may reveal an abdominal mass (the dilated kidney pelvis). An IVP or ultrasound will show the enlarged pelvis and the point of obstruction.

Hydronephrosis is a serious disorder because, if the pressure in the pelvis becomes too acute, back-pressure on the kidney will interfere with tubular function or destroy the nephrons. The treatment is surgical correction of the obstruction before glomerular or tubular destruction occurs.

DISORDERS AFFECTING NORMAL URINARY ELIMINATION

Interferences with urine elimination can arise from innocent conditions such as enuresis or extremely serious disorders such as kidney agenesis.

Enuresis

Enuresis is involuntary passage of urine past the age when a child should be expected to have attained bladder control (Weaver & Dobson, 2007). Because this is expected at age 2 to 3 years of age for daytime and age 4 years for nighttime, enuresis is said to occur at approximately 5 to 7 years. Enuresis may be nocturnal (occurs only at night), diurnal (occurs during the day), or both. It is primary if bladder training was never achieved, acquired or secondary if control was established but has now been lost.

Most enuresis is nocturnal; daytime enuresis occurs only rarely, except during naptime. Functional nocturnal enuresis (that with no known cause) occurs in approximately 8% to 12% of children age 8 years or younger. It is found more frequently in boys than in girls. It also tends to be familial (if it is present in a child, one of the parents probably experienced it, too).

Assessment

Children with enuresis who are older than 5 years of age need an evaluation to determine whether there is an organic cause for the disorder. During the history, ask how parents have tried to correct the problem; identify whether it is primarily a problem for the child or the parents (treatment will be most effective if the child wants the situation corrected). Assess whether there are stresses in the family, such as parents who expect more mature behavior of a child than the child can handle such as the introduction of a new brother or sister, an uncomfortable school situation such as being assigned to a "shouting" teacher, or marital discord.

If they wet only on nights when they are exceptionally tired or troubled, a functional rather than an organic cause is suggested. If children wet only when they are engrossed in an interesting activity, they may simply need more reminders to empty their bladder. If children have symptoms other than bedwetting, such as abdominal pain, burning, or frequency, UTI is suggested. It is a common practice for many parents to get children out of bed every night and take them to the

bathroom. At any point parents stop this practice, children may begin bedwetting because they have been conditioned to empty their bladder at that time of night.

Some children with enuresis have abnormal electroencephalographic patterns. Other children with the same abnormal patterns do not have enuresis, however, so this by itself is not a sufficiently specific finding to be helpful. In others, bedwetting seems to occur as children pass from a period of rapid eye movement sleep pattern to a type IV level, or it is primarily a sleep disorder. It may be associated with small bladder capacity (which would explain why the condition is familial).

Although usually not necessary to aid diagnosis, an IVP, VCUG, or ultrasound may be done to rule out organic disease. A clean-catch urine specimen should be collected to rule out bacteriuria. Specific gravity is assessed to rule out a defect in urine concentration. Protein and glucose levels are evaluated to determine evidence of kidney disease.

Therapeutic Management

The treatment of enuresis may be complex because the cause is generally unknown. If stress factors have been identified, an attempt should be made to correct these. Some stress factors, such as birth of a new sibling, cannot be changed, but frank discussion with children regarding what causes the stress and attempts to help children cope better with their daytime activities may improve enuresis (Box 46.4).

In many children, it helps to limit fluids after dinner. Urge parents to exercise common sense in this area. Remind them that a child may not be able to go every night without a drink from dinner until breakfast. Caution parents of children with sickle-cell anemia not to restrict fluid this way because increased sickling of cells occurs with dehydration.

BOX 46.4 ✻ Focus on Evidence-Based Practice

Does bedwetting (nocturnal enuresis) affect the quality of life of families?

For this study, 28 women who reported that their child had nocturnal enuresis and 38 women whose child had no urinary symptoms were asked to fill in three separate questionnaires: one on general health, one on risk of depression, and one on risk of anxiety. Results of the inventories showed that the mothers of children with nocturnal enuresis had significantly lower quality-of-life scores related to bodily pain and emotional well-being than did mothers whose child was symptom-free. They also scored significantly higher on a depression scale.

Suppose a parent tells you that her child has nocturnal enuresis but she knows it is only a stage of growth so she is not worried. Based on the above study, would you ask any further questions?

Source: Egemen, A., et al. (2008). An evaluation of quality of life of mothers of children with enuresis nocturna. *Pediatric Nephrology, 23*(1), 93–98.

BOX 46.5 ✻ Focus on Pharmacology

Desmopressin acetate (DDAVP)

Classification: A synthetic form of human antidiuretic hormone

Action: Promotes resorption of water in the renal tubule or decreases bladder filling; drug of choice for enuresis (Karch, 2009)

Pregnancy Risk Category: B

Dosage: In children 6 years of age and older, 20 μg (0.2 mL) intranasally at bedtime, possibly increasing the dose up to 40 μg if necessary; or 0.2 mg orally at bedtime, titrated up to 0.6 mg to obtain the desired response

Possible Adverse Effects: Transient headache, nausea, flushing, mild abdominal cramps, fluid retention

Nursing Implications

- Instruct parents and child that child should restrict fluid after dinnertime in addition to taking medication.
- If given intranasally, advise parents to refrigerate the solution.
- Teach parents and child the proper method for intranasal administration.
- Caution child and parents that nasal administration is less effective if the child develops a cold with draining rhinitis.

Alarm bells that ring when children wet at night are effective in some children. This type of system does not actually stop bedwetting. The alarm wakes the child, the child stops voiding, and then gets up and uses the bathroom. Over time, this type of conditioning may be effective, but once the urine alarm is removed, children may relapse. Bladder-stretching exercises—drinking a large quantity of water and then refraining from voiding as long as possible—to increase the functional size of the bladder can be helpful in some children. A bladder that can hold 300 to 350 mL of fluid will generally be large enough to contain urine during a night's sleep.

If these measures are not effective, synthetic antidiuretic hormone (ADH; desmopressin [DDAVP]) administered intranasally or orally is the drug of choice to reduce urinary output and enuresis (Glazener, Evans, & Peto, 2009; Box 46.5).

Enuresis is not a minor problem for either parents or for the child. As a general measure, children who wet their beds need to take baths in the morning rather than at bedtime to minimize urine odor and avoid teasing. Parents may find planning a vacation with hotel stays difficult. They may resent the daily linen washing. Children may exclude themselves from activities such as slumber parties or camping trips with friends to avoid embarrassment.

Enuresis may occur in hospitalized children because of the stress of their new surroundings. Preschool children may experience it because they are uncomfortable using strange bathrooms or do not understand which bathroom is theirs to use. As a rule, place as little stress or importance on enuresis as possible during an illness, and encourage parents to do the same.

Postural (Orthostatic) Proteinuria

A few children will spill albumin into the urine when they stand upright for an extended period (**postural proteinuria,** also called postural albuminuria). The amount of spilling decreases when they rest in a supine position. Children with this condition have no apparent damage to glomeruli; the phenomenon is apparently attributable to the effect of gravity on glomerular function.

To determine whether postural proteinuria exists, urine is collected after the child has been recumbent during the night (a first-voided specimen) and then again after the child has been up and active for several hours. Make certain when collecting these urine specimens to record the child's activity accurately. If the child stood by the crib rail crying for a parent or was held in a nurse's lap for most of the night, the urine may show protein in the morning specimen because it is not truly a "resting specimen." Likewise, for the specimen to be collected after the child has been active, make certain that the child is up and active, not lying in a supine position reading a book for most of the time. Play a game if necessary, such as follow the leader, so the child is active.

Postural proteinuria needs no therapy. However, be sure to document the condition because some of these children develop some form of kidney disorder later in life.

Kidney Agenesis

Agenesis means lack of growth (literally, lack of a beginning) or that no organ formed in utero. Absence of kidneys in a newborn is suggested when the volume of amniotic fluid on ultrasound or at birth is less than normal (oligohydramnios). This occurs because urine normally adds to the volume of amniotic fluid in utero. The infant with kidney agenesis often has *Potter's syndrome* or accompanying misshapen, low-set ears and hypoplastic (stiff, inflexible) lungs from the lack of amniotic fluid in utero. Without kidneys, the fetus cannot void urine. Bilateral absence of kidneys this way is obviously incompatible with life unless a renal transplantation can be accomplished, but the associated condition of nonfunctioning lungs makes a successful transplantation highly unlikely.

Polycystic Kidney

Polycystic kidney means that large, fluid-filled cysts have formed in place of normal kidney tissue. The most frequent type of polycystic kidney seen in children is inherited as an autosomal recessive trait. A more rare form is inherited as an autosomal dominant trait (Boyer et al., 2007). With either type, there is abnormal development of the collecting tubules. The kidneys are large and feel soft and spongy. If the disorder is bilateral, an infant will not pass urine. The mother will have had oligohydramnios during pregnancy. Children often have a typical appearance (*hypertelorism*—wide-spaced eyes, epicanthal folds, flattened nose; or *micrognathia*—small jaw), the findings of Potter's syndrome. Either *transillumination* or *ultrasound* will show the fluid-filled cysts.

If the condition is unilateral, urine production will be decreased (oliguria), not absent. Because kidneys are difficult to locate in newborns, a unilateral polycystic kidney may be missed until later in life, when, with increased kidney growth, an abdominal mass can be palpated. The cystic growth offers such resistance to blood circulation that systemic hypertension often results by school age.

In many children, the liver is filled with identical cysts. This is most evident later in life when increased difficulty with portal circulation occurs (blood cannot perfuse the cystic liver structures either).

The treatment for polycystic formation is surgical removal of a kidney if only one is cystic. If both kidneys are cystic, treatment is renal transplantation (difficult in the young child, because few infant kidneys are available for transplantation and because of the technical challenge presented by such small blood vessels).

Because this kidney disease is inherited, parents, and children at adolescence, need genetic counseling to inform them that future children may also have this problem.

Renal Hypoplasia

Hypoplasia means reduced growth. Hypoplastic kidneys contain fewer lobes than normal kidneys and are small and underdeveloped. The child with hypoplastic kidneys, in addition to having poor kidney function, may develop hypertension from stenosis of the renal arteries. If hypoplasia is bilateral, the child may need a kidney transplant in later life to maintain kidney function and prevent extreme hypertension.

Prune Belly Syndrome

Prune belly syndrome is severe urinary tract dilation that develops as early as intrauterine life from an unknown cause. Occurring mainly in boys, the severe dilation causes backpressure and destruction of kidneys. The infant is born with oligohydramnios and pulmonary dysplasia because of the lack of amniotic fluid in utero (Woods & Brandon, 2007).

The condition is marked by the presence of three symptoms: deficiency of usual abdominal muscle tone, bilateral undescended testes, and the dilated faulty development of the bladder and upper urinary tract. The infant's abdomen appears wrinkled (like a prune) because of the poorly developed abdominal muscles (Fig. 46.11). Without surgical remodeling, the infant will develop repeated UTIs, leading eventually to end-stage renal disease. Teach parents to protect their child's abdomen from trauma such as can happen from lap belts or baby walkers because their child lacks abdominal support. Some children need kidney transplants as

FIGURE 46.11 Prune belly syndrome. (Courtesy of Karen M. Polise, MSN, RN, Division of Nephrology, The Children's Hospital of Philadelphia.)

they reach school age because of destruction of glomeruli from back-pressure (Kamel et al., 2007).

Acute Poststreptococcal Glomerulonephritis

Glomerulonephritis, inflammation of the glomeruli of the kidney, may occur as a separate entity but usually occurs as an immune complex disease after infection with nephritogenic streptococci (most commonly subtypes of group A beta-hemolytic streptococci). Tissue damage occurs from a complement fixation reaction in the glomeruli (*complement* is a cascade of proteins activated by antigen–antibody reactions and actually plugs or obstructs glomeruli). IgG antibodies against streptococci may be detected in the bloodstream of children with acute glomerulonephritis, proof that the illness follows a streptococcal infection (Sinha et al., 2007).

Intravascular coagulation occurs in the minute renal vessels. Ischemic damage leads to scarring and decreased glomerular function. This results in a reduction in the glomerular filtration rate, leading to an accumulation of sodium and water in the bloodstream. Inflammation of the glomeruli increases permeability, allowing protein molecules to escape into the filtrate.

Assessment

Acute glomerulonephritis is most common in children between the ages of 5 and 10 years, the age group most susceptible to streptococcal infections. Boys appear to develop the disease more often than girls; it occurs more often during the winter and spring, as do pharyngeal streptococcal infections. The child typically has a history of a recent respiratory infection (within 7 to 14 days) or impetigo (within 3 weeks). All children who have had a "strep" throat, tonsillitis, otitis media, or impetigo caused by streptococcal infection, ideally, should have a urinalysis 2 weeks after the infection to evaluate that glomerulonephritis is not occurring. Many children do not receive this follow-up step, however, because of lack of health insurance coverage or compliance.

Acute glomerulonephritis is characterized by a sudden onset of hematuria and proteinuria. The protein content both of individual urine specimens and of total 24-hour urine volume is measured. Testing a single specimen will show 1+ to 4+ protein; a 24-hour urine specimen may contain as much as 1 g protein (normally, urine contains none).

The hematuria associated with acute glomerulonephritis is usually so gross that the child's urine appears tea-colored, reddish-brown, or smoky. Urinary sediment will contain white blood cells, epithelial cells, and hyaline, granular, and red blood cell casts. After these initial urine changes, the child develops oliguria. Specific gravity of urine is elevated. Hypertension from hypervolemia occurs. The child may have abdominal pain, a low-grade fever, edema, anorexia, vomiting, or headache. There may be cardiac involvement related to the difficulty in managing the excessive plasma fluid. Such children show signs of orthopnea, cardiac enlargement, enlarged liver, pulmonary edema, and a galloping heart rhythm. Electrocardiographic changes such as T-wave inversion and prolongation of the P-R interval may be seen. Heart failure may occur from circulatory overload.

Blood analysis will indicate a lowered blood protein level (hypoalbuminemia) caused by the massive proteinuria. Low serum complement will be present, and, as the blood volume expands, a mild anemia also will occur. As in all inflammatory diseases, the erythrocyte sedimentation rate will increase. Because the glomeruli cannot filter properly, concentrations of urea, nonprotein nitrogen (BUN), and creatinine in blood will increase. The antistreptolysin O (anti–DNase B) titer or antibody formation against streptococci is generally elevated.

If blood pressure reaches 160/100 mm Hg as part of the acute process, encephalopathy may occur, with symptoms of headache, irritability, seizures, vomiting, coma or lethargy, and perhaps transitory paralysis. This extreme elevation in blood pressure is probably related to the expanded circulatory volume. The cerebral symptoms are caused by *cerebral ischemia* (vasoconstriction of cerebral vessels to reduce cranial pressure).

Therapeutic Management

The course of acute glomerulonephritis is 1 to 2 weeks. During this time, there is little therapy specific for the disorder. Antibiotics usually are ineffective because the disease is caused not by an active infection but by an antigen–antibody inflammatory response to a past infection. Diuretics are of little value because obstructed glomeruli bases cannot be made to function; a course of ethacrynic acid or furosemide (Lasix) may be tried. If heart failure occurs, specific measures such as placing the child in a semi-Fowler's position, digitalization, and oxygen administration may be necessary. If diastolic blood pressure rises to more than 90 mm Hg, antihypertensive therapy with a calcium channel blocker may be necessary. Phosphate binders, such as aluminum hydroxide to reduce phosphate absorption in the GI tract, or a potassium-removing resin agent, such as sodium polystyrene sulfonate (Kayexalate), may be necessary in children who have rising phosphate and potassium levels.

Bedrest is unnecessary, although children should be encouraged to participate in quiet play activities. They can attend school and engage in normal activities after 1 or 2 weeks, but competitive activity is limited until kidney function has returned to normal to avoid overstressing the kidneys.

Diet is controversial. Although limiting protein intake reduces the amount of protein lost in urine, many children who are losing large quantities of protein need high-protein diets to supplement this loss. Salt restriction may be needed to reduce severe edema. Most children do well on a normal diet for their age, however, with normal salt and protein content. Weighing the child every day and calculating intake and output are important assessments in following the course of the disease.

In most children, acute glomerulonephritis runs a limited, benign course. After most symptoms fade, proteinuria and impaired clearance of urea and creatinine may remain for as long as 2 months, however. Caution parents that the results of a urine protein test may remain abnormal for up to a year; caution them that, if their child has this test as a routine screening procedure at a health checkup, they should not worry that this finding means reinfection or the beginning of further disease.

A few children will not completely recover from acute glomerulonephritis but will develop chronic nephritis. These children appear to suffer destruction from the initial inflammation that results in chronic renal insufficiency.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Situational low self-esteem, related to feelings of responsibility for onset of serious illness

Outcome Evaluation: Child (parent) admits guilt about inadequate treatment of initial infection; discusses plans and ways to maintain health; participates in care.

Glomerulonephritis is a frightening disease for both children and their parents. Children may be frightened by the initial hematuria. They may be upset at the appearance of periorbital edema, which makes their reflection in the mirror so strange to them. Children as young as early school age are aware that kidneys are necessary for life, and this means they recognize the seriousness of kidney disease.

If children were prescribed penicillin for pharyngitis 2 weeks before the development of the nephritis but refused to take it, they may believe that they caused this disease. The parents may feel guilty because they did not insist the child take the medicine. They worry that their child will develop chronic glomerulonephritis or die during the acute phase of this attack. These parents and children need to talk about their feelings openly. Provide frequent reports of subtle positive changes in a child's condition such as "His blood pressure is staying down by itself now; he does not need medicine for that anymore." "He weighs 2 pounds less today than 4 days ago; that generally means his kidneys are beginning to function more efficiently again."

Be certain that parents know the date and place of a return visit for follow-up care. Because this is a perplexing disease, be sure they have a telephone number to call if they have questions about their child's care or condition.

The most frequent type of acute glomerulonephritis can be avoided by the prevention or effective early treatment of group A beta-hemolytic streptococcal infections. Acute glomerulonephritis tends not to recur with subsequent streptococcal infections, so prophylactic penicillin to prevent further streptococcal infections is unnecessary.

IGA Glomerulonephritis

Acute glomerulonephritis may occur when there is no evidence of a prior infection (Watnick & Morrison, 2009). In these children, immunoglobin A is elevated. The gross hematuria resolves within a few days and is not apt to produce serious sequelae. Because of the benign course of the illness, no therapy is indicated except for careful observation for more serious signs such as severe proteinuria, hypertension, or renal insufficiency. If these symptoms occur, corticosteroids will halt the disease process. Omega-3 fatty acids present in fish oils may be prescribed but their use is not well established.

✔ Checkpoint Question 46.3

What is typically the first symptom of acute glomerulonephritis?

a. Low blood pressure from excessive aldosterone
b. "Old blood" in urine from kidney bleeding
c. Dependent edema from protein accumulation
d. Pain on urination from urethra inflammation

Chronic Glomerulonephritis

Although chronic glomerulonephritis occasionally follows acute glomerulonephritis or nephrotic syndrome, it also occurs as a primary disease (or after acute glomerulonephritis that was clinically so mild it was undiagnosed). The child is found to have proteinuria at a routine checkup. Further investigation may indicate hypertension and the presence of red cell or white cell casts and occult blood in urine. The specific gravity of the child's urine is below normal (below 1.003). Blood studies may indicate an increased BUN or creatinine level. A renal biopsy will show permanent destruction of glomeruli membranes.

Chronic glomerulonephritis may result in either diffuse or local nephron damage. The remaining functioning nephrons increase their glomerular filtration rate to compensate for those that are damaged. At some point in this chronic disease destruction process, however, compensatory mechanisms fail, and renal insufficiency or failure will result. **Alport's syndrome** that also includes hearing loss and ocular changes is a progressive chronic glomerulonephritis inherited as a X-linked or autosomal recessive disorder (Shaw et al., 2007).

During the illness, if the child has acute symptoms of edema, hematuria, hypertension, or oliguria, bedrest may be necessary. If children have only a chronic manifestation, such as proteinuria, and if they feel well, they can maintain normal activity, including attending school. Children should not engage in competitive activities such as contact sports, however, because of the risk of kidney injury.

Therapy is nonspecific and directed at symptom relief rather than the disease process itself, because the cause of the disease is unknown. Therapy with antihypertensive drugs such as hydralazine (Apresoline) or with diuretics to increase urine output such as ethacrynic acid (Edecrin) may be necessary. Corticosteroid therapy may reduce or halt the progress of the disorder by reducing inflammation. Children have difficulty accepting long-term corticosteroid therapy because of the side effects, in particular a typical "moon face" and extra body hair (Cushing's syndrome). Talk with them about these body changes and assure them that these changes will reverse when the drug is discontinued.

Children receiving corticosteroids are at an increased risk for infection because of the immunosuppressive activity of these drugs. They need to be shielded from other children and health care personnel with infection. Parents need to learn to take their child's temperature and recognize and report the earliest signs of infection.

Generally, the prognosis for children with chronic glomerulonephritis is poor. Although the illness may run a long-term course, eventually it leads to renal insufficiency and renal failure. Children may be maintained for long periods by peritoneal dialysis or hemodialysis. Kidney transplantation is a possibility.

Because children as young as early school age are aware of the importance of kidney function to life, most children with

chronic renal disease are aware of the likely outcome of their disease. Most children are adolescents or young adults before the disease runs its ultimate course. They indicate that they appreciate having health care personnel face this outcome with them honestly if kidney transplantation cannot be performed to prolong their life.

Nephrotic Syndrome (Nephrosis)

Nephrosis, altered glomerular permeability due to fusion of the glomeruli membrane surfaces, causes abnormal loss of protein in urine. Immunologic mechanisms are involved in instigating the process. The cause may be hypersensitivity to an antigen–antibody reaction or an autoimmune process. A T-lymphocyte dysfunction may be responsible. The highest incidence is at 3 years of age, and it occurs more often in boys than in girls (Lum, 2008).

Nephrotic syndrome in children occurs in three forms: (a) congenital, which occurs as an autosomal recessive disorder; (b) secondary, as a progression of glomerulonephritis or in connection with systemic diseases such as sickle cell anemia or systemic lupus erythematosus (SLE); or (c) idiopathic (primary). The congenital form is rare; in children, the idiopathic form is most common (Tkaczyk et al., 2008).

Nephrosis can be further classified according to the amount of membrane destruction. Minimal change nephrotic syndrome (MCNS) is the type most often seen in children (80%). As the name implies, with this type, little scarring of glomeruli occurs. Children with this degree of scarring respond well to therapy. Other types are focal glomerulosclerosis (FGS) and membranoproliferative glomerulonephritis (MPGN). Both of these types involve scarring of glomeruli, and these children will have a poorer response to therapy (Lu et al., 2007).

The four characteristic symptoms of nephrotic syndrome are proteinuria, edema, hypoalbuminemia (low serum albumin level), and hyperlipidemia (increased blood lipid level). Proteinuria occurs because increased glomerular permeability leads to protein loss in the urine and, subsequently, hypoalbuminemia. With a low level of protein in the bloodstream, osmotic pressure causes fluid to shift from the bloodstream into interstitial tissue, causing edema. As the blood volume decreases, the kidneys begin to conserve sodium and water, adding to the potential for edema. The hyperlipidemia occurs because the liver increases production of lipoproteins to try to compensate for protein loss. Lipids are too large to be lost in urine, so they rise to high levels in the blood serum. Some children have such high lipid levels that, when blood is drawn and placed into a test tube, a circle of white fat forms on the top of it. Figure 46.12 illustrates the process that leads to these common symptoms.

Assessment

Symptoms usually begin insidiously. Children develop edema around the eyes (periorbital edema), most noticeable when they wake in the morning from a head-dependent position. Parents may notice that clothing no longer fits a child around the waist, because edematous fluid is beginning to collect in the abdominal cavity (ascites). It is easy to dismiss these first symptoms as those of an upper respiratory tract infection and the normal "paunchy" belly of a toddler or preschooler. As edema progresses, the child's skin becomes pale, stretched, and taut. In boys, scrotal edema becomes extremely marked. Ascites may become so extensive that the resultant pressure on the stomach leads to anorexia or vomiting. Children may have diarrhea caused by intestinal edema and poor absorption by the edematous membrane. Because of poor nutrition, growth may stop. The child may become malnourished but yet appear deceptively obese because of the extensive edema (Fig. 46.13). When the ascites becomes even more extensive, children may have difficulty breathing as the abdominal fluid presses against the diaphragm, decreasing lung expansion. Parents report that children are irritable and fussy, probably from the feeling of abdominal fullness and generalized edema. An increased risk for clotting can occur from the decreased intravascular fluid volume.

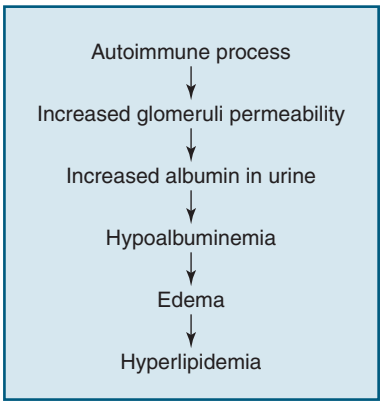

FIGURE 46.12 The process that results in the signs and symptoms of nephrotic syndrome.

Laboratory studies will reveal marked proteinuria. A single test will show a 1+ to 4+ protein; a 24-hour total urine test will show up to 15 g protein (normally urine contains no protein). The protein loss with nephrotic syndrome is almost entirely albumin, differentiating it from the proteinuria of glomerulonephritis, in which protein loss tends to be non-

FIGURE 46.13 A 2-year-old with nephrotic syndrome. Note the extensive edema of the face and hand. (From B. J. Zitelli & H. W. Davis [1997]. *Atlas of pediatric physical diagnosis* [3rd ed.]. St. Louis: Mosby–Year Book, Inc.)

TABLE 46.5 ✻ Comparison of Features of Acute Glomerulonephritis and Nephrotic Syndrome

Factor	Acute Glomerulonephritis	Nephrotic Syndrome
Cause	Immune reaction to group A beta-hemolytic streptococcal infection	Idiopathic; possibly a hypersensitivity reaction
Onset	Abrupt	Insidious
Hematuria	Profuse	Rare
Edema	Mild	Extreme
Hypertension	Marked	Mild
Hyperlipidemia	Rare or mild	Marked
Peak age frequency	5–10 yr	2–3 yr
Interventions	Limited activity; antihypertensives as needed; symptomatic therapy for congestive heart failure	Corticosteroid administration; cyclophosphamide administration; possibly a diuretic and potassium supplement
Diet	Normal for age	High-protein, low-sodium diet
Prevention	Prevention or thorough treatment of group A beta-hemolytic streptococcal infections	None known

specific. Some children with nephrotic syndrome exhibit hematuria at the onset, but it is minimal in contrast to that seen with acute glomerulonephritis. The erythrocyte sedimentation rate (demonstrating the inflammation of the glomeruli membrane) is elevated. Features of acute glomerulonephritis and nephrotic syndrome are compared in Table 46.5. A renal biopsy may be done to determine whether there is scarring of the glomerular membrane and document the type of nephrotic syndrome present.

Therapeutic Management

Therapy for a child with nephrotic syndrome is directed toward reducing the proteinuria and subsequently the edema with a course of corticosteroids, such as IV methylprednisolone or oral prednisone, and keeping the child free of infection while the immune system is suppressed. An initial dose of prednisone is given until diuresis without protein loss is accomplished; the dosage is then reduced for maintenance and continued for as long as 1 to 2 months.

Instruct parents to test the first urine specimen of the day for protein with a chemical reagent strip and keep an accurate chart showing the pattern of protein loss. Approximately once a week, they are usually asked to collect a 24-hour urine specimen so total protein loss can be measured.

After the initial 4 weeks, prednisone is generally given every other day rather than every day. Prednisone has the potential to halt growth and to suppress adrenal gland secretion. However, growth is apparently not delayed when the drug is given on alternate days and there is less alteration of adrenal steroid production (Karch, 2009). Parents may need to be assured that alternate-day therapy is best to keep them from changing the schedule to every day or giving twice the calculated dose by adding extra tablets on alternate days. To help parents remember to give medication on alternate days, have them choose either even or odd calendar days as the day of administration. Help them design a reminder chart. Prednisone tastes bitter, so parents may welcome suggestions regarding how to disguise the taste, such as by mixing it with applesauce.

Be certain both the parents and the child are aware that prednisone causes a cushingoid appearance or a "moon face," extra fat at the base of the neck, and increased body hair. Urge parents to plan ahead when getting pharmacy refills so that the prednisone therapy is not stopped abruptly because they ran out of medication; an abrupt stop can lead to adrenal insufficiency.

Diuretics are not commonly used to reduce the edema because they tend to decrease blood volume, which is already decreased. This could lead to acute renal failure. Children who respond poorly to prednisone alone, however, may need diuretic therapy with a drug such as furosemide (Lasix). When children are taking furosemide for extended periods, there is always a danger that too much potassium will be excreted, causing hypokalemia. Children on long-term diuretic therapy usually need frequent blood studies to determine that electrolyte levels, especially potassium, are adequate. They may need supplemental potassium and should eat foods high in potassium. IV albumin may be administered to temporarily correct hypoalbuminemia. As the serum albumin level rises, fluid shifts from subcutaneous spaces into the bloodstream. Children are then administered a rapidly acting diuretic to remove the extra fluid. It is important that the diuretic be administered after the albumin infusion or the child could develop a fluid overload and, subsequently, heart failure.

Some children are prednisone resistant or do not respond to corticosteroid therapy. A course of cyclophosphamide (Cytoxan), cyclosporine (Sandimmune), or mycophenolate mofetil (CellCept), stronger immunosuppressant agents, may be effective in reducing symptoms or preventing further relapses of the disease in these children (Pena et al., 2007). It is important to ensure adequate fluid intake with these drugs to prevent bladder irritation and bleeding. Cyclophosphamide is also used in chemotherapy for malignancy (see Chapter 53). Be certain that parents are not misled into believing that their child has cancer because their child is receiving a chemotherapeutic drug.

The prognosis for children with nephrotic syndrome varies. Almost all children with MCNS respond initially to steroid therapy. Although they may have a relapse, they will then remain free of the disease. Those with FGS and MPGN types will have relapses at frequent or infrequent intervals over the next several years. Children who have

frequent relapses have a relatively poorer chance of ever being free of the disorder. Many develop renal failure later. Kidney transplantation may be necessary to sustain life. All children and families need emotional support while the disease runs a long-term course.

✔ Checkpoint Question 46.4

What is an important nursing intervention for children with nephrotic syndrome?

a. Caution them not to eat salt, as salt irritates the bladder.
b. Encourage them to walk a mile daily for exercise.
c. Teach them to test their urine for proteinuria.
d. Teach them to take their temperature daily.

Nursing Diagnoses and Related Interventions ✻

Nursing Diagnosis: Imbalanced nutrition, less than body requirements, related to poor appetite, restricted diet, and protein loss

Outcome Evaluation: Child follows normal growth curve on standard growth chart.

For children with nephrosis, a good protein intake is necessary to offset protein loss. A good potassium intake through consumption of fruits and fruit juices, particularly bananas, is necessary to maintain sufficient serum potassium levels, especially if the child is receiving a potassium-losing diuretic (Table 46.6). This may be difficult for children, however, because they have poor appetites. During acute phases of the disease, fluid or sodium may be temporarily restricted. If this is so, most children are happiest with many small glasses of fluid spaced throughout the day, rather than several large drinks. It helps to make a chart showing the amount of fluid a child is allowed each day. As fluid is given, color in a portion of the chart corresponding to the amount given. This allows the child to tell from the uncolored portion how much more fluid is allowed that day. This is easier for toddlers and preschoolers (the age group usually affected by this disease) to understand rather than talking in terms of milliliters or even glassfuls.

TABLE 46.6 ✻ Foods High in Potassium

Food Group	Examples
Fruits	Bananas, peaches, prunes, raisins, oranges, and orange juice
Vegetables	Carrots, celery, lima beans, potatoes, collards, dandelion greens, spinach
Meat	Nuts, peanuts, red meat
Dairy products	Milk, whole or skim; low-sodium milk
Miscellaneous	Salt substitutes, chocolate and cocoa, bran

Parents need to weigh children daily to detect fluid accumulation (use the same scale with the child in the same clothing at the same time of day), and they also must measure intake and output accurately. If the child is hospitalized, taking pulse rate and blood pressure every 4 hours will help detect hypovolemia from excessive fluid shifts to interstitial tissue.

Nursing Diagnosis: Risk for impaired skin integrity related to edema

Outcome Evaluation: Child's skin is intact without erythema.

The edematous skin of children with nephrotic syndrome tends to break down easily, so they need frequent position changes while in bed. Check clothing to make certain that the elastic band at the waist of pajamas or other constricting parts is not tight. Soft gauze placed between skin surfaces, especially around the scrotum, tends to prevent skin irritation and breakdown. Edematous tissue does not heal well, so breaks in the skin easily become secondarily infected. The child who is not toilet-trained needs frequent diaper changes and thorough cleaning at each change to prevent skin breakdown in the diaper area.

Generally, children are more comfortable if they sleep with their head elevated in a semi-Fowler's position rather than a supine or prone position because this reduces periorbital edema. If children sleep in a head-flat position, edema can be so severe by morning that their eyes are swollen completely shut; their tongues are also swollen, so they cannot speak. At home, parents can provide a semi-Fowler's position by placing extra pillows on the child's bed or slipping a cardboard box under the head of the mattress to raise the end of the mattress.

Because medications are poorly absorbed from edematous skin areas, intramuscular (IM) injections should be kept to a minimum. Medication should be administered orally if possible (see Focus on Nursing Care Planning, Box 46.6).

Nursing Diagnosis: Knowledge deficit related to chronic illness

Outcome Evaluation: Parents describe course and nature of nephrosis and their role in care of child at home.

Parents often need support to manage children with a chronic illness at home. They need clear instructions about their responsibilities, including keeping their child free of infection, perhaps by limiting exposure to friends, and giving prednisone or oral diuretics and a potassium supplement. Review medication instructions with parents and have them repeat the instructions. Make certain they understand where and when they are to return for a follow-up visit and make certain they have a telephone number to call if they have questions or concerns about their child's care or health.

What if... You need to give an IM injection to Carol, who has extensive dependent edema from nephrotic syndrome? Would it be best to give it in a thigh or deltoid muscle, and why?

BOX 46.6 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Child With Nephrotic Syndrome

Carol is a 4-year-old girl admitted to the hospital with nephrotic syndrome. She has marked ascites and edema. "I kept asking everyone how she could be gaining so much weight, yet she doesn't eat anything," her grandmother tells you. "My daughter said this happened because Carol drank part of a beer I left on the coffee table. I didn't give her the beer; she just picked it up and drank it. Do you think that's what caused this?"

Family Assessment ✻ Child lives with grandparents in a trailer park while mother is incarcerated on a drug charge. Grandparents are both retired. Grandfather rates finances as, "Okay. I saved some money and we both get Social Security."

Client Assessment ✻ Child began "gaining weight" and becoming irritable a week ago. Yesterday, her face appeared "very puffy." Appetite has declined sharply in last 2 weeks. States she's "always full." Marked dependent edema (4+ over tibia) present. Urine tested and found to be 4+ for protein.

Nursing Diagnosis ✻ Excess fluid volume related to decreased kidney function and fluid accumulation

Outcome Criteria ✻ Child's edema decreases; urine proteinuria is less than 2+.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Assess whether child is able to carry out routine activities with ascites or edema.	Review with grandparents advantage of allowing child to continue usual activities.	Child's mobility may interfere with physical tasks; other children may make fun of her appearance at nursery school.	Child and grandparents state that child can continue with usual activities.
		Consultations		
Physician	Assess whether grandparents have legal guardianship for child and can give permission for health care.	Contact renal service and suggest child be admitted to service for evaluation.	Nephrotic syndrome is a chronic disorder that requires conscientious, specialized health supervision.	Grandparents state they have or will obtain legal guardianship; renal service personnel meet with child and grandparents for consultation.
		Procedures/Medications		
Nurse	Assess if child has experience with oral medication.	Administer oral prednisone as prescribed.	Prednisone, a corticosteroid, reduces immune response and proteinuria.	Child accepts oral prednisone and helps make out reminder sheet.
Nurse	Assess if grandparents have experience with dipstick urine testing and 24-hour urine collection.	Observe grandparents' technique for dipstick urine testing and urine collection and recording results.	Testing for protein in urine will reveal extent of protein loss.	Grandparents state they feel able to test and collect urine conscientiously and record results in diary.
		Nutrition		
Nurse/ nutritionist	Assess child's typical food intake for last 24 hours.	Suggest grandmother monitor child's intake to be certain it includes all food groups daily.	Ascites crowds stomach, so it can give a feeling of fullness and cause undernutrition.	Child describes yesterday's intake; grandmother voices intent to supervise child's intake to be certain it is nutritious.

(continued)

BOX 46.6 ✻ Focus on Nursing Care Planning (continued)

		Patient/Family Education		
Nurse	Assess grandparents' knowledge about kidney function and kidney disease.	Teach grandparents about kidney function and disease process as needed.	Understanding disease process can help grandparents to better carry out therapy.	Grandparents state they understand why edema has occurred and describe action of medicine to reverse this.
		Psychosocial/Spiritual/Emotional Needs		
Nurse	Assess whether grandparents are having childrearing concerns.	Review natural inquisitiveness of preschool children, which can lead them into unsafe areas.	Grandparent states she didn't supervise child well so child drank beer off coffee table.	Grandparent states that although caring for a preschooler is difficult, she feels adequate to give care.
		Discharge Planning		
Nurse	Assess if grandparents have transportation to return for follow-up appointment.	Schedule return appointment for 1 week at kidney clinic.	As nephrotic syndrome is a long-term disorder, child will need continued follow-up for years to come.	Grandparents state they are aware of long-term nature of disorder and will keep follow-up appointments.

Henoch-Schönlein Syndrome Nephritis

Henoch-Schönlein purpura is discussed in Chapter 44. Approximately one quarter of the children who develop this type of purpura develop renal disease as a secondary complication. The renal involvement becomes apparent within a few days after the manifestations of purpuric symptoms. Children may show only urinary abnormalities such as proteinuria or may have a rapidly progressing glomerulonephritis. Fortunately, most children recover completely. Only a few develop chronic symptoms, but in those who do, long-term kidney disease can develop (Ambruso, Hays, & Goldenberg, 2008).

Systemic Lupus Erythematosus

SLE is an autoimmune disease in which autoantibodies and antigens cause deposits of complement in the kidney glomerulus (see Chapter 20). Because of this, some children with SLE develop symptoms of acute or chronic glomerulonephritis, the ultimate cause of death in many adults with SLE (Hellmann & Imboden, 2009). Therapy with corticosteroids or cytotoxic agents may be effective. If kidney transplantation is required, the same damage rarely occurs in the transplanted kidney.

Hemolytic-Uremic Syndrome

With hemolytic-uremic syndrome, the lining of glomerular arterioles becomes inflamed, swollen, and occluded with particles of platelets and fibrin. The child's red blood cells and platelets are damaged as they flow through the partially occluded blood vessels. As the damaged cells reach the spleen, they are destroyed by the spleen and removed from circulation. This leads to hemolytic anemia.

Ninety percent of children who develop this syndrome have recently experienced an *E. coli* GI infection. The most likely source of the *E. coli* is undercooked hamburger, because *E. coli* is found in the intestine of beef cattle. It occurs more frequently in infants who have their initial *E. coli* infection treated with an antibiotic than those who are not treated (Raffaelli et al., 2007).

Assessment

The syndrome occurs most often during the summer and in children 6 months to 4 years of age. Children usually develop only a transient diarrhea, although this can progress to severe fluid loss and bowel wall necrosis. Fever may be so elevated that the child experiences stupor and hallucinations. Oliguria accompanied by proteinuria, hematuria, and urinary casts in urine follows. The oliguria will lead to increased serum creatinine, BUN, and extensive edema. Children appear pale from anemia; easy bruising or petechiae may be present from *thrombocytopenia* (reduced platelet level). Laboratory studies will show fibrin split products in the serum as the fibrin deposits in glomerular vessels are degraded. Thrombocytopenia is present because platelets are damaged by the irregular blood vessels. An increased reticulocyte count indicates that red blood cells are rapidly being replaced.

Therapeutic Management

The child needs supportive therapy to maintain kidney and heart function. The extreme oliguria can be treated with peritoneal dialysis; anemia can be corrected by careful transfusion of packed red cells. Peritoneal dialysis can be extremely frightening to parents and the child because it involves penetration of the child's abdomen. Be certain they understand that the actual dialysis procedure is not painful and they can hold the child during infusion.

Ensure that parents understand the importance of follow-up care and have an appointment for this. Help them begin

to view the child as well again so they do not continue to shelter the child unnecessarily but allow for normal growth and development.

Despite the extent of the illness, most infants with hemolytic-uremic syndrome recover completely. Some children, however, die of the acute illness or continue to have chronic renal involvement.

Acute Renal Failure

Renal failure occurs in either an acute or chronic form. The acute form most often occurs because of a sudden body insult, such as severe dehydration. The chronic form results from extensive kidney disease, such as hemolytic-uremic syndrome or glomerulonephritis (Reddy & Murra, 2009).

Other causes of acute renal failure include prolonged anesthesia, hemorrhage, shock, severe diarrhea, or sudden traumatic injury. It also can occur in children who are placed on cardiopulmonary bypass while undergoing heart surgery, who receive common antibiotics (aminoglycosides, penicillin, cephalosporins, and sulfonamides), who swallow a poison such as arsenic (found in rat poison), or who are exposed to industrial wastes such as mercury. All of these conditions appear to lead to renal ischemia, which ultimately leads to acute renal failure.

Assessment

One of the first symptoms noted with acute renal failure is *oliguria,* a urine output of less than 1 mL/kg of the child's body weight/hour. An indwelling urinary catheter may be inserted to rule out the possibility that urinary retention in the bladder rather than kidney dysfunction is causing the severe oliguria.

Azotemia (accumulation of nitrogen waste in the bloodstream) will occur because of the oliguria. *Uremia* (extra accumulation of nitrogen wastes in the blood, with additional toxic symptoms such as cerebral irritation) also may occur. The BUN rises progressively as renal insufficiency continues and the breakdown products of protein cannot be excreted. A BUN level greater than 80 to 100 mg/100 mL is toxic and needs correction, usually by dialysis. Urine creatinine is another measure that can be used as an indicator of function, because it is normally excreted at a uniform rate. A rate of less than 10 mg/100 mL indicates severe renal failure. As the kidneys become unable to dilute or concentrate urine, the specific gravity of urine often becomes "fixed" at 1.010.

Hyperkalemia (elevated potassium level) may occur if potassium cannot be excreted. Hyperkalemia is manifested by a weak, irregular pulse, abdominal cramps, lowered blood pressure, and muscle weakness. Acidosis will follow shortly with acute renal failure from the inability of H^+ ions to be excreted. As total output decreases, phosphorus levels will rise in the bloodstream. A high serum phosphorus level leads to a low calcium serum level (recall that phosphorus and calcium have an inverse proportional relationship). Severe hypocalcemia can lead to muscle twitching and seizures (*tetany*); chronic hypocalcemia can lead to withdrawal of calcium from bones (*osteodystrophy*).

An IVP or radioactive uptake scan may be ordered to substantiate the lack of kidney function. Parents and children need support for this type of study, because the results may be disappointing and so different from what they hoped they would be.

Therapeutic Management

Because acute renal failure is a reaction to body stress caused by acute disease or insult, attempts to treat it focus on supporting the child's body systems while correcting the underlying condition. If the child is dehydrated (as with diarrhea or hemorrhage), IV fluid is needed to replace plasma volume. Administer such fluid slowly enough to avoid heart failure; extra fluid cannot be removed by the kidneys because they are not functioning. The fluid should not contain potassium until it is established that kidney function is adequate; buildup of potassium may otherwise cause heart block. Potassium levels greater than 6 mEq/L are corrected by the IV administration of calcium gluconate (as the glucose moves into cells, it carries potassium with it), by the oral administration of a cation exchange resin such as Kayexalate, or by dialysis. Administering sodium bicarbonate may cause a shift of potassium from the bloodstream into cells, temporarily reducing the circulating potassium level. Administration of a combination of IV glucose and insulin may also be effective (insulin helps glucose move into cells).

A diuretic such as furosemide (Lasix) may be ordered in an attempt to increase urine production. Diet should be low in protein, potassium, and sodium and high in carbohydrate to supply enough calories for metabolism yet limit urea production and control serum potassium levels. Fluid intake may be limited to prevent heart failure due to accumulating fluid that cannot be excreted. Weigh children daily (same scale, same clothing, same time of day) and maintain accurate intake and output recordings to evaluate fluid status. If children are so ill that they cannot eat, total parenteral nutrition may be necessary. Regulate amounts carefully to prevent fluid overload (see Chapter 37 for administration techniques).

When recovery from acute renal failure begins, children generally have a degree of diuresis as the extra fluid accumulated by the body is cleared. The increase in urine must be noted, because children may need additional fluid intake at this point to prevent hypovolemia, which could lead once more to renal failure. Parents usually remain anxious for an extended period after an episode of acute renal failure because they fear that the restoration of kidney function is only temporary. Reassure them that urine output is remaining at a normal level. This helps them to relax and interact effectively with their child.

Chronic Renal Failure

Chronic renal failure results from developmental abnormalities, when acute failure becomes long term, or when chronic kidney disease has caused extensive nephron destruction (Lum, 2008). The nephrons that are not destroyed by long-term disease appear to function normally; they simply are inadequate in number to sustain kidney function. Glomeruli can adjust so that kidney functions continue normally until 50% of nephrons are destroyed. After this point, kidney function diminishes by degrees until the child develops end-stage kidney disease, where the kidneys cannot maintain normal function.

Assessment

With loss of nephron function, kidneys cannot concentrate urine. This results in polyuria, possibly manifested as enuresis.

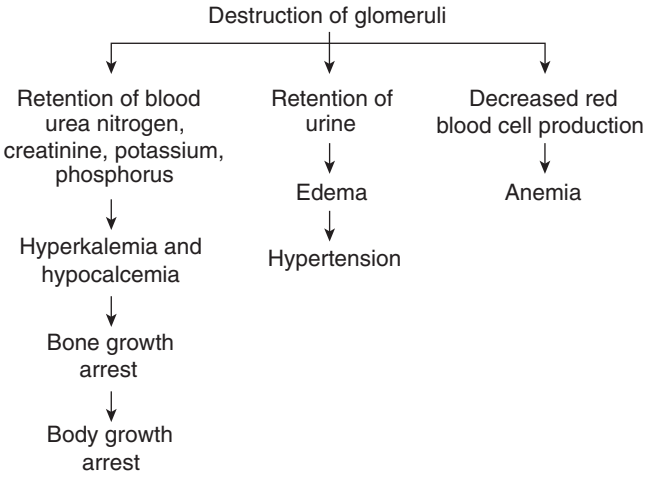

FIGURE 46.14 Pathology of chronic renal failure.

The few functioning nephrons present cannot reabsorb enough sodium to maintain a functioning level of body fluid, so dehydration occurs. As additional nephrons are lost, oliguria and anuria occur. Inability to excrete H^+ ions leads to acidosis. Hypocalcemia and hyperphosphatemia occur from the kidney's inability to excrete phosphate. Osteodystrophy occurs as calcium is withdrawn from bones to compensate. Kidneys are responsible for synthesizing vitamin D to its active form. With poor kidney function, vitamin D cannot be used. Without this, calcium cannot be absorbed from the GI tract and deposited in bones. Bones become so calcium depleted that growth halts and the bones lose strength (renal rickets).

Erythropoietin, formed by the kidneys, stimulates red cell production. With decreased erythropoietin production, anemia develops. Pruritus may be present from skin irritation due to excretion of nitrogenous wastes in sweat from high levels of BUN and serum creatinine. These changes are summarized in Fig. 46.14.

Therapeutic Management

Children with chronic renal failure are generally placed on a low-protein, low-phosphorus, low-potassium diet to prevent rapid urea and phosphate buildup. Children may take aluminum hydroxide gel with meals to bind phosphorus in the intestines and prevent absorption. Milk usually is not given because it is high in sodium, potassium, and phosphate—electrolytes children may have difficulty clearing. Meat is restricted and even beans are high enough in protein to be eliminated from the diet. This can be difficult for parents and children to understand because they are taught that meats are high in protein but vegetables are not. Letting children have some choice about what foods they eat each day helps to promote adjustment to this restricted diet. Whoever prepares meals needs good instructions on selecting low-protein foods. Low-electrolyte, low-protein formulas are commercially available for infants with renal failure.

Total daily fluid intake may need to be restricted, although restriction should be as minimal as possible or it can present an area of tremendous conflict between the child and parents. Many children need sodium intake restricted, and others need a normal sodium intake (but no excessively salty foods such as lunch meats, potato chips, or pretzels). Other children may actually need additional salt because, due to poor tubular reabsorption, they dump sodium in urine. Low-sodium formulas such as Lonalac are recommended for children with heart failure who need a low-sodium intake. Use them cautiously in children with renal insufficiency, because their high potassium content can lead to toxic potassium blood levels. Diuretics may be ordered to help children regulate sodium and fluid levels and prevent edema.

As renal failure becomes prolonged, a child may need supplemental calcium to prevent muscle cramping, rickets, tetany, or seizures. As hypertension becomes more and more acute from the accumulating blood volume, a daily antihypertensive drug may be prescribed. A blood transfusion may be needed to correct anemia, but it must be given cautiously so volume overload does not occur. Recombinant human erythropoietin may be prescribed to stimulate red blood cell formation. Effective excretion of urea can be accomplished by dialysis or by replacing the nonfunctioning kidneys with kidney transplantation. Growth hormone may increase height in some children who have fallen behind in stature (Vimalachandra et al., 2009).

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for interrupted family processes related to chronically ill family member

Outcome Evaluation: Family members express feelings about illness to each other and to health care providers; participate in care of ill member.

Children with renal failure grow poorly because of the alteration in calcium metabolism. It is easy for them to become depressed because of chronic fatigue and an unappetizing diet. If children are taking corticosteroids or other immunosuppressive drugs because of glomerulonephritis, they may be angry or disheartened about their change in appearance. Help them stay as active as possible by doing age-appropriate activities.

Caring for a child with chronic renal disease is not only time-consuming but also financially and socially devastating for parents. Parents caring for such children at home need opportunities at periodic health assessments to voice their frustrations, fears, and anxieties. They need time to do those things important to them as individuals, whether taking a weekend trip or attending an evening show or program. Ask parents at clinic or follow-up visits, "Do you ever get out of the house or have the opportunity to do anything for yourself?" "What can we do for *you*?" Help of this kind ultimately improves children's care, because it improves the lives and mental attitudes of those around them.

KIDNEY TRANSPLANTATION

The ultimate possibility for prolonging the life of children with renal failure is kidney transplantation. With complete renal failure, children who have extensive hypertension may

have their damaged kidneys removed and may be placed on hemodialysis or CCPD to await kidney transplantation. Kidney removal this way is an important step for parents and the child. Although parents realize that their child's kidneys are no longer functioning, this step removes all hope that a miracle might happen and make them function once more. Parents may ask whether it is possible to leave one of the child's kidneys, because only one kidney will be transplanted (this is not recommended, because the hypertension would continue). Parents need a thorough explanation of why hypertension is destructive, that is, it could lead to cerebrovascular accident or coronary artery disease. They must understand that renal biopsy shows that, short of a miracle, their child's kidneys will not function again, so that removal of them is not a loss but only recognition of a loss.

Preoperative Care

Kidney transplantation is most effective (the kidney is less likely to be rejected) if the kidney is taken from a living twin, parent, or sibling (Lim, 2007). In these instances, the success rate is as high as 90% (Chan et al., 2007). Rejection occurs at a higher incidence if a kidney comes from a cadaver or recently deceased child. Most people consider that children should be of legal age to give consent to supply a kidney for transplantation, so few children have a sibling who is eligible to donate a kidney. Tissue studies done to determine the best donor (matched for human leukocyte antigens [HLA]) may show that the person in a family most willing to donate a kidney is not the best person in terms of tissue compatibility. This can cause bitterness and hopelessness in the family, compounding an already stressed family life. Many children anticipate that the characteristics of the donor will be transmitted to them by the kidney, so they are reluctant to accept the kidney of a family member with a character trait they do not like (perhaps a bad temper). They need to be assured that transplanted organs do not carry this type of problem with them. Adult-sized kidneys may be transplanted into children, although if the child weighs less than 10 kg, a kidney this large may lead to hypertension, excessive diuresis, and abdominal complications because of the lack of space. Transplanted kidneys are placed in the abdomen, not the usual kidney space.

People who cannot donate a kidney include those with multiple bilateral small renal arteries, bilateral renal disease, renal infection, advanced medical illness, severe obesity, or hypertension. Although kidney removal can be done by laparoscopy, donors must understand that removal of a kidney involves major surgery. Tests that kidney donors can expect to have preoperatively include HLA typing, electrolyte blood analysis, complete blood count, bleeding time, urinalysis and urine culture, 24-hour urine sample for protein, a renal arteriogram, and IV pyelography. They will have urine samples collected after surgery to assess that their remaining kidney is capable of maintaining full function and they are still in good health.

Before surgery, children who are to receive a transplant may be dialyzed to clear their body of excessive potassium and fluid. If the donated kidney will be from a relative, there is adequate time for thorough preoperative preparation. If the donor kidney is from a cadaver, the announcement of surgery will be sudden and time for preoperative instruction and procedures may be limited.

Children who receive pretransplantation blood transfusions have an improved chance of transplant success (Suthanthiran, Hartono, & Strom, 2007). Most children, therefore, receive at least five blood transfusions while awaiting surgery. The mechanisms by which this operates are unclear, but transfusion-induced production of antibodies or immune complexes appears to mediate graft survival.

Human Leukocyte Antigen Typing

HLAs are a group of antigens found on the surfaces of all cells with a nucleus, including blood components such as leukocytes and platelets. The name is derived from the fact that they were first identified on white blood cells. Such antigens are inherited from both parents and are specific for each individual. They denote tissue type or determine which tissue the immune system identifies as foreign tissue. They are carried on the short arm of chromosome 6 in each cell.

Such antigens also serve as the basis for paternity typing. They may cause reactions to blood product transfusions and bone marrow and organ transplants. When two people have like HLA antigens, they are said to be *histocompatible.* Identical twins have complete histocompatibility and family members have partial histocompatibility; any two people can have histocompatibility at least on one antigen site.

Children who are awaiting kidney transplantation are tissue typed, and this information is circulated to major medical centers. When a kidney is available for transplantation, the child's tissue type is compared with the donor kidney. For tissue typing, lymphocytes from both a donor and recipient are grown together in a culture medium and then examined for like characteristics. With new immune suppressive drugs, however, even unmatched donor kidneys have a chance to successfully graft.

Postoperative Care

After renal transplantation, children are cared for in an environment that is as sterile as possible. They are placed on immunosuppressive therapy such as cyclosporine, azathioprine [Imuran], and methylprednisolone [Solu-Medrol]) to reduce the possibility of kidney rejection. Antilymphocyte globulin and antithymocyte globulin may be added to aid immunosuppression.

Although some transplanted kidneys begin to function immediately, hemodialysis may be continued until the implanted kidney can fully function after the insult of transplantation. Be prepared to help a child and parents through a "honeymoon" period after the transplantation.

Help children understand that acceptance or rejection of a kidney depends on a multitude of factors—the condition of renal veins and arteries, the transplanted kidney, or antigen–antibody formation—but none of these factors is related to whether the child is good or bad or deserves or does not deserve to have the transplantation work (Box 46.7).

Children with end-stage renal disease usually fail to grow despite treatment. Although the rate of growth is improved after kidney transplantation, they will probably never reach full height. Part of this growth restriction is related to the need for corticosteroid maintenance therapy to continue immunosuppression.

BOX 46.7 ✻ Focus on Communication

Carol's grandmother tells you Carol has "changed completely" since she became ill.

Less Effective Communication

Nurse: Mrs. Hendricks, in what way has Carol changed?
Mrs. Hendricks: She used to whine all the time, and constantly ask for things. Now she entertains herself. It's like heaven.
Nurse: That sounds wonderful. Let's review her medicine routine to be sure that's going well.
Mrs. Hendricks: That's another thing she does perfectly: never fusses a bit about anything she has to take.

More Effective Communication

Nurse: Mrs. Hendricks, in what way has Carol changed?
Mrs. Hendricks: She used to whine all the time, and constantly ask for things. Now she entertains herself. It's like heaven.
Nurse: Do you think she's acting a little too perfect?
Mrs. Hendricks: Well, it does seem a bit strange for her.
Nurse: Do you think she could be worrying that if she misbehaves, her medicine won't work?
Mrs. Hendricks: I never thought of that. I would feel better if she started to act like her old self.

What the grandmother above is describing is a "honeymoon" period that children may pass through after being told their kidneys are important for life. Parents often need help seeing this for what it is so they can begin to reassure children that behaving perfectly will not influence the outcome of their illness and that, because they loved them as they were, they will continue to love them regardless.

Transplant Rejection

Acute transplant rejection, if it occurs, usually develops within the first 3 months after transplantation. Children begin to develop fever, proteinuria, oliguria, weight gain, hypertension, and tenderness over the kidney. Serum creatinine and BUN levels will rise. Increasing the dose of immunosuppressants may be effective in relieving this type of rejection.

Rejection may also be *chronic,* in which the transplanted kidney gradually loses function after the first 6 months. Hypertension and anemia result. A biopsy will show vascular changes such as narrowing of arterial lumens and interstitial changes such as fibrosis and tubular atrophy. This type of rejection is difficult to halt, although it may be such a slow, steady process that it is 2 or 3 years before the kidney fails. If a kidney is rejected, it is removed and a child is returned to a program of hemodialysis. Because one kidney was rejected does not mean that a second transplant will be rejected also. Unfortunately, however, the number of kidneys available for transplantation is limited, so kidney rejection becomes an ominous sign for the child's long-term survival.

Malignant disease is more common in transplantation recipients than in the normal population, probably because of the long-term immunosuppression (Villeneuve et al., 2007). The original disease for which the child underwent transplantation may recur in the transplanted kidney. This is most apt to occur in glomerulonephritis. During adolescence, typically an age of poor adherence to medication regimens, kidney recipients need to be followed closely to be certain they are taking their immunosuppressive therapy. Parents cannot help but overprotect the child; they worry that a rough-housing session with a sibling or playing a game such as baseball may injure the transplanted kidney. The child may be afraid to engage in any activity for the same reason unless you help a family fully adjust to this major life change.

✔ Checkpoint Question 46.5

How would you best explain kidney transplantation to a child?

a. A new kidney will be placed in your abdomen.
b. The new kidney will be placed in your bladder.
c. You must never eat eggs after a kidney transplant.
d. Your urine will be brown for the rest of your life.

Key Points for Review

- Many urinary tract disorders, such as polycystic kidneys, urethral obstruction, and bladder exstrophy, are evident on a fetal ultrasound. Early identification this way allows therapy to begin in utero or immediately at birth.
- Many urinary tract disorders, such as polycystic kidneys or chronic renal failure, are long-term conditions requiring years of therapy. Be certain that parents are well informed about their child's condition so they can continue to participate in planning their child's care.
- Congenital structural abnormalities of the urinary tract include patent urachus, exstrophy of the bladder, hypospadias, and epispadias. Surgical correction is required for all of these.
- Urinary tract infection tends to occur more often in girls than boys. "Honeymoon cystitis" refers to a urinary tract infection occurring with first-time sexual intercourse.
- Vesicoureteral reflux is the backflow of urine into ureters with voiding. It occurs because the valve that guards the entrance to the ureters is lax or misplaced. Surgical correction may be necessary to prevent repeated urinary tract infection.
- Kidney dysfunction can occur for structural reasons such as kidney agenesis, polycystic kidney, and renal hypoplasia.
- Acute poststreptococcal glomerulonephritis is inflammation of the glomeruli after a streptococcal infection. It is characterized by an acute episode of hematuria and proteinuria.
- Nephrotic syndrome is an immunologic process that results in altered glomerular permeability.
- Diminished kidney function leads to both fluid and electrolyte imbalances. Creative techniques are necessary to encourage children to continue to ingest a restricted-protein diet.

- Renal failure can be acute or chronic. Peritoneal dialysis or hemodialysis may be used to remove body wastes until kidney function can be restored.
- Kidney transplantation may be an option for some children with kidney disorders. This is extensive surgery and requires the child to remain on immunosuppressive therapy to counteract transplant rejection.

CRITICAL THINKING EXERCISES

1. Carol is the preschooler with nephrotic syndrome whom you met at the beginning of the chapter. Her grandmother asked you whether a sip of beer could have caused Carol's kidney disease. What would you tell her is the cause of nephrosis? What discharge instructions can you anticipate you will need to review with Carol's grandmother?
2. Carol's grandmother is afraid Carol will need a kidney transplant. Carol tells you she hopes she has been good enough to deserve being chosen for a transplant. What would you want to teach this family about the transplantation selection process?
3. Suppose Carol receives continuous ambulatory peritoneal dialysis and wants to go to her church camp this summer. Her grandmother asks you whether this would be a good experience for her. What factors would you want to know about the camp? About Carol? About her procedure?
4. Examine the National Health Goals related to renal disorders and children. Most government-sponsored funds for nursing research are allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to Carol's family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to renal or urinary tract disorders in children. Confirm your answers are correct by reading the rationales.

Chapter 47

Nursing Care of a Family When a Child Has a Reproductive Disorder

KEY TERMS

- amenorrhea
- anovulatory
- cryptorchidism
- dysmenorrhea
- endometriosis
- fibrocystic breast disease
- gynecomastia
- hermaphrodite
- hydrocele
- menorrhagia
- metrorrhagia
- mittelschmerz
- orchiectomy
- orchiopexy
- pelvic inflammatory disease (PID)
- premenstrual dysphoric disorder
- pseudohermaphrodite
- sexually transmitted infection (STI)
- toxic shock syndrome
- varicocele
- vulvovaginitis

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe common reproductive disorders in children.
2. Identify National Health Goals related to reproductive disorders that nurses can help the nation achieve.
3. Analyze ways that nursing care for a child with a reproductive disorder can be more family centered.
4. Assess a child with a reproductive disorder.
5. Formulate nursing diagnoses for a child with a reproductive disorder.
6. Develop expected outcomes for a child with a reproductive disorder.
7. Plan nursing care related to reproductive disorders in children.
8. Implement nursing care for a child with a reproductive disorder, such as teaching about normal menstruation.
9. Evaluate expected outcomes for achievement and effectiveness of care.
10. Identify areas related to the care of children with reproductive disorders that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of reproductive disorders in children with the nursing process to achieve quality maternal and child health nursing care.

Navi is a 15-year-old girl you meet in a pediatric clinic. She has been diagnosed with gonorrhea because of a purulent vaginal discharge and burning on urination. When you ask her if she is sexually active, she says no; she thinks she contracted the infection from sharing a towel in a locker room. As she leaves the clinic, you hear her tell the receptionist, "I'm glad I got this early in life. Now I won't have to worry about getting it again."

Previous chapters described the growth and development of well children and illnesses that occur in other body systems. This chapter adds information about the dramatic changes, both physical and psychosocial, that occur when children develop reproductive disorders. Such information forms the basis for care and health teaching in this area.

What kind of health education does Navi need?

Reproductive disorders in children range from mild infections to serious anatomic malformations. All of these disorders require prompt and careful treatment so that children can reach adulthood in good reproductive health, with unaltered fertility, and with a positive sense of sexuality. Reproductive infections may suggest child abuse, so children with these also need careful assessment to rule out this possibility (see Chapter 55). National Health Goals related to reproductive disorders in children are highlighted in Box 47.1.

Nursing Process Overview

For Care of a Child With a Reproductive Disorder

Assessment

Assessment of reproductive health begins with the first physical examination at birth and continues at health assessments throughout childhood and adolescence. As this is a sensitive area for many people to discuss, parents may not be as comfortable inquiring about or describing disorders of the reproductive tract as they are about other disorders. Unless they have clear, thorough explanations of the disease process and prescribed therapy, their reluctance to pursue the subject may leave them confused or misinformed. Even young children can sense that illness affecting the genitalia or their reproductive tract is viewed by some adults as different from other diseases so may not ask as many questions as they do about other diseases.

Nursing Diagnosis

Nursing diagnoses formulated for reproductive illnesses in children focus not only on the result of the disease symptoms but on the anxiety this type of disorder can cause. Examples of nursing diagnoses are:

- Risk for infection transmission related to lack of knowledge of safer sex practices
- Pain related to symptoms of vaginal infection
- Disturbed body image related to fibrocystic breast disease
- Anxiety related to absence or irregularity of menstrual periods in adolescent
- Fear related to surgery on genital organs

Outcome Identification and Planning

Assessment of a child's knowledge about the reproductive system and ways that illness can affect reproductive and sexual functioning forms the foundation for developing appropriate outcomes. Educating the child about reproductive health may be one of the first areas to plan. When establishing expected outcomes with adolescents, work with them to establish a plan that will correlate with their schedules. Adolescents need to be involved in the decision making process.

Organizations helpful for referral for adolescents include the National Women's Health Network (http://www.womenshealthnetwork.org) and the National Adolescent Health Information Center (http://nahic.ucsf.edu).

Implementation

Interventions for children with reproductive disorders should always include education about reproductive functioning and measures for maintaining reproductive and sexual health and preventing illness. Health education regarding the importance of testicular self-examination for adolescent males should be stressed at health care visits (see Chapter 34). Guidelines for teaching about menstrual health and safer sex (covered in Chapter 5) are also important.

Essential nursing interventions also include supporting parents and children through difficult decisions and frightening procedures and providing close observation and empathic counseling after surgery. For example, surgery for undescended testes is a procedure that can be traumatic for a child, especially if it is performed during a developmental stage in which a boy views such surgery as castrating (a psychological reason in addition to a physical reason why it is done early in life). As all children with any reproductive disorder reach puberty, they need honest explanations about any effect such a condition will have on

BOX 47.1 ✻ Focus on National Health Goals

Because sexually transmitted infections (STIs) not only cause short-term distress as a result of painful lesions but also can have long-term implications for fertility and future childbearing, several National Health Goals specifically address them. These goals are:

- Reduce the proportion of adolescents with *Chlamydia trachomatis* infections from baselines of 12% (females) and 15% (males) to a target of 3%.
- Reduce the annual incidence of new cases of gonorrhea in adolescent females from a baseline of 279 cases per 100,000 people to no more than 42 cases per 100,000 people.
- Reduce the incidence of primary and secondary syphilis from a baseline of 3.2 per 100,000 people to no more than 0.2 case per 100,000 people.
- Reduce the incidence of congenital syphilis from a baseline of 28 per 100,000 live births to 1 per 100,000 live births.
- Reduce the incidence of genital herpes from a baseline of 17% to no more than 14%.
- Reduce the proportion of females with human papillomavirus infection (no target set as yet).
- Reduce the incidence of pelvic inflammatory disease among women aged 15 through 44 years from a baseline of 8% to no more than 5% (http://www.nih.gov).

Nurses can help the nation achieve these goals by educating adolescents about effective ways to prevent STIs and how to recognize the signs and symptoms of these illnesses. Areas that could benefit from additional nursing research and evidence-based practice in this area include the most effective ways to teach adolescents about safer sex practices, the reasons adolescents continue to believe that they cannot contract infectious diseases, and strategies that would make it easier for parents to discuss this topic with adolescents.

interpersonal relationships, sexual functioning, or childbearing.

Outcome Evaluation

The responses of children to reproductive dysfunction vary both with the severity of the illness and with the specific age and fears of the child. It is safe to assume, however, that children who have experienced such an illness are at risk for a loss of self-esteem or confusion about their body image. Therefore, outcome evaluation should include long-term evaluation of the child's coping abilities and self-image. If a child contracts a sexually transmitted infection (STI), evaluation should also address the child's knowledge about avoiding STIs in the future and willingness to seek help should an infection recur.

The following are examples suggesting achievement of outcomes:

- Adolescent states that discomfort from vaginal infection is tolerable after beginning medication.
- Adolescent states she is able to view self as competent despite fibrocystic breast disease.
- Child states that she is able to wait 6 months without worrying about not yet having a menstrual period.
- Child states that he feels less fearful about impending surgery after talking with his health care provider.

ASSESSING REPRODUCTIVE DISORDERS IN CHILDREN

Reproductive disorders in children may be congenital or acquired so assessment for these must be ongoing throughout childhood (Box 47.2) (Fitzgerald, 2009).

As with other parts of a health interview, questions regarding reproductive health and illness are generally addressed to the parents until the child is able to answer history questions reliably and independently. Once a girl has reached adolescence, a gynecologic history (Box 47.3) should be included in the health assessment. To preserve their privacy, adolescents of both genders may prefer not to be accompanied by a parent during a physical examination for reproductive dysfunction.

Some adolescents visit health care facilities on their own. They may be worried that they have contracted an STI. They may suspect that they have become pregnant or want to receive some form of contraception. Before they can admit their chief concern, however, they may "test" a health care provider by eliciting a reaction to a minor problem. Be aware that an adolescent who consults a health care provider with a seemingly minor concern may be misinterpreting symptoms and be truly worried that a minor symptom is serious; on the other hand, the adolescent actually may be seeking help for another problem. Asking the adolescent, "Is there anything else that worries you? Is there any other way we can help you today?" may help you elicit the adolescent's primary concern (Box 47.4).

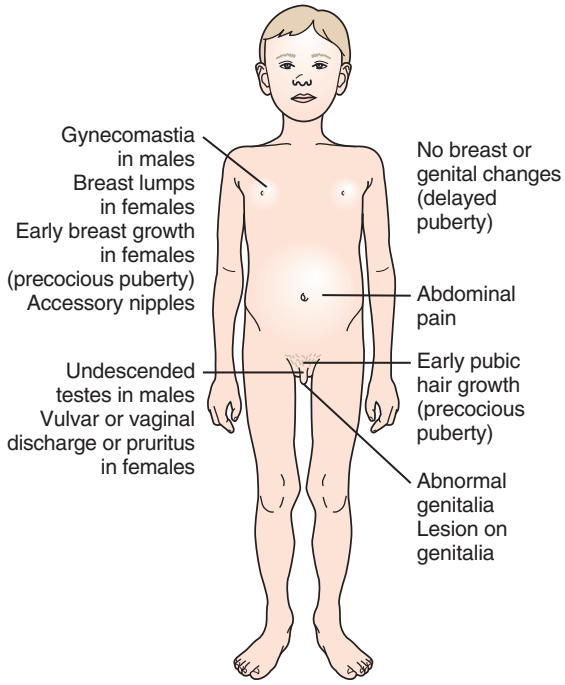
A pelvic examination is unnecessary for girls who have not yet reached adolescence. However, if vaginal walls need to be inspected (because of an inflammation or infection or the suspicion of sexual abuse), an otoscope and ear tip can be used in place of a speculum. Cotton-tipped applicators can be used to take culture specimens without causing discomfort.

For the adolescent girl, the pelvic examination becomes part of routine health care around the age of 18 to 20 years if the teen is not sexually active and is not having problems. Because the first pelvic examination can be stressful for some teens, spend time with the girl before the procedure to teach her about what is being assessed. A three-dimensional model of internal organs and some representative instruments may be more useful when describing the examination than a verbal description of anatomy. A small speculum should be used for examining young girls. For their comfort, warm the speculum first. Let the girl look at and handle a speculum before it is used.

Remaining beside an adolescent as a support person helps to reduce the stress the teen may be experiencing. To protect her self-esteem, be sure a girl meets the person who will examine her before she is placed in a lithotomy position. Different cultures have different attitudes toward reproductive disorders. Adolescents in Middle Eastern countries, for example, are extremely modest, and so they are extremely uncomfortable having pelvic examinations done for reproductive disorders. Girls from these countries may be more comfortable if the examiner is a woman.

A young adolescent may be uncomfortable in a lithotomy position and can be examined in a dorsal recumbent position instead (see Chapter 11 for information on assisting with a pelvic examination). Allow an adolescent to choose whether she wants a parent to remain in the room with her.

Box 47.2 Assessment
Assessing a Child with a Reproductive Disorder



BOX 47.3 ✻ Taking a Gynecologic History

When assessing an adolescent for a gynecologic health history, be especially conscious of an adolescent's sense of modesty and need for privacy. To ensure privacy, conduct the interview without the parent or caregiver present.

Menstrual History

At what age did you begin menstruating?
How often do your menstrual periods occur and how long do they usually last?
What is the amount of menstrual flow? (Document by number of pads or tampons used.)
Do you experience discomfort? (Document if discomfort occurs on first day, all days, and so forth, and action taken to relieve it.)
Do any sisters or your mother have discomfort or pain during their menstrual periods (dysmenorrhea) also (endometriosis is familial)?
Do you experience any symptoms of irritability, moodiness, headache, or diarrhea (premenstrual dysphoric disorder) 1 or 2 days before menses?
What were the dates of your last two menstrual periods? How long did they last (duration)? Was the flow light or heavy?

Reproductive Tract History

Have you had any vaginal discharge? (Document amount and whether pad is necessary—include duration, frequency, description, associated symptoms, actions taken.)
Is there vaginal itching (pruritus)?
Is there any vaginal odor?
Have you had reproductive tract surgery? Have you ever been pregnant? Have you ever had an abortion or miscarriage?

Sexual History

Have you had a sexually transmitted infection such as herpes, gonorrhea, or syphilis?
Are you currently sexually active? What is the gender of your partner?
Do you experience any discomfort during sexual activity (dyspareunia) or any spotting afterward (postcoital spotting)?
Do you have any concerns such as being worried about frequency, position, partner's satisfaction with coitus? Do you experience orgasm?

Contraception History

Do you use any type of birth control? If so, what contraceptive do you use? (Document length of time used, satisfaction, any problems.)
Have you used any other type in the past?

Breast Health

Have you ever noticed any abnormality such as a lump, discharge, or pain in your breasts?
Have you ever had breast surgery?
Have you breastfed a child?
Do you have a yearly breast examination by a health care provider?

BOX 47.4 ✻ Focus on Communication

Navi, age 15 years, is seen at your pediatric clinic. She has mild upper respiratory tract symptoms.

Less Effective Communication

Nurse: Navi? Doctor Jensen doesn't believe you need anything for your cold. Just drink a little extra fluid and take it easy for a couple days.
Navi: Don't I need a prescription? Some penicillin or something?
Nurse: No. Colds are caused by viruses. Penicillin isn't necessary.
Navi: I want to be sure I get over this. I'd really like an antibiotic of some kind.
Nurse: One really isn't necessary.
Navi: I have a bad cough. I don't think I mentioned that.
Nurse: Doctor Jensen listened to your chest. You don't have anything serious there.
Navi: My stomach doesn't feel very good either. Can't I have something?
Nurse: Sorry. Goodbye now.

More Effective Communication

Nurse: Navi? Doctor Jensen doesn't believe you need anything for your cold. Just drink a little extra fluid and take it easy for a couple days.
Navi: Don't I need a prescription? Some penicillin or something?
Nurse: No. Colds are caused by viruses. Penicillin isn't necessary.
Navi: I want to be sure I get over this. I'd really like an antibiotic of some kind.
Nurse: One really isn't necessary.
Navi: I have a bad cough. I don't think I mentioned that.
Nurse: Doctor Jensen listened to your chest. You don't have anything serious there.
Navi: My stomach doesn't feel very good either. Can't I have something?
Nurse: It seems that you have more symptoms than you mentioned. Are you worried about something other than cold symptoms?
Navi: Well, I have this rash and . . .
Nurse: And . . . ? Go on . . .
Navi: And I'm scared I might have a sex disease.

Adolescents can have difficulty discussing reproductive tract symptoms. If they have too much difficulty, they can try to obtain an antibiotic by describing respiratory or abdominal symptoms. Being alert to this possibility helps you to recognize a "growing" history of this type.

HEALTH PROMOTION AND RISK MANAGEMENT

Newborns need a thorough examination at birth to rule out congenital reproductive disorders so these can be diagnosed and management can begin. All children need education about sexually healthy decisions and caring for their bodies. Adolescents may state they are not interested in this information because they are certain that they are choosing abstinence. It is still important to provide the education in regards to making sexually healthy decisions and reward positive choices to staying healthy.

DISORDERS CAUSED BY ALTERED REPRODUCTIVE DEVELOPMENT

Genetic sex or *biologic gender* (sex chromosomes XX or XY) is determined at conception. However, development of the reproductive system, including external genitalia, occurs over two distinct periods. Reproductive organs and genitalia begin to differentiate in utero by the 8th week, with growth and refinement occurring over the next several months. This period constitutes the first phase of reproductive development. The second phase occurs with specific endocrine changes that are triggered during puberty; this is a period of maturation of primary and secondary sexual characteristics.

Ambiguous genitalia, which is a rare condition with various causes that occurs during fetal development, and precocious puberty or delayed puberty, which are second phase disorders, are examples of altered reproductive development. (For a discussion of genetic disorders, see Chapter 7.)

Ambiguous Genitalia

Ambiguous genitalia refers to genitalia that are not clearly defined in a newborn (Gollu et al., 2007). Understanding how reproductive organs develop in utero is important to the understanding of why ambiguous genitalia occur. Although external sexual characteristics generally follow from the presence of the XX or XY chromosomes, under certain circumstances it is possible for structures usually considered "male" or "female" to develop in individuals of either chromosomal gender. Usually, a diagnosis of ambiguous genitalia means that external sexual organs in the child did not follow the normal course of development, so that, at birth, they are so incompletely or abnormally formed that it is impossible to clearly determine the child's gender by simple observation. For instance, a male infant with *hypospadias* (urethral opening on the underside of the penis) and cryptorchidism (undescended testes) may appear more female than male on first inspection (see Chapter 46 for a discussion of hypospadias). A chromosomal female (XX) fetus may become "masculinized" with exposure to androgen in utero; in such children, the clitoris may be so enlarged that it appears more like a penis, the labia may be partially fused and difficult to tell from a male perineum, or the urethra may be displaced so far forward that it is located on the clitoris. When this occurs, the newborn will appear to be a boy on initial inspection. Likewise, under certain conditions, a chromosomal male (XY) may become "feminized," with a lack of fusion of the labioscrotal folds and an incompletely formed penis.

The most common cause of in vitro virilization of females is *congenital adrenocortical syndrome.* The adrenal gland produces androgen instead of adequate cortisone, causing the clitoris to become the size of a typical newborn male's penis (see Chapter 48).

If testosterone was produced in utero but development of the müllerian duct (female) was not suppressed, a child may be intersexed (formerly termed **hermaphrodite**), with both ovaries and testes and either male or female external genitalia. Children with ambiguous genitalia are often termed pseudointersexed or **pseudohermaphrodites** because, as infants, they have some external features of both sexes, although only either ovaries or testes (or neither) are present.

Assessment

If there is any question about a child's gender, karyotyping helps to establish whether the child is genetically male or female (see Chapter 7). This involves drawing a specimen of blood, allowing the white blood cells to reach a division stage, and then examining them. *Laparoscopy* (introduction of a narrow laparoscope into the abdominal cavity through a half-inch incision under the umbilicus) or possibly exploratory surgery may be necessary to determine if ovaries or undescended testes are present. Intravenous pyelography or ultrasound can be used to establish whether a male has a complete urinary tract.

Therapeutic Management

Once the child's true chromosomal gender has been documented, the extent of necessary reconstructive surgery is determined in consultation with the parents. This may involve correction of a hypospadias or cryptorchidism, removal of labial adhesions, or surgical removal of an enlarged clitoris. If removal of an enlarged clitoris is involved, the parents must consider what the absence of this organ will mean to the girl in terms of later sexual enjoyment. Parents may be well advised to delay this type of surgery until the girl can decide for herself whether she wants it done (Verkauskas et al., 2007). If a vagina will be constructed, surgery for this is usually delayed until adolescence when growth is complete.

If an infant is chromosomally male but does not have an adequate penis, a decision to raise the child as a female might be made, although construction of an artificial penis is more likely. Nonfunctioning ovaries or testes are generally removed to prevent malignancy later in life.

Nursing Diagnoses and Related Interventions

When identifying expected outcomes, be aware that parents under stress may have difficulty making long-range plans. The birth of a child with a perplexing defect produces a particularly high level of stress, hampering parents' ability to think clearly and calmly about their situation.

Nursing Diagnosis: Anxiety related to ambiguous gender of child at birth

Outcome Evaluation: Parents voice willingness to support treatment plan, including additional necessary

tests, and state they are prepared to make decisions with guidance from health care team.

If the gender of a child is unclear, the parents should be told this immediately. If told first that their child is a boy, only to be told 24 hours later that "he" is really a girl, parents can have difficulty accepting this drastic change. During this period when the baby's gender is yet to be determined, avoid calling the baby "it." Rather, say "the baby" or "your child." Explain how sexual organs form in utero and that every child has the potential to be externally female or male.

To promote bonding, help parents understand that their child is otherwise perfect (assuming this is true). As the child grows, additional counseling may be needed to provide education about the congenital defect.

Precocious Puberty

Although development of breasts or pubic hair before age 8 years or menses before age 9 years may be just early maturation, such development has traditionally been considered precocious sexual development (Cesario & Hughes, 2007). Often, such development is limited to breast tissue or pubic hair growth but can proceed to complete secondary sex characteristics, spermatogenesis, or menstrual function. Precocious puberty occurs more often in girls than in boys (Carel & Leger, 2008).

This condition is caused by the early production of gonadotropins by the pituitary gland; gonadotropins stimulate the ovaries or testes to produce sex hormones. Such stimulation can occur because of a pituitary tumor, cyst, or traumatic injury to the third ventricle next to the pituitary gland. It also can occur because of estrogen-secreting cysts or tumors of the ovary or testosterone-secreting cysts of the testes. In rare instances, it occurs because of an estrogen- or testosterone-secreting adrenal tumor. In girls, ingestion of a mother's oral contraceptive pills can initiate menarche-like changes. Overstimulation by the enzyme aromatase which converts androgens into estrogens by a process called aromatization may be yet anther cause.

In children affected by precocious puberty, a tumor must be ruled out. If no physical cause, such as a tumor, is detected, the phenomenon appears to occur only because the *gonadostat* of the hypothalamus (the trigger that begins the development of secondary sex characteristics) was turned on several years too early. It is categorized as either central precocious puberty (gonadotropin-releasing hormone [GnRH]–dependent), in which gonadotrophic hormones are elevated, or as peripheral precocious puberty (Gn-RH–independent), which is basically elevation of sexual steroids produced by the gonads or adrenals.

Assessment

With precocious puberty, children have increased breast and genital development and accelerated skeletal maturation. Girls have menstrual bleeding with little pubic or axillary hair because of still low androgen secretion. Boys have obvious genital growth. The diagnosis of early puberty is confirmed by serum analysis for estrogen or androgen; these will be at adult levels.

BOX 47.5 ✻ Focus on Pharmacology

Leuprolide acetate (Lupron)

Classification: Leuprolide is a hormonal agent, specifically a luteinizing hormone-releasing hormone (LH-RH) agonist.

Action: Occupies pituitary gonadotropin-releasing hormone (GnRH) receptors, preventing GnRH from functioning (Karch, 2009).

Pregnancy Risk Category: X

Dosage: Daily subcutaneous (SQ) or monthly intramuscular (IM) injection

Possible Adverse Effects: Nausea, vomiting, anorexia, hot flashes, headache, pain at injection site

Nursing Implications

- Administer only with the syringes supplied with the drug.
- Vary injection sites to decrease local irritation.
- Monitor injection sites for bruising and rash.
- Instruct parents in method for proper administration.
- If monthly doses are prescribed, assist parents with preparing a realistic schedule for administration. Encourage the use of a calendar for accurate timing.

Therapeutic Management

A synthetic analog to GnRH is available as leuprolide acetate (Lupron) (Box 47.5). Administration of this analog desensitizes GnRH receptors, making stimulation by GnRH ineffective and halts sexual maturation at the point to which it has advanced (Nebesio & Eugster, 2007). The preparation is administered subcutaneously every day. After it is discontinued at age 12 or 13 years, puberty progresses normally. Therapy may also include use of aromatase inhibitors, which are able to block the enzyme aromatase and therefore decrease signs of estrogen effects (Shulman et al., 2008).

Nursing Diagnoses and Related Interventions ✻

Nursing Diagnosis: Disturbed body image related to precocious puberty

Outcome Evaluation: Child voices an understanding of what is happening and does not evidence excessive shyness or reluctance to interact with peers.

Children who develop precociously may have difficulty interacting with peers because they appear so different from other members of their age group. Parents may worry about children becoming sexually active, particularly about girls becoming pregnant. Both parents and children need reassurance that, after reaching the age of normal puberty, the child will maintain normal growth and development.

Parents must also understand that the child is fully fertile and able to inseminate or conceive when early

puberty occurs. Oral contraceptives are not advisable for girls this young, because the increased load of estrogen hastens the closing of epiphyseal lines of long bones too early, possibly stunting the child's growth permanently.

Parents may need to be reminded that, although their child appears to be much older, the changes are only in sexual characteristics. Household tasks, responsibility, and expectations must be geared to the child's chronologic age, not to outward appearance.

Delayed Puberty

Secondary sex characteristics normally are present by age 14 years in girls and 15 years in boys. Delayed puberty, as the name implies, is the failure of pubertal changes to occur at the usual age. The family history of many children reveals a family tendency for late maturation. If so, the child needs a thorough physical examination to disclose whether some secondary sex characteristics are present or whether endocrine stimulation is beginning.

If girls have not begun to menstruate by age 17 years and pathology has been ruled out, menstrual cycles can be initiated by administering estrogen. Many girls worry considerably about delayed menstruation, but, once reassured that development is merely delayed, they are usually willing to wait for menarche to occur on its own. Similarly, boys who are distressed by their lack of development may receive testosterone supplements to stimulate pubic hair and genital growth.

✔ Checkpoint Question 47.1

Suppose a school-age girl develops precocious puberty. What advice would you give her parents?

a. Excess estrogen causes children to be intersexed or hermaphrodites.
b. Although her sexual appearance is advanced, the girl cannot conceive.
c. Treat the child appropriately for her chronologic, not appearance, age.
d. To not allow the child to eat processed meats, which contain hormones.

REPRODUCTIVE DISORDERS IN MALES

Common reproductive disorders in males include structural alterations in the penis or testes such as phimosis and cryptorchidism, inflammation such as balanoposthitis, and, in adolescents, testicular cancer.

Balanitis (Balanoposthitis)

Balanoposthitis is inflammation of the glans and prepuce of the penis. It is usually caused by poor hygiene and may accompany a urethritis or a regional dermatitis.

Assessment

The prepuce and glans become red and swollen; a purulent discharge may be present. The boy may have difficulty voiding because of crusting at the meatal opening and because acidic urine touching the denuded surface of the glans causes pain (Hsieh, Chang, & Chang, 2007).

Therapeutic Management

Medical treatment involves local application of heat; this can be carried out with warm wet soaks or warm baths. A local antibiotic ointment may be prescribed. If *phimosis* (a tight foreskin) appears to be contributing to the condition, circumcision may be advocated after the inflammation subsides to prevent the condition from recurring.

Although balanoposthitis is painful, a boy may tolerate the discomfort for several days because he is too embarrassed to discuss the problem. He may think it was caused by masturbation (which can contribute to the irritation) or by sexual activity and may be reluctant to seek help for fear of being criticized. He can be reassured that the problem is local and will have no long-range effect. Any discharge should be cultured to rule out an STI such as gonorrhea. On the other hand, in developing countries where balanitis can become chronic because of lack of bathing or shower facilities, it may be associated with the development of penile cancer (Bunker, 2008).

Phimosis and Paraphimosis

Phimosis is the inability to retract the foreskin from the glans of the penis. The foreskin is tight at birth and may even be held fast by adhesions so cannot be retracted in newborns. After a few months, the adhesions dissolve and the foreskin becomes retractable; if it does not, the infant has phimosis. If a foreskin is extremely tight it can interfere with voiding. Balanoposthitis may develop because the foreskin cannot be retracted for cleaning. Circumcision of newborns (discussed in Chapter 18) is no longer routinely advised but is used to relieve phimosis (Johnson et al., 2007). Paraphimosis is the inability to replace the prepuce over the glans once it has been retracted. This is an emergency situation to address before circulation to the glans is impaired (Yigiter, Arda, & Hicsonmez, 2008).

Cryptorchidism

Cryptorchidism is failure of one or both testes to descend from the abdominal cavity into the scrotum (Kollin et al., 2007). Normally, the testes descend into the scrotal sac during months 7 to 9 of intrauterine life. They may descend any time up to 6 months after birth; they rarely descend after that time.

The cause of undescended testes is unclear. It may be associated with caffeine intake during pregnancy (Mongraw-Chaffin et al., 2008). Fibrous bands at the inguinal ring or inadequate length of spermatic vessels may prevent descent. Testes apparently descend because of stimulation by testosterone; hence, it is possible that a lower than normal level of testosterone production prevents descent. About 17% of premature infants and 3% to 4% of full-term infants are born with undescended testes.

Assessment

Early detection of undescended testes is important, because the warmth of the abdominal cavity may inhibit development of the testes, ultimately affecting spermatogenesis. After puberty, sperm production deteriorates rapidly in undescended testes,

and the testes may even undergo a malignant change (Walsh et al., 2007). Anchoring the testes in the scrotal sac may not prevent malignancy, but it will allow the boy to perform preventive measures such as testicular self-examination.

It is more common for the right testis to remain undescended than the left one. In approximately 20% of all boys, both testes remain undescended. Some boys may be diagnosed with undescended testes when, in fact, the testes have retracted and have made the palpation assessment difficult.

If the child is supine or the examining room is chilly, the scrotal sac may appear to be empty. Excessive palpation or stroking of the inner thigh may also stimulate the cremasteric reflex and cause retraction. In these instances, testes descend when the child is standing or after a warm bath.

An undescended testis may be at the inguinal ring (true undescended testis) or ectopic (still in the abdomen). Laparoscopy is effective in identifying undescended testes. Because testes arise from the same germ tissue as the kidneys, the kidney function of a child with ectopic testes is usually evaluated. If undescended testes and other factors such as ambiguous genitals pose questions about the child's gender, a *karyotype* may be done to determine true gender.

Therapeutic Management

Because the testes sometimes descend spontaneously during the first year of life, treatment is usually delayed for 6 to 12 months. Boys may be given chorionic gonadotropin hormone for about 5 days to stimulate testicular descent, but this therapy is successful only in approximately 25% of infants (Fitzgerald, 2009).

If necessary, surgery **(orchiopexy)** by laparoscopy by 1 year of age corrects the condition.

Nursing Diagnoses and Related Interventions

If an orchiopexy is scheduled, the focus is on parent and child teaching, preoperative preparation, and postoperative care.

Nursing Diagnosis: Deficient knowledge related to parents' and child's inexperience with surgical procedure and postoperative treatment plan

Outcome Evaluation: Parents (and child, if old enough) accurately describe what will be accomplished by surgery.

Boys who are old enough to understand need good preparation for this type of surgery. Use an anatomically correct picture to point out the exact site at which surgery will be performed. Reassure the boy that the penis itself will not be cut. The child may not voice a fear of mutilation, but you can assume that it exists, especially in preschool children.

During surgery, internal sutures may be inserted to hold the testis in place. Although the child may be discharged from the hospital on the same day, his activity will be limited until approximately the second day after surgery, to ensure that the internal suture line remains intact.

Nursing Diagnosis: Disturbed body image related to change in physical appearance

Outcome Evaluation: Child (if verbal) states that he views self as a whole person and interacts with peers without excessive shyness or hesitancy.

Postoperative evaluation should reveal that the suture line is healing well and that both testes can be palpated in the scrotum. It should also address the boy's feelings about the surgery and the changes in his body. He may need an opportunity to express his fears about mutilation or castration by playing with puppets or dolls after surgery. Even after a repair, boys who had bilateral cryptorchidism may be less fertile as adults. When boys reach puberty, teach them testicular self-examination to assess any early symptoms of malignancy, such as nodules or abnormal growth (see Chapter 34).

Hydrocele

When a testis descends into the scrotum in utero, it is preceded by a fold of tissue, the *processus vaginalis.* Occasionally, fluid collects in this fold. If this occurs, **hydrocele** (the fluid) can be revealed by prenatal ultrasound. At birth, the collection of fluid makes the scrotum of the newborn appear enlarged (Bouhadiba, Godbole, & Marven, 2007). On *transillumination* (the shining of a light through the scrotal sac), the area is illuminated by the water and shines or glows. Ultrasound also can reveal this fluid collection. If the hydrocele is uncomplicated, the fluid will gradually be reabsorbed and no treatment is necessary. The child's parents can be assured that the hydrocele is only excess fluid and that the scrotal enlargement is not caused by an abnormal testis, tumor, or hernia.

A hydrocele may form later in life due to *inguinal hernia* (abdominal contents extruding into the scrotum through the inguinal ring, with accompanying fluid). If this happens, the hernia must be repaired for the hydrocele to be reabsorbed (see Chapter 45). Injection of a drug to decrease fluid production (*sclerotherapy*) may also be effective.

Varicocele

A **varicocele** is abnormal dilation of the veins of the spermatic cord (Fig. 47.1). It is important to identify varicoceles in adolescents because although it may not cause a difference, the increased heat and congestion in the testicles could be a cause of subfertility (Zampieri et al., 2007). No treatment is necessary unless fertility becomes a concern, at which time the varicocele can be surgically removed. The adolescent may report some local tenderness and edema for a few days after surgery. Edema can be minimized by applying ice for the first few hours postoperatively.

Testicular Torsion

Testicular torsion (twisting of the spermatic cord) is a surgical emergency. Although it can be present in newborns, it occurs most frequently during early adolescence (Brown-Guttovz, 2007). Less than normal testicular support apparently allows the spermatic cord to twist. Testicular torsion

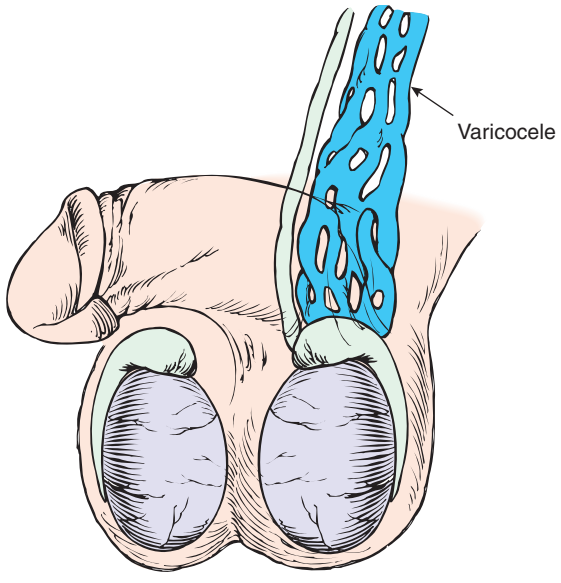


FIGURE 47.1 A varicocele. Identifying varicocele in adolescent males is important because the condition may be associated with subfertility.

usually results from a sports activity. The boy experiences severe scrotal pain and perhaps nausea and vomiting from the severity of the pain. The testis feels tender to palpation, and edema begins to develop. If the condition is not recognized promptly (within 4 hours), irreversible change in the testis can occur from lack of circulation to the organ. Boys need to be educated about the phenomenon so that they report symptoms promptly. The torsion can be reduced manually under ultrasound guidance (Park et al., 2007). Laparoscopic surgery, however, is usually necessary to reduce the torsion and re-establish circulation.

Testicular Cancer

Testicular cancer is rare (only 1% of all malignancies). It usually occurs between ages 15 and 35 years, often in association with cryptorchidism (Walsh, 2007). Symptoms include painless testicular enlargement and a feeling of heaviness in the scrotum. The disease metastasizes rapidly, leading to abdominal and back pain due to retroperitoneal node extension, weight loss, and general weakness. Human chorionic gonadotropin (hCG) and alpha-fetoprotein (AFP), tumor markers, can be detected in blood serum. **Gynecomastia** (enlargement of the breasts) may arise because of hCG produced by the tumor.

Therapy for testicular malignancy is **orchiectomy** (removal of the testis) followed by radiation or chemotherapy (Einhorn et al., 2007). After surgical removal, a gel-filled prosthesis can be inserted to provide a symmetric appearance to the scrotum. Subfertility in the opposite testis results after radiation therapy. For some patients, "sperm banking," or preserving frozen sperm before the procedure, may be presented as an option for future family planning.

Teaching males to perform testicular self-examination for early cancer detection is important to help them detect symptoms at an early point (see Chapter 34).

REPRODUCTIVE DISORDERS IN FEMALES

The most frequent reproductive disorders in females involve vaginal or menstrual irregularities. Other disorders are caused by structural alterations of the reproductive organs such as imperforate hymen, by pelvic inflammatory disease (PID), or infections caused by STIs.

Menstrual Disorders

Because menstruation is an ongoing process throughout half of a woman's life, it affects her self-image significantly. An irregularity such as painful cycles can exert a major influence on daily activities.

Menstrual disorders fall into two categories: (a) menstruation that is painful or uncomfortable and (b) infrequent or too-frequent cycles.

Mittelschmerz

Some women experience abdominal pain during ovulation from the release of accompanying prostaglandins. Pain may also be caused by a drop or two of follicular fluid or blood that spills into the abdominal cavity. This pain, called **mittelschmerz,** can range from a few sharp cramps to several hours of discomfort. It is typically felt on one side of the abdomen (near an ovary) and may be accompanied by scant vaginal spotting.

An advantage of mittelschmerz is that it clearly marks ovulation. If pain is felt in the right lower quadrant, it can be differentiated from appendicitis by the lack of associated symptoms such as nausea, vomiting, fever, abdominal guarding, and rebound tenderness as well as by its occurrence in the menstrual cycle. Usually mittelschmerz is of limited discomfort. It can be relieved by a mild analgesic such as acetaminophen.

Dysmenorrhea

Dysmenorrhea is painful menstruation. For generations, it was thought to be mainly psychological, needing no treatment other than reassurance that it was a normal phenomenon and something women should endure. Today, it is known that the pain is caused by the release of prostaglandins in response to tissue destruction during the ischemic phase of the menstrual cycle (Harel, 2007). Prostaglandin release causes smooth muscle contraction and pain in the uterus.

Dysmenorrhea can also be a preliminary symptom of an underlying illness such as PID, uterine myomas (tumors), or endometriosis (abnormal formation of endometrial tissue).

Assessment. During the first year or two of menstruation, dysmenorrhea rarely occurs, because early menstrual cycles are usually **anovulatory** (without ovulation). As ovulation begins, typical menstrual discomfort also begins. Dysmenorrhea can be categorized as mild (no interference with normal activities), moderate (some interference), or severe (interference with the majority of everyday activities). As many as 80% of adolescents have some discomfort with menstruation; in approximately 10%, the discomfort seriously interferes with daily living (Rapkin & Howe, 2007).

Dysmenorrhea is *primary* if it occurs in the absence of organic disease; it is *secondary* if it occurs as a result of organic disease. Symptoms may begin with a "bloated" feeling and light cramping 24 hours before menstrual flow. Pain is mainly noticed, however, when the flow begins. Colicky (sharp) pain is superimposed on a dull, nagging pain across the lower abdomen. Accompanying this is an "aching, pulling" sensation of the vulva and inner thighs. Some adolescents have mild diarrhea with the abdominal cramping. Mild breast tenderness, abdominal distention, nausea and vomiting, headache, and facial flushing may also be present.

Therapeutic Management. Painful symptoms can usually be controlled by an analgesic such as acetylsalicylic acid (aspirin) or ibuprofen (Advil, Motrin). Acetylsalicylic acid (aspirin) works well as an analgesic for dysmenorrhea because it is a mild prostaglandin inhibitor. Although adolescents are usually advised not to take aspirin because of its link to Reye's syndrome, girls may take it safely at the beginning of a menstrual period as long as they do not have additional flulike symptoms. Ibuprofen is a stronger prostaglandin inhibitor and relieves more severe menstrual pain. Naproxen sodium (Aleve) is also effective. Be certain that girls know not to take these drugs on an empty stomach, because they can be extremely irritating to gastric mucosa. Low-dose oral contraceptives to prevent ovulation may also be effective if pregnancy is not desired. One disadvantage of this therapy is the possible adverse effects of long-term estrogen administration. Adolescents may choose to be prescribed long-acting oral contraceptives so that they have menstrual periods only every 3 months (Pavone & Burke, 2007). Several alternative therapies such as imagery and transcutaneous electrical nerve stimulation (TENS) are also effective to relieve menstrual pain (Proctor et al., 2009)

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Pain related to dysmenorrhea

Outcome Evaluation: Client states that she has some control over pain through nonpharmacologic or pharmacologic methods.

Several nonpharmacologic solutions such as yoga and exercise may help relieve dysmenorrhea (Hall, 2009). Decreasing sodium intake for a few days before an expected menstrual flow, by omitting salty foods such as potato chips, pretzels, ham, and other luncheon meats and by not adding salt to foods, may help reduce "bloated" feelings. Abdominal breathing (breathing in and out slowly, allowing the abdominal wall to rise with each inhalation) may also be helpful. Applying heat to the abdomen with a heating pad or taking a hot shower or tub bath may relax muscle tension and relieve pain. Acupressure, although short lived, might also be of help (Jun et al., 2007). Caution young girls not to apply heat to their abdomen for abdominal pain until their menstrual flow begins; if the pain results from an inflamed appendix, heat can cause rupture of the appendix and life-threatening peritonitis. Resting may help to relieve vulvar pain; abdominal massage (effleurage or light massage) may feel soothing. Adolescents who remain sexually active during their menses may discover that orgasm helps relieve pelvic engorgement and cramping.

Menorrhagia

Menorrhagia is an abnormally heavy menstrual flow, usually defined as greater than 80 mL per menses. It may occur in girls close to puberty and it occurs again in women nearing menopause because of anovulatory cycles. Without ovulation and subsequent progesterone secretion, estrogen secretion continues and causes extreme proliferation of endometrium. A heavy flow can indicate endometriosis (see later discussion), a systemic disease (anemia), blood dyscrasia such as a clotting defect, or a uterine abnormality such as a myoma (fibroid) tumor. It can be a symptom of infection such as PID or an indication of early pregnancy loss that is coincidentally occurring at the time of an expected menstrual period. It can occur because of a previously undiagnosed bleeding disorder such as von Willebrand disease (Aydinok, Egemen, & Balkan, 2007). It can occur from breakthrough bleeding from an oral contraceptive (Grover, 2007). There is often an unusual amount of flow in girls using intrauterine devices (IUDs). With oral contraceptives, the flow is often light; for this reason, it may seem alarmingly heavy once pills are discontinued, when this is just a return of the adolescent's normal flow.

Assessment and Therapy. It is difficult to determine when a menstrual flow is abnormally heavy, but one method is to ask the girl how long it takes her to saturate a sanitary napkin or tampon. A sanitary napkin or tampon holds approximately 25 mL of fluid. If a pad or tampon is saturated in less than 1 hour, the flow is considered heavier than usual.

Determining the cause of menorrhagia is important, because it can lead to anemia from excessive iron loss. If anemia occurs, iron supplements may be necessary to achieve sufficient hemoglobin formation. The adolescent who is losing excessive blood because of anovulatory cycles may be prescribed progesterone during the luteal phase to prevent proliferative growth during this phase of the cycle; if the ability to conceive is unimportant, adolescents may be prescribed a low-dose oral contraceptive or GnRH inhibitor to decrease the flow.

Metrorrhagia

Metrorrhagia is bleeding between menstrual periods (Gray & Emans, 2007). This is normal in some adolescents who have spotting at the time of ovulation ("mittelstaining"). It may also occur in teenagers taking oral contraceptives (breakthrough bleeding) during the first 3 or 4 months of use. Additionally, vaginal irritation from infection can cause midcycle spotting. Spotting may also represent a temporarily low level of progesterone production and endometrial sloughing (dysfunctional uterine bleeding or a luteal phase defect), although this condition most often occurs near the end of the reproductive years.

If metrorrhagia occurs for more than one menstrual cycle in a teenager who is not taking oral contraceptives, she should be referred to her primary care provider for examination, because abnormal vaginal bleeding can be an early sign of uterine carcinoma or ovarian cysts.

Endometriosis

Endometriosis is the abnormal growth of extrauterine endometrial cells, often in the cul-de-sac of the peritoneal cavity or on the uterine ligaments or ovaries. This abnormal tissue results from excessive endometrial production and a reflux of blood and tissue through the fallopian tubes during a menstrual flow. As many as 25% of women in the United States have endometriosis, and as many as 50% of adolescents seen for dysmenorrhea have endometriosis (Yates & Vlahos, 2007).

The condition tends to occur most often in white nulliparous women, but there is also a familial tendency. Daughters of women with endometriosis may develop symptoms of dysmenorrhea early in life. They may want to consider having children before overgrowth of the endometrium becomes so extensive that it interferes with conception.

The excessive production of endometrial tissue may be related to a deficient immunologic response. In many women, it appears to be related to excess estrogen production or a failed luteal menstrual phase. Many women with endometriosis do not ovulate or ovulate irregularly. Therefore, endometriosis is discovered at a higher than usual rate among women undergoing subfertility testing (Vercellini et al., 2007).

In these women, estrogen secretion continues through the cycle rather than becoming secondary to progesterone late in the cycle, as happens with normal ovulation. The resulting proliferation of tissue forces the blood back into the fallopian tubes.

Endometriosis causes dysmenorrhea when the abnormal tissue responds to estrogen and progesterone stimulation by swelling and then sloughing its layers in the same manner as the uterine lining. This causes inflammation of surrounding tissue in the abdominal cavity and an even greater release of prostaglandins. Abnormal tissue in the pelvic cul-de-sac can cause *dyspareunia* (painful coitus) because it puts pressure on the posterior vagina. Subfertility may result if the fallopian tubes become immobilized and blocked by tissue implants or adhesions, preventing peristaltic motion and transport of ova (see Chapter 8).

Assessment. Pelvic examination may show that the uterus is displaced by tender, fixed, palpable nodules. Nodules in the cul-de-sac or on an ovary also may be palpable. If the endometriosis is minimal, the girl will not experience related symptoms. If the condition is moderate or extensive, she may experience extreme dysmenorrhea or dyspareunia.

Therapeutic Management. Treatment for endometriosis can be medical or surgical, depending on the extent of the condition. Estrogen/progesterone-based oral contraceptives may stimulate implant regression as the tissue sloughs under the influence of the progesterone. Danazol (Danocrine), a synthetic androgen, can be prescribed to help shrink the abnormal tissue. Administration of a GnRH agonist, such as leuprolide acetate (Lupron), can reduce hormone stimulation and cause the same effect (see Box 47.5). Laparotomy with excision by laser surgery is the most effective measure, but, because this is a highly invasive procedure, a course of conservative medical treatment may be tried first.

Amenorrhea

Amenorrhea, or absence of a menstrual flow, strongly suggests pregnancy but is by no means definitive, because it can also result from tension, anxiety, fatigue, chronic illness, extreme dieting, or strenuous exercise. Amenorrhea as a sign of pregnancy is discussed in Chapter 10. Competitive swimmers, long-distance runners (50 to 75 miles weekly), and ballet dancers notice that intensive training causes their periods to become scant and irregular. This appears to be associated with their low ratio of body fat to body muscle, which leads to excessive secretion of prolactin. An elevation in prolactin causes a decrease in GnRH from the hypothalamus, followed by declines in follicle-stimulating hormone (FSH), follicular development, and estrogen secretion. Menstrual cycles usually return to normal within 3 months after discontinuation of strenuous training and conditioning.

Adolescents who wish to maintain a normal cycle while training for a sports event may take bromocriptine (Parlodel), which can reduce high prolactin levels by acting on the hypothalamus and initiating menstruation each month. Many adolescents, however, view the absence of menstrual periods as a benefit during sports training. If a menstrual flow is delayed and pregnancy is suspected, bromocriptine should be discontinued, because it is potentially teratogenic.

Amenorrhea also occurs among females who diet excessively, partially as a natural defense mechanism to limit ovulation and as a means of conserving body fluid. Adolescents with *anorexia nervosa* or *bulimia* (eating disorders described in Chapter 54) often develop amenorrhea after approximately 3 months of excessive dieting or binging and dieting; as in athletes, this is caused by an increase in prolactin.

Premenstrual Dysphoric Disorder

Premenstrual dysphoric disorder (PDD) is a condition that occurs in the luteal phase of the menstrual cycle and is relieved by the onset of menses. It has both behavioral and physiologic symptoms. Because of the variety of possible symptoms, as many as 30% of women experience some degree of PDD; at least 3% experience a cluster of symptoms that include anxiety, fatigue, abdominal bloating, headache, appetite disturbance, irritability, and depression. For about 3% of women, these symptoms are so extreme that they are incapacitating (Stotland, 2007).

The cause of PDD is unproved but, contrary to previous beliefs, it must be due to more than a drop in progesterone just before menses. A syndrome similar to PDD can occur in women after tubal ligation; a decrease in the blood supply to the ovary apparently results in decreased luteal function. In some women, a vitamin B–complex deficiency may lead to estrogen excess, causing an abnormal ratio of estrogen to progesterone; other related causes may be poor renal clearance leading to water retention, or hypoglycemia leading to a surge of epinephrine and low calcium levels and interference with serotonin synthesis.

Symptoms of PDD vary from cycle to cycle and throughout life. Therapy is aimed at correcting specific symptoms (Yonkers, O'Brien, & Eriksson, 2008).

Adolescents who think they have PDD should keep a diary of when symptoms occur. If they are aware of recurring patterns that indicate PDD, they will be better able to recognize the cause. They should be certain their diet is high in vitamins and calcium and low in salt. Agents that suppress ovarian function, such as oral contraceptives or the GnRH agonist leuprolide, may be prescribed. If depression is a major symptom, an antidepressant such as buspirone

(BuSpar) can be helpful. Paroxetine (Paxil) is a selective serotonin reuptake inhibitor that is specifically designed for PDD therapy in adults. Antidepressants are prescribed with caution in adolescents, however, because they may be responsible for an increase in suicidal behavior (Kaplan & Love-Osborne, 2007).

Additional Reproductive Disorders in Females

Female Circumcision

Female circumcision is incision and removal of the clitoris (Elnashar & Abdelhady, 2007). There is no medical reason or advantage of the procedure but it is regarded as a coming of age ritual in some cultures. Although not a custom practiced in the United States, adolescents or women who have had this done in another country may be seen in gynecology settings. They may have difficulty with childbirth because of vulvar scarring and contraction.

Imperforate Hymen

The *hymen* is the membranous ring of tissue that partly obstructs the vaginal opening. An *imperforate hymen* totally occludes the vagina, preventing the escape of vaginal secretions and menstrual blood (Dane et al., 2007).

Before menarche, the child with an imperforate hymen usually has no symptoms. With onset of menstruation, the menstrual flow is obstructed. It builds up in the vagina, causing increased pressure in the vagina and uterus and eventually abdominal pain. Palpation of the abdomen reveals a lower abdominal mass. On vaginal examination, an intact, bulging hymen is evident.

The treatment is surgical incision or removal of the hymenal tissue. The girl may have local pain after the incision, which can be relieved by a mild analgesic and warm baths.

Careful explanation of this condition will help the girl understand that it will not interfere with sexual relations or future childbearing. Because most girls of early menstrual age have scant knowledge of anatomy, pictures of the reproductive tract help to explain that this is a local and minor problem.

Toxic Shock Syndrome

Toxic shock syndrome (TSS) is an infection that usually is caused by toxin-producing strains of *Staphylococcus aureus* organisms. Although organisms can enter the body by other means, they typically enter through vaginal walls that have been damaged by the insertion of tampons at the time of a menstrual period (Kansal et al., 2007).

Assessment. The symptoms of TSS are described in Box 47.6. Some women have mild diarrhea as a normal accompaniment to dysmenorrhea, but any female who develops fever with diarrhea and vomiting during a menstrual period should suspect TSS.

Therapeutic Management. Women or adolescents with suspected TSS need a careful vaginal examination and removal of any tampon particles, as well as cervical and vaginal cultures for *S. aureus.* Iodine douches may reduce the number of organisms present vaginally. *S. aureus* is usually resistant to penicillin but not to penicillinase-resistant antibiotics such as the cephalosporins, oxacillins, or clindamycins, so these are prescribed. Intravenous fluid therapy to restore circulating fluid volume and increase blood pressure, or vasopressors such as dopamine (Intropin), may be necessary to increase the blood pressure. Osmotic therapy to shift fluid back into the intravascular circulation may be necessary to prevent renal and cardiac failure. Recovery occurs in 7 to 10 days; fatigue and weakness may remain for months afterward.

The rate of TSS recurrence is 28% to 64%, usually within 2 months after the first attack. Recurrence probably happens because the organism is not completely eliminated from the body. Therefore, be certain that girls complete their entire antibiotic prescription. Be sure to educate girls about menstrual hygiene (Box 47.7). All girls should use the lowest-absorbency tampon appropriate for their individual flow. Girls who develop TSS should avoid tampon use in the future.

BOX 47.6 ❇ Symptoms of Toxic Shock Syndrome*

- Temperature greater than 102° F (38.9° C)
- Vomiting and diarrhea
- A macular (sunburn-like) rash that desquamates on palms and soles 1 to 2 weeks after illness
- Severe hypotension (systolic pressure less than 90 mm Hg)
- Shock, leading to poor organ perfusion
- Impaired renal function with elevated blood urea nitrogen or creatinine at least twice the upper limit of normal
- Severe muscle pain or creatine phosphokinase at least twice the upper limit of normal
- Hyperemia of mucous membrane
- Impaired liver function with increased total bilirubin and increased serum glutamate oxaloacetate transaminase (aspartate aminotransferase) at twice the upper limit of normal
- Decreased platelet count
- Central nervous system symptoms of disorientation, confusion, severe headache

*Three symptoms must be present for diagnosis.

Vulvovaginitis

In **vulvovaginitis,** inflammation of the vulva or vagina is accompanied by pain, odor, pruritus, and a vaginal discharge (Hansen et al., 2007). Vaginal bleeding may be present. This condition may occur in a girl of any age, but it tends to be more frequent as girls reach puberty. The change to adult pH and the presence of vaginal secretions make the vagina more receptive to infections. Box 47.8 discusses common measures to relieve discomfort.

Preschool and School-Age Children. Vaginal discharge may occur before menarche, but bleeding is rarely seen at this age. If bleeding is present, its cause must be determined. Cystitis can cause urethral bleeding; scratching due to rectal pruritus can lead to rectal bleeding. The cause of true vaginal bleeding in this early age group is usually either irritation caused by an inserted foreign object in the vagina, infestation of

Preventing Toxic Shock Syndrome

Q. Navi says to you, "I've heard so much about a disease called toxic shock syndrome. What is it and how can I make sure that I don't get it?"

A. Although toxic shock syndrome can occur for other reasons, it most often occurs during a menstrual flow when tampons are used. The following are measures to help prevent the syndrome:

- Use only tampons made of natural materials such as cotton, not synthetics such as cellulose or polyester, and avoid high-absorbency tampons.
- Change tampons at least every 4 hours during use.
- Alternate use of tampons with use of sanitary pads.
- Avoid handling the portion of the tampon that will be inserted vaginally.
- Do not use tampons near the end of a menstrual flow, when excessive vaginal dryness can result from scant flow.
- Do not insert more than one tampon at a time, to avoid abrasions and to keep the vaginal walls from becoming too dry.
- Avoid deodorant tampons, deodorant sanitary pads, and feminine hygiene sprays; these products can irritate the vulvar–vaginal lining.
- If fever, vomiting, or diarrhea occurs during a menstrual period, discontinue tampon use and immediately consult a health care provider, because these are symptoms of TSS.
- Anyone who has had one episode of TSS is well advised not to use tampons again, or at least not until two vaginal cultures for *Staphylococcus aureus,* the bacteria usually responsible for TSS, are negative.

BOX 47.8 * Focus on Family Teaching

Tips for Relieving the Pain of Vulvitis

Q. Navi says to you, "I have a vaginal discharge. The itching is awful. Is there anything I can do to relieve it?"

A. Here are some tips that might help:

- Wash the area twice a day with mild, nonperfumed soap and water, and pat dry. This removes secretions and decreases irritation. Wash and dry from front to back, to prevent spreading rectal contamination forward.
- Take sitz baths or apply warm, moist compresses three times a day to soothe the area and keep it free of irritating drainage.
- After drying the cleansed area, apply cornstarch for comfort and to absorb residual moisture.
- Avoid bubble baths and feminine hygiene sprays, because the ingredients may cause additional local irritation or contribute to urinary tract infections.
- Take acetaminophen (Tylenol) every 4 hours. Acetaminophen is an analgesic that relieves pain and reduces itching, a mild pain sensation.
- Avoid scratching, which may increase abrasions and introduce a secondary infection. Instead, apply a cold compress to relieve the itching sensation.
- Wear cotton underwear, which allows air to circulate and moisture to evaporate, rather than nylon or silk, which prevents air circulation and retains moisture.
- Sleep without underwear.
- Use an anesthetic spray or hydrocortisone cream only as prescribed.
- Carefully follow instructions from your health care provider about caring for a vaginal infection; only after the infection subsides will the vulvitis clear.

pinworms, or *vaginitis* (vaginal inflammation or infection). Sexual abuse must be investigated as a cause of any bleeding, tenderness, or infection (see Chapter 55). Precocious puberty must also be ruled out.

Treatment for pinworm is discussed in Chapter 43. If there is a foreign body in the vagina, it obviously should be removed. Vaginal examination is necessary, first to locate the object and then to confirm that it has been fully removed. This may be difficult for girls to accept, because vaginal manipulation and stretching can be painful. Use of a small speculum helps reduce the pain. A local antibiotic ointment or warm bath may be ordered to reduce accompanying infection and inflammation afterward. Sometimes, daily bubble baths cause vulvar irritation. This can be quickly remedied by discontinuing the bubble baths; irritation from such compounds can lead not only to local discomfort but to urinary tract infection as well (Schilling McCann et al., 2007).

A few preschool or school-age children develop a vaginitis due to *Streptococcus* or to *Escherichia coli* introduced from the anus by improper perineal care after voiding or bowel movements. A tight hymen then traps the microorganisms in the vagina and leads to infection. The girl needs to be reminded to wipe from front to back after voiding or bowel movements.

Adolescents. As a girl enters puberty, she may notice a slight vaginal discharge caused by increased vaginal secretions. She can be reassured that this is normal. To keep from developing vulvar irritation, caution girls to wear cotton underpants rather than nylon (so that moisture is absorbed better) and to dry the vulva thoroughly after bathing or swimming.

Some girls develop vulvar irritation after using personal hygiene sprays or douches. These products are unnecessary so should be discontinued. Good hygiene can be achieved by daily washing and frequent changing of tampons or sanitary pads during menstruation. This will prevent chafing or stasis of menstrual blood and help prevent irritation and excessive odor.

Pelvic Inflammatory Disease

Pelvic inflammatory disease (PID) is infection of the pelvic organs: the uterus, fallopian tubes, ovaries, and their supporting structures. The infection can extend to cause pelvic peritonitis. Although sexual transmission accounts for approximately 75% of all instances of PID (gonorrheal and chlamydial organisms are frequently responsible), infections from other causes such as *E. coli* or *Streptococcus* are beginning to occur more frequently and may be as severe.

Adolescents and young adults have a higher incidence of PID than other age groups (Soper, 2007).

PID begins with a cervical infection that spreads by surface invasion along the uterine endometrium and then out to the fallopian tubes and ovaries. It is most likely to occur at the end of a menstrual period, because menstrual blood provides an excellent growth medium for bacteria and there is loss of the normal barrier of cervical mucus during this time.

Assessment. With acute PID, an adolescent notices severe pain in the lower abdomen. She may have an accompanying heavy, purulent discharge. As the infection progresses, she will develop a fever. Leukocytosis and an elevated erythrocyte sedimentation rate will be present on laboratory testing. During a pelvic examination, any manipulation of the cervix causes severe pain. It may be difficult to palpate the ovaries because of tenderness and abdominal guarding. As peritoneal tissue becomes inflamed and edematous, a purulent exudate forms. If the process is untreated, it enters a chronic phase and fibrotic scarring with stricture of the fallopian tubes results. If the PID enters a chronic phase, the abdominal pain lessens but dyspareunia and dysmenorrhea may be extreme. If the ovaries are affected, intermenstrual spotting may occur. Diagnosis can be aided by ultrasound or laparoscopy.

Therapeutic Management. Therapy involves administration of analgesia for comfort plus specific broad-spectrum antibiotics such as cefoxitin (Mefoxin), doxycycline (Vibramycin), or clindamycin (Cleocin). Limiting activity also helps relieve the pain. In some women, a pelvic abscess forms and must be drained through the cul-de-sac before healing can occur.

Women who have had one episode of PID have an increased chance of a second occurrence, because the immune protection of the tubes and ovaries may be damaged. They should not have coitus with an infected partner, and they should avoid coitus during menstruation, when their protective mechanisms are lowest. Early childbearing may be recommended if they plan to have children, because extensive tubal scarring could impair fertility. It is important for adolescents to recognize the symptoms of PID and to seek early help for the best outcome.

BREAST DISORDERS

Although males have few breast disorders, these can occur in either males or females.

Gynecomastia (enlarged breast tissue) may occur temporarily in preadolescent boys in response to a rising estrogen level. Particularly noticeable in obese males, this enlargement fades with a normal increase in testosterone production (Diamantopoulos & Bao, 2007). It may also occur in teens who participate in body-building sports as a result of steroid use. If this is the cause, counseling regarding drug use is crucial.

Accessory Nipples

As the name implies, *accessory nipples* are additional breast nipples (Oztas & Gurer, 2007). They occur along the mammary lines and can be present in either male or female (Fig. 47.2). They are present from birth but usually are not as protuberant as true nipples; they also lack areolar pigmentation. Parents should be told what they are, so that they can inform their daughter later, because some growth in accessory nipples may occur at puberty or during pregnancy in response to estrogen stimulation. Many girls are unaware that they have an accessory nipple and think it is a large mole until puberty.

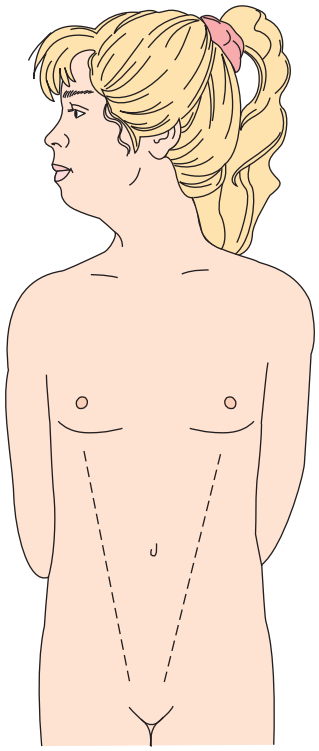

FIGURE 47.2 Nipple lines along which accessory nipples occur.

In a few instances, actual breast tissue is present beneath the accessory nipple. If so, it is subject to the same diseases as other breast tissue. If the accessory nipple or accessory breast tissue is cosmetically distressing to an adolescent, it can be removed by simple surgical excision.

What if... Navi has an accessory nipple with breast tissue underneath? Is this breast tissue susceptible to breast cancer?

Breast Hypertrophy

Breast hypertrophy is abnormal enlargement of breast tissue. In the average girl, breast development halts after puberty, as soon as progesterone levels rise to mature strength. Progesterone levels are low until menstruation cycles are fully established; however, if this process is a lengthy one, breast growth may last for several years, resulting in larger than usual breasts.

Breast hypertrophy can lead to both physical and emotional stress. A girl may feel pain and fatigue in the back or shoulders from attempting to maintain good posture despite the weight of heavy breast tissue. She may feel self-conscious and try to minimize her breast size by slouching,

resulting in poor posture or rounded shoulders (Sigurdson et al., 2007).

Adolescent girls with large breasts may find it difficult to adapt to such a new appearance. They may be treated as provocative sex objects and believe they should live up to this image. This can make it difficult for them to find their own identity. They may hear comments such as, "I wish I had your problem," rather than receiving support and understanding from parents, peers, and health care providers.

If breast hypertrophy interferes with a girl's physical and emotional well-being, surgical breast reduction is a possibility. Adolescents need to seriously consider the consequences of this procedure, however, before undertaking it at this early age. If a large amount of glandular tissue is removed, breastfeeding may no longer be possible. The adolescent needs to be told realistically that changing her physical appearance will reduce physical discomfort, but changing her self-concept must come from within. An adolescent with large breasts must conscientiously schedule a yearly breast examination, because it is easier for a cancerous lesion to escape detection in large amounts of breast tissue than in a smaller breast. Pregnancy and lactation may be particularly difficult times, because breasts that are already large become even heavier with milk formation.

Breast Hypoplasia

Breast hypoplasia is less-than-average breast size. In most instances, this does not represent a decreased amount of glandular or functional breast tissue but a reduced amount of fatty tissue. If an adolescent feels that having small breasts interferes with self-esteem, she can have surgical augmentation to increase breast size but, again, this needs careful consideration regarding whether it is necessary at this young age.

For augmentation, an incision is made under the breast and either a silicon or a saline implant is inserted under the breast tissue, next to the musculus pectoralis major. It is important for the adolescent to realize that her breast tissue is not being replaced by the implant; she could still develop breast cancer in later years.

A woman may notice decreased nipple sensation for approximately 1 year after an implant procedure. Breasts with implants in place may feel firmer than normal on palpation due to the formation of a fibrotic band or capsule around the implant.

Breast implants do not interfere with breastfeeding as they are placed behind the milk glands. A traumatic blow to the breast, such as could occur from an automobile accident, requires examination by the augmentation surgeon to be certain that the implant did not rupture, causing its contents to leak into the breast tissue.

Breast Tenderness or Fullness

Many women notice a day or two of premenstrual breast fullness and tenderness each month. Some may find palpable granular or fine nodular lumps in their breasts during this time. This is a benign occurrence and is part of the monthly changes that occur from hormone stimulation. If a lump or tenderness persists beyond a menstrual flow, an adolescent should consult a health care provider for additional assessment and care, because this continuing change might signal a lesion or other problem.

Fat Necrosis

If breast tissue is struck during a fall or other traumatic injury, it can become tender, painful, inflamed or reddened, and possibly bruised. Seat belt shoulder restraints are a major cause of this (Majeski, 2007). A few days after the injury, necrosis or disintegration may occur in the fatty layer. As the area heals, fibrotic scar tissue forms. This may leave a firm, palpable lump in the breast. It is not freely movable; it can, however, cause skin or nipple retraction or dimpling on the skin surface. Unlike malignant breast growths, posttraumatic breast lumps tend to be well delineated because of the scar tissue.

It is generally recommended that such fibrotic areas be biopsied and then excised. The surgical procedure usually leaves little scarring, and the woman no longer needs to worry about the lump in her breast. Although at one time breast trauma was thought to be a precipitating factor of breast carcinoma, no direct correlation between the two has been established. The association may exist because a woman who examines her breasts after an injury may find an already existing carcinoma.

Fibrocystic Breast Disease

Fibrocystic breast disease is the most common benign breast condition in women of all ages. It can occur as early as puberty, when estrogen rises to adult levels. More commonly, however, it affects women between the ages of late adolescence and 45 years. It may be caused by *H. pylori*, the bacteria also responsible for peptic ulcers transmitted during sexual foreplay (Kast, 2007). Round, fluid-filled cysts form in the connective breast tissue (Fig. 47.3). The adolescent is able to palpate freely movable, well-delineated breast lumps. Lumps may also be visible on the surface of the breasts (most often in the upper outer quadrant). The consistency of these lesions varies with the menstrual cycle, changing from firm and hard to soft and flexible, depending on the amount of serous fluid present. The lesions tend to shrink or even disappear during pregnancy and lactation, and they totally disappear with menopause (Grube & Giuliano, 2007).

Fibrocystic breasts may feel painful; the breasts may feel tender and "stretched," interfering with active sports and

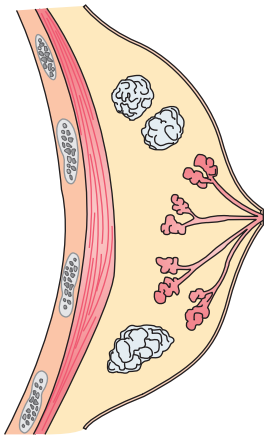

FIGURE 47.3 Round, fluid-filled cysts form in breast tissue in fibrocystic breast disease.

other strenuous activity. This discomfort can be relieved with a simple analgesic, such as acetaminophen (Tylenol), or warm compresses, avoidance of trauma, and firm bra support. The formation of fibrocystic lesions may be increased in some women with the use of methylxanthines found in caffeine, theophylline, and theobromine. Avoiding foods such as coffee, cola drinks, tea, chocolate, some toffee candy, and medications such as aspirin compound or Excedrin that contain caffeine reduces pain. Discontinuing smoking can also decrease the occurrence of fibrocystic lesions. Decreased sodium intake or short-term use of a mild diuretic just before menses can reduce fluid retention.

If these measures do not decrease the fibrocystic symptoms, cysts may be aspirated under a local anesthetic by injection of a thin sterile needle attached to a small syringe. This procedure not only reduces the size of the cyst but also provides fluid for biopsy (Chaiwun & Thorner, 2007).

Danazol (Danocrine), a synthetic androgen, may help reduce the symptoms by suppressing estrogen formation in the ovaries (Giuliano, 2009). In addition to being physically distressed, women with fibrocystic breasts may worry that each lump could be malignant. They can be reassured that the disease itself does not lead to breast carcinoma. Breast carcinoma does occur in women with fibrocystic breast disease, however, and it may even metastasize before a woman seeks health consultation, if she assumes that all her breast lesions are benign. Therefore, in addition to a yearly breast examination, women need an annual breast ultrasound, which involves no x-ray exposure and can efficiently locate fluid-filled cysts.

Fibroadenoma

Fibroadenomas are tumors that consist of both fibrotic and glandular components and occur in response to estrogen stimulation. The tumors may increase in size during adolescence, during pregnancy and lactation, or when a woman takes an estrogen source such as an oral contraceptive (Chang & McGrath, 2007).

Unlike fibrocystic lesions, fibroadenomas are round and well delineated, feeling firmer and more rubbery than fluid-filled cysts. Occasionally, they calcify and feel extremely hard. They are typically painless and freely movable and tend not to cause skin retraction. Like fibrocystic lesions, they do not become malignant.

Such tumors can be surgically excised so that a woman no longer has to worry about them. Because the incision is small, it leaves little scarring at the site.

✔ Checkpoint Question 47.2

Navi, 15, asks if she is too young to have breast augmentation. What advice would you give her?

a. She will not be able to breastfeed after augmentation.
b. Breast implants cause a high degree of fibrocystic disease.
c. Breast growth may not be fully complete at age 15.
d. Implants increase the risk of breast cancer and so are dangerous.

Mastitis

Mastitis is inflammation or infection of the breast (Betzold, 2007). As this usually occurs as a complication of breastfeeding, it is discussed in Chapter 25.

SEXUALLY TRANSMITTED INFECTIONS

Sexually transmitted infections (STIs) are diseases that are spread through sexual contact with an infected partner. They range in severity from easily treated infections, such as trichomoniasis, to human immunodeficiency virus (HIV) infection, which, despite advances in therapy, is life-threatening. If these diseases are discovered in young children, the possibility of sexual abuse has to be considered (Reading & Rannan-Eliya, 2007). STIs may be spread among women having sex with women or men having sex with men (Evans et al., 2007). Male circumcision does not appear to reduce the spread (Box 47.9).

Abstinence or condom use provides the best protection against STIs. Additional measures are voiding immediately after coitus, washing the genitals well with soap and water, and choosing sexual partners who are at low risk for infection (avoiding persons who are intravenous drug users or those with multiple sexual partners). Educating adolescents about safer sex practices, including the need for condom use (see Chapter 5) and the importance of health screening for these disorders, is an important nursing responsibility. STIs are becoming more difficult to treat because the causative organisms are becoming more and more resistant to antibiotics. Always reinforce the fact that little immunity develops from STIs, so such diseases can be contracted repeatedly. In most instances, an infected partner should also be treated or the disease can recur from cross-infection. Treatment of most STIs begins with determining the causative organism so that the appropriate antimicrobial or antifungal agent can be prescribed.

BOX 47.9 ✻ Focus on Evidence-Based Practice

Does male circumcision help prevent sexually transmitted infections?

It is often theorized that male circumcision might help reduce the possibility of contracting or transmitting sexually transmitted infections. To discover if this is true, researchers enrolled a cohort of children born in 1972–1973 and asked them about their sexual experiences at 21, 26, and 32 years of age. Of the 499 men studied, 201 (40.3%) had been circumcised. The circumcised and uncircumcised groups differed little in socioeconomic characteristics and sexual behavior. Overall, up to age 32 years, the incidence rates for all STIs were not statistically significantly different—23.4 and 24.4 per 1000 person-years for the uncircumcised and circumcised men, respectively.

Based on the above, if an adolescent asks you if circumcision would reduce his risk for gonorrhea, how would you advise him?

Source: Dickson, N. P., et al. (2008). Circumcision and risk of sexually transmitted infections in a birth cohort. *Journal of Pediatrics, 152*(3), 383–387.

Pregnancy and Sexually Transmitted Infections

Several STIs such as syphilis are known to be teratogenic. All of them are suspected of being a causative factor of preterm birth. Chapter 26 discusses care for the newborn affected by these diseases.

Candidiasis

Candidiasis is a vaginal infection spread by the fungus *Candida,* an organism that thrives on glycogen. Candidiasis is so common that as many as 90% of women will have it sometime in their life. As many as 40% of sexually active females have asymptomatic candidal vaginal infections; this rate rises even higher during pregnancy, when high estrogen levels lead to glycogen levels that produce a favorable environment for fungal growth. Because oral contraceptives produce a pseudopregnancy state, women using oral contraceptives also have frequent vaginal candidal infections. When a woman is being treated with an antibiotic (which destroys normal vaginal flora and lets fungal organisms grow more readily), she is also particularly susceptible to this infection. Incidence is also strongly associated with immune suppression and diabetes mellitus, because hyperglycemia provides a glucose-rich environment for candidal growth (Tanner & Alexander, 2007).

Assessment

Because of the scant mucus production in the period before menses, symptoms may be most acute at this time. An adolescent will notice vulvar and vaginal reddening, burning and itching, and even bleeding from hairline fissures. The vagina sometimes shows white "patches" on the walls. The patches are adherent and cannot be scraped away without bleeding. A thick, cream cheese–like discharge can usually be observed at the vaginal introitus. There may be pain on coitus or on tampon insertion. Candidal infections may also be present at other body sites, such as the oral cavity or a moist area such as the umbilicus. In immunosuppressed individuals, it can become systemic (Blyth, Palasanthiran, & O'Brien, 2007).

Candidal infections are diagnosed by removing a sample of the discharge from the vaginal wall and placing it on a glass slide; three or four drops of a 20% potassium hydroxide (KOH) solution are then added, and the mixture is protected by a coverslip. Under a microscope, typical fungal hyphae indicate the presence of *Candida* organisms (Table 47.1). An at-home test kit (Vagasil Screening Kit) is available that gives results instantly. A woman inserts a pH wand into her vagina and in a few seconds compares the color of the swab to a pH color chart. If the reading is above 5.0, it suggests that she may have a bacterial infection and should see a doctor. A normal pH level of 4.5 plus itching and/or burning, unusual discharge, or a yeasty odor suggests a yeast infection and it would be all right for her to use an over-the-counter treatment.

Therapeutic Management

Therapy for candidal infections includes vaginal suppositories or cream applications of antifungal preparations such as miconazole (Monistat) or clotrimazole (Lotrimin), once a day for 3 to 7 days. Oral fluconazole (Diflucan) can be ad-

TABLE 47.1 ✻ Common Vulvovaginal Infections

Causative Agent	Symptoms	Common Therapy
Candida	Vulvar reddening and pruritus; thick, white, cheeselike vaginal discharge	Nystatin or miconazole (Monistat) suppositories or fluconazole (Diflucan) orally; bathing with dilute sodium bicarbonate solution may relieve pruritus
Trichomonas	Thin, irritating, frothy, gray-green discharge; strong, putrid odor; itching	Metronidazole (Flagyl) orally; douching with weak vinegar solution to reduce pruritus
Herpesvirus type II	Painful pinpoint vesicles on an erythematous base with a watery vaginal discharge possible; voiding may be irritating and painful	Bathing with dilute sodium bicarbonate solution, applying lubricating jelly to lesions or an oral analgesic such as aspirin may be necessary for pain relief; topically applied acyclovir (Zovirax) helps heal lesions
Gardnerella	Edema and reddening of vulva, milky gray discharge, fishlike odor	Metronidazole (Flagyl) or clindamycin
Chlamydia trachomatis	Watery, gray-white vaginal discharge, vulvar itching	Tetracycline or doxycycline; erythromycin during pregnancy
Neisseria gonorrhoeae	Possibly symptomless; may have profuse yellow-green vaginal discharge	Ceftriaxone and doxycycline; oral amoxicillin
Enterobius vermicularis (pinworm)	Rectal pruritus, especially on rising in the morning	Oral administration of an anthelmintic, such as mebendazole (Vermox)
Treponema pallidum (syphilis)	Painless ulcer on vulva or vagina	Benzathine penicillin, administered intramuscularly
Streptococcus	Vaginitis, vulvar itching; edema and reddening of vulva	Antibiotic (e.g., amoxicillin)
Foreign body	Vaginal discharge; odor	Removal of foreign body during pelvic examination

BOX 47.10 * Focus on Pharmacology

Fluconazole (Diflucan)
Classification: Antifungal agent
Action: Increases fungal cell wall permeability, thereby exerting fungicidal or fungostatic action (Karch, 2009)
Pregnancy Risk Category: C
Dosage: 150 mg orally as a single dose
Possible Adverse Effects: Nausea, vomiting; diarrhea, abdominal pain, headache

Nursing Implications

- Instruct the adolescent that this drug is given as a one-time single dose.
- Teach the adolescent about safer sex measures and hygiene practices to help prevent reinfection after therapy.
- Urge the adolescent to watch for signs and symptoms of possible reinfection and report them to the primary care provider.

ministered as a one-time oral dose (Box 47.10). Antifungal creams are purchased over-the-counter. Teach women to insert these or antifungal suppositories at bedtime so the drug does not drain from the vagina immediately afterward. During the day, a girl may want to wear a sanitary pad to avoid staining from vaginal discharge. Treatment should not be interrupted until it is complete, even during a menstrual period. Because miconazole and clotrimazole are available without prescription, be certain that adolescents know how to differentiate a candidal infection from other infections or to consult a health care provider for assistance and treatment if they are not sure.

If a girl has frequent candidal infections, her urine should be tested for glucose to rule out diabetes mellitus. If she is using an oral contraceptive, she might be counseled to use another contraceptive method. If an adolescent is sexually active, treatment of the male partner may be necessary to break a reinfection cycle.

Pregnancy and Candidiasis. Candidiasis occurs more frequently during pregnancy than usual because of the increased estrogen level present during pregnancy, which causes the vaginal pH to be less acidic. It occurs frequently in pregnant women with gestational diabetes and in women with HIV infection. Women with repeated infections should have their urine tested for glucose to determine whether gestational diabetes is present.

Both miconazole (Monistat) for 7 days or a single dose of oral fluconazole (Diflucan) are approved for use during pregnancy. Treating the infection during pregnancy is important not only because the profuse vaginal discharge and pruritus can be uncomfortable but if the infection is still present in the vagina at the time of childbirth, it may cause a candidal infection, or thrush, in the newborn (see Chapter 43). Caution pregnant women to call their primary health care provider before using an over-the-counter product to double-check the product is safe to use during pregnancy and so that her primary care provider can know that a vaginal infection is occurring because, although it is not well established, antifungal use during the first trimester of pregnancy is possibly associated with hypoplastic heart disease in newborns (Carter et al., 2008).

What if... Navi tells you she feels safe from contracting an STI because she knows she is up to date with her immunizations? How would you counsel her?

Trichomoniasis

Trichomonas vaginalis is a single-cell protozoan that is spread by coitus and affects between 3% and 13% of adult men and women in the United States (Sutton et al., 2007). The incubation period is 4 to 20 days.

Assessment

With a trichomonal infection, females notice vaginal irritation and a frothy white or grayish-green vaginal discharge. The frothiness of the discharge is an important typical finding. The upper vagina is reddened and may have pinpoint petechiae. Extreme vulvar itching is present. By contrast, males with the same infection rarely report any symptoms.

The infection is diagnosed by microscopic examination of a sample of the vaginal discharge after it is combined with lactated Ringer's or normal saline solution. Trichomonads typically appear as rounded, mobile structures. Be aware that *Trichomonas* infections cause such inflammatory changes in the cervix or vagina that a Pap test taken during this time may be misinterpreted as showing abnormal tissue.

Therapeutic Management

Oral metronidazole (Flagyl) eradicates trichomonal infections. Treatment with Flagyl and use of condoms by sexual partners help prevent recurrence of *Trichomonas* in both parties. Because the drug interacts with alcohol to cause acute nausea and vomiting, advise women not to drink alcoholic beverages during the course of treatment.

Pregnancy and Trichomoniasis. Trichomoniasis infections are associated with preterm labor, premature rupture of membranes, and postcesarean infection (Hay & Czeizel, 2007). The drug of choice is single-dose oral metronidazole. Metronidazole was once thought to be teratogenic but is now considered to be safe in either early or late pregnancy (Karch, 2009).

Bacterial Vaginosis

Bacterial vaginosis is the invasion of an organism such as *Gardnerella vaginalis.* This organism thrives in the vagina, a body area with a reduced oxygen level. When the infection is present vaginal discharge appears milk-white to gray and has a fishlike odor. Pruritus can be intense. Microscopic examination of the discharge in normal saline solution shows gram-negative rods adhering to vaginal epithelial cells, which are termed *clue cells* (Burke & Rogers, 2007).

The treatment is oral or vaginal metronidazole for 7 days; the woman's sexual partners should also be treated to prevent recurrence of the infection.

Pregnancy and Bacterial Vaginosis

The treatment during pregnancy is oral metronidazole or clindamycin for 7 days. Untreated *G. vaginalis* infections are associated with amniotic fluid infections and, perhaps, preterm labor as well as premature rupture of the membranes (Soper, 2007).

Chlamydia trachomatis Infection

Chlamydia trachomatis infections have become the most common bacterial cause of STI in the United States (Wendel & Zenilman, 2007). Symptoms include a heavy, grayish-white discharge and vulvar itching. The incubation period is 1 to 5 weeks. Diagnosis is made by culture of the organism. Therapy is oral doxycycline or tetracycline for 7 days or azithromycin in a single dose. Because it has become so common, most public health departments require that cases now be reported. Long-term effects of chlamydial infections are PID, possibly leading to subfertility. Because there is a strong association between gonorrhea and *Chlamydia*, if a chlamydial infection is documented, women are usually tested for gonorrhea as well. Home tests are available for both *Chlamydia* and gonorrhea. Encouraging women to use these could increase the number of infections treated yearly (Cook et al., 2007).

Pregnancy and *Chlamydia*

Screening for *Chlamydia* via a vaginal culture is usually done during a woman's first prenatal visit. If a woman has multiple sexual partners, screening may be repeated again in the third trimester. Doxycycline (Vibramycin), the therapy for nonpregnant women, is contraindicated during pregnancy because of possible fetal long-bone deformities; azithromycin (Zithromax) or amoxicillin (Amoxil) is used instead (Tanner & Alexander, 2007). A woman's partner also should be treated to prevent her from becoming reinfected. As with nonpregnant women, because there is a strong association between gonorrhea and *Chlamydia*, if a chlamydial infection is documented, women are usually tested for gonorrhea as well.

Chlamydial infections must be treated during pregnancy because they are associated with premature rupture of the membranes, preterm labor, and endometritis in the postpartum period. An infant who is born while a chlamydial infection is present can suffer conjunctivitis or pneumonia after birth (Hahn & Giunta, 2007) (see Chapters 50 and 40).

Human Papillomavirus

The human papillomavirus (HPV) causes fibrous tissue overgrowth (sometime called genital warts) on the external vulva, vagina, or cervix (condyloma acuminatum). At first, lesions appear as discrete papillary structures; they then spread, enlarge, and coalesce to form large, cauliflower-like lesions. The infection may be present in as many as 10% to 30% of women and is most common in women who have multiple sexual partners (Howley & Lowy, 2007). Therapy for such lesions is aimed at dissolving the lesions and also ending any secondary infection present. Small growths may be removed by applying podophyllin (Podofin). Large lesions may be removed by laser therapy, cryocautery, or knife excision. With cryocautery, edema at the site is evident immediately; lesions become gangrenous, and sloughing occurs in 7 days. Healing will be complete in 4 to 6 weeks with only slight depigmentation at the site. Sitz baths and a lidocaine cream may be soothing during the healing period. Children (both male and female) with HPV infections should be further investigated for sexual abuse (Reading & Rannan-Eliya, 2007). HPV infections are serious because they are associated with the development of cervical cancer later in life (Soper, 2007). Women who have had one episode of infection should be conscientious about having yearly Pap tests for the rest of their lives. The vaccine, Gardasil, is recommended to be routinely administered to early teenage girls in three doses. A second dose is 2 months after the first dose and the third dose is 6 months after the first dose. Immunizing young teenage girls against HPV infection should reduce not only the incidence of HPV infections in the future but the rate of cervical cancer as well (Deglin & Villarand, 2009).

Pregnancy and Human Papillomavirus Infection

HPV lesions tend to increase in size during pregnancy because of the high vascular flow in the pelvic area. They may become secondarily ulcerated and infected; when this occurs, a foul vulvar odor may develop.

Podophyllum is contraindicated during pregnancy because of possible toxic effects on the fetus. Trichloroacetic acid (TCA) or bichloroacetic acid (BCA) applied to the lesions weekly may be effective and can be used during pregnancy. Women who do not find the lesions bothersome may choose to leave them in place during pregnancy and have them removed during the postpartum period.

The presence of vulvar lesions appears to have no effect on the fetus during pregnancy, but if they are present at the time of birth and so large that they obstruct the birth canal, a cesarean birth may be scheduled.

Herpes Genitalis (Herpes Simplex Type 2)

Genital herpes is caused by *herpesvirus hominis* type 2 (also called herpes simplex virus type 2, or HSV-2). This is one of four similar herpesviruses: cytomegalovirus, Epstein-Barr, varicella-zoster, and herpes types 1 and 2. Genital herpes occurs in epidemic proportions in the United States, and its incidence appears to be growing yearly (Wendel & Zenilman, 2007). Unlike most other STIs, although the virus can be contained, there is no known cure. The disease involves a lifelong process, therefore, and, although it is not a precursor to cervical cancer, women with cervical cancer tend to have more antibodies against herpes genitalis than others or probably have been exposed to the virus more than others. The virus is spread by skin-to-skin contact, entering through a break in the skin or mucous membrane. In the newborn, the virus can be systemic or even fatal (see Chapter 26).

Assessment

Herpes is diagnosed by culture of the lesion secretion from its location on the vulva, vagina, cervix, or penis or by isolation of HSV antibodies in serum. The incubation period is 3 to 14 days. On first contact, extensive primary lesions originate as a group of pinpoint vesicles on an erythematous base. Within a few days, the vesicles ulcerate and become moist, painful, draining, open lesions. An adolescent may have accompanying flulike symptoms with increased temperature;

vaginal lesions may cause a profuse discharge. Pain is intense on contact with clothing or acidic urine.

After the primary stage that lasts approximately 1 week, lesions heal but the virus lingers in a latent form, affecting the sensory nerve ganglia. The condition will flare up and become an active infection during illness, just prior to menstruation, fever, overexposure to sunlight, or stress. A secondary response usually produces only local lesions rather than systemic symptoms.

Therapeutic Management

Acyclovir (Zovirax) is an example of an antiviral that controls the virus by interfering with deoxyribonucleic acid reproduction and decreasing symptoms (Watkins, 2008). The drug is available as a topical ointment. If applying this to a client, be certain to protect yourself with a finger cot or glove so that you do not contract the virus or absorb the drug. Sitz baths three times a day may be helpful to reduce discomfort. An emollient (A&D Ointment) can also reduce discomfort, but its moisture tends to prolong the active period of the lesions. Topical imiquimod (Aldara) or Foscarnet (Foscavir) may be prescribed for resistant lesions.

Condoms (male or female) help prevent the spread of herpes among sexual partners. Valacyclovir (Valtrex) may be prescribed as a preventive measure to help limit the disease spread. Because of the possible association with cervical cancer, any female with genital herpes should have yearly Pap tests for the rest of her life.

People with herpes may have difficulty establishing sexual relationships for fear of infecting a partner. Because herpes is communicated only by direct contact, infected people need to inform their partners when they have any active lesions and avoid sexual contact or use a condom to decrease the danger of spreading the virus.

Pregnancy and Herpes Simplex Virus Type 2 Infection. If a woman contracts a herpes type 2 infection during pregnancy, herpes can be transmitted across the placenta to cause congenital infection in the newborn. If a woman has primary or secondary active lesions in the vagina or on the vulva at the time of birth, herpes infection can be transmitted to the newborn at birth. When infection in the newborn occurs, congenital herpes, a severe systemic infection that is often fatal, can result (see Chapter 26). To help avoid transmission, women with active lesions are scheduled for cesarean birth. If no lesions are present, a vaginal birth is preferable (Tanner & Alexander, 2007).

Diagnosis of the disorder is made by the appearance of the lesions and on the results of a Pap smear and an enzyme-linked immunosorbent assay (ELISA). The drug of choice for the treatment of herpes infection is the same as for nonpregnant women (acyclovir [Zovirax] or valacyclovir [Valtrex]) (Karch, 2009). Women can reduce the pain of the lesions by taking sitz baths or applying warm, moist tea bags to the area.

Hepatitis B and Hepatitis C

Both hepatitis B and hepatitis C can be spread by semen as well as blood and therefore are considered STIs. These are discussed in Chapter 45, with other forms of hepatitis. Because hepatitis B can be spread by sexual intercourse, adolescents who did not receive immunization against this as an infant need immunization against this updated.

Gonorrhea

Gonorrhea is transmitted by *Neisseria gonorrhoeae,* a gram-positive diplococcus that thrives on columnar transitional epithelium of the mucous membrane. Symptoms begin after a 2- to 7-day incubation period. In males, they include *urethritis* (pain on urination and frequency of urination) and a urethral discharge. Without treatment, the infection may spread to the testes, scarring the tubules and causing permanent sterility. Untreated, the infection is easily spread among sexual partners. It often occurs concurrently with chlamydial infection (Wendel & Zenilman, 2007).

Although symptoms of gonorrhea in females are not as visible, there may be a slight yellowish vaginal discharge. Bartholin's glands may become inflamed and painful. If left untreated, the infection may spread to pelvic organs, most notably the fallopian tubes (PID). Tubal scarring can result in permanent sterility. In both males and females, untreated gonorrhea can lead to arthritis or heart disease from systemic involvement.

Assessment

A urine culture for the gonococcal bacillus, in addition to vaginal and urethral cultures, should be obtained from all children with vulvovaginitis or a urethral discharge. In males, a first voiding may reveal gonococci if a midstream urine specimen is inconclusive.

Therapeutic Management

Although gonorrhea has traditionally been treated with amoxicillin and probenecid, the incidence of penicillinase-producing strains has made this traditional therapy ineffective. Therefore, oral cefixime (Suprax) or intramuscular ceftriaxone (Rocephin) plus oral doxycycline (Vibramycin) for 7 days is the current recommended therapy. This treatment regimen is effective for both gonorrhea and *Chlamydia*. Sexual partners should receive the same treatment.

Approximately 24 hours after treatment, gonorrhea is no longer infectious. Approximately 7 days after treatment, a client should return for a follow-up culture to verify that the disease has been completely eradicated (few adolescents take this precaution). Adolescents are usually assessed for syphilis along with the gonorrheal culture, although the dose of ceftriaxone and doxycycline is also effective treatment for syphilis. Most states require that gonorrhea be reported to the health department; adolescents are asked to name sexual contacts.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Anxiety related to having contracted a reportable STI

Outcome Evaluation: Adolescent voices confidence in ability to cope with this problem and demonstrates understanding of the illness, the treatment regimen, and future prevention options.

People who seek treatment for an STI need to believe that they can trust health care personnel and reveal information without fear of criticism. Assure the ado-

lescent of absolute confidentiality in naming sexual contacts. Without being told who put them at risk, these people can then be notified by a health department investigator that they have been exposed to a particular STI. This vital information helps prevent further spread of the disease.

Reassure people that the treatment is not prolonged and as simple as taking medication. This is an insidious disease, and, even though no symptoms are apparent, it can have disastrous long-term effects if left untreated (see Focus on Nursing Care Planning Box 47.11).

BOX 47.11 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for an Adolescent With Gonorrhea

Navi is a 15-year-old female high school student you meet at a pediatric clinic. She describes intense vulvar irritation from a yellowish vaginal discharge.

Family Assessment ✻ Navi lives with mother in studio apartment in inner city. Mother works at home as a freelance journalist. Mother describes finances as "good."

Client Assessment ✻ Well-proportioned female; sexual maturity Tanner stage 3. Has not had first menstrual period as yet. Sexually active for approximately 1 year with same partner. "He doesn't use a condom anymore because he's only dating me."

Vulva reddened and excoriated. Yellow-green discharge noted at vaginal introitus. Reddened areas noted on vaginal walls. One dose of intramuscular (IM) ceftriaxone (Rocephin), plus oral doxycycline (Vibramycin) for 7 days, is prescribed. She asks, "How did I get this? From my boyfriend? Does he need to be treated too?"

Nursing Diagnosis ✻ Deficient knowledge related to cause and treatment of sexually transmitted infection (STI).

Outcome Evaluation ✻ Adolescent states that she understands cause of STI; reports boyfriend has an appointment within 48 hours for evaluation.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Assess whether adolescent understands importance of washing hands well after using bathroom and avoiding sexual intercourse during treatment.	Discuss how disease can be spread to other body parts by unclean hands.	Gonorrhea is particularly hazardous, because it can cause eye infections with corneal scarring.	Adolescent states that she will take precautions to wash hands well; she will avoid sexual intercourse until repeat culture.
		Consultations		
Nurse	Confer with STI counselor.	Meet with STI counselor regarding procedure for STI contacts.	Gonorrhea is a reportable disease.	STI counselor assumes responsibility for securing STI contacts.
		Procedures/Medications		
Nurse	Assess whether adolescent has experience with taking medicine. Assess if a reminder sheet would be helpful.	Administer ceftriaxone (Rocephin) IM; give instructions for oral doxycycline (Vibramycin) for 7 days as prescribed.	The antibiotics chosen for gonorrhea treatment are also effective against *Chlamydia*, which is frequently associated with gonorrhea.	Adolescent accepts IM injection; states she understands importance of taking oral antibiotic for full 7 days.
Nurse	Assess whether adolescent has access to a bathtub at home.	Recommend the use of sitz baths before and after school.	Sitz baths are soothing and help keep the area free of irritating discharge.	Adolescent states she will use home bathtub for sitz baths twice daily.

(continued)

BOX 47.11 ✻ Focus on Nursing Care Planning (continued)

		Nutrition		
Not applicable	NA	NA	NA	NA
		Patient/Family Education		
Nurse	Assess whether adolescent is aware that STIs are spread through sexual intercourse.	Teach adolescent about the cause, means of spread, and treatment for gonorrhea.	Adolescent must be aware of STIs to prevent them in the future.	Adolescent states that she understands STIs are spread by sexual relations.
		Psychosocial/Spiritual/Emotional Needs		
Nurse	Assess intensity of adolescent's pruritus or pain from vulvitis on a scale of 1 to 10.	Discuss the use of acetaminophen or ibuprofen for pain and pruritus as prescribed.	Acetaminophen and ibuprofen are effective analgesics for mild pain and itching.	Adolescent describes correct dosage of analgesics and states intention to use them.
STI counselor	Assess whether adolescent has had sexual contacts other than current boyfriend.	Ask adolescent to name any additional sexual contacts.	Sexual contacts need to be notified so they also can receive treatment.	Adolescent names any other sexual contacts; possibility of rape or abuse is ruled out.
		Discharge Planning		
Nurse	Assess whether adolescent understands that she must ask boyfriend to use a condom for sexual relations.	Discuss the possibility that, because he contracted an STI, his relationship with her may not be monogamous. Explain that nonmonogamous relations make condom use even more important, not less important.	STI was spread to her by a sexual contact.	Adolescent states she will be more conscientious about insisting boyfriend use a condom.
Nurse	Assess whether child or parent has any questions about disease or therapy.	Schedule child for a return appointment in 1 week for reculture.	A repeat culture will reveal whether antibiotic therapy has been effective.	Child and parent state that they understand the importance of a repeat culture and will keep return appointment.

Pregnancy and Gonorrhea. Gonorrhea is associated with spontaneous miscarriage, preterm birth, and endometritis in the postpartum period. Pregnant women cannot be administered doxycycline because it has the potential to be teratogenic. Instead, they are prescribed amoxicillin or azithromycin. It is important that gonorrhea be identified and treated during pregnancy because if the infection is present at the time of birth, it can cause a severe eye infection that can lead to blindness in the newborn (ophthalmia neonatorum; see Chapter 26) (Heidary & Kazlas, 2008).

Syphilis

Syphilis is a systemic disease caused by the spirochete *Treponema pallidum.* It is transmitted by sexual contact with a person who has an active spirochete-containing lesion (Tanner & Alexander, 2007). Like gonorrhea and *Chlamydia*, it must be reported to public health departments.

After an incubation period of 10 to 90 days, a typical lesion appears, usually on the genitalia (penis or labia) or on the mouth, lips, or rectal area from oral–genital or genital–anal contact. The lesion (termed a *chancre*) is a deep

ulcer and is usually painless despite its size. Swollen lymph nodes may be present but these are unlikely to be noticed by the affected person. A lesion in the vagina may not be detected. Without treatment, a chancre lasts approximately 6 weeks and then fades.

Approximately 2 to 4 weeks after the chancre disappears, a generalized, macular, copper-colored rash appears. Unlike many other rashes, it affects the soles and the palms. A serologic test for syphilis yields a positive result at this time. There may be secondary symptoms of generalized illness, such as low-grade fever. With or without treatment, this stage of syphilis also fades.

The next stage is a latency period that may last from only a few years to several decades. The only indication of the disease is the serologic test, which continues to yield a positive result.

The final stage of syphilis is a destructive neurologic disease that involves major body organs such as the heart and the nervous system. Typical symptoms are blindness; paralysis; severe, crippling neurologic deformities; mental confusion; slurred speech; and lack of coordination. This third stage must be identified before the disease becomes fatal.

Assessment

Syphilis is diagnosed by recognition of the various symptoms of the three stages and by serologic serum tests, usually the Venereal Disease Research Laboratory test (VDRL), the automated reagin test (ART), the rapid plasma reagin test (RPR), or the fluorescent treponemal antibody–absorption test (FTA-ABS).

Therapeutic Management

Benzathine penicillin G, given intramuscularly in two sites, is effective therapy. For the adolescent who is sensitive to penicillin, either oral erythromycin or tetracycline can be given for 10 to 15 days. Sexual partners are treated in the same way as the person with the active infection. Therapy effectively arrests the disease at whatever stage it has reached. After therapy, adolescents may experience a sudden episode of hypotension, fever, tachycardia, and muscle aches. This is called a Jarisch-Herxheimer reaction and is caused by the sudden destruction of spirochetes. The reaction lasts about 24 hours and then fades (Wendel & Zenilman, 2007). Because syphilis can be treated so easily, one would think it would be easy to eradicate. In reality, however, because the primary chancre is painless, many people are either unaware of it or choose to ignore it, thereby transmitting the disease to unsuspecting partners. Adolescents, in particular, need accurate information about syphilis to become aware of the symptoms and safer sex practices. They should believe that they can report the disease to health care personnel and can name sexual contacts without fear of being criticized (Leung-Chen, 2008).

Pregnancy and Syphilis. Early in pregnancy (before week 18), the placenta appears to provide some protection against syphilis. After this time, however, the spirochete crosses the placenta freely and may be responsible for spontaneous miscarriage, preterm labor, stillbirth, or congenital anomalies in the newborn (see Chapter 12). All pregnant women are screened for syphilis at a first prenatal visit with a VDRL, ART, or FTA-ABS antibody reaction test. Those who have multiple sexual partners are tested again at about week 36 of pregnancy. In some institutions, women are screened again at the beginning of labor and newborns are screened for congenital syphilis by a cord blood sample. One injection of benzathine penicillin G is the drug of choice for the treatment of syphilis during pregnancy the same as for those who are not pregnant.

If a woman does contract syphilis during pregnancy and it is untreated, a congenital form of the disease can occur in the newborn as the spirochete crosses the placenta readily in the last four months of pregnancy. Severely infected infants will be stillborn; others, less infected, are born with congenital anomalies. Moist lesions of the infant (the cord and nasal secretions) are generally infectious.

Unlike adults, the infant does not develop a chancre but about a week after birth, will develop a typical copper-colored rash, most prominent over the face, soles of feet, and palms of hands. Bullous lesions on the palms and soles may also develop. The infant's nose may show a severe rhinitis (snuffles). Radiography of the long bones reveal changes of epiphyseal lines at about 1 to 3 months of age. By 5 to 6 months, these bone changes may no longer be visible and so may be missed.

When the child's permanent teeth erupt at 5 or 6 years of age, they may be pegged or notched (Hutchinson's teeth). This is most noticeable in the upper central incisors. All teeth tend to be of poor quality and decay easily. If the disease remains untreated, interstitial keratitis, an inflammatory reaction of the cornea that can result in scarring and blindness, may develop when the child is school age. As the disease progresses further, it may become tertiary or lead to severe neurologic symptoms.

Infants born to a woman with a positive VDRL are given a course of penicillin at birth. FTA-ABS is a sensitive, specific test for IgM antibodies against syphilis and may be helpful for diagnosis in the newborn.

Group B Streptococcal Infection

Although streptococcus B infection is a less publicized disease than STIs such as herpes type 2 or gonorrhea, it may actually occur at a higher incidence than those diseases. It produces few symptoms. For a pregnant adolescent, however, consequences can be urinary tract infection (UTI), intraamniotic infection, perhaps preterm birth, and postpartum endometritis.

Pregnant women are screened for streptococcus B at 35 to 38 weeks of pregnancy. This screening is important, because approximately 40% to 70% of neonates whose mothers have an active infection at the time of birth will become infected from placental transfer or from direct contact with the organisms. Infected neonates may develop severe pneumonia, sepsis, respiratory distress syndrome, or meningitis (Heath & Schuchat, 2007). These effects on the neonate are discussed in Chapter 26.

A broad-spectrum penicillin such as ampicillin is the treatment of choice. Women who experience rupture of membranes at less than 37 weeks of pregnancy and so have not yet been screened may be treated with intravenous ampicillin to reduce the risk of spreading the infection to the newborn.

Human Immunodeficiency Virus (HIV)

HIV is carried by semen as well as other body fluids, so infection with this virus is considered an STI. Invasion of the virus is discussed with other immune disorders in Chapter 42.

✔ Checkpoint Question 47.3

Candidal vaginal infections can occur as an opportunistic infection when adolescents are prescribed antibiotics. What are the typical symptoms of a candidal vaginal infection?

a. Yellow pinpoint vaginal lesions.
b. Pruritic reddened vaginal walls.
c. White, cheeselike vaginal discharge.
d. Vaginal atrophy with final scarring.

Key Points for Review

- Children who are born with a reproductive tract disorder frequently adjust well when young. They may need counseling at puberty or when they become aware of the impact of their disorder on sexual functioning or their ability to reproduce.
- The cause of ambiguous genitalia is unknown but may be related to the level of testosterone produced in utero. The true gender of children is established by a karyotype of chromosomes.
- The development of breast or pubic hair before age 8 years or menses before age 9 years is considered precocious sexual development. Children may be treated with a synthetic analog of gonadotropin-releasing hormone to reduce development. Without effective support, such children are at high risk for disturbed body image.
- Delayed puberty is the failure to develop secondary sex characteristics by the age of 17 years. Girls may be administered estrogen to promote development; boys may be administered testosterone.
- Balanoposthitis (inflammation of the glans and prepuce of the penis) and phimosis (constricted foreskin) occur in boys. Phimosis can be treated with circumcision.
- Cryptorchidism is failure of one or both testes to descend during intrauterine life. The condition is surgically corrected to prevent subfertility and to detect testicular cancer later in life.
- Testicular cancer is rare but tends to occur in young men. Boys need to be taught testicular self-examination for early detection.
- Dysmenorrhea, or painful menstruation, occurs frequently in adolescent girls. Therapy is the use of a prostaglandin inhibitor such as ibuprofen.
- Untreated endometriosis (the abnormal growth of extrauterine endometrial tissue) can lead to subfertility later in life. Therapy is administration of a synthetic androgen or gonadotropin-releasing hormone receptor inhibitor or surgery to reduce the size of the abnormal tissue.
- Vulvovaginitis (inflammation of the vulva and vagina) and pelvic inflammatory disease are infections that can occur in adolescents. Therapy to prevent fallopian tube scarring and subfertility later in life is essential. Girls need to be taught, in addition, ways to avoid toxic shock syndrome.
- Conditions such as fibrocystic breast disease can occur in adolescents. Reducing intake of caffeine and sodium can minimize symptoms.
- Sexually transmitted infections (STIs) such as candidiasis, trichomoniasis, *C. trachomatis* infection, genital warts, herpes genitalis, gonorrhea, and syphilis are increasing in incidence in the adolescent population. An important health-teaching area for adolescents is the need to follow safer sex practices.
- STIs such as candidiasis, trichomoniasis, *Chlamydia*, syphilis, herpes type 2, gonorrhea, papilloma, and HIV may occur during pregnancy. These illnesses need to be treated promptly. Women need to use safer sex practices to help prevent these diseases.
- When teaching about STIs, it is important to stress that they do not confer immunity and therefore can be contracted more than once. If an STI occurs in a young child, the potential for child abuse should be investigated.

CRITICAL THINKING EXERCISES

1. Navi is the 15-year-old girl you met at the beginning of the chapter, who was diagnosed as having gonorrhea. She says she is glad she contracted the disease early in life, because now she will never get it again. She also states that she is not sexually active. What health teaching does Navi need to be better informed about her disease? What other follow-up is needed?
2. Navi has almost no breast development and also has not menstruated yet. She asks you if it is time to worry. How would you counsel her?
3. Ryan, the boy whom Navi dates, was born with undescended testes. He had surgery for this condition when he was 2 years old. He is concerned now that he is at high risk for testicular cancer. How would you counsel him?
4. Examine the National Health Goals related to reproductive disorders in children. Most government-sponsored funds for nursing research are allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to Navi's family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to

further sharpen your skills and grow more familiar with NCLEX style questions related to reproductive disorders in children. Confirm your answers are correct by reading the rationales.

Chapter 48

Nursing Care of a Family When a Child Has an Endocrine or a Metabolic Disorder

KEY TERMS

- carpal spasm
- exophthalmos
- glycosuria
- hormones
- hyperglycemia
- hypoglycemia
- hypothalamus
- ketoacidosis
- latent tetany
- manifest tetany
- pedal spasm
- polydipsia
- polyuria
- sella turcica
- Somogyi phenomenon

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe the structure and function of the endocrine glands and why metabolic illnesses occur.
2. Identify National Health Goals related to childhood endocrine or metabolic disorders that nurses could help the nation achieve.
3. Analyze ways that care of a child with altered endocrine or metabolic function can be made more family centered.
4. Assess a child with a disorder of endocrine or metabolic function.
5. Formulate nursing diagnoses for a child with altered endocrine or metabolic function.
6. Develop expected outcomes for a child with endocrine or metabolic dysfunction.
7. Plan nursing care for a child with altered endocrine or metabolic function.
8. Implement nursing care such as teaching medicine administration to a child with an endocrine or metabolic disorder.
9. Evaluate expected outcomes for achievement and effectiveness of care.
10. Identify areas related to care of children with endocrine or metabolic disorders that could benefit from additional nursing research or application of evidence-based practice.
11. Synthesize knowledge of endocrine and metabolic dysfunctions and the nursing process to ensure quality maternal and child health nursing care.

Rob Tebecco is a 16-year-old boy with type 1 diabetes whom you meet in the emergency department, where he was taken after he became comatose while ice skating. His diabetes was diagnosed when he was 7 years old. His records indicate that his disease has generally been under good control over the past years, but in the last 6 months he has "forgotten" to take his insulin at least once a week. When you ask him about this, he tells you that ice skating practice every morning and a new girlfriend have occupied his time and interrupted what used to be a strict schedule of home-cooked meals and a rigid routine.

Previous chapters described the growth and development of well children. This chapter adds information about the dramatic changes, both physical and psychosocial, that occur when children develop an endocrine or metabolic disorder. This is important information because it builds a base for care and health teaching.

Is Rob's history unusual for an adolescent? What health teaching do you think will most help him re-establish control?

The endocrine system is composed of a small group of ductless glands that work together with the neurologic system to regulate and coordinate all body systems (Fig. 48.1). The glands produce chemicals called **hormones,** which are secreted into surrounding tissue and picked up by the bloodstream, where they act individually and in concert to affect various organ systems. (The word *hormone* is from the Greek *hormaein,* which means "to set in motion.") Each gland of the endocrine system has specific functions that are necessary for regulating body processes; each hormone secreted acts on a specific target (or designated) organ (Masharani, 2009).

Dysfunction of the glands or action of the hormones results in a variety of disorders, most of which have long-term implications. Parents—and children, as soon as they are old enough—need to understand the causes and symptoms of these diseases and to participate in their long-term plan of care. National Health Goals related to endocrine and metabolic disorders in children are presented in Box 48.1.

Nursing Process Overview

For Care of a Child With an Endocrine or Metabolic Disorder

Assessment

Endocrine and metabolic disorders as a group commonly cause changes in normal growth or activity patterns. This is usually detected when a child's height and weight are assessed and compared with standards for the child's age at a health visit. An acute loss in weight is often the first symptom of type 1 diabetes mellitus in children. Thyroid deficiencies or type 2 diabetes mellitus may be revealed by overweight. As more children become obese, more children develop type 2 diabetes. Pituitary difficulties may be revealed by short or unusually tall stature.

The way people view endocrine disorders can be culturally influenced. Because many of these disorders are inherited, they tend to cluster in various populations, so that either the incidence of the condition in family or friends is high, or else people know nothing about the condition. In the past, because many endocrine disorders led to changes in body appearance, particularly overgrowth or undergrowth, and because the reason for these changes was poorly understood, children with these disorders found themselves poorly accepted by peers. Being aware of the way these diseases used to be viewed aids in understanding a parent's anxiety at diagnosis of these disorders and helps with nursing care planning to include reassurance and modern concepts of therapy in education. Also, be sure to ask parents if they are using alternative therapies, because many herbs are advertised to suggest that they increase growth.

To obtain information on activity, take a day history by asking a parent or child to describe all of the child's actions on a typical day. This type of information yields clues that are helpful in distinguishing between a normally "quiet" child and one who is experiencing inactivity and chronic fatigue as a result of decreased endocrine function. For example, the quiet child lies down after school and reads; the ill child lies down and sleeps. Taking a day

BOX 48.1 ✻ Focus on National Health Goals

Diabetes mellitus is an endocrine disorder with serious consequences in both children and pregnant women. Several National Health Goals address reducing the incidence of this disease:

- Reduce the diabetes-related death rate from a baseline of 77 per 100,000 to no more than 46 per 100,000 people.
- Increase the proportion of persons with diabetes who receive formal diabetes education from a baseline of 45% to a target of 60% (http://www.nih.gov).

Nurses can help the nation achieve these goals by educating women about the possible effects of diabetes on pregnancy and by educating children about ways to prevent the long-term effects of the illness. Nursing research could shed additional light on these goals by asking questions such as: How should women be taught that fetal anomalies from hyperglycemia occur very early in pregnancy, so they must be certain to enter pregnancy in good glucose control? Long-term effects of diabetes are not noticeable in childhood, but how can children be educated to plan a healthy lifestyle to prevent these effects in adult life? At what age can children be expected to be responsible for glucose monitoring and insulin injection? What methods are best for encouraging children to be in charge of their own nutrition?

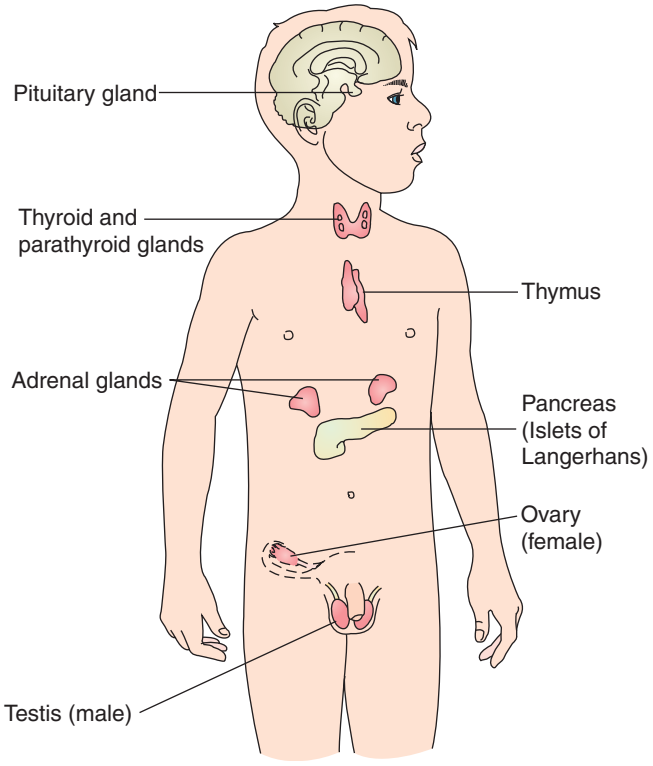

FIGURE 48.1 Location of the endocrine glands.

history also helps to differentiate between a child who is merely active and one who is overly active because of hyperthyroidism. For example, the healthy child appears to "go constantly" but can sit through a favorite television program or a meal. The child with increased thyroid hormone production may be unable to sit quietly at all.

Also assess dietary and elimination habits. Extreme thirst or appetite may occur with an endocrine disorder such as diabetes insipidus or type 1 diabetes mellitus. Frequent voiding in children most often reflects a urinary tract infection, but it may be evidence of excessive urine excretion **(polyuria),** possibly from pituitary dysfunction or diabetes mellitus.

On physical examination, observe a child's general appearance, noting any excessive tiredness, scaling or dry skin, drooping eyelids, protrusion of the eyeballs **(exophthalmos),** or poor muscle tone, all indications of endocrine disorders.

Nursing Diagnosis

Because endocrine glands control vital body functions, nursing diagnoses relevant to children with endocrine or metabolic disorders include both physiologic functions and the child's response to those changes. Some examples of such nursing diagnoses are:

- Deficient fluid volume related to constant excessive loss of fluid through urination
- Risk for imbalanced nutrition, less than body requirements, related to inability to use glucose because of diabetes mellitus
- Disturbed body image related to abnormal height
- Health-seeking behaviors related to self-administration of insulin
- Deficient knowledge related to long-term treatment needs
- Fear related to potential illness outcome
- Anticipatory grieving related to presumed losses associated with diagnosis of long-term illness
- Interrupted family processes related to child's chronic illness

Outcome Identification and Planning

Although most endocrine and metabolic disorders have long-term implications, parents and children may find it easier to work with outcomes initially that are short-term—particularly if they are having difficulty accepting the diagnosis and the long-term nature of the disorder. Because symptoms usually are not acute, children may easily forget to take medications or the parents may forget to give the medications. Helping parents create reminder charts is an effective measure to increase adherence.

Evaluate the school as well as the home situation for any child with a chronic illness. You may need to instruct teachers about the child's health problem (with the parents' permission) so that they do not make excessive or inappropriate demands such as insisting that a child with hyperthyroidism submit neat handwriting assignments when the child cannot do so.

Selected organizations for referral include American Diabetes Association (http://www.diabetes.org), Congenital Adrenal Hyperplasia Support Group (http:// www.cah.org.uk), Little People of America (http:// www.lpaonline.org), and National Tay-Sachs and Allied Diseases Association (http://www.ntsad.org).

Implementation

Interventions for children with endocrine or metabolic disorders must always be carried out with long-term aspects of care in mind. Bribing children to take medicine, for example, is never good practice. It has no place with children who must continue to take a medication for the rest of their lives (bribery quickly becomes ineffective). As children grow older and can better understand their disorder, explanations of why they must continue to take medication need to become more detailed.

Outcome Evaluation

Children with disorders of endocrine or metabolic function need to be evaluated periodically throughout childhood, because growth and changing activities necessitate changes in medication dosages or schedules. These checkups provide good opportunities for health teaching to equip children to meet new situations that arise as they mature. For example, body appearance such as being like, not unlike, their peers becomes increasingly important as children enter adolescence. Because of this, seemingly well-adjusted school-age children may develop extreme difficulty continuing to accept their illness as they get older. Adherence to a medication program may become erratic. Only by periodic re-evaluation can these problems be identified so that health care plans can be modified and adapted to the child's needs, enabling the child and family to continue coping with a long-term illness.

The following examples suggest that the desired outcomes have been achieved:

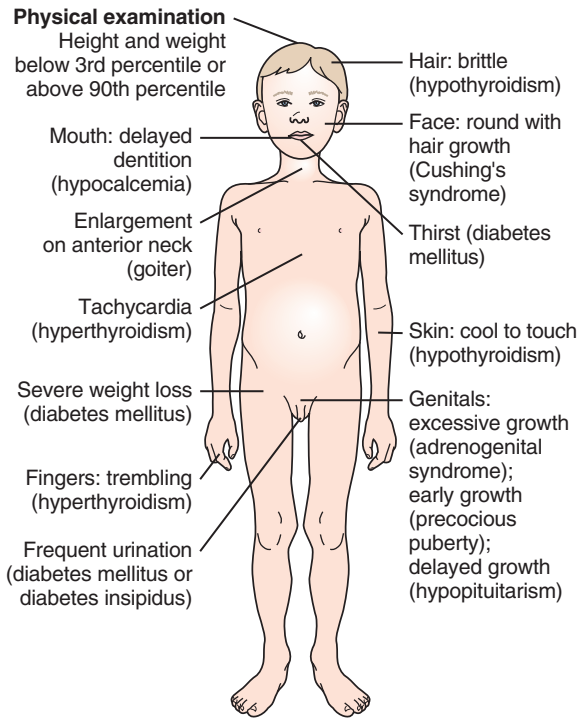
- Child brings to clinic written record illustrating conscientious medicine ingestion.
- Parents list developmentally appropriate, not size appropriate, activities for their child with short stature.
- Child's blood pressure and pulse remain within normal limits for age; specific gravity of urine is between 1.003 and 1.030; skin turgor is good; child states thirst is not excessive.
- Parents demonstrate correct insulin injection technique and state they are comfortable administering an injection to their child.

HEALTH PROMOTION AND RISK MANAGEMENT

Many endocrine and metabolic disorders are inherited so education and genetic counseling are important preventive measures (Box 48.2).

Type 2 diabetes mellitus is strongly associated with obesity so is at an epidemic incidence as obesity in school-age children is also at epidemic proportions. School nurses can be instrumental not only in counseling and helping students manage their disorder during school hours but in helping prevent type 2 diabetes by serving as an advisor to what foods and snacks are available in school settings.

Box 48.2 Assessment
Assessing a Child With an Endocrine Disorder



THE PITUITARY GLAND

The work of the pituitary gland is directed by the **hypothalamus,** an organ located in the center of the brain that is the regulator of the autonomic nervous system. About 1 cm long, 1.0 to 1.5 cm wide, and 0.5 cm thick, the pituitary rests in the **sella turcica,** a depression of the sphenoid bone. It is covered by a tough membrane, which also joins the gland to the hypothalamus.

The pituitary gland has several distinct regions: the anterior lobe, or *adenohypophysis;* the posterior lobe, or *neurohypophysis;* and the intermediate lobe (*pars intermedia*), which lies between the anterior and posterior lobes. Each of these regions appears to have its own function and secretes specific hormones.

Pituitary Hormones

The regions of the pituitary gland store and release eight different hormones. Four of these—antidiuretic hormone, thyrotropin, corticotropin, and somatotropin—are prominently involved in childhood illnesses (Table 48.1).

PITUITARY GLAND DISORDERS

Illnesses caused by pituitary dysfunction can result from a tumor growing in the pituitary or hypothalamus, interference with circulation to the gland, trauma, inflammation, structural abnormalities, erratic or nonfunctional feedback mechanisms, and, possibly, autoimmune responses (see Box 28.2). Interference from these reasons can result in hypopituitarism (lack of growth hormone), hyperpituitarism (excess secretion of growth hormone), or diabetes insipidus (undersecretion of antidiuretic hormone).

Growth Hormone Deficiency

If production of human growth hormone (GH, or somatotropin) is deficient, children cannot grow to full size (Quillen, 2008). As a result, children remain in proportion but well below the average on a standard growth chart. Deficient production of GH may result from a nonmalignant cystic tumor of embryonic origin that places pressure on the pituitary gland or from increased intracranial pressure as a result of trauma. In most children with hypopituitarism, the cause of the defect is unknown. It may have a genetic origin (Hernandez, Lee, & Camacho-Hubner, 2007).

If a child with hypopituitarism is not treated, predicting exactly what height will be reached is difficult because height varies with each individual. Without treatment, however, most children will not reach more than 3 or 4 feet in height.

Assessment

The child with deficient production of GH is usually normal in size and weight at birth. Within the first few years of life, however, the child begins to fall below the third percentile of height and weight on growth charts. The face appears infantile because the mandible is recessed and immature; the nose is usually small. The child's teeth may be crowded in a small jaw (and may erupt late). The child's voice may be high pitched, and the onset of pubic, facial, and axillary hair and genital growth is delayed. History, physical findings, and a decreased level of circulating GH contribute to the diagnosis.

Evaluate the family history for traits of short stature or constitutional delay (familial late development). If at all possible, obtain estimates of the parents' height and siblings' height and weight during their periods of growth. Assess thoroughly the child's prenatal and birth history for any suggestion of intrauterine growth restriction or severe head trauma at birth, which could have injured the pituitary gland. Assess the health history for any chronic illness, such as a heart, kidney, or intestinal disorder, that could have contributed to the decreased level of growth. Take a 24-hour nutrition history and ask carefully about urinary and bowel function. Parents often report that their child is a "picky eater," yet the 24-hour history does not reveal a poor appetite that is extensive enough to halt growth. Be certain to assess not only the child's actual height but also his or her feelings about being short.

A pituitary tumor must be ruled out as the cause of decreased GH production. Sudden halted growth suggests a tumor; gradual failure suggests an idiopathic involvement. A history of vision loss, headache, increase in head circumference, nausea, and vomiting (signs of increased intracranial pressure) also suggests a pituitary tumor. The history of a child with GH deficiency typically reveals a well child except for the abnormal lack of growth. Growth failure is so marked, however, that the parents may be suspected of child neglect.

A physical assessment, including a funduscopic examination and neurologic testing, is necessary to detect a lesion or tumor. Blood studies for hypothyroidism, hypoadrenalism, and hypoaldosteronism are performed, because these

TABLE 48.1 ✻ Common Pituitary Hormones and Their Purposes

Pituitary Hormone	Source and Target Organs	Actions and Effects
Antidiuretic hormone (ADH)	Secreted by the neurohypophysis *Target organ:* Kidney	• ADH helps regulate fluid volume and urine output. It decreases urinary output by increasing water resorption. This action increases extracellular fluid volume, resulting in a vasoconstrictor effect (increased blood pressure). When the plasma concentration increases or overall circulating vascular volume decreases, more ADH is released. • If blood pools in the body periphery, decreasing core body volume, ADH is released. • Postural changes (from a lying to a standing position) and exposure to high temperatures (blood shifts to peripheral structures to begin the cooling process) stimulate ADH release. • Trauma, pain, and anxiety increase ADH release. • When ADH levels fall, little or no water is reabsorbed, and urinary output increases. • Alcohol consumption inhibits ADH secretion; as a result, urine output increases.
Corticotropin (ACTH)	Secreted by the adenohypophysis *Target organ:* Adrenal glands	• ACTH stimulates the adrenal gland to produce glucocorticoid and mineralocorticoid hormones. Increased production of adrenal gland secretions decreases ACTH production and vice versa. • If a child receives synthetic ACTH or a corticosteroid, natural ACTH production is temporarily depressed. If these synthetic hormones are given for a long time, then stopped abruptly, the decreased amount of natural ACTH may not be enough to stimulate adrenal gland activity. The child will experience symptoms of adrenal insufficiency. • When discontinuing ACTH and high doses of long-term corticosteroids, dosage must be reduced gradually to protect adrenal function. The medication should never be stopped abruptly.
Somatotropin (growth hormone [GH])	Secreted by the adenohypophysis *Target organ:* None; acts on all body cells	• GH increases bone and cartilage growth and increases gastrointestinal absorption of calcium. If GH production is inhibited, undergrowth will occur; if GH production is excessive, overgrowth will occur. • GH decreases catabolism of protein in cells by freeing fatty acids for energy, which, in turn, frees glucose for glycogen storage (GH is both protein and glucose sparing). • GH production increases when hypoglycemia occurs and during sleep. • GH is released from the adenohypophysis based on a release factor from both the hypothalamus and the liver. • The amount of GH secretion is influenced by exercise, sleep, nutrition, and thyroid and adrenal function.
Thyrotropin (TSH)	Secreted by the adenohypophysis *Target organ:* Thyroid gland	• TSH stimulates the thyroid gland to produce thyroid hormones (thyroxine and triiodothyronine). • Too little TSH leads to atrophy and inactivity of the thyroid gland; too much TSH causes hypertrophy (increase in size) and hyperplasia (increase in the number of cells) of the gland. • A feedback message of increased thyroid secretion lowers TSH production; decreased thyroid production increases TSH production.

conditions also influence growth. The wrist is examined radiographically to determine bone age. Epiphyseal closure of long bones is delayed with GH deficiency but is proportional to the height delay. A skull series, computed tomography (CT) scanning, magnetic resonance imaging (MRI), or ultrasound will be performed to detect possible enlargement of the sella turcica, which would suggest a pituitary tumor. Blood is drawn for measurement of growth factor binding proteins.

Therapeutic Management

GH deficiency is treated by the administration of intramuscular (IM) recombinant human growth hormone (rhGH) two or three times a week (Box 48.3). The timing of the dose affects the hormone's effectiveness; GH is usually given at bedtime, the time of day at which GH normally peaks. Because these children have delayed epiphyseal closure, if treatment is started early, they will be able to reach a targeted height. Some may need suppression of luteinizing hormone–releasing hormone (LHRH, or gonadotropin-releasing hormone [GnRH]) to delay epiphyseal closure. Other children may need supplements of gonadotropin or other pituitary hormones if these are deficient as well (Zeitler, 2008). Children who do not respond to growth hormone stimulation may be offered a course of a newer synthetic recombinant insulin-like growth factor I (Rosenbloom, 2007). Growth hormone has been used irresponsibly by athletes in the hope that it improves muscle growth and overall stamina. Caution children that use of the drug when there is no medical use for it is potentially dangerous so they should not share the drug with anyone asking them to do that.

BOX 48.3 ✻ Focus on Pharmacology

Somatropin (Nutropin, Humatrope)

Classification: Somatropin is a recombinant human growth hormone (rhGH).

Action: Used for the long-term treatment of children who have growth failure from inadequate production of pituitary hormone, renal failure, or Turner's syndrome; may be used to promote healing in severe burns (Karch, 2009)

Pregnancy Risk Category: C

Dosage: Somatropin dosage is individualized. The drug is administered by injection.

Possible Adverse Effects: Injection site pain, glucose intolerance, hypothyroidism, bone problems (particularly the hip), blood abnormalities, rare intracranial hypertension in first 8 weeks of therapy

Nursing Implications

- Advise parents that radiographs of the wrist or hip are performed before therapy begins. Thereafter, parents should be alert for limping or knee or hip pain, which should be reported to their primary care provider. Slipped capital epiphysis is associated with rhGH supplementation.
- Reinforce the need for periodic thyroid function tests and funduscopic examination (to detect rare intracranial hypertension).
- Tell parents that rhGH may interact with glucocorticoid therapy such as prednisone, causing a decrease in the effectiveness of the rhGH. Urge parents to inform all health care practitioners that the child is receiving rhGH.
- Keep in mind that administration of rhGH is associated with a possible increased risk of leukemia.

Nursing Diagnoses and Related Interventions ✻

Nursing Diagnosis: Situational low self-esteem related to short stature

Outcome Evaluation: Child speaks positively about self; identifies friends and activities enjoyed with peers.

If a child has been consistently behind in growth since early life, parents may simply assume in early childhood that the child is going to be short as an adult. The parents then may become concerned only after the child reaches puberty and fails to develop secondary sex characteristics. If investigation at that time reveals the child's true problem, parents may feel guilty that they did not become alarmed earlier. They may feel resentment toward health care personnel who did not alert them to the problem earlier. Encourage parents to discuss these feelings, and provide support to help them accept their child in this new light as well as participate in making the new plan of care a success (Box 48.4). You may need to remind parents to assign duties and responsibilities to children that match their chronologic age, not their physical size, in order to promote children's feelings of maturity and self-esteem. Children, too, may need some help in accepting themselves at the ultimate height they achieve, especially if this is only in the 5th percentile, not the 50th (Webb & Badia, 2007).

Growth Hormone Excess

Overproduction of GH usually is caused by a benign tumor of the anterior pituitary (an adenoma). If an overproduction occurs before the epiphyseal lines of the long bones have closed, excessive growth results (Guven et al., 2007). Weight is excessive also, but it is proportional to height. The skull circumference typically exceeds normal, and the fontanelles may close late or not at all. Such excessive growth usually becomes evident at puberty, when prepubertal growth is greatly accelerated. *Acromegaly* (enlargement of the bones of the head and soft parts of the hands and feet) may accompany the early excessive growth in stature, although acromegaly becomes more pronounced after the epiphyseal lines of the long bones close and linear growth is no longer possible. Acromegaly can cause the tongue to be so enlarged and thickened that it protrudes from the mouth, giving the child a dull, apathetic appearance and difficulty in articulating words. If the condition remains untreated, a child may reach a height of more than 8 feet. Radiographs or ultrasounds of the skull reveal enlargement of the sella turcica.

BOX 48.4 * Focus on Communication

Rob, a 16-year-old with diabetes, is short in stature. While observing him and his mother, you notice that Rob is wearing clothes more suitable for a preteen than an adolescent.

Less Effective Communication

Nurse: Mrs. Tebecco, do you have any questions about Rob's care?

Mrs. Tebecco: No. I'm worried that soon he'll be wanting a driver's license. I'm lucky he's so short he can't really drive yet.

Nurse: Is he happy being so short?

Mrs. Tebecco: It's made him better at gymnastics than the taller boys. Probably because he looks so much younger than he is.

Nurse: Well, that's good. Sometimes it's hard for children with a chronic disease to be happy.

More Effective Communication

Nurse: Mrs. Tebecco, do you have any questions about Rob's care?

Mrs. Tebecco: No. I'm worried that soon he'll be wanting a driver's license. I'm lucky he's so short he can't really drive yet.

Nurse: Is he happy being so short?

Mrs. Tebecco: It's made him better at gymnastics than the taller boys. Probably because he looks so much younger than he is.

Nurse: But how does he feel about his size? How do you think he'll feel in the future?

Mrs. Tebecco: I can't even think about that. I don't want to lose my baby.

Nurse: Let's talk a little bit about how his growing up makes both of you feel before we review his insulin injection technique.

Many children with endocrine or metabolic disorders are short in stature. This characteristic causes them to be viewed as cute and petite by parents and treated as if they were younger than their true chronologic age. Parents can enjoy their child's short stature, because it makes it seem as if the child will remain a child longer, and not grow up and be independent. Exploring how parents and the child feel about this misperception can help them see that all children grow older chronologically even if they appear still young.

If the cause of the increased hormone production is a tumor, laser surgery to remove the tumor or cryosurgery (freezing of tissue) is the primary treatment. If no tumor is present, irradiation or radioactive implants of the pituitary may be successful in reducing the abnormal GH production. In other children, a GH antagonist is prescribed. Because other hormones may be affected when GH secretion is halted in this way, it may be necessary for the child to receive supplemental thyroid extract, cortisol, and gonadotropin hormones in later life. Bromocriptine (Parlodel) taken orally or octreotide (Sandostatin), taken by injection, both reduce GH production and so, in addition to surgery, may be helpful.

It is difficult for a child always to be bigger and taller than playmates, and the problem continues to be very real and distressing in adulthood. These children need to be identified during regular health screening to determine the cause of excessive growth and to offer treatment.

Diabetes Insipidus

Diabetes insipidus is a disease in which there is decreased release of antidiuretic hormone (ADH) by the pituitary gland (Rivkees, Dunbar, & Wilson, 2007). This causes less reabsorption of fluid in the kidney tubules. Urine becomes extremely dilute, and a great deal of fluid is lost from the body. Diabetes insipidus may reflect an X-linked dominant trait, or it may be transmitted by an autosomal recessive gene. It may result from a lesion, tumor, or injury to the posterior pituitary; or it may have an unknown cause. In a rare type of diabetes insipidus, pituitary function is adequate, but the kidneys' nephrons are not sensitive to ADH (a kidney-related etiology).

Assessment

The child with diabetes insipidus experiences excessive thirst **(polydipsia)** that is relieved only by drinking water, not breast milk or formula, as well as polyuria. The specific gravity of the urine is low (1.001 to 1.005); normal values are more often 1.010 to 1.030. Urine output may reach 4 to 10 L in a 24-hour period (normal range, 1 to 2 L), depending on age.

Signs and symptoms of diabetes insipidus usually appear gradually. Parents may notice the polyuria first as bedwetting in a toilet-trained child. Weight loss occurs because of the large loss of fluid. If the condition remains untreated, the child will lose such a quantity of water that dehydration and death can result.

Radiography, CT scanning, or ultrasound study of the skull reveals whether a lesion or tumor is present. A further test is the administration of vasopressin (Pitressin) to rule out kidney disease. After the child's urine output has been measured, to establish a baseline, vasopressin is administered. The drug decreases the blood pressure, alerting the kidney to retain more fluid to maintain vascular pressure. If the fault that is causing the dilute urine is with the pituitary, not the kidney, the child's urine output will decrease; if the fault is with the kidney, urine will remain dilute and excessive in amount as the kidney cannot concentrate fluid.

Therapeutic Management

Surgery is the treatment of choice if a tumor is present. If the cause is idiopathic, the condition can be controlled by the administration of desmopressin (DDAVP), an arginine vasopressin. In an emergency, this drug can be given intravenously (IV). For long-term use, it is given intranasally or orally. If desmopressin is given as an intranasal spray, children should use the small tube supplied with the medication to deposit the prescribed dose well into the nose. Nasal irritation may result from intranasal administration, and such administration will not be effective if the child has an upper respiratory tract infection and swollen mucous membranes. Caution children that they will notice an increasing urine output just before the next dose is due (Karch, 2009).

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for deficient fluid volume related to constant, excessive loss of fluid through urination

Outcome Evaluation: Child's blood pressure and pulse are within normal limits for age; specific gravity of urine is between 1.003 and 1.030; skin turgor is good; child states thirst is not excessive.

Teach About Long-Term Therapy. Rules that are helpful for families who will need to administer medicine long term are shown in Box 48.5. If an IM medication is prescribed, the child and at least one parent must learn the injection technique to ensure adherence. Be sure to explain the difference between diabetes insipidus and diabetes mellitus, the disorder most people think of when they hear the word "diabetes," so that the family is not confused about differences in therapy. Help the family establish a routine to ensure that the child receives adequate fluid to discourage a feeling of thirst and has access to bathroom facilities possibly more frequently than others.

Encourage Communication. Caution parents that, when seeking any type of health care, they should always notify health care providers that the child has diabetes insipidus. For example, surgery poses particular dangers because of the fluid restrictions that accompany most procedures. Encourage children to wear a medical alert tag identifying them as having diabetes insipidus. With the child's and parents' permission, inform school personnel that the child may need to use the bathroom frequently; help the child and family plan frequent bathroom stops and adequate fluid intake on long trips or activity-filled days.

BOX 48.5 Focus on Family Teaching

Guidelines for Successful Long-term Medicine Administration

Q. Rob's mother says to you, "Rob keeps forgetting to take his insulin. What can we do to make sure that he continues to take it regularly for the rest of his life?"

A. Here are some helpful tips to increase the success of long-term medication therapy:

1. Teach children about the type and purpose of the medicine they will be taking. Knowing the purpose of something maintains interest and cooperation.
2. If mixing a medication with food or fluid, use only a small amount of fluid or food to avoid opposition from the child and ensure that the child takes the necessary dose.
3. Always be certain to anticipate the need to obtain prescriptions, so that a ready supply is on hand before vacations, summer camp, and holidays.
4. Avoid bribing children to get them to take their medicine. After a time, a bribe becomes too difficult to maintain.
5. Begin involving your child early in administering his or her own medication. The earlier you can involve children in administering their own medication, the sooner they can achieve an independent lifestyle.
6. Be aware of the life span of the medicine being administered, so that outdated medication is not used.
7. Do not store medicine carelessly. Consider all medicine a potential poison, and keep it out of the reach of small children.
8. Use a dose-reminder system, such as a chart on the refrigerator, bathroom door, or school locker.
9. Plan times for medication administration that allow for a normal lifestyle such as not having to wake up at 2 AM or having to interrupt a school class for an injection.

Syndrome of Inappropriate Antidiuretic Hormone

Syndrome of inappropriate antidiuretic hormone (SIADH) is overproduction of antidiuretic hormone by the posterior pituitary gland. This results in a decrease in urine production and water intoxication. As sodium levels fall in proportion to water, the child develops hyponatremia or a lowered sodium plasma level. It can be caused by central nervous system infections such as bacterial meningitis (see Chapter 49), long-term positive pressure ventilation, or pituitary compression such as could occur from edema or a tumor.

Mild symptoms of hyponatremia are weight gain, concentrated urine (increased specific gravity), nausea, and vomiting. As the hyponatremia grows more severe, coma or seizures occur from brain edema.

Therapy consists of restriction of fluid and supplementation of sodium by IV fluid if needed. Demeclocycline (Declomycin) may be prescribed. Demeclocycline is a tetracycline antibiotic which has the side effect of blocking the action of ADH in renal tubules and reducing resorption of water (Frederick & Danzl, 2008).

THE THYROID GLAND

The thyroid gland is responsible for controlling the rate of metabolism in the body through production of the hormones thyroxine (T_4) and triiodothyronine (T_3) by its follicular cells.

A third hormone, thyrocalcitonin, is produced by the interstitial cells of the gland. Thyrocalcitonin is released if a high serum calcium level occurs. This hormone inhibits bone resorption, thereby slowing the rate of release of calcium from bone to plasma and resulting in a lowered serum calcium level. It reflects the reverse action of parathyroid hormone, which elevates serum calcium levels.

Assessment of Thyroid Function

Radioimmunoassay of T_4 and T_3 is a specific blood study to determine how much protein-bound iodine (PBI) is present. If a child has recently taken large amounts of cough medicine containing iodide or underwent a study using an iodine-based

contrast medium (studies such as urography or bronchography), the PBI level may be abnormally elevated. The small amount of iodine ingested from iodized salt does not affect PBI levels.

Children who have low circulating albumin levels can have abnormally low PBI levels, because iodine is carried bound to protein. Phenytoin (Dilantin), a common anticonvulsant medication prescribed for children with recurrent seizures, may displace thyroxine from binding globulin and further contribute to low PBI levels.

Another test of thyroid function is a radioactive iodine uptake test. The child is given an oral dose of a solution containing radioactive iodine (^{123}I). The thyroid gland "traps" this iodine, and 24 hours later, after the maximum amount has been trapped, the amount of radioactive iodine present can be determined. It is important in this type of test that the child swallows all the solution. In infants, the solution usually is given as a gavage feeding, so that accuracy of the dose can be ensured.

An uptake of less than 10% of the test dose suggests hypothyroidism. If the child vomits after ingesting the substance, this event should be recorded and called to the attention of the laboratory; it will obviously result in a lower uptake value, because only a part of the actual dose will be available for uptake. Be certain that the child does not receive iodine or thyroid extract in any other form during the test time, because it will compete with uptake of the radioactive iodine and, again, produce a falsely low value.

THYROID GLAND DISORDERS

Congenital Hypothyroidism

Thyroid hypofunction causes reduced production of both T_4 and T_3. Congenital hypofunction (reduced or absent function) occurs as a result of an absent or nonfunctioning thyroid gland in a newborn. The disorder occurs in 1 of every 4000 live births and about twice as often in girls as in boys (Jameson & Weetman, 2008). The cause of the disorder is usually unknown although if a woman has hyperthyroidism during pregnancy this can cause the fetal thyroid to not fully develop as it is so bombarded by thyroid hormones it does not need to function (Kempers et al., 2007). The condition may not be noticeable initially, because the mother's thyroid hormones maintain adequate levels in the fetus during pregnancy. The symptoms of congenital hypothyroidism become apparent, however, during the first 3 months of life in a formula-fed infant and at about 6 months in a breastfed infant. Because congenital hypothyroidism causes progressive physical and cognitive challenges, early diagnosis is crucial.

Assessment

A screening test for hypothyroidism is mandatory at birth (using the same few drops of blood obtained for a Guthrie or phenylketonuria [PKU] test) (Korada et al., 2008). If an infant should miss this screening procedure, an early sign that parents report is that their child sleeps excessively. The tongue becomes enlarged, causing respiratory difficulty, noisy respirations, or obstruction. The child may suck poorly because of sluggishness or choking. The skin of the extremities usually feels cold, and the overall body temperature may be subnormal because of slowed metabolism. A slow metabolic rate is also revealed by slow pulse and respiratory rates. Prolonged jaundice may be present, due to the immature liver's inability to conjugate bilirubin. Anemia may increase the child's lethargy and fatigue.

The child's neck appears short and thick. The facial expression becomes dull, as the result of becoming cognitively challenged, and open-mouthed because of the child's attempts to breathe around the enlarged tongue. The extremities appear short and fat, with hypotonic muscles, giving the infant a floppy, rag-doll appearance. Deep tendon reflexes are decreased from normal. Generalized obesity usually occurs. Hair is brittle and dry. Dentition is delayed, or teeth may be defective when they do erupt. An ultrasound reveals a small or absent thyroid gland.

The hypotonia affects the intestinal tract as well, so the infant develops chronic constipation; the abdomen enlarges because of intestinal distention and poor muscle tone (Fig. 48.2). Many infants have an umbilical hernia. Overall, the skin is dry and perhaps scaly, and the child does not perspire. Infants have low radioactive iodine uptake levels, low serum T_4 and T_3 levels, and elevated thyroid-stimulating factor. Blood lipids are increased. Radiographs may reveal delayed bone growth.

Therapeutic Management

The treatment for hypothyroidism is oral administration of synthetic thyroid hormone, sodium levothyroxine. A small dose is given at first, and then the dose is gradually increased to therapeutic levels. The child needs to continue taking medication indefinitely to supplement that which the thyroid does not make. Supplemental vitamin D may also be given to prevent the development of rickets when, with the administration of thyroid hormone, rapid bone growth begins (Delvecchio et al., 2007).

Further cognitive challenges can be prevented as soon as therapy is started, but any degree of impairment that is already present cannot be reversed.

Helping parents administer medication over a long period is a major nursing role. Be certain that parents know the rules for long-term medication administration with children, particularly the rule about not putting medicine in a large amount of food (thyroxine tablets must be crushed and

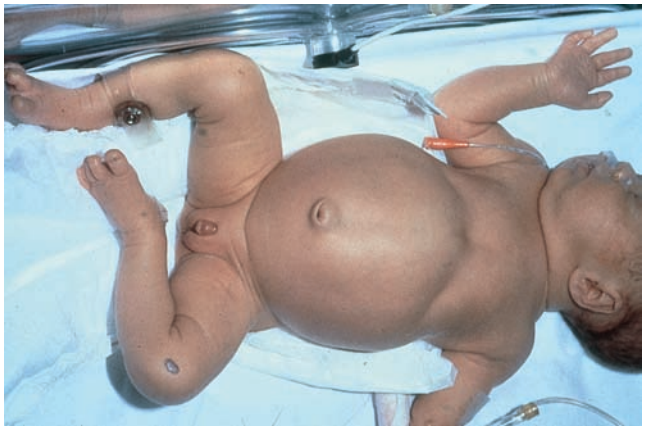


FIGURE 48.2 An infant with congenital hypothyroidism. Notice the short, thick neck and enlarged abdomen. (© David/NMSB/Custom Medical Stock Photograph.)

added to food or a small amount of formula or breast milk). Periodic monitoring of T_4 and T_3 helps to ensure an appropriate medication dosage. If the dose of thyroid hormone is not adequate, the T_4 level will remain low, and there will be few signs of clinical improvement. If the dose is too high, the T_4 level will rise, and the child will show signs of hyperthyroidism: irritability, fever, rapid pulse, and perhaps vomiting, diarrhea, and weight loss.

Acquired Hypothyroidism (Hashimoto's Thyroiditis)

Hashimoto's disease is the most common form of acquired hypothyroidism in childhood; the age at onset is often 10 to 11 years. There may be a family history of thyroid disease. It occurs more often in girls than in boys. The decrease in thyroid secretion is caused by the development of an autoimmune phenomenon that interferes with thyroid production. Excretion of thyroid-stimulating hormone (TSH) from the pituitary increases when thyroid hormone production decreases, in an attempt to cause the thyroid to be more effective (Fitzgerald, 2008).

Assessment

In response to TSH, hypertrophy of the thyroid gland (goiter) occurs, and body growth is impaired by lack of thyroxine. In infants, congenital goiter can lead to airway obstruction; in children, prominent symptoms are obesity, lethargy, and delayed sexual development.

Antithyroid antibodies will be present in serum if the illness was caused by an autoimmune process. The thyroid not only enlarges but may become nodular in response to the oversecretion of TSH. Although in childhood a nodular thyroid is usually benign, an investigation into the possibility of thyroid malignancy must be considered. For diagnosis, children are administered radioactive iodine. If the nodes are benign, there is generally a rapid uptake of radioactive iodine ("hot nodes"). If there is no uptake ("cold nodes"), carcinoma is a much more likely diagnosis (rare at this age).

Therapeutic Management

Treatment for acquired hypothyroidism is the administration of synthetic thyroid hormone (sodium levothyroxine), the same as for congenital hypothyroidism. With adequate dosage, the obesity diminishes and growth begins again. It is important that the disease be recognized as early as possible so there is time to stimulate growth before the epiphyseal lines close at puberty.

If acquired hypothyroidism exists in a woman during pregnancy, her infant can be born cognitively challenged. Therefore, it is important that girls with this syndrome be identified before they reach childbearing age.

Hyperthyroidism (Graves' Disease)

Hyperthyroidism is oversecretion of thyroid hormones by the thyroid gland. In children, it usually occurs at the time of puberty or during adolescence and is more common in girls than in boys (Lee & Masharani, 2009). Overactivity of the thyroid gland can occur from the gland's being overstimulated by TSH from the pituitary gland due to a pituitary tumor. More frequently, hyperthyroidism in children is caused by an autoimmune reaction that results in overproduction of immunoglobulin G (IgG), which stimulates the thyroid gland to overproduce thyroxine. An exophthalmos-producing pituitary substance causes the prominent-appearing eyes that accompany hyperthyroidism in some children.

Assessment

Graves' disease often follows a viral illness or a period of stress. Some children may have a genetic predisposition to development of the disorder. With overproduction of T_3 and T_4, children gradually experience nervousness, loss of muscle strength, and easy fatigue. Their basal metabolic rate is high; blood pressure and pulse are increased. They perspire freely. They are always hungry, and, although they eat constantly, they do not gain weight and may even lose weight because of the increased basal metabolic rate. On radiography, bone age appears advanced beyond the chronologic age of the child. Unless the condition is treated, the child will not be able to reach normal adult height, because epiphyseal lines of long bones will close before normal height is attained.

The thyroid gland, which usually is not prominent in children, appears as a swelling on the anterior neck (goiter). This enlargement can be confirmed by ultrasound. When the child protrudes the tongue or extends the hands, fine tremors are noticeable. In a few children, the eye globes are prominent (exophthalmos), giving the child a wide-eyed, staring appearance. Laboratory tests show elevated T_4 and T_3 levels and increased radioactive iodine uptake. TSH is low or absent because the thyroid is being stimulated by antibodies, not by the pituitary gland.

Therapeutic Management

Therapy consists first of a course of a beta-adrenergic blocking agent, such as propranolol, to decrease the antibody response (Glaser & Styne, 2008). After this, the child is placed on an antithyroid drug, such as propylthiouracil (PTU) or methimazole (Tapazole), to suppress the formation of thyroxine. While the child is taking these drugs, the blood is monitored for leukopenia (decreased white blood cell count) and thrombocytopenia (decreased platelet count), side effects of the drugs. If either of these results, the drug is discontinued until the white blood cell or platelet count returns to normal, so the child does not develop an infection or experience spontaneous bleeding.

Because the thyroid stores considerable thyroid hormone that must be used up first, it takes about 2 weeks for these drugs to have an effect. The child usually has to take the drug for 2 to 3 years before the condition "burns itself out." The exophthalmos may not recede, but it will not become worse after therapy is instituted.

If the child has a toxic reaction to medical management (severely lowered white blood cell count or platelet count) or is noncompliant about taking the medicine, radioiodine ablative therapy with ^{131}I to reduce the size of the thyroid gland can be accomplished (Rivkees & Dinauer, 2007). Surgical removal of part or almost all of the thyroid gland, which may be necessary in a young adult, also can be completed safely (Lee, Grumbach, & Clark, 2007). After both radioiodine ablative therapy and thyroidectomy, supplemental thyroid hormone therapy may be needed indefinitely because the gland is no longer able to produce an adequate amount. It is

important that adolescent girls be carefully regulated before they consider childbearing as high hyperthyroidism during pregnancy can lead to hypothyroidism in a fetus (Kempers et al., 2007).

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Situational low self-esteem related to lack of coordination and presence of prominent goiter

Outcome Evaluation: Child states positive traits about self and identifies friends and activities enjoyed.

Hyperthyroidism begins gradually and may become fairly involved before it is detected. Suspect children at puberty of having hyperthyroidism if they are losing weight or having behavior problems in school because of hand tremors and tongue tremors that make it hard for them to write or speak. Behavior problems may also arise because of nervousness and inability to sit still during class.

Offer parents support to supervise medication administration, so that they can be certain the child takes their medicine every day. Caution children not to stop taking the medicine abruptly or a thyroxine crisis (sudden onset of extreme symptoms of hyperthyroidism) can occur. Parents may ask if their child can have surgery as a cure so that long-term administration of medicine will not be required. Help them understand that surgery may not dispel the need for medication; if a large portion of the thyroid gland is removed, it may be necessary to give medicine indefinitely to make up for the missing gland. In any event, it is preferable to try a course of medical management before resorting to surgery.

Because the onset of hyperthyroidism is gradual, children may be aware of their difficulties in school before their parents are. Exophthalmos may lead to an appearance about which other children tease them. After therapy, encourage children to return to activities that require fine coordination or social interaction and to think of themselves as well again.

✔ Checkpoint Question 48.1

Rob's sister developed hyperthyroidism (Graves' disease) at puberty. Which is a typical appearance she would have shown?

a. Slow, lethargic movements.
b. Swollen protuberant abdomen.
c. Jittery, nervous mannerisms.
d. Reduced intellectual processing.

THE ADRENAL GLAND

The two adrenal glands are located retroperitoneally, just above each kidney (because of their location, they are also referred to as suprarenal glands). The adrenal glands are made up of two distinct parts, which differ not only in tissue origin but also in function. The *adrenal medulla* is a small core surrounded by the *adrenal cortex.* Although each of these parts has different functions and releases different hormones, together they protect the body against acute and chronic forms of stress.

Adrenal Hormones

The adrenal cortex produces cortisol (a glucocorticoid), androgen, and aldosterone (a mineralocorticoid)—three hormones, each of which can cause childhood illness. Norepinephrine and epinephrine, hormones important for maintaining blood pressure, are produced by the adrenal medulla.

Cortisol

Cortisol, a glucocorticoid that is necessary for glucose and protein metabolism, is released by the adrenal cortex in response to adrenocorticotropic hormone (ACTH) stimulation from the pituitary gland. ACTH is strongly influenced by biorhythm or circadian rhythms. In the hours just before and after a person awakens, ACTH reaches its highest peak. The level decreases again gradually throughout the day and night. The level of ACTH secretion also increases during periods of emotional stress, leading to increased production of cortisol. Severe trauma, major surgery, hypotension, extreme cold, and acute or chronic illness also increase production of cortisol.

Cortisol is necessary during a time of stress to provide the body with readily available glucose and protein for emergency processes. It elevates serum glucose by increasing the amount of glucose formed by the liver (gluconeogenesis), decreasing use of glucose by tissue, and releasing free fatty acids from tissue stores into the plasma, to make them available for energy. To increase available protein, protein synthesis in cells is halted, which frees up amino acids for liver production of protein.

Cortisol is also important in decreasing an inflammatory response. In the bloodstream, it causes a reduced number of eosinophils and lymphocytes, whereas production of red blood cells and platelets is increased. A drawback of this response is that the decreased number of lymphocytes may allow infection to occur.

Aldosterone

Aldosterone is secreted in response to the renin-angiotensin system, serum potassium, and sodium levels. Renin is released from kidney nephrons in response to a lowered blood pressure; shortly thereafter, it is converted to angiotensin II. In the presence of angiotensin II, aldosterone is released from the adrenal cortex. This causes retention of sodium and water and elevates blood pressure. When angiotensin is decreased, the production of aldosterone stops. When serum potassium levels rise, aldosterone secretion increases. Lowered levels of potassium decrease aldosterone secretion. Sodium influences aldosterone by a reverse process: when sodium levels are low, aldosterone secretion increases; an increased sodium concentration inhibits aldosterone secretion.

The end result of aldosterone secretion is always sodium retention by the body. As sodium is retained, fluid is also retained. Aldosterone plays a direct role in stabilizing blood volume and pressure because of its role in maintaining sodium balance. Infants born with an inability to produce aldosterone quickly become dehydrated, and their lives can be in immediate danger.

Androgen

Androgen is the hormone responsible for muscular development, increase in linear size, growth of body hair, male libido, and the increase in sebaceous gland secretions that cause typical acne at puberty (see Chapter 33).

ADRENAL GLAND DISORDERS

Disorders of the adrenal glands include those related to hypofunction, which can lead to acute or chronic insufficiency, and those related to hyperfunction (overactivity), which most often leads to overproduction of androgen or cortisol.

Acute Adrenocortical Insufficiency

Insufficiency (hypofunction) of the adrenal gland may be either acute or chronic. In many adrenal syndromes, only one hormone is involved, and the symptoms are directly related only to that hormone. In acute adrenocortical insufficiency, the function of the entire cortical adrenal gland suddenly becomes insufficient. Usually this occurs in association with severe overwhelming infection, typically involving hemorrhagic destruction of the adrenal glands. It is seen most commonly in meningococcemia. It also can occur when corticosteroid therapy that has been maintained at high levels for long periods is abruptly stopped.

Assessment

The symptoms of acute adrenocortical insufficiency are acute and sudden. The blood pressure drops to extremely low levels; the child appears ashen gray and may be pulseless. Temperature becomes elevated; dehydration and **hypoglycemia** (an abnormally low concentration of blood glucose) are marked. Sodium and chloride blood levels are very low, but serum potassium is elevated, because there is usually an inverse relationship between sodium and potassium values. The child is prostrate, and seizures may occur. Without treatment, death can occur abruptly (Menon & Lawson, 2007).

Therapeutic Management

Treatment involves the immediate replacement of cortisol (with IV hydrocortisone sodium succinate [Solu-Cortef]); administration of deoxycorticosterone acetate (DOCA), the synthetic equivalent of aldosterone; and IV 5% glucose in normal saline solution to restore blood pressure, sodium, and blood glucose levels. A vasoconstrictor may be necessary to elevate the blood pressure further.

Acute adrenocortical insufficiency is a medical emergency. Although it is seen less often now than in the past, because of the availability of antibiotics that quickly halt the course of infectious disease, it is not an obsolete entity. Now that more conditions are being treated with corticosteroids, the chances that acute adrenocortical insufficiency will occur from sudden withdrawal of high-dose steroids is actually increasing.

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia is a syndrome that is inherited as an autosomal recessive trait. The primary defect is an inability of the adrenal glands to synthesize cortisol from its precursors. Because the adrenal gland is unable to produce cortisol, the level of ACTH increases, stimulating the adrenal glands to improve function. Although the adrenals enlarge (hyperplasia), they still cannot produce cortisol; instead, they overproduce androgen (Trinh et al., 2007).

Assessment

The excessive androgen production masculinizes the female fetus or increases the size of genital organs in a male fetus (Zeitler, 2008). Because this process begins as early as fetal life, the female infant is born with a clitoris so enlarged that it appears more like a penis (Fig. 48.3). Internal female organs are usually normal, although a sinus between the urethra and vagina may be present (see discussion of ambiguous genitalia in Chapter 47). Because the labia are typically fused as well, the girl resembles a boy with undescended testes and hypospadias. If the condition is not recognized at birth and the child remains untreated, pubic and axillary hair and acne will appear precociously and a deep masculine voice will develop. The bone age is usually advanced, so the epiphyseal line of the long bones closes early. This closure prevents the child from reaching adult height unless treatment is initiated. At puberty, there will be no breast development or menstruation.

The male child may appear normal at birth, but by 6 months of age signs of sexual precocity appear. By 3 or 4 years of age, these boys have pubic hair and enlargement of the penis, scrotum, and prostate. They may have acne and a deep, mature voice. The testes do not enlarge, however, and, although they are normal in size, they appear small in relation to the size of the penis. Spermatogenesis does not occur, so the child is infertile.

Children with congenital adrenogenital hyperplasia have increased levels of androgen, an important point for diagnosis. By determining the levels of other adrenal hormones, the exact degree of the metabolic defect in production of cortisol can be measured.

Therapeutic Management

Both male and female infants are given a corticosteroid agent, such as oral hydrocortisone, to replace what they cannot produce naturally. When a corticosteroid is given to the

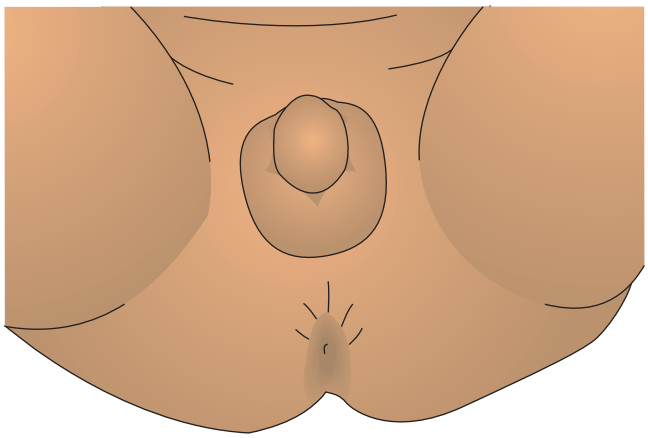

FIGURE 48.3 A female infant with congenital adrenogenital hyperplasia. Note the fused labia and abnormally enlarged clitoris.

child in this way, stimulation by ACTH decreases, production of androgen returns to normal limits, and no further masculinization occurs. Corticosteroid therapy needs to continue indefinitely. The child needs periodic analysis of serum cortisol levels and growth measurements to estimate the effectiveness of the therapy.

It is possible to identify the fetus with congenital adrenogenital hyperplasia as early as 6 to 8 weeks of pregnancy by means of chorionic villi sampling and at 15 weeks by amniocentesis (see Chapter 9). Treatment of a mother with dexamethasone (a corticosteroid), which crosses the placenta to the fetus, can prevent masculinization in the fetus for the remainder of the pregnancy.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Situational low self-esteem related to genital formation at variance with true gender

Outcome Evaluation: Child identifies positive traits about self and describes activities enjoyed with peers; expresses satisfaction with gender identity.

If children with congenital adrenogenital hyperplasia are not closely examined at birth, they can be wrongly identified as boys when chromosomally they are actually girls. Therefore, all newborns require an extensive physical examination at birth (Raab, 2007). It is sometimes recommended that a girl's enlarged clitoris be reduced by plastic surgery early in life. This treatment is controversial, however, because clitoral reduction can also result in reduced clitoral sensation. Fortunately, with finer surgical techniques, diminished sensation should be minimal.

Parents of females with congenital adrenogenital hyperplasia may need a great deal of support during the first few days of their child's life if they feel that their child is imperfect in an embarrassing, hard-to-explain way. When they are told the results of the chromosome analysis, parents may react with grief for the loss of the son they thought had been born to them. Parents need support from health care personnel who recognize that the child is simply lacking a completely formed hormone but is complete in every other way.

Nursing Diagnosis: Health-seeking behaviors related to lack of knowledge about long-term treatment needed to sustain adequate growth and development

Outcome Evaluation: Parents state plans for incorporating medication administration into child's daily routine whether at home or away on vacation or summer camp.

Parents, and children as they grow older, need to understand the importance of continuing to take the oral medication prescribed. When this condition is first diagnosed, it is easy for parents to remember to give the drug. As the years pass, however, it becomes more difficult to remember medication administration, because the child has no acute symptoms. Cortisol is necessary for glucose and protein metabolism, however. The body needs adequate levels to allow it to react to physical and emotional stress. When plans are made for summer camp or vacation away from home, special arrangements for regular medicine administration need to be made. Children may need to have a routine dose increased when they are undergoing periods of stress, such as surgery or infection. They may need support throughout life if their body image is distorted because of body changes at birth.

Salt-Losing Form of Congenital Adrenogenital Hyperplasia

If there is a complete blockage of cortisol formation, aldosterone production will also be deficient. Without adequate aldosterone, salt is not retained by the body, so fluid is not retained. Almost immediately after birth, affected infants begin to have vomiting, diarrhea, anorexia, loss of weight, and extreme dehydration. If these symptoms remain untreated, the extreme loss of salt and fluid can lead to collapse and death as early as 48 to 72 hours after birth (Finkenzeller & Loveless, 2007).

About one third of children with congenital adrenogenital hyperplasia are affected by this complete deficiency. Because boys with this syndrome appear normal at birth, the symptoms may be incorrectly diagnosed as pyloric stenosis, intestinal obstruction, or failure to thrive. In girls, because of the ambiguous genitalia, the correct diagnosis can be made more easily.

Assessment

The salt-losing form of congenital adrenogenital hyperplasia must be detected in infants before they reach an irreversible point of salt depletion. Weighing of a newborn at birth and again at 24 hours aids in detecting this condition. Weighing of infants at each well-child health checkup is also important. In boys, the inability to gain back their birth weight may be the first sign of the syndrome.

Therapeutic Management

Children with the salt-losing form of congenital adrenogenital hyperplasia need to take supplements of hydrocortisone in conjunction with a high amount of salt and DOCA, a synthetic aldosterone, to maintain a balance of fluid and electrolytes. A long-acting form of DOCA can be given once a month IM. Capsules of DOCA can also be implanted subcutaneously (SC) as another form of long-acting therapy. As the child grows older, fludrocortisone (Florinef), a mineralocorticoid, may be given orally to aid salt retention.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for deficient fluid volume related to loss of body fluid

Outcome Evaluation: Child's skin turgor remains good; specific gravity of urine is between 1.003 and 1.030.

Teach parents about the body's critical need to balance aldosterone, salt, and water, so that they understand the drastic consequences if their child skips a

dose of medication. Help them to set up a schedule as necessary for measuring their child's weight, giving medication, or measuring urine output. Help them to understand that, although salt seems to be an "extra" in their own diet, it is as vital to their child's intake as digitalis is in heart disease or insulin in diabetes.

Cushing Syndrome

Cushing syndrome is caused by overproduction of the adrenal hormone cortisol; this usually results from increased ACTH production due to a pituitary tumor. It may occur from a malignant or benign tumor of the adrenal cortex. The peak age of occurrence is 6 or 7 years, but the syndrome can occur as early as infancy (Batista et al., 2007). Overproduction of cortisol results in increased glucose production; this causes fat to accumulate on the cheeks, chin, and trunk, causing a moon-faced, stocky appearance. Cortisol is catabolic, so protein wasting occurs. This leads to muscle wasting, making the extremities appear thin. Loss of protein matrix in bones causes osteoporosis (loss of calcium in bones). Cortisol also suppresses the immune system, so humoral immunity is decreased, leaving children susceptible to infection. Additionally, it causes vasoconstriction, so extreme hypertension may occur.

Hyperpigmentation occurs from the melanin-stimulating properties of ACTH. This causes the child's face to be unusually red, especially the cheeks. Signs of abnormal masculinization or feminization may occur from accompanying overproduction of androgen or estrogen. Purple striae resulting from collagen deficit appear on the child's hips, abdomen, and thighs, similar to those seen in pregnancy (Fig. 48.4).

Polyuria develops as the body tries to excrete increased glucose levels. Growth ceases, and, if the condition is not reversed before the epiphyseal lines close, short stature results.

Children who receive high doses of synthetic corticosteroids, such as prednisone, over a long period may develop the same symptoms as those observed in Cushing syndrome. Such children are said to have a *cushingoid appearance.* Cushing syndrome is often suspected as the cause of obesity in children, and some obese children do have elevated levels of plasma corticosteroids, a fact that complicates the diagnosis. However, these elevated levels of corticosteroids are secondary to the obesity; they are not the cause. Children with natural obesity are generally tall; those with Cushing syndrome are short.

Assessment

Children with Cushing syndrome have elevated plasma cortisol and increased urinary free-cortisol levels. A dexamethasone suppression test confirms the diagnosis. If a child without the syndrome is given a test dose of dexamethasone (a glucocorticoid), the plasma level of adrenal cortisol will fall. It will not fall in children with adrenocortical tumors, because the tumor continues to stimulate the adrenal glands to oversecretion. If cosyntropin (Cortrosyn), a synthetic corticotropin, or ACTH is administered, plasma cortisol levels will normally rise. In patients with an adrenal tumor, the gland is already functioning at full capacity, so no cortisol elevation occurs. A CT scan or ultrasound reveals the enlarged adrenal or pituitary gland, confirming the diagnosis.

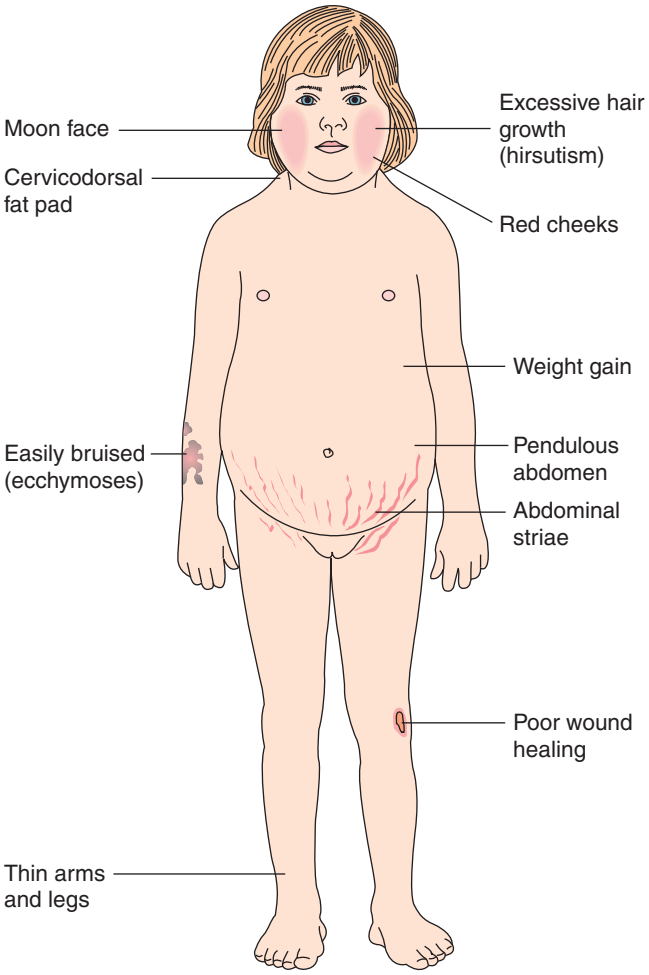

FIGURE 48.4 Signs and symptoms of Cushing syndrome.

Therapeutic Management

Treatment of Cushing syndrome is surgical removal of the causative tumor. The prognosis depends on whether the tumor is benign or malignant; carcinoma of this type tends to metastasize rapidly. If a major part of the adrenal gland is surgically removed, the child will need replacement cortisol therapy indefinitely.

If a major portion of the pituitary gland is removed because the problem was overproduction of ACTH, replacement of all pituitary hormones may be necessary. After adrenal surgery, observe the child carefully for signs of shock: without epinephrine from the adrenal gland, the body's ability to maintain blood pressure is severely compromised, and severe hypotension can result.

✔ Checkpoint Question 48.2

Rob has his adrenal gland function assessed. What is the effect on a child when sufficient aldosterone cannot be produced?

a. Substantially fewer red blood cells are produced.
b. There is an overall decreased urine output.
c. An excessive amount of sodium is lost in urine.
d. The child's growth rate increases abnormally.

THE PANCREAS

The pancreas is a unique organ in that it has both endocrine (ductless) and exocrine (with duct) types of tissue. The *islets of Langerhans* form the endocrine portion; these cells are scattered in-between the exocrine cells like small islets—hence, their name. The islet cells represent only about 1% of the total weight of the pancreas. Alpha islet cells secrete glucagon; beta islet cells secrete insulin.

Insulin is essential for carbohydrate metabolism and is important in the metabolism of fats and protein. It is formed by two amino acid chains from a precursor, *proinsulin,* at a rate of 35 to 50 U/day in adults and proportionately less in children. The actual amount of insulin produced is regulated by serum glucose levels. When serum glucose that passes through the pancreas exceeds 100 mg/dL, beta cells immediately increase insulin production. When blood serum levels are lowered, production decreases. Both the ability to secrete additional insulin and the action to decrease production are immediate responses.

Also important in the secretion of insulin is the presence of gastrointestinal hormones, such as gastrin, that rise when the stomach is full, because these also stimulate the pancreas to produce necessary insulin. Other hormones that stimulate insulin production include glucagon, cortisol, GH, progesterone, and estrogen. In contrast, increasing levels of epinephrine or norepinephrine inhibit the secretion of insulin to preserve glucose.

The principal childhood disorders associated with pancreatic dysfunction are type 1 and type 2 diabetes mellitus and cystic fibrosis. Because the nursing care for children with cystic fibrosis includes many respiratory care procedures, it is discussed in Chapter 40.

Type 1 Diabetes Mellitus

Type 1 diabetes is a disorder that involves an absolute or relative deficiency of insulin in contrast to type 2 where insulin production is only reduced (Table 48.2). Type 1 diabetes (formerly referred to as juvenile diabetes or insulin-dependent diabetes) occurs almost exclusively in childhood. The disease affects as many as 1 in 1500 children before 5 years of age and increases to 1 in 350 by age 16 (Masharani, 2009). The incidence is equal among girls and boys. Children with this type of diabetes must take insulin to replace what their pancreas cannot produce.

Etiology

The disease apparently results from immunologic damage to insulin-producing cells in susceptible individuals. Environmental effects may be necessary to create this immunologic response. Why autoimmune destruction of islet cells occurs in some children and not in others is unknown, but children with this disorder have a high frequency of certain human leukocyte antigens (HLA), particularly HLA-DR3 and HLA-DR4, located on chromosome 6 that may lead to susceptibility.

Although these specific HLA antigens predispose a child to developing diabetes, they do not always result in the actual disease. An environmental factor, such as a viral infection, must trigger active pancreatic dysfunction through an autoimmune process. Symptoms of the disease usually are not manifested until preschool or school age.

If one child in a family has diabetes, the chance that a sibling will also develop the illness is higher than in other families, because siblings also tend to have one of the specific HLA antigens that lead to the development of the disease. Because no prevention measures are available to stop diabetes from developing, children are not routinely tissue-typed for the disorder, although this may be done experimentally. Administration of immune suppressors to stop destruction of insulin-secreting cells is a possibility, although the long-term effects of immune suppression, such

TABLE 48.2 ✻ Comparison of Type 1 and Type 2 Diabetes

Assessment	Type 1	Type 2
Age at onset	5–7 years or at puberty	40–65 years (may occur in adolescents as maturity-onset diabetes of youth [MODY])
Type of onset	Abrupt	Gradual
Weight changes	Marked weight loss often initial sign	Associated with obesity
Other symptoms	Polydipsia	Polydipsia
	Polyuria (often begins as bedwetting)	Polyuria
	Fatigue (marks fall in school)	Fatigue
	Blurred vision (marks fall in school)	Blurred vision
	Glycosuria	Glycosuria
	Polyphagia (excessive eating)	
	Pruritus	Pruritus
	Mood changes (may cause behavior problems in school)	Mood changes
Therapy	Hypoglycemia agents never effective; insulin required	Diet, oral hypoglycemic agents, or insulin
	Diet recommended as 55% carbohydrates, 15% protein, and 30% fat; no dietary foods used	Nutrition concentrating on no excess weight gain and balanced intake of carbohydrates, protein, and fat
	Common-sense foot care for growing children	Meticulous skin and foot care necessary
Period of remission	Period of remission for 1–12 months ("honeymoon period") generally after initial diagnosis	Not demonstrable

as development of opportunistic infections, limit the use of these drugs.

Disease Process

Insulin can be thought of as a compound that opens the doors to body cells, allowing them to admit the glucose needed to function. It does not play a major role in glucose transport into the brain, erythrocytes, leukocytes, intestinal mucosa, or kidney epithelium. These cells can survive insulin deficiency but not glucose deficiency.

If glucose is unable to enter body cells because of a lack of insulin, it builds up in the bloodstream **(hyperglycemia),** and this underlying defect leads to other metabolic consequences. When the kidneys detect hyperglycemia (greater than the renal threshold of about 160 mg/dL), the kidneys attempt to lower it to normal levels by excreting excess glucose into the urine, causing **glycosuria.** While attempting to excrete this excess glucose, the body also excretes a large amount of fluid (polyuria). Excess fluid loss, in turn, triggers the thirst response (polydipsia) producing the three cardinal symptoms of diabetes: polyuria, polydipsia, and hyperglycemia.

Because body cells are unable to use glucose but still need a source of energy, the body breaks down protein and fat for cell utilization. If large amounts of fat are metabolized in this way, weight loss occurs and ketone bodies, the acid end-product of fat breakdown, begin to accumulate in the bloodstream and spill into the urine. Because the blood bicarbonate cannot effectively continue to buffer this high an acid level, the pH of the blood becomes acidic, resulting in severe acidosis. The breakdown of fat also leads to increased serum cholesterol levels. Potassium and phosphate, attempting to serve as buffers, pass from body cells into the bloodstream. As they are evacuated, the body loses these important electrolytes.

Untreated diabetic children, therefore, lose weight, are acidotic due to the buildup of ketone bodies in their blood (a state known as **ketoacidosis),** are dehydrated because of the loss of water, and experience an electrolyte imbalance because of the loss of electrolytes in urine. Because large amounts of protein and fat are being used for energy instead of glucose, these children lack the necessary components for growth; they therefore remain short in stature and underweight (Chase & Eisenbarth, 2008).

Assessment

Although children may be prediabetic for some time, the onset of symptoms in childhood is usually abrupt. The first symptoms likely to be reported are increased thirst and increased urination. Increased urination may begin as bedwetting (enuresis) in a previously toilet-trained child. In addition, children may have constipation because of the dehydration.

Laboratory Studies. In some children, diabetes is detected at a routine health screening. For others, although the disease has been progressing internally for some time, outward symptoms have such an abrupt onset that the child is in coma from acidosis and hyperglycemia by the time it is detected. Laboratory studies usually show a random plasma glucose level greater than 200 mg/dL (normal range, 70 to 110 mg/dL fasting, 90 to 180 mg/dL not fasting) and significant glycosuria (Table 48.3).

TABLE 48.3 ✻ Acceptable Blood Glucose Ranges for Young Children

Timing	Value (mg/dL)
Before a meal	70–110
1 h after a meal	90–180
2 h after a meal	80–150
Between 2 and 4 AM	70–120

Two diagnostic tests, the fasting blood glucose test and the random blood glucose test, are used to diagnose diabetes. A diagnosis of diabetes is confirmed based on finding one of the following three criteria on two separate occasions:

- Symptoms of diabetes with a random blood glucose level greater than 200 mg/dL
- Fasting blood glucose level greater than 126 mg/dL
- Two-hour plasma glucose level greater than 200 mg/dL during an oral glucose tolerance test (GTT)

Typically, a GTT, which involves oral ingestion or IV administration of a concentrated glucose solution followed by blood glucose levels drawn at fasting (baseline), after 1 hour, and after 2 hours, is rarely performed in children. This test is difficult for children to undergo, because it requires them to fast and submit to painful, intrusive procedures (routine application of EMLA cream to fingerstick or venipuncture sites and use of intermittent infusion devices greatly reduces this problem). Do not take blood for glucose analysis from functioning IV tubing, because the glucose in the IV solution will cause the serum reading to be abnormally high.

Other Diagnostic Tests. If diabetes is detected, the diagnostic workup also usually includes analysis of blood samples for pH, partial pressure of carbon dioxide (P_{CO_2}), sodium, and potassium levels; a white blood cell count; and glycosylated hemoglobin (HbA_{1c}) evaluation. Normally, red blood cells carry only a trace of glucose incorporated into the hemoglobin. If serum glucose is excessive, however, excess glucose attaches itself to hemoglobin molecules, causing glycosylated hemoglobin. The higher the serum glucose level, the higher the HbA_{1c} becomes. In nondiabetic children, the usual HbA_{1c} value is 1.8 to 4.0. A value greater than 6.0 reflects an excessive level of serum glucose. Measuring glycosylated hemoglobin provides information about what the child's glucose levels have been during the preceding 3 to 4 months, because red blood cells have a life span of 120 days.

If the potassium level of the blood is low, a child may need an electrocardiogram to observe for T-wave abnormalities, the mark of potassium deficiency. The white blood cell count of a child with diabetes may be elevated even though no infection is present, apparently as a response to the ketoacidosis. The presence of infection must always be suspected, however, because it is often a precipitant to a diabetic crisis. For this reason, nose and throat cultures may be obtained as well.

Therapeutic Management

Therapy for children with type 1 diabetes involves five measures: insulin administration, regulation of nutrition and exercise, stress management, and blood glucose and urine ketone monitoring. Children with newly suspected diabetes mellitus may be admitted to the hospital for a few days for diagnosis or may be managed on home care as regulation of insulin dosage and education, although hospitalization may not be necessary if the child's symptoms are minimal (Clar, Waugh, & Thomas, 2009). Teaching the parents and the child the techniques of intensive management (frequent insulin injections and adherence to nutritional guidelines with regulation of exercise) produces immediate well-being and reduces the incidence of long-term complications. Allow parents and children time to adjust to this illness, which will require constant vigilance in the months and years to come.

Initial Regulation of Insulin. When children are first diagnosed with diabetes, they are usually hyperglycemic and perhaps ketoacidotic. To correct the metabolic imbalance, they are given insulin administered IV at a dose of 0.1 to 0.2 U per kilogram of body weight per hour. This initial IV infusion of insulin is followed by dose reductions once the blood glucose level is lower than 200 mg/dL. The actual dosage prescribed depends on the change in the acidosis and the degree of glycosemia and ketonuria. Some controversy exists regarding the belief that insulin binds to the plastic IV tubing. Therefore, check your institution's policy and be prepared to change the IV tubing as frequently as required. Ideally, within 12 hours, the acidosis is considerably less than when a child was admitted to the hospital, and the serum glucose level is near the normal range. The insulin given for emergency replacement this way is regular (short-acting) insulin (Humulin-R), because this is the form that takes effect most quickly when administered IV in normal saline. Lispro (Humalog) or insulin aspart, which are also rapid acting, are other possibilities.

It may seem that, in a diabetic child in a state of acidosis, the administration of glucose would not be warranted. Because the child is being given insulin, however, body cells soon become ready to use glucose, and they incorporate and use available glucose quickly. If more is not provided, cells are forced to continue to break down fats and protein, and the acidosis can increase, not decrease. Glucose may be added to the infusion, if necessary, therefore, to meet this need.

After 24 hours, as the child's serum glucose returns to normal, oral feedings may replace the IV route. Further management in the days after this first crucial 24-hour period is based on the serum glucose determinations. A child may remain on regular insulin alone (given three or four times a day) for the first 1 or 2 days. Typically, intermediate-acting insulin is then prescribed as soon as oral fluids are taken, usually on the second day of therapy.

Insulin Administration. Before insulin was discovered in 1920, few children with type 1 diabetes lived to adulthood. Even after its discovery, not all children responded well to insulin administration, because early forms were manufactured from a pork or beef base that caused development of antibodies against insulin, making the therapy less effective than predicted. Today, insulin is manufactured by a recombinant DNA technique to simulate human insulin (Humulin, Novolin), and this has largely eliminated the problem of antibody reaction.

Types of insulin vary as to their time of onset, peak action, and duration of action (Table 48.4). Regular insulin is usually referred to as short-acting insulin; Humulin-L and Humulin-N are examples of intermediate-acting insulins, and Humulin-U is long acting. Children are regulated on a variety of insulin programs, but most receive a dose of 0.4 to 0.7 U per kilogram of body weight daily in two divided doses (one before breakfast and one before dinner); adolescents may need as much as 1.2 U/kg daily. The most common mixture of insulin used with children is a combination of an intermediate-acting insulin and a regular insulin, usually in a 2:1 ratio or ⅔ units of the intermediate-acting insulin to ⅓ units regular insulin, and given in the same syringe, although this prescription varies for individual children. The morning dose is two thirds of the total daily dose; the evening dose is the remaining one third. The peak effects of the short-acting insulins are at 3 to 4 hours (see Table 48.4). This means that the child who takes insulin before breakfast will notice a peak effect between 10 AM and 12 noon; that is the time of day when hypoglycemia (a reaction to an excessive insulin level) is most likely to occur. The

TABLE 48.4 ✻ Common Types of Human Insulin

Preparation	Onset (hr)	Peak Effect (hr)	Duration of Effect (hr)
Lispro (Humalog)	Immediate	30 min–1	3–4
Aspart	15 min	30–40 min	3–5
Regular (Humulin-R)	0.5–1.0	2–4	5–7
Lantus	1	5	24
Humulin-N	1–2	4–12	24+
Humulin-L	1–3	6–14	24+
Humulin-U	6	16–18	36+

Source: Karch, A. M. (2009). *Lippincott's nursing drug guide.* Philadelphia: Lippincott Williams & Wilkins.

peak effect period of the intermediate-acting insulins is 8 to 14 hours, or late afternoon, just before dinner. This is another prime time for hypoglycemia.

Some children require a program of insulin therapy that includes three injections daily (a short-acting and intermediate-acting insulin before breakfast, a short-acting insulin before supper, and a bedtime injection of an intermediate-acting insulin). Still others receive an injection of regular or Humalog insulin before each meal, plus a bedtime injection of intermediate-acting insulin (a total of four injections daily). Although a regimen with the fewest injections daily at first seems advantageous, multiple injections allow for greater variation in activity and meal consumption.

In the past, fixed doses of insulin were prescribed, and parents were advised not to vary the dose. Today, parents are educated to be able to vary the dose based on an insulin algorithm or protocol determined by the child's level of activity, the size of meals consumed, and the time of the injection (referred to as "thinking scales"). The time between the insulin injection and a meal is known as "lag time." If a child's premeal blood glucose level is above a target range, parents learn that increasing the lag time will help prevent hyperglycemia. If the blood glucose is low at a premeal test, decreasing the lag time could help prevent hypoglycemia. If it is anticipated that the child will eat an unusually large meal such as at a special birthday dinner, parents can increase the size of the premeal regular insulin injection. If the child is to participate in a strenuous sport in the afternoon that will utilize glucose, the regular insulin injection can be decreased. Lantus is a new long-acting insulin that lasts 24 hours. A disadvantage of this insulin is its pH, which is so low that it cannot be mixed in a syringe with other insulins. In some children, glucose levels can be regulated on Lantus plus three doses of Humalog before meals.

Injection Technique. When insulins are mixed in one syringe, the regular or short-acting insulin should be drawn into the syringe first. Then, if mixing accidentally occurs in the bottle, the time of effectiveness of the short-acting insulin (which needs to be kept short-acting for emergency treatment) will not be lengthened by the addition of the intermediate-acting insulin.

Insulin is always injected SC except in emergencies, when half the required dose may be given IV. SC tissue injection sites include those of the upper outer arms and the outer aspects of the thighs (Fig. 48.5). The abdominal SC tissue injection sites may be preferred for injection, because many children have a greater amount of subcutaneous tissue there. However, most children dislike this site. Children should be encouraged to rotate sites in a pattern based on their planned activity. Absorption is increased if the muscles at the injection site are exercised after an injection, so it is best to choose sites that will not be exercised soon after the injection. If a child will be jogging after an injection, for example, the thigh probably should not be used. Similarly, if the child will be playing tennis, the injection probably should not be given in the dominant arm.

Work out a plan of rotation with children so that everyone who will be working with the child and giving injections knows what injection site should be used next. In the hospital, record the injection site in the child's chart or nursing plan of care, so that each nurse can check it before an injection and not repeat an injection site. If the same injection site is used repeatedly, a great deal of subcutaneous atrophy (lipodystrophy) can occur at the site, causing deep, obvious pockmarks. However, this is less of a problem now that synthetic human insulin is available.

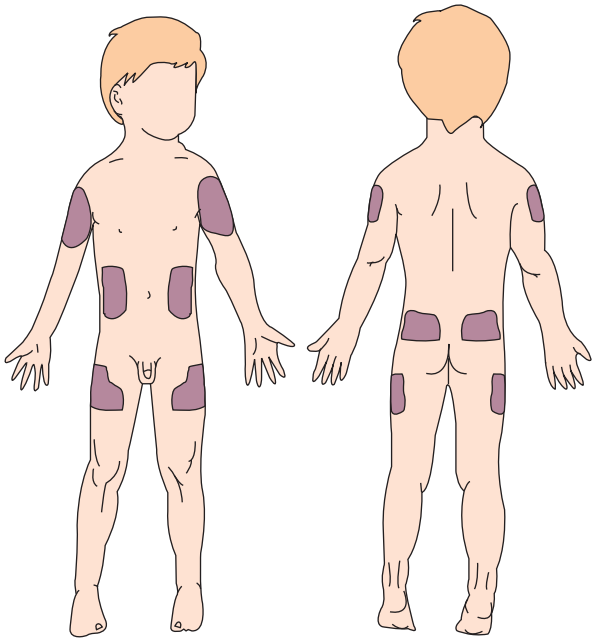

FIGURE 48.5 According to the American Diabetes Association, insulin injection sites in children and adults are the upper outer portions of the arms; the thighs—4 inches below the hip and 4 inches above the knee (adjusted proportionally for children); and the abdominal area just above and just below the waist. The navel and a circular area just around it are excluded as injection sites. In some children, the abdominal area may not be an appropriate injection site.

Children quickly learn that, if they continuously give injections in the same site, scar tissue (lipohypertrophy) forms there, and no pain will be felt on injection. This is a dangerous practice, however, because insulin no longer absorbs well from this site. The dose will have to be increased beyond what the child actually needs for glucose metabolism, because a portion of each dose is "locked" in the tissue. Should the child then inject this larger dose of insulin into a new site, there is a potential for overdose (which would cause hypoglycemia).

Insulin should be given at room temperature. This diminishes subcutaneous atrophy and ensures peak effectiveness. Parents may keep additional bottles in the refrigerator to increase the insulin's shelf life.

If a short needle (less than 0.4 inch) is used, children can administer insulin without bunching skin at the site and can give the injection to themselves at a 90-degree angle, a technique more closely resembling that of IM rather than SC injection. Because the needle is so short, the insulin is deposited in the subcutaneous tissue. This technique is easier for children to learn, because it takes less coordination to administer an injection at a 90-degree angle than at a 45-degree subcutaneous angle (Fig. 48.6). Automatic injection devices, such as pens and jet injectors, are easy for children to use, promote early independence, and can be given with the 90-degree technique (Fig. 48.7).

FIGURE 48.6 Insulin is usually injected at a 90-degree angle with a short needle. This angle places the insulin in the subcutaneous space. (© Lesha Photography.)

FIGURE 48.7 Injection of insulin by an automatic device. (© Lesha Photography.)

Insulin Pumps. An insulin pump is an automatic device approximately the size of an iPod. It delivers insulin at a constant rate, so it regulates serum glucose levels better than periodic injections. It has the potential to decrease future complications (Marschilok, 2007). To use a pump, a syringe of regular insulin is placed in the pump chamber; a length of thin polyethylene tubing leads to the child's abdomen, where it is implanted into the subcutaneous tissue by a small-gauge needle. Throughout the day, the pump edges the syringe barrel forward, infusing insulin at a continuous rate into the subcutaneous tissue. Before a snack or meal, the parent or child presses a button on the pump and forces a bolus of insulin forward, thus increasing the amount of insulin injected in order to manage these times of high carbohydrate intake. Children need to inspect the site of the pump insertion daily to make sure that it is not inflamed; the site is cleaned and changed every 48 to 72 hours to ensure that absorption is still optimal.

Restrictions with pump therapy include keeping the pump dry: the child must remove the pump (not the syringe and tubing) while showering unless it is a brand that is waterproof or is equipped with a waterproof pouch so it can be taken into a shower or swimming pool. A disadvantage of pump therapy is that the pump is always present. Children usually prefer to wear clothing that hides the pump's outline (it can be held against the abdomen by an over-the-shoulder sling or hung from a belt around the waist). To assess the pump's delivery of insulin, the child must do blood glucose determinations about four times a day. When pump therapy first begins, a parent must wake at 2 AM and test the child's blood glucose level, because this is such a vulnerable time for hypoglycemia as the pump is delivering insulin, but the child has not eaten since bedtime. Most children adjust well to pump therapy and prefer it to daily injections.

Inhalation Insulin. In the future, insulin may be administered by way of inhalation, because it is absorbed well across mucous membranes. This method releases the child from the chore of daily injections. However, if the child develops a cold or allergies that cause edema of the nasal membrane, drug absorption is reduced. Absorption also can be influenced by whether the child is upright or lying down at the time of administration (Karch, 2009).

Nutrition. Children with type 1 diabetes need to consume a diet appropriate for their age in the proportion of 55% carbohydrate, 15% protein, and 30% fat. The meal pattern should include three spaced meals high in fiber plus a snack in the midmorning, midafternoon, and evening (Rolfes, Pinna, & Whitney, 2009).

Urine Testing. Urine testing has the disadvantage of not being as accurate as blood serum testing to detect glucose levels; it is now used only to test for ketonuria if the child's blood glucose level is above 200 mg/dL. A dipstick technique is used. Acetone appearing in the urine is a sign that fat is being used for energy; this situation occurs with infection or if not enough food has been ingested.

Self Blood Glucose Monitoring (SBGM). Children as young as early school age can learn the techniques of finger puncture and reading a computerized monitor. Using a spring-loaded puncture device or a new ultrasensitive monitor to obtain the blood sample helps minimize pain, and an automatic readout monitor, such as a glucometer, simplifies the procedure and gives a more accurate reading than does matching the shade

FIGURE 48.8 A child uses an automatic lancet for blood sampling (*left*). Blood glucose level will be determined by the glucometer (*right*). (© Lesha Photography.)

of blood on a test strip to the colors on the test strip container (Fig. 48.8). Some meters measure the whole blood value, not the serum glucose level. This means that the result will be about 15% higher than a serum determination or a blood determination of 115 mg/dL equals 100 mg/dL of serum. Newer meters automatically convert the whole blood value to a plasma value. Be sure that parents and children understand the type of monitor they are using.

The "Honeymoon" Period. After a child's diagnosis has been confirmed and the blood glucose level has been initially regulated by insulin, a honeymoon period may follow, during which only a minimal amount of insulin, or none at all, is needed for glucose regulation. This apparently occurs because the exogenous insulin stimulates the islet cells to produce a small amount of natural insulin, as if they are being reminded of their true function. After a month or even up to a year, however, the islet cells begin to fail once again, and diabetic symptoms recur. This can be upsetting to parents if they began to believe that their child was wrongly diagnosed or that a cure had taken place. Caution both the parents and the child that symptoms will inevitably recur. Sometimes, a child is maintained on a minimum amount of insulin during this period to prevent unrealistic expectations of a cure. This practice may also help to reduce islet cell destruction.

Stress Adjustment. Whenever children with diabetes undergo a stressful situation, either emotionally or physically, they may need increased insulin to maintain glucose homeostasis. When children are seen at health care facilities for periodic checkups, ask them whether they are having any difficulty with blood testing or insulin injection and how things are at home and at school.

Try to interview children separately from their parents, so they can feel free to talk about anything that may be happening or going wrong. There must be cooperation between primary health care personnel and school health care personnel so that conflicts about the child's regimen do not cause problems or tensions at school. Parents may have to meet with schoolteachers to help them view the child as well, not ill, so that they will allow participation in all activities, including sports. Sometimes, children are embarrassed to have to do blood glucose testing in school, especially in the public lavatory. It may be easier for them if they can go to the nurse's office for privacy when testing.

Complications. If temperature rises and infection occurs, counter-regulatory hormones increase, causing insulin resistance and increasing the need for more insulin. Teach parents to notify their primary health care provider if their child appears to be ill (particularly if the child is nauseated or vomiting) for careful observation and a change in insulin dosage if necessary. If a child with diabetes is scheduled for surgery, careful regulation on the day of surgery and in the immediate postoperative period is essential, especially if oral fluids will be restricted (Masharani & German, 2007).

Many long-term body changes that occur because of chronic hyperglycemia are not a major part of disease management in childhood because their onset does not begin until late adolescence or adulthood. These changes include arteriosclerosis (hardening of artery walls), which can lead to general poor circulation and kidney disease, and thickening of retinal capillaries and cataract formation, which ultimately can result in blindness. Some children may notice blurred vision when their disease is not in control, but this should not be confused with the final retinopathy that may result with older age. It is a temporary change in depth of the eye globe related to hyperglycemia. Because women with diabetes eventually develop some degree of arteriosclerosis in adulthood, women with type 1 diabetes are encouraged not to delay childbearing past 35 years of age. Current research supports the use of low-dose progestin and estrogen combination oral contraceptives (high doses of estrogen can elevate blood glucose) if they want to use a reproductive life planning measure. Alternative measures of birth control, such as the diaphragm or vaginal foam along with condoms for their sexual partner, also should be discussed. Care of the woman with diabetes mellitus during pregnancy is discussed in Chapter 20.

Pancreas Transplantation. For children who develop severe kidney disease or retinopathy, pancreas transplantation may be considered. In contrast to other organ transplantation procedures, the original pancreas is not removed entirely. The portion that supplies digestive enzymes is still functioning and is left in place. During surgery, a new pancreas is grafted to the iliac artery and vein, to allow insulin from the new organ to enter the systemic circulation. For this reason, pancreatic replacement is more accurately called grafting. The digestive enzymes of the new pancreas can be diverted into the intestine or bladder, or the pancreatic ducts can be sclerosed so that the digestive enzymes do not leave the transplanted organ. Grafts may be taken from cadavers or from live donors, who can lose up to 45% of their pancreas and still maintain a functioning organ for themselves.

To reduce the child's immune response and protect against graft rejection, drugs such as antilymphocyte globulin, cyclosporine, prednisone, or azathioprine (Imuran) are administered after surgery. If rejection does start to occur, the patient is given monoclonal T-cell antibodies (OKT3).

Pancreatic transplantation is a last-resort solution for children, because the outcome is guarded (about 50% of transplanted organs are rejected) and the outcome—continuous immunosuppressive medication for life—may not be regarded as a major improvement over the original illness, which would require continuous daily insulin for life (Chase & Eisenbarth, 2008).

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Health-seeking behaviors related to self-administration of insulin, balanced exercise, and hygiene

Outcome Evaluation: Child demonstrates insulin injection technique to nurse, describes steps correctly, and discusses plans for an exercise and hygiene program.

Self-Administration of Insulin. From about 8 years of age, children can be taught to administer their own insulin (Fig. 48.9). Many children younger than this do not have the dexterity to handle a syringe or an understanding of the importance of sterile technique and proper dosage. They may skip injections if they are tired or busy.

Do not underestimate how difficult it is for children to learn to give injections to themselves. Although it may seem like a two-step process (draw up the medication, and then inject it), in actuality more than 25 separate steps are involved.

If the child has to mix insulins, the number of steps increases. Besides lacking dexterity and adult-level fine motor skills, children have to face *injecting themselves.* There is no such thing as getting used to injections. Children grow used to the *idea* of self-injection, not to the injections themselves.

Even if children are taught to give their own insulin from the beginning, at least one adult in the family should be taught to give it as well. There will be days when the child refuses to administer his or her own insulin or is not feeling well and needs to have or appreciates having someone do it for them. Parents may have a hard time giving their child a painful injection; teaching them to view it as a helping action helps to alleviate their distress.

Exercise. Exercise is an important component of care, because it uses up carbohydrates and helps reduce hyperglycemia. No type of exercise is restricted for children with diabetes.

FIGURE 48.9 A school-age child is taught insulin administration using a teaching doll for practice. (© Lesha Photography.)

A problem that arises with vigorous exercise, however, is the development of hypoglycemia due to increased absorption of insulin from the injection site and utilization of glucose by active body cells. One way to minimize this effect is to choose the injection site that is least likely to be exercised. Another method is to eat additional carbohydrate or decrease the regular insulin injection according to an established protocol (algorithm) before exercise. Keep in mind that hypoglycemia may be delayed for up to 18 hours after exercise.

Teach children to design a consistent daily exercise program such as briskly walking the dog or 10 minutes of aerobics every day before school. Once a daily program is established, the child needs to continue this type of exercise every day (including weekends) to avoid becoming hyperglycemic on days of no exercise (Box 48.6).

Hygiene. Skin care, particularly foot care, is extremely important for adults with diabetes, because arteriosclerosis causes loss of circulation to the feet, and decreased circulation leads to poor healing ability. This is not as important a concern with children, but they (and all children) should be taught to cut their toenails straight across, to prevent ingrown toenails, and to tend to cuts and scrapes promptly so that healing can begin right away. Properly fitting shoes are essential. Girls may need to be reminded of good perineal care to prevent vaginal infections.

Nursing Diagnosis: Parental anxiety related to newly diagnosed diabetes mellitus in a child

BOX 48.6 ✻ Focus on Evidence-Based Practice

Does an exercise program lead to long-term insulin/glucose balance in children with type 1 diabetes?
Exercise programs can have major effects on children with type 1 diabetes as exercise utilizes glucose: the child requires less insulin. For this study, researchers designed a 2-week summer camp program of high-volume, low-intensity physical activity for 20 children 10 to 14 years of age who had type 1 diabetes. The program included three exercise sessions daily plus a controlled daily caloric intake. Blood glucose levels were measured at 10 days and 2 months following completion of the program to assess results. Results at the 10-day time interval showed that the number of children with normal serum glucose levels had doubled. Unfortunately, at 2 months post program, the beneficial results of the program had disappeared.

Based on the above study, would you recommend that an exercise program is healthy for children with type 1 diabetes?

Source: Ruzic, L., Sporis, G., & Matkovic, B. R. (2008). High volume-low intensity exercise camp and glycemic control in diabetic children. *Journal of Paediatrics and Child Health, 44*(3), 122–128.

Outcome Evaluation: Parents accurately describe their child's illness and treatment and ways in which the disease will affect their lifestyle. They state a specific plan for daily routine child care and identify potential problems in the schedule and ways they can be managed.

Parents whose child is newly diagnosed with diabetes mellitus have a great deal of new responsibility. Be sure that they have the telephone number of the health care facility, liaison, or home care person to call during the first days of home management. During these days, most parents appreciate having someone to consult before they give insulin, for reassurance that they are giving the correct dose.

Encourage Expression of Feelings. Although parents may be aware that other family members have the disease, they may be surprised that it has occurred in their child. Both the parents and the child need time to describe their perceptions of diabetes. If there are other family members with the illness, children may have heard many false stories about the disorder and may have been told how difficult it was in the past to achieve insulin control. These misconceptions need to be corrected so children can begin to accept the diagnosis and view themselves as basically well except for faulty insulin release.

What if... Rob wants to try out for soccer on his school team, but the soccer coach thinks diabetic children should be excluded from sports? What information can you give the parents about diabetes that they could share with the coach?

Teach About Disease and Principles of Care. Teaching is one of the main interventions necessary for children newly diagnosed with diabetes. Review general principles of care, including the fact that insulin injections, supervised intake of food, and exercise all decrease the blood glucose level, and increased intake of food increases it. Infection and emotional upset also increase insulin requirements. If this process is not explained, parents may attempt to keep the child relatively quiet, unaware that exercise is actually healthful.

Teach that an episode of hypoglycemia is an extremely serious condition and must be prevented, if possible. Otherwise, parents may view continuous low blood glucose levels as a positive sign rather than a potentially threatening condition that deprives body cells of glucose. If early signs are not recognized and treated, hypoglycemia can lead to coma and seizures. Severe glucose depletion can lead to permanent brain damage with mental and motor impairment, because brain cells need glucose for metabolism.

Be certain that parents have opportunities to practice supervised insulin injection and blood glucose testing so that they can become familiar with these procedures and any accompanying problems. Help them make a fair appraisal of how much care their child will be able to undertake independently. In the beginning, it is often better to limit a child's share of care to one blood glucose testing session and one self-administered insulin injection per day. This helps parents to avoid expecting too much from their child, and possibly growing frustrated if the child does not meet their expectations. It makes successful management of the child's diabetes a rewarding experience rather than a chore.

Teach parents about the type of insulin their child will be taking. However, avoid giving too much confusing detail about all the different types. If the insulin is changed at a later date, the new form can be described in greater depth at that time. Also, urge the parents or the child to begin keeping a log of blood glucose test results in a permanent notebook so that these numbers can be evaluated for any unusual patterns at periodic checkups.

Establish Mode of Supervision and Support. Children with diabetes need frequent health supervision visits, approximately every 3 months. Those who appear to accept their diagnosis initially may have difficulty later, when their true feelings about their disorder surface. When they reach adolescence and are rebelling against a multitude of things, they may choose to rebel against blood glucose testing and insulin administration. Assess that children with diabetes have supportive friends to help them through "bad days." Sometimes what is needed most from health care personnel is understanding and appreciation of the difficulties encountered by children living with diabetes.

Serving as an active support person for the parents is also necessary. Often, parents are so concerned with learning the techniques of insulin administration and blood glucose testing that they do not think through other problems of everyday living that will arise later. Make sure that the parents can identify support people and others to contact if they have problems or questions.

Nursing Diagnosis: Risk for imbalanced nutrition, less than body requirements, related to decreased insulin level

Outcome Evaluation: Child's growth follows percentile curve on standard growth chart; serum glucose is between 70 and 110 mg/dL fasting; child states that nutrition and exercise program is being followed.

Plan Nutrition Program. At one time, children with diabetes were placed on rigidly specified diets in which each food item had to be weighed. Then followed a period when children were allowed free diets, and any resulting glycosuria was managed by increasing their insulin doses. Today, it is generally accepted that conscientious diet modification, within lifestyle and cultural preferences, is necessary, because chronic hyperglycemia can lead to vascular disease in later years. General guidelines for good nutrition are shown in Box 48.7.

Teach Hypoglycemic Management. Symptoms of hypoglycemia occur when the blood glucose level falls to about 60 mg/dL. At this point, there is no glycosuria. Parents and children, as soon as they are old enough

to understand, need to be aware of the reasons for hypoglycemia and what measures they must take to counteract it if it occurs.

Hypoglycemia can result from the administration of too much insulin, excessive exercise (because exercise uses up glucose), or failure to eat enough food. Typically, beginning symptoms include nervousness, weakness, dizziness, sweating, or tremors. In many children, the first signs of hypoglycemia are behavior problems: temper tantrums, stubbornness, silliness, irritability, or simply "not acting like usual self." A few children become insensitive to the symptoms of hypoglycemia (termed *hypoglycemia unawareness*) and are then unable to recognize that it is occurring. Such children need more blood glucose determinations built into their routine (see Focus on Nursing Care Planning Box 48.8).

When the signs of hypoglycemia are recognized, a child needs an immediate source of carbohydrate. Fifteen grams of a fast-acting carbohydrate such as that contained in a half-glass of orange juice or regular soda is recommended. It is easy for children always to carry glucose tablets or hard candy such as Lifesavers with them and have them available for these times. If there is no improvement in symptoms and the blood glucose level has not risen by 15 mg/dL after 15 minutes, more carbohydrate (perhaps juice) should be given.

If the child is comatose when first discovered or is too upset or uncooperative to take oral sugar, parents can inject a specified dose of glucagon hydrochloride. This converts the glycogen that is stored in the liver to glucose. Usually, enough glycogen is converted after the drug injection to bring the child out of coma, after which an oral form of glucose can be given. The drug is not effective if the child's supply of glycogen is depleted.

If parents cannot give their child an injection and oral sugar cannot be given, honey, corn syrup, cake icing gel, or glucose can be rubbed onto the gums or inside the cheek (of course, parents should be taught how to prevent aspiration); corn syrup can be given as an enema. As soon as children are out of coma or are cooperative, they should take a source of complex carbohydrate, such as crackers or toast, to prevent further hypoglycemia. The primary health care provider needs to be notified of the incident so that its cause can be determined and steps taken to prevent hypoglycemia from occurring again.

Urge parents to anticipate occasions when hypoglycemia is likely to occur and to take preventive measures. Hypoglycemia is most likely to occur at the peak effective time of the insulins being given such as just before lunch or just before dinner. This means that many children who are attending school need to be scheduled for the first lunch period, not the second, or need a snack before lunch. Encourage the child and parents to discuss lunch times with the physician and dietitian so that appropriate meal planning is coordinated with the child's insulin schedule. Follow-up at 6-month intervals is advised to make adjustments for changes in growth and school schedules. Children also should eat dinner at a regular time or have a snack to tide them over until dinner. Additionally, children need a snack before bedtime, to prevent hypoglycemia from developing during the night.

If children are going to engage in an active sport, such as swimming, tennis, or basketball, they should ingest a source of sugar before participation. This precaution is extremely important before swimming, because a child who suddenly becomes weak in the middle of a pool may be unable to reach the side safely. Although eating before swimming is something that children typically are taught not to do, the child with diabetes must be taught to break this rule—sensibly, of course: before swimming, the child eats a complex carbohydrate, such as crackers, not a full meal. Day and residential camps are available to help children learn more about diabetes and common measures other athletic children use to prevent hypoglycemia.

Occasionally, insulin overuse and persistent hypoglycemia cause a rebound hyperglycemic response; this is referred to as the **Somogyi phenomenon**. This

BOX 48.7 ✻ Focus on Family Teaching

Nutritional Guidelines for Children With Type 1 Diabetes

Q. Rob's mother is concerned that Rob, as an adolescent, doesn't eat well. She asks you, "How can we make sure our child, who has diabetes, gets adequate nutrition?"

A. Here are some nutritional guidelines to help you:

- Plan well-balanced and appealing meals. Caloric content should be appropriate for your child's age group.
- Provide three meals throughout the day, plus snacks. Total daily caloric intake is divided to provide 20% as breakfast, 20% as lunch, 30% as dinner, and 10% as morning, afternoon, and evening snacks. Distribution of calories should be 55% carbohydrate, 30% fat, and 15% protein.
- Do not use dietetic food. This food is expensive and not necessary.
- Urge your child not to omit meals. Getting him to eat at every meal calls for creative planning so the child likes the foods served and eats readily.
- Maintain a positive outlook by stressing the foods your child is allowed to eat, not those he must avoid.
- Steer clear of concentrated carbohydrate sources, such as candy bars; be sure to include foods with adequate fiber, such as broccoli, because fiber helps prevent hyperglycemia.
- Keep complex carbohydrates available to be eaten before exercise, such as swimming or a softball game, to provide sustained carbohydrate energy sources.
- Teach children about meal planning so they can wisely select what to eat at school or at a friend's home. This teaching will promote independent self-care.

BOX 48.8 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for an Adolescent With Type 1 Diabetes Mellitus

Rob Tebecco is a 16-year-old boy with type 1 diabetes whom you meet in the emergency department, where he was taken after he became comatose while ice skating. His diabetes was diagnosed when he was 7 years old. His records indicate that his disease has generally been under good control over the past years, but in the last 6 months he has "forgotten" to take his insulin at least once a week. When you ask him about this, he tells you that ice skating practice every morning and a new girlfriend have occupied his time and interrupted what used to be a strict schedule of home-cooked meals and a rigid routine.

Family Assessment ✻ Adolescent lives with one younger sister and parents. Father works as Zamboni operator at professional hockey arena. Mother works part time at local post office. Family rates finances as, "We have everything we need."

Client Assessment ✻ Child was skating at local ice rink when he suddenly collapsed. Was brought to emergency department by EMT service, unconscious and breathing deeply. Breath smelled sweet. Blood glucose was 700 mg/dL. Received regular insulin IV. As soon as blood glucose returned to normal, he regained consciousness. Arterial blood gases: pH, 7.20; P_{CO_2}, 10 mm Hg; HCO_3, 10 mEq/mL. Right heel has red and inflamed ulcer.

Currently takes short-acting and intermediate-acting insulin every morning before breakfast and intermediate-acting insulin before dinner. Child self-injects with automatic injection device with some parental supervision. Child performs fingerstick blood glucose levels four times a day. Blood glucose levels normally range between 105 and 115 mg/dL. Dietary history reveals three meals per day with midmorning, afternoon, and bedtime snack. Rob states, "Okay. I'm ready to do better. That was scary to black out."

Nursing Diagnosis ✻ Health-seeking behaviors related to need to follow more conscientious diabetes regimen.

Outcome Evaluation ✻ Child and parents voice intention to be more conscientious about consistent insulin administration and serum glucose testing. Child voices willingness to try insulin pump therapy.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Explore with child and parents their understanding of the interrelationship of nutrition, exercise, and diabetes.	Review and reinforce the importance of insulin administration, blood glucose monitoring, and exercise.	Exploration and review provide baseline information for identifying teaching needs and developing possible strategies.	Adolescent and parent state they understand new regimen; glucose levels do not fluctuate higher than 126 mg/dL.
		Consultations		
Physician	Assess whether adolescent is candidate for insulin pump therapy to increase adherence.	Consult with diabetic service team to present new method of insulin administration.	Use of an insulin pump offers a continuous supply of insulin; can be advantageous for busy adolescent.	Diabetic service team meets with adolescent and parent to present possibility of using insulin pump.
		Procedures/Medications		
Nurse	Assess adolescent's level of understanding about action of insulin with pump therapy.	Demonstrate and observe adolescent draw up, refill insulin syringe, and begin insulin pump infusion.	Adolescent's return demonstration best reveals whether he understands how to maintain insulin pump.	Adolescent demonstrates proper preparation and administration of insulin pump.

		Nutrition		
Nutritionist	Assess adolescent's usual meal pattern and determine who prepares food.	Review importance of regular meals plus bedtime snack to keep glucose within consistent levels.	Irregular meal patterns can cause hypoglycemia with pump therapy and inconsistent exercise.	Parents and adolescent state that they will try to arrange a more regular pattern of meals. Will test blood glucose according to set schedule.
		Patient/Family Education		
Nurse/diabetic service team member	Assess whether adolescent and parents are aware of actions to take if hypoglycemic symptoms should occur with pump therapy.	Review signs and symptoms of hypoglycemia. Review need to always carry a source of carbohydrate.	Having a readily available source of carbohydrate helps raise blood glucose levels quickly should hypoglycemia occur.	Adolescent and parents describe signs of hypoglycemia and action of carbohydrate to prevent this.
Nurse/diabetic service team member	Assess whether adolescent and parents are aware of necessity to safeguard feet against trauma.	Review necessity to wear properly fitting shoes and skates and to clean any cuts or scrapes promptly.	Diabetes can result in decreased circulation to the feet and slowed healing, increasing the possibility for infection, which can ultimately affect glucose control.	Adolescent states he will be more conscientious about foot care; acknowledges foot infection may have contributed to his hyperglycemic episode.
		Psychosocial/Spiritual/Emotional Needs		
Nurse/nurse practitioner	Assess whether child's busy schedule allows for adequate diabetic control.	Encourage parents to discuss adolescent's needs with him and ways he could modify schedule to better accommodate diabetic routine.	Poor medicine adherence may be a way adolescents express identity.	Parents and child plot out a weekly schedule that allows both freedom for new activities and conscientious diabetic care.
		Discharge Planning		
Nurse	Assess whether child has experience with keeping a diabetic care journal.	Advise adolescent to keep a written diary of blood glucose levels, dietary intake (including snacks), and any symptoms of hypoglycemia and measures used.	A written diary provides objective evidence for evaluation of the new regimen, indicating the need for possible changes or adjustments.	Adolescent agrees to keep a detailed journal until return to clinic for follow-up visit.
Nurse	Assess whether adolescent or parents have any additional questions.	Arrange for a follow-up appointment in 1 week. Encourage adolescent and parents to call with any questions or concerns.	Follow-up visit provides a means for evaluating effectiveness of new regimen and child's adaptation.	Adolescent and parents state they understand importance of follow-up visit for regulation of insulin pump therapy.

TABLE 48.5 ✻ Comparison of Hypoglycemia and Hyperglycemia

Comparison Factor	Hypoglycemia	Hyperglycemia
Cause	Excessive insulin injection Excessive exercise Limited food intake	Inadequate insulin injection Excessive food intake Stress from infection, surgery, etc.
Symptoms	Hunger Lethargy Sensorium changes Pallor Sweating Seizures Coma	Glycosuria and ketonuria Polyuria, polydipsia Kussmaul respirations Flushing Sweet (acetone) breath Decreased CO_2 combining power Dehydration Lowered sodium, potassium, bicarbonate, chloride, and phosphate levels Vomiting, abdominal pain Coma
Danger	Brain cells need glucose for function and survival	Fatty acids are used and acidosis develops
Major nursing interventions	Administration of source of glucose by oral or IV route Education to prevent recurrences	Re-establishment of electrolyte balance and hydration Education to prevent recurrences

phenomenon is suspected when children have nighttime (2 or 3 AM) hypoglycemia followed by high early-morning hyperglycemia. These children need to be referred to their health care provider, because they actually need less insulin rather than more to correct the problem.

Teach Signs of Ketoacidosis. It is often difficult to distinguish between hypoglycemia (occurring from too much insulin) and hyperglycemia (occurring from too little insulin for the level of glucose present in the bloodstream). Hyperglycemia leads to ketoacidosis, with symptoms of vomiting and abdominal pain and the same kind of behavior changes exhibited with hypoglycemia.

If a parent does not know the cause of the upset, the child should be offered a carbohydrate, as if the problem were hypoglycemia. The added carbohydrate will do no harm if the problem is already hyperglycemia, whereas giving insulin is harmful if the cause is hypoglycemia. Inability to void suggests that the problem is hypoglycemia. With hyperglycemia, urine output is copious—one of the primary signs of diabetes. The real key to differentiating ketoacidosis from hypoglycemia is the blood glucose level. Assessing the blood glucose concentration by fingerstick solves the problem of whether symptoms relate to hypoglycemia or hyperglycemia.

If ketoacidosis is severe, respirations become deep and rapid (Kussmaul breathing) as the body attempts to "blow off" carbon dioxide and lessen the acidotic state. The breath smells sweet because of the presence of ketone bodies, and the pulse rate may be rapid. Children may have signs of dehydration, including dry mucous membranes and skin, sunken eyeballs, and no tears. This may be the picture when children with diabetes are first diagnosed. It is often seen in children with diabetes who develop gastroenteritis and hence eat poorly for several meals. Because the child is not eating well, parents may omit giving insulin. In actuality, because of an increased metabolic rate due to fever, the child may need more insulin and glucose than usual during these times. A comparison of hypoglycemia and hyperglycemia appears in Table 48.5.

✔ Checkpoint Question 48.3

When Rob was first diagnosed with diabetes mellitus, he experienced a "honeymoon" period. This means

a. He developed an unnatural craving for sweets.
b. Puberty occurred because of glucose stimulation.
c. His need for injectable insulin was drastically reduced.
d. He became lightheaded or "giddy" every afternoon.

Type 2 Diabetes Mellitus

Type 2 diabetes (formerly known as non–insulin-dependent diabetes), which is characterized by diminished insulin secretion and not caused by autoimmune factors, is a separate disease from type 1 diabetes (Powers, 2008). Usually, individuals with type 2 diabetes do not need daily insulin, because their disease can be managed with diet alone or with diet and an oral hypoglycemic agent. Once thought to occur only in older adults, type 2 diabetes is now seen in overweight adolescents, termed maturity-onset diabetes of youth (MODY) (Franks, 2007).

Between 8% and 45% of newly diagnosed children with diabetes have type 2. At the time of diagnosis, it may not be possible for the classification to be correctly determined, because symptoms and findings are so similar.

Type 2 diabetes usually occurs in children who have a strong family history of diabetes and who are overweight at diagnosis. Children are typically from African, Hispanic, Asian, or Native

Indian descent. Because the pancreatic islet cells are not devoid of function, the pancreas continues to secrete at least minimal amounts of insulin. Symptoms often become apparent at puberty because increasing sex hormones naturally increase insulin resistance and require more insulin production. Children will have sugar in their urine but few ketones in urine. They have lessened amounts of thirst and increased urination. About 90% of children with type 2 have dark shiny patches on the skin (*acanthosis nigricans*), which are most often found between the fingers and between the toes and on the back of the neck ("dirty neck") and in axillary creases. Development of polycystic ovary syndrome (PCOS) (see Chapter 8) is strongly associated with the disorder.

Children whose family has a history of type 2 diabetes, are from susceptible genetic groups, or have symptoms such as acanthosis nigricans, PCOS, or high blood pressure should be screened by a fasting blood sugar test at puberty and again every 2 years.

Therapy consists of nutrition and exercise regulations the same as for type 1 diabetes combined with an oral antiglycemic agent such as a biguanide (Metformin), which decreases the amount of glucose produced by the liver and may increase insulin sensitivity in both the liver and muscle cells. If this therapy is not effective, a sulfonylurea (Glyburide), which stimulates the beta cells in the pancreas to produce more insulin, can be added to the child's regimen.

Type 2 diabetes is a chronic condition that will extend into adulthood and be present for life. Eventfully it leads to atherosclerosis with thickening of arteries and capillaries. This leads to kidney disease, poor healing ability, and blindness because of poor circulation to body organs. In order to prevent these complications, teenagers who develop type 2 diabetes need good instruction in how to manage their illness so whether they are home with their parents supervising their care or away from home at camp or college, they can prevent hyperglycemia and the irritation to blood vessels which it causes.

THE PARATHYROID GLANDS

The four parathyroid glands, located posterior and adjacent to the thyroid gland, function to regulate serum levels of calcium in the body; they control the rate of bone metabolism by secretion of parathyroid hormone. This hormone is not under the control of the pituitary gland but is controlled by a negative feedback from the circulating serum levels of calcium. If blood calcium levels fall, parathyroid hormone secretion increases; if blood calcium levels increase, hormone production decreases. Vitamin D is necessary for absorption of calcium from the gastrointestinal tract into the bloodstream, so it also influences parathyroid hormone secretion. Calcitonin (thyrocalcitonin), secreted by the thyroid gland, opposes the action of parathyroid hormone, decreasing blood calcium levels.

Hypocalcemia

Hypocalcemia is a lowered blood calcium level (Potts, 2008). It occurs to some extent in all newborns before they begin eating well. Phosphorus and calcium levels are maintained in an inverse proportion to each other in the bloodstream or if phosphorus levels rise, calcium levels decrease; if calcium levels rise, phosphorus levels decrease. Hypocalcemia, therefore, may be caused by changes in either calcium or phosphorus metabolism.

Assessment

Hypocalcemia tends to occur in infants who experienced birth anoxia (phosphorus is released with anoxia), in immature infants (the parathyroid gland is immature), and in infants of diabetic mothers (it tends to accompany the hypoglycemia that occurs in these infants shortly after birth). It may be caused by the imbalance between phosphorus and calcium in cow's milk; such an imbalance does not exist in breast milk and is modified in commercial formulas.

Latent Tetany. The chief sign of hypocalcemia is neuromuscular irritability, often referred to as **latent tetany**. This occurs if the blood calcium level is less than 7.5 mg/dL. Newborns with latent tetany are jittery when they are handled, or they cry for extended periods.

Four methods can be used to produce the clinical manifestations of tetany for diagnosis of hypocalcemia; these are shown in Table 48.6. These are all useful tests to determine or suggest whether a newborn's jitteriness is a result of hypocalcemia, a central nervous system problem, or some other cause.

If tetany is caused by infant formula, it occurs at about day 7 of life. A community health nurse making a follow-up visit after a home birth might be the one to recognize the problem initially.

TABLE 48.6 ✻ Tests for Detection of Hypocalcemia

Sign	Description
Chvostek's	When skin anterior to external ear (just over sixth cranial nerve) is tapped, facial muscles surrounding eye, nose, and mouth contract unilaterally.
Trousseau's	When upper arm is constricted by tourniquet for 2–3 min and area becomes blanched, carpal spasm is elicited (hand abducts, wrist flexes, thumb is positioned across cupped palm).
Peroneal	When fibular side of leg over peroneal nerve is tapped, foot abducts and dorsiflexes.
Erb's	This test is dramatic to see demonstrated, although it requires a mild galvanic current so is not used routinely. A person with tetany has greater muscular irritability than a person with a normal calcium level; therefore, when a mild current is applied over the peroneal nerve just below the head of the fibula, the foot on that side will abduct and dorsiflex.

Manifest Tetany. If the blood calcium level falls well below 7 mg/dL, **manifest tetany** may result, commonly observed as muscular twitching and carpopedal spasms. A **carpal spasm** (hand spasm) involves abduction of the hand and flexion of the wrist with the thumb positioned across the palm. In **pedal spasm** (foot spasm), the foot is extended, the toes flex, and the sole of the foot cups. Generalized seizures may occur. There may be spasm of the larynx, with the infant emitting a high-pitched, crowing sound on inspiration because of the constricted airway. If the spasm is prolonged, respirations may cease.

Therapeutic Management

Treatment is aimed at increasing the calcium level in the blood above the point of latent tetany. Calcium may be administered orally as 10% calcium chloride if the infant can and will suck. It can be given IV as a 10% solution of calcium gluconate if the tetany has so progressed that the child does not have enough muscular coordination to take oral fluid safely. Calcium gluconate should not be given IM or SC, because necrosis may occur at the injection site. Newborns who are having generalized seizures may require anticonvulsant therapy in addition to the calcium gluconate to halt the seizures. Emergency equipment for intubation to relieve laryngospasm should be available.

After immediate therapy to increase the low blood calcium levels, infants are given oral calcium therapy until their calcium level stabilizes at greater than 7.5 mg/dL. Because vitamin D is necessary for absorption of calcium and phosphorus from the gastrointestinal tract, the infant also may be given a vitamin D supplement.

METABOLIC DISORDERS

Earlier in this chapter, ways in which overproduction or underproduction of certain hormones can seriously hinder body metabolism—creating such problems as hypothyroidism, congenital adrenogenital hyperplasia, and type 1 diabetes mellitus—were discussed. There are many causes for hormonal deficiency or excess, most of which are related to the endocrine glands and the highly complex system of feedback and communication between these glands and the hypothalamus. The neuroendocrine regulation of hormonal balance is so sensitive that it is affected by the body's internal and external environments such as injury, stress, and emotional changes.

In addition to endocrine disorders, a group of hereditary biochemical disorders also affect metabolism. These are caused largely by some specific defect in the body biochemistry that disrupts one step of the metabolic process. The term *inborn errors of metabolism* is used to refer to these disorders. Most of them are caused by a lack of or deficiency in a particular enzyme, which seriously impairs the ability of the body to metabolize properly the components of food for energy.

Inborn errors of metabolism affect the metabolism of amino acids and proteins, carbohydrates, and lipids. Many of these disorders are evident at or soon after birth and can cause severe symptoms rapidly. Early detection and treatment are essential to prevent irreversible cognitive challenge and early death. Gene therapy is expected to be available in the future to reverse symptoms of these disorders.

Phenylketonuria

PKU is a disease of metabolism that is inherited as an autosomal recessive trait. Absence of the liver enzyme phenylalanine hydroxylase prevents conversion of phenylalanine, an essential amino acid, into tyrosine (a precursor of epinephrine, thyroxine, and melanin). As a result, excessive phenylalanine builds up in the bloodstream and tissues, causing permanent damage to brain tissue and leaving children severely cognitively challenged (DeRoche & Welsh, 2008).

The metabolite phenylpyruvic acid (a breakdown product of phenylalanine) spills into the urine to give the disorder its name. It causes urine to have a typical musty or "mousy" odor that is so strong it often pervades not only the urine but the entire child (Huemer et al., 2007).

Tyrosine is necessary for building body pigment and is incorporated into thyroxine. Without it, body pigment fades and the child becomes very fair skinned, light blonde haired, and blue eyed. The child fails to meet average growth standards because of the lack of thyroxine production. Many children develop an accompanying seizure disorder. The skin is prone to eczema (atopic dermatitis). There is such a strong association between these two disorders that all infants with atopic dermatitis need to be rescreened for PKU (Itin & Goldsmith, 2008).

PKU is found in 1 of every 10,000 births in the United States. It occurs rarely in people of African or Jewish ancestry. If the condition remains untreated, the child with PKU usually will have an IQ below 20. In addition, about one third of affected children have recurrent seizures, and about half have muscular hypertonicity and spasticity. PKU cannot be detected by amniocentesis or percutaneous umbilical cord blood sampling as a routine screening measure, because the phenylalanine level does not rise in utero, while the infant is still under the control of the mother's enzyme system. Recombinant DNA techniques can be used for carrier detection and prenatal diagnosis.

Assessment

Early identification of the disorder is essential to prevent the child from becoming severely cognitively challenged. Infants are screened at birth after receiving 2 full days of feedings (at least 120 mL of formula at a concentration of 20 calories per ounce, or the equivalent amount obtained by breastfeeding). The screening is done by pricking the infant's heel with a blood lancet and letting a few drops of blood fall onto a specially prepared filter paper. The filter paper is then analyzed by a bacterial inhibition process for the amount of phenylalanine contained in the infant's blood (the Guthrie test). If an infant is born at home or is discharged from a hospital or birthing center before the second day of life, the parents will need to have the test performed on the second or third day after birth. If there is a question as to whether a breastfed baby has received only colostrum, a repeated Guthrie test should be performed by the second week of life, during a health care visit.

Some infants demonstrate a benign, transitory, elevated level of phenylalanine shortly after birth, apparently due to immature processing of amino acids. This benign, transitory form needs to be differentiated from the actual disease so that parents are not frightened unnecessarily and the child is not unnecessarily placed on a restricted diet.

Therapeutic Management

Infants in whom this disease is detected during the first few days of life are placed on a formula that is extremely low in phenylalanine, such as Lofenalac. Beginning the diet early helps to keep the child from becoming cognitively challenged. A dietitian may recommend that a small amount of milk be added to the infant's diet every day so the child does receive some phenylalanine (this essential amino acid is necessary for growth and repair of body cells). As a result, a mother who wants to breastfeed may be able to do so on a limited basis.

Parents of children with PKU need a realistic prognosis of their child's potential. If the disorder was detected during the first few days of life and the child's diet is well controlled to avoid any abnormally high level of phenylalanine, the child's IQ will not be adversely affected. On the other hand, if the disorder was not detected until some brain involvement or other symptoms were noticeable, such symptoms cannot be reversed.

Providing nutrition for a child with PKU is a difficult task. There is no natural protein with both a low phenylalanine concentration and normal levels of other essential amino acids. A diet that simply restricted protein would result in restriction of all essential amino acids and would be incompatible with life. Specially manufactured formulas such as Lofenalac are synthetic compounds that have a low phenylalanine concentration but contain enough other essential nutrients so that, with the exception of some additional milk, they are the only food required in early infancy. Unfortunately, amino acid formulas have a rather disagreeable taste. When infants are given these formulas in the first few days of life, however, they do not seem to react to the flavor and will drink them readily into adulthood. These formulas can cause stools to be loose.

As children grow older and have solid foods added to their meals, these foods also must be low in phenylalanine so that the phenylalanine level of the child's blood stays below 8 mg/dL. Foods highest in phenylalanine are those that are rich in protein, such as meats, eggs, and milk. Foods low in phenylalanine include orange juice, bananas, potatoes, lettuce, spinach, and peas. A formula such as Lofenalac can be used to prepare treat foods, such as ice cream, milk shakes, birthday cakes, and puddings (foods that would otherwise be forbidden because they are made with milk). Children need their blood and urine monitored frequently for phenylalanine levels. Hemoglobin levels should also be closely monitored to ensure that the child is not becoming anemic, because iron is found primarily in protein-rich foods, which the child must avoid.

At health visits, offer parents an opportunity to express their feelings about the difficulty of maintaining a young child on such a restricted diet. In addition, assess the child's ability to cope with the illness; by the time they reach adolescence, children grow tired of the constant testing and restrictive diet (Olsson, Montgomery, & Alm, 2007).

When to discontinue the diet is controversial because of reports of progressive neurologic deterioration in children who no longer follow a restricted diet. Generally, current advice is for children to follow the diet indefinitely although discontinuing the diet in adolescence may lead to only subtle differences (Channon et al., 2007). A woman who has PKU must anticipate when she wants to have children as an adult; if she has not been following her diet conscientiously, she must return to a low-phenylalanine diet for about 3 months before conception and remain on the diet during pregnancy (see Chapter 13). Otherwise, her fetus will be exposed to high levels of phenylalanine during pregnancy and will be born cognitively challenged (Maillot et al., 2007).

Maple Syrup Urine Disease

Maple syrup urine disease is a rare disorder, inherited as an autosomal recessive trait, in which there is a defect in metabolism of the amino acids leucine, isoleucine, and valine that leads to cerebral degeneration similar to that observed in children with PKU (Simon et al., 2007).

Assessment

Like PKU, infants are screened at birth for the disorder (Silao, Padilla, & Matsuo, 2008). Infants who have the disorder appear well at birth but quickly begin to show signs of feeding difficulty, loss of the Moro reflex, and irregular respirations. The symptoms progress rapidly to *opisthotonos,* generalized muscular rigidity, and seizures. If the condition remains untreated, an infant may die of the disease as early as 2 to 4 weeks of age.

Although the disorder is rare, it is mentioned here because it is relatively easy to detect. By the first or second day of life, the urine of the child develops the characteristic odor of maple syrup; hence the name of the disease. The odor is caused by the presence of ketoacids, the same phenomenon that makes the breath of diabetic children in severe acidosis smell sweet. Because nurses change newborn diapers so are likely to detect the characteristic urine odor in the first few days of life, they should be aware of this disorder so that they do not discount the pleasant urine odor as an innocent finding. Prenatal detection is possible by analyzing cells obtained by amniocentesis.

Therapeutic Management

If maple syrup urine disease is diagnosed during the first day or two of life and the child is placed on a well-controlled diet that is high in thiamine and low in the amino acids leucine, isoleucine, and valine, the cerebral degeneration can be prevented, just as it can be prevented in PKU. Such a diet is extremely difficult to maintain, however, because of its low protein content. Parents need intensive nutritional counseling. Hemodialysis or peritoneal dialysis can be used to temporarily reduce abnormal serum levels at birth or during a childhood infection, when catabolism of cells releases increased amino acids into the bloodstream.

Galactosemia

Galactosemia is a disorder of carbohydrate metabolism that is characterized by abnormal amounts of galactose in the blood (*galactosemia*) and in the urine (*galactosuria*). It occurs in about 1 in every 60,000 births, most often as an inborn error of metabolism, transmitted as an autosomal recessive trait. The child is deficient in the liver enzyme galactose 1-phosphate uridyltransferase (Rubio-Gozalbo et al., 2007).

Lactose (the sugar found in milk) normally is broken down into galactose and glucose; galactose is then further broken down into additional glucose. Without the galactose 1-phosphate uridyltransferase enzyme, this second step, the conversion of galactose into glucose, cannot take place, and

galactose builds up in the bloodstream and spills into the urine. When it reaches toxic levels in the bloodstream, it destroys body cells.

Assessment

Symptoms appear as soon as the child begins formula feeding or breastfeeding and include lethargy, hypotonia, and perhaps diarrhea and vomiting. Next, the liver enlarges as cirrhosis develops. Jaundice is often present and persistent; bilateral cataracts develop. The symptoms begin abruptly and worsen rapidly. If the condition remains untreated, a child may die by 3 days of age. Untreated children who survive beyond this time may be cognitively challenged and have bilateral cataracts. Because early detection is the key to preventing brain damage, nursing assessment is particularly important in this disorder.

Diagnosis is made by measuring the level of the affected enzyme in the red blood cells. A screening test (the Beutler test) can be used to analyze cord blood if a child is known to be at risk for the disorder.

Therapeutic Management

The treatment of galactosemia consists of placing the infant on a diet that is free of galactose or on a formula made with milk substitutes such as casein hydrolysates (Nutramigen). Once the child's condition is regulated on this diet, symptoms of the disease do not progress; however, any neurologic or cataract damage that is already present will persist. The duration of the restricted diet is controversial, but probably it should be followed for life (Bosch, 2007).

Glycogen Storage Disease

Glycogen storage disease refers to a group of genetically transmitted disorders that involve altered production and use of glycogen in the body. Twelve of the 13 described types are inherited as autosomal recessive traits; the other is a sex-linked disorder (Chen, 2008).

Glycogen is normally stored in the liver to provide a reserve supply of glucose. When the body needs glucose for energy, this glycogen is transformed back to glucose. In children with glycogen storage disease, glycogen is deposited normally, but an enzyme deficiency prevents retransformation of the glycogen back to glucose. As a result, children's livers rapidly increase in size from the stored glycogen. Children with this disorder are susceptible to periods of hypoglycemia, because their only source of ready glucose is oral intake.

In one form of this disorder (type II or Pompe's disease), children deposit large stores of glycogen, not only in the liver, but in the muscle and heart as well (Muller-Felber et al., 2007). The muscles begin to feel hard to palpation due to the deposits of glycogen. The heart becomes enlarged, and often an arrhythmia is present. Without therapy, children with this form usually die of heart failure before they reach adulthood.

Assessment

A common sign of glycogen storage disease is liver enlargement, because the liver must store such a large supply of glycogen. Consequently, the abdomen protrudes. Over a long period, the child's growth is stunted because there is not enough glucose for any function but immediate energy. If hypoglycemic episodes have been severe, brain damage may result. Many children have a tendency toward epistaxis or hemorrhage and are at risk when having surgery performed because of impaired clotting ability due to decreased platelet adhesiveness.

Therapeutic Management

Children with glycogen storage disease need to be maintained on a high-carbohydrate diet with snacks between meals to prevent hypoglycemia. In addition, a continuous glucose nasogastric or gastrostomy feeding during the night may be necessary to prevent hypoglycemia while sleeping. Therapy with diazoxide (Proglycem), an antihypoglycemic drug that inhibits insulin release, may help regulate the glucose level to provide additional growth. Liver transplantation may be a possibility, but it will not cure the basic enzyme deficiency (Iyer et al., 2007).

Tay-Sachs Disease

Tay-Sachs disease is an autosomal recessively inherited disease in which the infant lacks hexosaminidase A, an enzyme necessary for lipid metabolism. Without this enzyme, lipid deposits accumulate on nerve cells, leading to cognitive challenge due to deposits on brain cells and blindness due to deposits on optic nerve cells (Leavitt & Kotagal, 2007).

Tay-Sachs disease is found primarily in the Ashkenazi Jewish population (Eastern European Jewish ancestry). Children generally appear normal in the first few months of life except for an extreme Moro reflex and mild hypotonia. At about 6 months of age, they begin to lose head control and are unable to sit up or roll over without support. On ophthalmoscopic examination, a cherry-red macula is noticeable (caused by lipid deposits). By 1 year of age, children have developed symptoms of spasticity and are unable to perform even simple motor tasks. By 2 years of age, generalized seizures and blindness have occurred. Most children die of cachexia (malnutrition) and pneumonia by 3 to 5 years of age.

There is no cure for Tay-Sachs disease. The disorder may be detected in utero by amniocentesis. Carriers for the disease trait may be identified by hexosaminidase A assay.

What if... You are helping at a preschool and notice a teacher assistant urging a little boy with PKU to drink his milk? When you suggest that milk might not be good for him, the teacher says, "Of course it is. Milk is nature's perfect food." How would you respond? What would you do?

Key Points for Review

- Endocrine disorders are almost all long-term disorders. Helping parents and children remember to take medicine on a long-term basis is an important nursing responsibility.
- Children with endocrine or metabolic disorders often develop height or weight discrepancies. Help children continue to feel high self-esteem by concentrating on the things they are able to do despite a growth lag.
- Growth hormone (GH) deficiency, a pituitary disorder, results in short stature. Therapy for children consists of the injection of synthetic GH. Children can experience

situational low self-esteem if they do not receive adequate emotional support from significant others.

- Other pituitary disorders include GH excess and diabetes insipidus. As the name implies, with GH excess, there is overproduction of GH and overgrowth of body tissues. With diabetes insipidus, there is decreased release of antidiuretic hormone. Urine becomes dilute, and large amounts are excreted. Therapy is administration of desmopressin, an arginine vasopressin. Children with this are at high risk for fluid volume deficit.
- Congenital hypothyroidism occurs as a result of an absent or nonfunctioning thyroid gland. The condition is discovered by a blood test at birth. The therapy is oral administration of synthetic thyroid hormone.
- Acquired hypothyroidism (Hashimoto's disease) is an autoimmune phenomenon that interferes with thyroid gland function. Therapy is administration of synthetic thyroid hormone.
- Acute adrenocortical insufficiency can occur in children from causes such as an overwhelming infection in which there is hemorrhagic destruction of the adrenal gland. A more common disease in children is congenital adrenogenital hyperplasia. Girls are born masculinized; either sex may be unable to retain sodium, which results in rapid fluid loss. Therapy is administration of hydrocortisone and aldosterone if sodium loss is also present.
- Cushing syndrome is caused by overproduction of cortisol by the adrenal gland. This usually results from a tumor in the gland. Children appear abnormally obese. Therapy is surgical removal of the tumor.
- The most frequently occurring pancreatic disorder is type 1 diabetes mellitus. This may be an autoimmune process in which there has been destruction of insulin-producing islet cells. Therapy is a combination of administration of insulin, diet, and exercise. Type 2 diabetes is now also occurring in children. Therapy is diet, exercise, and an oral antiglycemic agent.
- Hypocalcemia, a parathyroid gland disorder, results in a lowered blood calcium level causing tetany to develop. Therapy is the administration of calcium.
- Various disorders of metabolism that interfere with carbohydrate, amino acid, or fat metabolism occur in children. Representative of these are phenylketonuria, galactosemia, and Tay-Sachs disease.

CRITICAL THINKING EXERCISES

1. Rob is the 16-year-old boy diagnosed as having type 1 diabetes whom you met at the beginning of the chapter. In the last 6 months, he has "forgotten" to take his insulin at least once a week. Is Rob's history unusual for an adolescent? What health teaching do you think will most help him re-establish control?
2. A 12-year-old girl with GH deficiency is only 3 feet tall and has been told she probably will not grow taller than 4 feet 6 inches. Her parents tell you they find her "cute," so they do not want her to receive GH. How would you approach this family? To what extent should the child be able to contribute to this decision?
3. A newborn is diagnosed as having the salt-losing form of congenital adrenal hyperplasia. What would be the most important measure to teach her parents before she is discharged from the hospital? How may having a child with this disorder change this family's life?
4. Examine the National Health Goals related to endocrine or metabolic disorders in children. Most government-sponsored funds for nursing research are allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to the Tebecco family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to endocrine or metabolic disorders in children. Confirm your answers are correct by reading the rationales.

Chapter 49

Nursing Care of a Family When a Child Has a Neurologic Disorder

KEY TERMS

- astereognosis
- automatisms
- autonomic dysreflexia
- choreoathetosis
- choreoid
- decerebrate posturing
- decorticate posturing
- diplegia
- dyskinetic
- graphesthesia
- hemiplegia
- infantile spasms
- kinesthesia
- paraplegia
- pulse pressure
- quadriplegia
- status epilepticus
- stereognosis

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe common neurologic disorders in children.
2. Identify National Health Goals related to neurologic disorders and children that nurses could help the nation achieve.
3. Analyze ways in which care of a child with a neurologic disorder can be optimally family centered.
4. Assess a child with a neurologic disorder.
5. Formulate nursing diagnoses for a child with a neurologic disorder.
6. Establish expected outcomes for a child with a neurologic disorder.
7. Plan nursing care for a child with a neurologic disorder.
8. Implement nursing care, such as monitoring medicine effectiveness, for a child with a neurologic disorder.
9. Evaluate expected outcomes for achievement and effectiveness of care.
10. Identify areas related to care of children with neurologic disorders that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of neurologic disorders and the nursing process to achieve quality maternal and child health nursing care.

Tasha is a 2-year-old girl who is brought to an emergency department by her mother because she had a seizure. Her physician suspects she may have meningitis. Her parent is visibly upset. She says, “Does this mean she’ll always have seizures? How can she ever be independent?”

Previous chapters described normal growth and development in children and nursing care of children with disorders of other systems. This chapter adds information about the dramatic changes, both physical and psychosocial, that occur when a child is born with a neurologic disorder. Such information builds a base for care and health teaching for children with these disorders.

What education does this parent need about recurrent seizures?

Neurologic disorders encompass a wide array of problems resulting from congenital disorders, acquired dysfunction, infection, or trauma. Many of these disorders can cause severe illness. Others can result in life-threatening complications. In the future, stem cell research may offer a cure for neurologic disorders, but in the present, because neural tissue does not regenerate like other body tissue, any nervous system degeneration is permanent. Whenever possible, prevention must be the highest priority for keeping the nervous system healthy. If degeneration has already occurred, nursing care focuses on helping the child and family develop strategies for dealing with the associated loss in mental or physical functioning, making the child comfortable, and providing an environment conducive to the child's development and self-esteem. Two major causes of neurologic dysfunction in children are addressed in National Health Goals. These are shown in Box 49.1.

Nursing Process Overview

For Care of a Child With a Neurologic System Disorder

Assessment

Neurologic disorders often manifest themselves with vague symptoms. Parents may report that their child seems to be "walking strangely" or is "just not herself." A thorough history and neurologic examination provide the best sources of information regarding the cause of the child's problem.

The neurologic examination covers six areas of neurologic functioning, including mental or cognitive processes as well as motor and sensory functioning. If more information is needed, numerous diagnostic laboratory tests may be ordered. The parents and child need considerable support throughout the assessment process. Although the neurologic examination can be made "fun" for a child, other procedures such as a computed tomography (CT) scan or lumbar puncture can be frightening. Additionally, the anxiety of not knowing what is wrong and fearing the worst can make the waiting period for test results especially difficult for the child's parents.

Nursing Diagnosis

Nursing diagnoses for children with neurologic disorders vary according to the child's needs. Initially, a child may need emergency care and constant observation, and the parents may need to discuss their fears about their child's illness. If the child undergoes surgery, nursing diagnoses should address immediate preoperative and postoperative care and long-term care such as rehabilitation and home care, taking into account the child's specific limitations and health care needs. Two nursing diagnoses should be kept in mind throughout these treatment phases:

- Risk for disuse syndrome related to neurologic deficit affecting one area of functioning
- Interrupted family processes related to stress associated with the long-term effects of neurologic dysfunction

Other nursing diagnoses are described along with specific disorders in this chapter.

BOX 49.1 ✻ Focus on National Health Goals

Bacterial meningitis and head injuries are major causes of neurologic damage and subsequent disability in children. Three National Health Goals address children with disabilities:

- Reduce the proportion of children and adolescents with disabilities who report being sad, unhappy, or depressed from a baseline of 31% to a target level of 17%.
- Reduce the number of people 21 years of age and younger with disabilities who are in congregate care facilities from a baseline of 24,300 to 0.
- Increase the proportion of children and youth with disabilities who spend at least 80% of their time in regular education programs from 45% to 60% (http://www.nih.gov).

Nurses can help the nation achieve these goals through helping prevent neurologic injury by educating children and parents about the use of helmets for bicycle and motorcycle safety, by administering and teaching paramedical personnel to administer safe care at accident scenes so that children's heads and necks are protected, and by decreasing the possible spread of bacterial meningitis through good handwashing and infection control precautions in hospitals.

Topics of nursing research that might help prevent neurologic injury or disease and subsequent disability include: What kinds of programs can school nurses initiate that would effectively teach bicycle safety? Could serious outcomes of bacterial meningitis be reduced if parents were educated about the symptoms of meningitis and brought children with such symptoms to health care facilities earlier?

Outcome Identification and Planning

Be realistic when establishing expected outcomes. Children who have permanent limitations may not be able to achieve in some areas. When neurologic disorders are first diagnosed, for example, parents may be able to focus only on the short term, such as whether the child will survive meningitis or whether the child has stopped convulsing. Later, they may need help to look at the long-term picture: Will they need assistance to care for the child at home? What type of education setting will be best for their child? What type of exercise program will be required?

Before a diagnosis is confirmed, parents may attribute their child's functional deficits to immaturity (she is not walking yet because she is simply too young). They insist that, with age, her ability to function will improve. They are unable to make plans because they have not accepted their child's neurologic deficits. Until this occurs, they will not be ready for specific planning. When parents begin to adjust to the new reality, the time is right for support and help in solving problems.

Long-term care needs can be a source of stress, physically, emotionally, socially, and financially. Numerous

organizations are available for assistance and support such as Epilepsy Foundation of America (http://www.epilepsyfoundation.org), National Information Center for Children and Youth With Disabilities (http://www.nichcy.org), National Fibromatosis Foundation (http://www.ctf.org), National Spinal Cord Injury Association (http://www.spinalcord.org), and United Cerebral Palsy Association (http://www.ucp.org).

Implementation

Nursing interventions for a child with a neurologic problem must address both short- and long-term needs. For instance, while feeding an infant with increased intracranial pressure (ICP), demonstrate a caring attitude by showing parents how to gently handle the infant. For parents of a child with seizures, explain that turning him gently to his side will prevent him from choking. This can help them feel less anxious about future seizures. The child, too, will feel more in control of his illness if he believes that both he and his parents will be able to handle any acute symptoms. Providing nursing care that meets everyone's needs takes a great deal of sensitivity and planning.

Outcome Evaluation

Evaluation of a child with a neurologic disorder should address not only the child's progress in regaining physical function but also the child's level of self-esteem. Further planning to maintain the child's self-esteem is necessary if the disorder is long-term. Some examples indicating achievement of possible outcomes are:

- Child states he is aware of potential for injury related to recurrent seizures.
- Family members state they are able to maintain family cohesiveness yet sustain contact with hospitalized child.
- Child practices exercises daily to reduce possibility of contracture from disuse syndrome.

ANATOMY AND PHYSIOLOGY OF THE NERVOUS SYSTEM

Nerve cells (*neurons*) are unique among body cells in that, instead of being compact, they consist of a cell nucleus and extensions: one axon and several dendrites. The *dendrite* transmits impulses to the cell nucleus; the *axon* transmits impulses away from the cell nucleus to body organs. These cells vary in size, ranging from a few inches to several feet long, reaching from distant body sites such as the feet, through the spinal cord, and to the brain. Although their great length is vital to motor and sensory function, it also makes nerve cells more susceptible than other body cells to injury.

The nervous system continues to mature through the first 12 years of life. It actually consists of two separate systems: the *peripheral nervous system (PNS)* and the *central nervous system (CNS)*. The PNS consists of the cranial nerves, the spinal nerves, and the somatic and visceral divisions. The visceral division includes the autonomic system.

The CNS consists of the brain, the spinal cord, and the surrounding membranes or meninges that protect the brain and spinal cord from normal trauma. These tissues are also protected by the skull, the vertebral column, and the *cerebrospinal fluid (CSF),* the fluid in the subarachnoid space, which serves as a cushion.

Because brain protection is so important, the brain is covered by three separate membranes: the *dura mater* (a fibrous, connective tissue containing many blood vessels), the *arachnoid membrane* (a delicate serous membrane), and the *pia mater* (a vascular membrane) (Fig. 49.1).

Four fluid-filled cavities, or ventricles, lie within the brain (Fig. 49.2). CSF forms in the two lateral ventricles in the choroid plexus of the pia mater and flows through the foramen of Monro into the third ventricle, then through a narrow canal (the aqueduct of Sylvius) to the fourth ventricle. It leaves the fourth ventricle by the foramen of Magendie and the two foramens of Luschka and flows into the cisterna magna, a collection pool at the base of the skull. From the

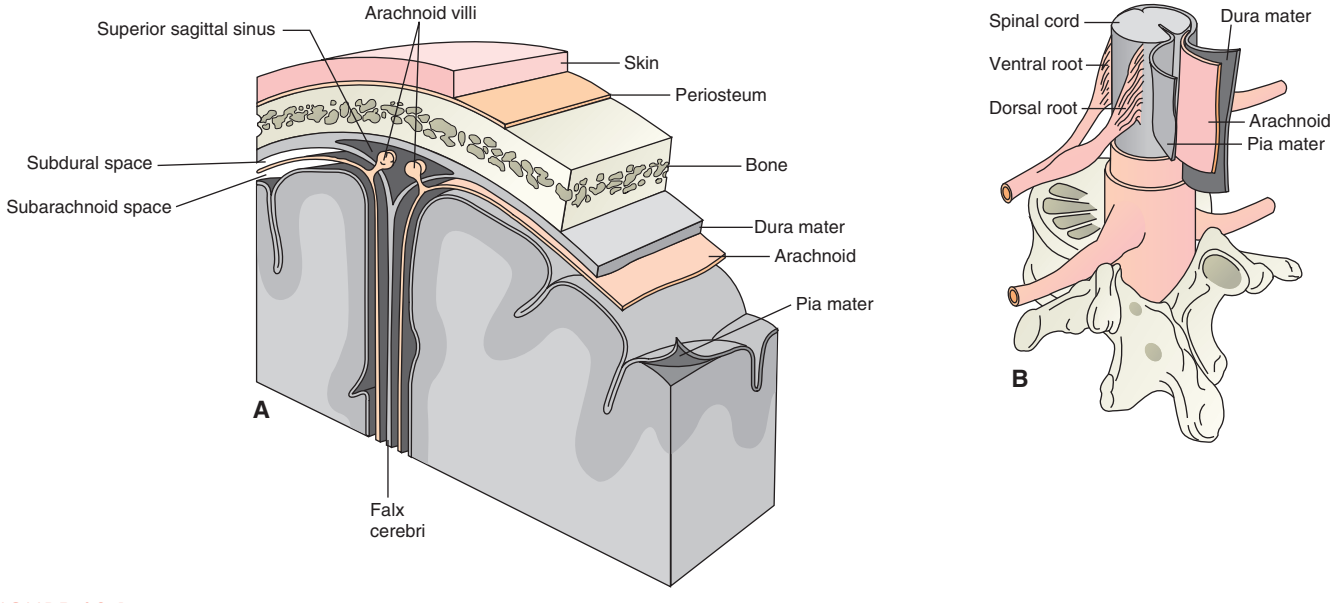

FIGURE 49.1 Meninges of the (**A**) brain and (**B**) spinal cord.

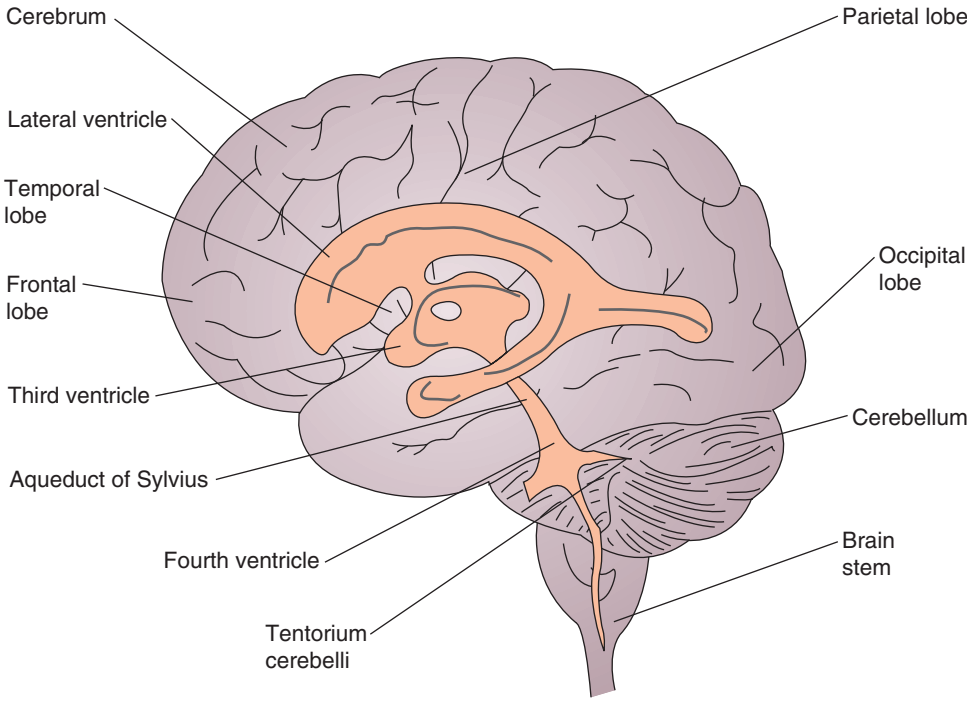

FIGURE 49.2 Ventricles of the brain. Cerebrospinal fluid flows from the lateral ventricles into the third ventricle, then through the narrow aqueduct of Sylvius to the fourth ventricle.

TABLE 49.1 ✻ Normal Properties of Cerebrospinal Fluid

Parameter	Normal Finding	Abnormal Finding: Possible Significance
Opening pressure	60–160 cm H_2O	Lowered pressure usually indicates that there is subarachnoid obstruction in the spinal column above the puncture site. Elevated pressure suggests intracranial compression, hemorrhage, or infection. Pressure increases if a child coughs or pressure is applied to the external jugular vein (Valsalva maneuver).
Appearance	Clear and colorless	If cloudy, indicates possible infection with an increased number of white blood cells (WBCs). If reddened, color is probably red blood cells (RBCs).
Cell count	0–8/mm^3	Granulocytes suggest CSF infection. Lymphocytes suggest meningeal irritation and inflammation. A few RBCs and WBCs are normally present in the newborn CSF due to the trauma of birth.
Protein	15–45 mg/100 mL	Elevated count (> 45/100 mL) occurs if RBCs are present. If both protein content and RBC count are elevated, meningitis or subarachnoid hemorrhage is suggested. If protein content alone is elevated, it more likely suggests a degenerative process such as multiple sclerosis.
Glucose	60%–80% of serum glucose level	Decreased glucose level suggests that a glycolytic process is occurring. Bacterial meningitis causes a marked decrease in CSF glucose; invasion of fungi, yeast, tuberculosis, or protozoans into the CSF results in some decrease in glucose level. Viral infections do not cause a decrease in CSF glucose and may occasionally cause a slight increase.
Albumin/globulin (A/G)	8:1	Increased level suggests infection or A/G ratio neurologic disorder.

cisterna magna, the fluid circulates to the subarachnoid space, bathing both the brain and the spinal cord. The fluid is then absorbed by the arachnoid membrane. The time span for replacement is approximately 6 hours.

The properties of CSF are shown in Table 49.1. It is basically a colorless, alkaline fluid with a specific gravity of approximately 1.004 to 1.008, containing traces of protein, glucose, lymphocytes, and body salts. The fluid circulates downward to the level of the second sacral vertebra (S2). In infants, the spinal cord ends at the third lumbar vertebra (L3); in adolescents and adults, at L1 or L2. This configuration leaves a space near the cord base containing CSF that can be tapped safely (lumbar puncture) without fear of causing spinal cord damage.

ASSESSING THE CHILD WITH A NEUROLOGIC DISORDER

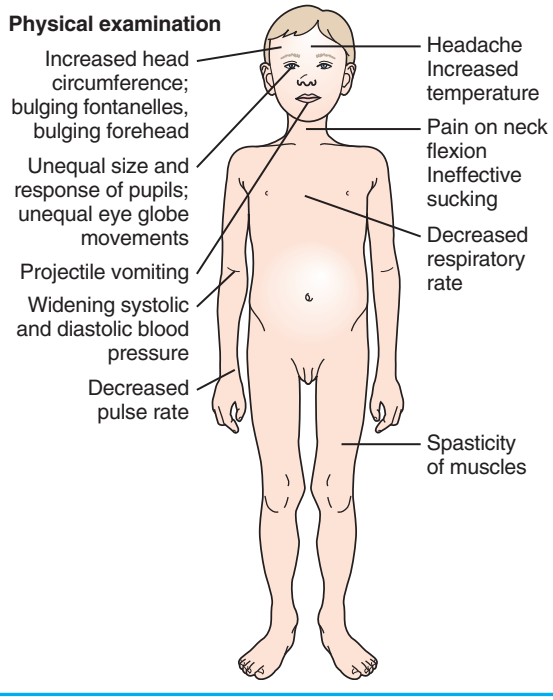
Neurologic symptoms, such as headache, an unsteady gait, or lethargy, are often insidious. Both a thorough history and a neurologic examination are needed to reveal the cause and extent of such symptoms (Box 49.2).

Box 49.2 Assessment
Assessing a Child for Signs and Symptoms of a Neurologic Disorder

History

Chief concern: Seizure, loss of consciousness, delay in developmental tasks, headache, clumsiness at motor tasks.
Past medical history: Infection during pregnancy; difficult birth; difficulty with initiating respirations at birth; head injury from fall or accident.
Family medical history: History of seizures or headaches in other family members.

Physical examination



Health History

The child's history may first reveal symptoms of a neurologic disorder. Because many neurologic problems result from fetal injury, it is important to obtain the mother's pregnancy history as well.

At primary care visits, ask parents about their child's developmental milestones and ability to perform age-appropriate tasks successfully. A Denver Developmental Screening Test can indicate whether a parent's concern about a preschool child is well founded. The ability to perform well in school is important documentation for an older child.

Neurologic Examination

A complete neurologic examination takes at least 20 minutes. It requires patience and skill to keep a child's attention while observing for possible indications of neurologic disease. For a full examination, six areas are assessed: cerebral, cranial nerve, cerebellar, motor, sensory, and reflex function.

Cerebral Function

Both general and specific cerebral functions are evaluated. General cerebral function is indicated by level of consciousness, orientation, intelligence, performance, mood, and general behavior (Jacobs, Guglielmo, & Chin-Hong, 2009).

Evaluate the child's level of consciousness through conversation. Note any drowsiness or lethargy and whether the child is oriented to surroundings. Allow a child to answer questions without prompting, and listen carefully that the answer is appropriate to the question.

Orientation refers to whether children are aware of who they are, where they are, and what day it is (person, place, and time). Be careful to take into account a child's age and development; children younger than 4 years of age, for example, may not know both their first and last names. Children may be of school age before they know their address. Children younger than 7 or 8 years of age may have difficulty with the days of the week, confusing "yesterday" with "today" or "tomorrow." Intellectual performance (IQ) can be determined by the child's score on a standard intelligence test. Estimates of intellectual function can be made by asking the child questions on common topics.

Immediate recall is the ability to retain a concept for a short time. Ask the child to repeat numbers after you. A child who is 4 years old can usually repeat three digits. A child older than 6 years can repeat five digits. *Recent memory* covers a slightly longer period. Show the preschool child an object such as a key and ask him to remember it, because later you will ask him to tell you what it was. After about 5 minutes, ask whether he remembers what object you showed him. Ask older children what they ate for breakfast to test recent memory.

Remote memory is long-term recall. Ask preschoolers what they ate for breakfast that morning (to them, that was a long time ago); ask older children the name of their first-grade teacher.

Specific cerebral function can be measured by assessing language, sensory interpretation, and motor integration. When assessing language, listen to the child's ability to articulate. Remember that many preschoolers substitute "w" for "r," saying "west time" instead of "rest time."

Stereognosis refers to the ability to recognize an object by touch and tests sensory interpretation. Ask the child to close her eyes; then place a familiar object, such as a key, a penny, or a bottle cap, in her hand and ask her to identify it. This is a skill even preschoolers are able to do successfully.

Graphesthesia is the ability to recognize a shape that has been traced on the skin. Ask a preschooler to close his eyes; trace first a circle, then a square, on the back of his hand, and ask him whether the shapes are the same or different. Be sure that the child understands the concept of "different" by first showing him objects such as two keys and a bottle cap and documenting that he is able to identify the keys as being the same and the bottle cap as being different. For older children, trace numbers (8, 3, 0, and 1 work well) and ask the child to identify each one.

Kinesthesia is the ability to distinguish movement. Have a child close her eyes and extend her hands in front of her. Raise one of her fingers and ask her whether it is up or down. Hold the finger by its sides so that your other fingers do not brush against the child's palm or the back of her hand (this will reveal the finger position). Repeat the same movement with a toe on each foot. For preschoolers, first determine whether the child understands the concept of up and down.

Measure motor integration by asking a child to perform a complex motor skill, such as folding a piece of paper and putting it into an envelope. A child of 4 years or older should be able to do this neatly.

Children do best when these tests are presented as a game. Be certain to convey that there are no right or wrong answers. A child who believes that he has failed these tests may not respond well to further testing.

Cranial Nerve Function

Testing for cranial nerve function consists of assessing each pair of cranial nerves separately. Methods of cranial nerve testing are described in Table 49.2.

Cerebellar Function

Tests for cerebellar function are tests for normal balance and coordination. Observe the child walking. Does she do so naturally and freely? (Most children walk at least a little self-consciously when they know they are being observed.) Ask the child to stand on one foot. A child as young as 4 years should be able to do this for as long as 5 seconds. Ask the child to attempt a tandem walk (walk a straight line, one foot

TABLE 49.2 ✻ Cranial Nerve Function

Cranial Nerve	Function	Assessment
I (olfactory)	Sense of smell	Assess child's ability to recognize common odors (e.g., peanut butter, an orange) while eyes are closed.
II (optic)	Vision	Assess vision fields and visual acuity; examine retinas.
III (oculomotor)	Motor control and sensation for eye muscles and upper eyelid elevation	Assess ability to move eyes to follow an object in all directions. Note nystagmus (jerking motion). Assess pupillary size, equality, and reaction to light. Cranial nerves III, IV, and VI are tested together.
IV (trochlear)	Movement of major eye globe muscles	As for nerve III.
V (trigeminal)	Mastication muscles and some facial sensations	Assess ability to discern light touch to test sensory component; assess symmetry and strength of bite to test motor component.
VI (abducens)	Movement and muscle sense of eye globe	As for nerves III and IV.
VII (facial)	Impulses for hyoid and facial muscles, salivation, and taste	Assess motor strength by asking child to close eyes while you attempt to open them. Note symmetry of facial expression (such as smile) and movement (such as wrinkling forehead). Assess taste by asking child to identify salt or sugar.
VIII (acoustic)	Equilibrium and hearing	Assess hearing by the response to a whispered word or a Weber or Rinne test. Equilibrium is not tested routinely.
IX (glossopharyngeal)	Motor impulses to heart and other organs; sensation from pharynx, thorax, and abdominal organs	Assess gag reflex by pressing on rear of tongue with tongue blade. Note midline uvula (tested together with nerve X).
X (vagus)	Swallowing and gag reflexes	Assess ability to swallow; elicit gag reflex by pressing a tongue blade on posterior tongue.
XI (accessory)	Impulses to striated muscles of pharynx and shoulders	Ask child to turn head to the side; try to turn it to center. Ask the child to elevate shoulders while you press down on them.
XII (hypoglossal)	Motor impulses to tongue and skeletal muscles; sensation from skin and viscera	Ask child to protrude tongue. Assess for tremors. Ask child to press on side of cheek with tongue; assess tongue strength.

FIGURE 49.3 Cerebellar function tests. (**A**) A child attempting a tandem walk. (**B**) Nose-to-finger test. (© Lesha Photography.)

directly in front of the other, heel touching toe) (Fig. 49.3A). A child older than 4 years of age should be able to do this for about four consecutive steps. Ask the child to touch his nose with his finger, then reach and touch your finger with the same hand (held about 1½ feet in front of him) (see Fig. 49.3B). Tell him to repeat this action, and move your finger to a new position each time. The average child rarely reaches past your finger or stops before touching it.

Ask the child to pat one knee with the palm of her hand, then quickly turn the hand over and pat the knee with the back of her hand; repeat over and over. She should be able to do this rapid, coordinated motion without much difficulty. Always ask her to do the motion one hand at a time. Preschoolers will mirror the movement of the actively moving hand by moving the inactive hand as well. Older children should not demonstrate this (or should show only a small amount of movement).

Ask the child to touch each finger on one hand with the thumb of that hand in rapid succession. Ask him to run the heel of one foot down the front of his other leg while he is lying supine (he should be able to do this without "running off" the leg). While he is still lying on the examining table, ask him to close his eyes and to draw a circle or figure 8 in the air with his foot.

Tests of cerebellar function are all fun for children to do, as long as they know that there are no passes or failures. Show approval for effort even if they are having difficulty with a task, so that they have confidence to try another one.

Motor Function

Muscle size, strength, and tone are part of motor function assessment. Compare the size of the extremities on each side. If in doubt about symmetry, measure the circumference of the calves and thighs or upper and lower arms for comparison. Palpate muscles for tone. Move the extremities through passive range of motion; evaluate for symmetry, spasticity, and flaccidity bilaterally. Ask the child to extend her arms in front of her and resist your action as you push down or up on her hands or push them out to the side. Do the same with the lower extremities.

Sensory Function

If children's sensory systems are intact, they should be able to distinguish light touch, pain, vibration, hot, and cold. Have a child close his eyes and then ask him to point to the spot where you touch him with an object. Light touch is tested by using a wisp of cotton, deep pressure by pressure of your finger, pain by a safety pin, temperature by test tubes filled with hot or cold water. Vibration is tested by touching the child's bony prominences (iliac crest, elbows, knees) with a vibrating tuning fork. Warn the child that on pin testing, he will feel a momentary prick. Otherwise, he may be unwilling to close his eyes again for further testing.

Reflex Testing

Deep tendon reflex testing, which is part of a primary physical assessment (see Chapter 34), is also a basic part of a neurologic assessment. In newborns, reflex testing is especially important, because the infant cannot perform tasks on command to demonstrate the full range of neurologic function (see Chapter 18).

✔ Checkpoint Question 49.1

Tasha has a full neurologic examination after a seizure. What cranial nerve is assessed when you ask a child to raise her shoulders as you push against them?

a. Nerve VII or facial.
b. Nerve VIII or auditory.
c. Nerve XI or accessory.
d. Nerve XII or hypoglossal.

Diagnostic Testing

A variety of diagnostic tests may be ordered to provide more information should any abnormalities be detected in the health history, physical examination, or neurologic examination. Many of these tests are invasive, so it is best to try to schedule the least invasive procedures first, before the painful or more frightening procedures are done, to help promote the child's cooperation. Ensuring that the child and family are well prepared for these procedures is an important nursing responsibility. When explaining tests, take into account not only the child's chronologic age but also the child's level of cognitive functioning. Otherwise, explanations may not be well understood. Be sure to provide an explanation that includes a description of all of the sensory experiences the child might undergo—that is, not only what will be done but also how the child might feel, or what the child might see or hear or even smell or taste (if appropriate).

Lumbar Puncture

Lumbar puncture involves the introduction of a needle into the subarachnoid space (under the arachnoid membrane) at the level of L4 or L5 to withdraw CSF for analysis. The procedure is used most frequently to diagnose hemorrhage or infection in the CNS or to diagnose an obstruction of CSF flow. Lumbar puncture is contraindicated if the skin over the needle insertion site is infected (to avoid introducing pathogens into the CSF) or if there is a suspected elevation of CSF pressure. In the latter instance, if fluid is removed, the higher pressure in the intracranial space could cause the brainstem to be drawn down into the spinal cord space, compressing the medulla and compromising the action of the cardiac and respiratory centers. EMLA or lidocaine cream can be applied to the puncture site 1 hour before the procedure to reduce pain. Alternatively, the child may receive conscious sedation for the procedure (see Chapter 39).

For a lumbar puncture, a newborn is seated upright with the head bent forward (Fig. 49.4A). The older infant or child is placed on one side on the examining table. The head is flexed forward, the knees are flexed on the abdomen, and the back is arched as much as possible. This position opens the space between the lumbar vertebrae, facilitating needle insertion (see Fig. 49.4B). Children younger than school age need to be held in this position, because they may be so frightened by someone working on their back unseen that they are unable to hold this arched position; they may try to turn over or turn their head to see what is happening. It helps a school-age child or adolescent if you stand by the table facing him and gently rest your hand on the back of the head, keeping it bent forward. This helps to maintain good position without the impression of being restrained.

Children need good preparation for a lumbar puncture, because they cannot see what is happening. Be certain that they know that the health care provider performing the procedure will wash their back with a solution that feels cold and inject a local anesthetic that might sting like a bee sting (if an analgesic cream was not applied before the procedure). Caution children that they probably will feel pressure but not pain as the lumbar puncture needle is inserted. Remind them to remain absolutely still throughout the procedure. You might describe the position as "rolling into a ball" or "folding up like an astronaut in a small spaceship." Occasionally during a lumbar puncture, the needle will press against a dorsal nerve root and the child will experience a shooting pain down one leg. If this happens, reassure the child that this feeling passes quickly and does not indicate an injury.

When the insertion stylette is removed and CSF drips from the end of the needle, the procedure has been successful. An initial pressure reading is made, which varies with the child's age. To confirm that the subarachnoid space in the cord is patent with that in the skull, the examiner may ask a child who is older than 3 years of age to cough, or the examiner may ask you to press on the child's external jugular vein during the procedure. Either of these measures will cause an increase of CSF pressure if fluid is flowing freely through the subarachnoid space. Typically, three tubes of CSF, containing 2 to 3 mL each, are collected, a closing pressure reading is taken, and the needle is withdrawn. Samples are usually sent for culture, sensitivity, glucose level, and presence of red blood cells. Other evaluations are determining whether there is an alteration in the albumin/globulin ratio in the CSF and

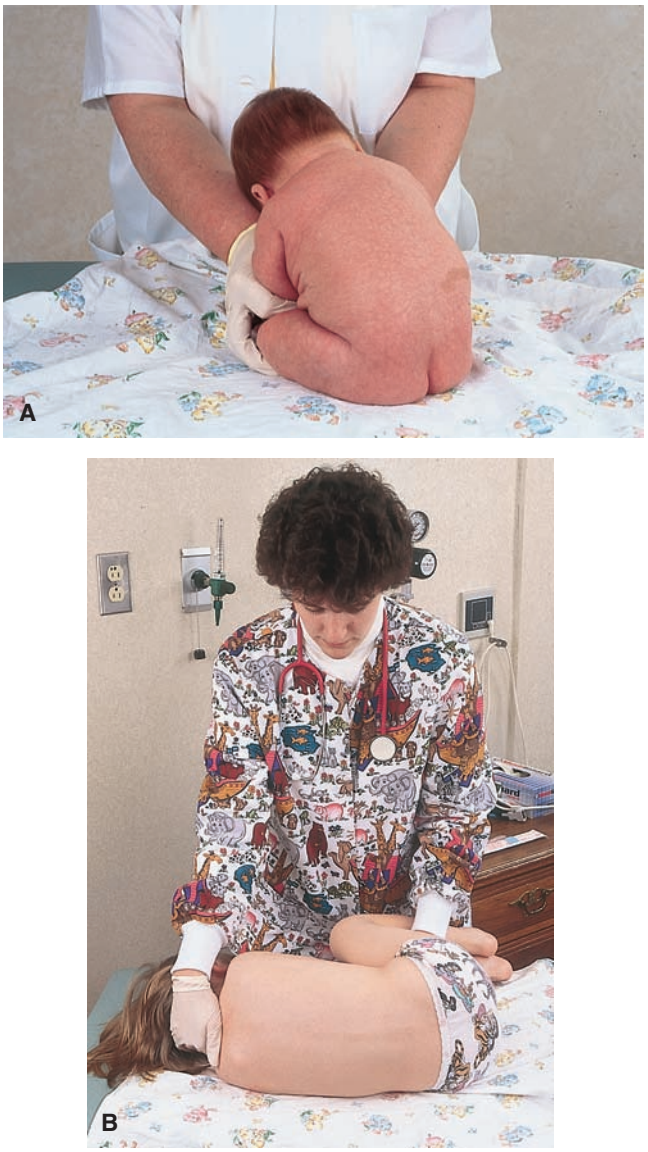


FIGURE 49.4 (**A**) Positioning an infant for a lumbar puncture. (**B**) Positioning a young child for a lumbar puncture. (© Barbara Proud.)

measuring the gamma-globulin level. An increased level of gamma-globulin is suggestive of multiple sclerosis or meningitis. The first sample obtained may contain blood or skin pathogens from the puncture, so it should not be the sample sent for determination of red blood cell content or culture. Throughout the procedure, sterile technique must be strictly observed to ensure that an uncontaminated sample of fluid is sent for culture and to avoid the introduction of pathogens into the CSF.

Lumbar puncture involves at least momentary pain, so children need to be comforted afterward. A child may develop a headache after a lumbar puncture as a result of the reduction in CSF volume or invasion of a small air pocket during the puncture, although this is rare because of the small needle used. Encouraging the child to lie flat for about 30 minutes and to drink a glass of fluid can help prevent cerebral irritation caused by air rising in the subarachnoid space and helps increase the amount of CSF. Some children have a headache despite these precautions and may need an analgesic for pain relief (Lee, Sennett, & Erickson, 2007). Although postlumbar puncture headache is seen less frequently in young children than in adults, assessing for it is important to reduce the risk of pain for the child.

If a child had minimally increased CSF pressure at the time of the puncture, closely observe the child after the procedure to prevent respiratory and cardiac difficulty from medulla pressure. An increase in blood pressure or a decrease in pulse and respiration are important signs of increased intracranial compression. Other important signs include a change in consciousness, pupillary changes, and a decrease in motor ability.

Ventricular Tap

In infants, CSF may be obtained by a subdural tap into a ventricle through the coronal suture or anterior fontanelle. A small space on the scalp over the insertion site is shaved or clipped, and the area is prepared with an antiseptic. The infant's head must be held firmly in a supine position to prevent movement during the procedure, which could cause the needle to strike and lacerate meningeal tissue.

Fluid must be removed from this site slowly, rather than suddenly, to prevent a sudden shift in pressure that could cause intracranial hemorrhage. After the procedure, a pressure dressing is applied to the site, and the infant is placed in a semi-Fowler's position to prevent prolonged drainage from the puncture site. After the procedure, comfort the infant or allow the parents to do so; this both reduces the stress of a painful procedure and prevents the infant from crying excessively, an action that could increase ICP.

X-Ray Techniques

A flat-plate skull x-ray film may be used to obtain information about increased ICP or skull defects such as fracture or craniosynostosis (premature knitting of cranial sutures). Increased ICP is suggested if skull sutures are separated. If the process is chronic, other subtle changes, such as a flattening of the sella turcica or an increase in the convolutions of the inner table of the skull, may be present.

Cerebral Angiography. Cerebral angiography is an x-ray study of cerebral blood vessels that involves the injection of a contrast material into an extracranial artery. Serial radiographs are then taken as the dye flows through the blood vessels of the cerebrum. The injection site chosen is often a femoral artery, although a carotid artery may be used. The study shows any vessel defects or space-occupying lesions that are occluding cranial blood vessels.

Myelography. Myelography is the x-ray study of the spinal cord that involves the introduction of a contrast material into the CSF by lumbar puncture. It is used to show the presence of space-occupying lesions of the spinal cord. After the procedure, keep the head of the child's bed elevated to prevent contrast medium from reaching the meninges surrounding the brain.

Computed Tomography (CT) and Magnetic Resonance Imaging (MRI). CT involves the use of radiography to reveal densities at multiple levels or layers of brain tissue. It is helpful in confirming the presence of a brain tumor or other encroaching lesions. Single-photon emission computed tomography (SPECT) is a similar procedure used mainly for blood flow evaluation. MRI uses magnetic fields to show differences in tissue composition, revealing normal versus abnormal brain tissue. Both CT and MRI are discussed in greater detail in Chapter 37.

Nuclear Medicine Studies

Brain Scan. For a brain scan, a radioactive material is injected intravenously (IV), and, after a fixed time during which the injected material is deposited in cerebral tissue, radioactivity levels over the skull are measured. If the blood–brain barrier is not functioning, the radioactive material will accumulate in specific areas, suggesting possible tumor, subdural hematoma, abscess, or encephalitis.

Positron Emission Tomography. The diagnostic technique of positron emission tomography (PET) involves imaging after injection of positron-emitting radiopharmaceuticals into the brain. These radioactive substances accumulate at diseased areas of the brain or spinal cord. PET is extremely accurate in identifying seizure foci.

Echoencephalography

Echoencephalography involves the projection of ultrasound (high-frequency sound waves above the audible range) toward the child's head or spinal cord (an ultrasound). Ultrasound may be used to outline the ventricles of the brain. Because this technique of scanning is noninvasive, produces no discomfort, and has no known complications, it may be repeated frequently to monitor changes in the size of ventricles or an invading lesion.

Electroencephalography

The electroencephalogram (EEG) reflects the electrical patterns of the brain (Moe, Benke, & Bernard, 2008). It summarizes the physical and chemical interactions within the brain at the time of the test. Normally, a tracing indicates four types of waves: delta (1 to 3 waves per second), theta (4 to 7 waves per second), alpha (8 to 12 waves per second), and beta (13 to 20 waves per second).

To reduce extraneous movements of the eyes, head, or muscles that would affect the tracing, the child must be

cooperative and quiet during the procedure. Traditionally, parents are asked to keep their child up later than usual the night before so that the child will be sleepy. Good preparation and encouragement are also important in helping a child relax. Caution children that the room will probably be darkened to help them rest. Compare the electrode wires attached to their scalp with adhesive paste to those attached to astronauts in space. Reassure them that these electrodes are not painful. Be careful not to use the word *electrical.* Children as young as 3 years of age know that electrical wires are ordinarily dangerous and can hurt them. They cannot relax if they are worried that they may be shocked or even electrocuted by the procedure.

Children who are unable to lie still and cooperate even after careful explanation may need conscious sedation although sedation alters the electrical pattern of the cortex and should be avoided if possible (Weinstein et al., 2007). For example, chloral hydrate, a frequently used sedative for this procedure, may increase the fast activity of brain waves; chlorpromazine (Thorazine) may increase slow activity. Because phenobarbital and phenytoin sodium (diphenylhydantoin [Dilantin]) also cause an increase in fast activity, be sure to inform the person interpreting the recording what medications the child is receiving. Parents should be given specific instructions about the preparation for the EEG prior to coming for testing as they may need to omit an anticonvulsant medication on the morning of testing.

Although EEGs can show important information about brain activity, they are not helpful in all circumstances. For example, approximately 15% of children who are well demonstrate some abnormality on an EEG. Most brain tumors in pediatric patients are in the posterior fossa, but the activity of this region does not show up well on an EEG. This limitation means that an EEG may appear normal even if a brain tumor is present, unless the tumor is pressing on more distal brain portions. On inspection of the symmetry of hemispheres, local lesions may be suggested. Where there is a lesion, there will be slower waves, a higher voltage pattern, and an overall more irregular pattern. A subdural lesion (perhaps from a hematoma) can interfere with transmission of the electrical impulses, lowering the voltage pattern.

An EEG is most beneficial in diagnosing absence seizures. The typical pattern with this disorder is discussed later in this chapter.

Visual stimulation, such as having a child look at a whirling disk, may be used in connection with the EEG, because various types of electrical discharges increase with rapid eye movements. In a child who is sensitive to this type of stimulation, the testing may produce a seizure. If this occurs, the child may be very disturbed and disoriented after the procedure. Describe what has happened, letting him know that the seizure is over to help him relax.

After an EEG, children will be sleepy if they have been sedated or had an EEG while sleep-deprived. Allow them to sleep as long as needed.

HEALTH PROMOTION AND RISK MANAGEMENT

Health promotion for nervous system health begins prenatally with measures to ensure optimal fetal growth and development and prevention of problems associated with anoxia. It continues throughout childhood with routine health maintenance visits, screening for possible neurologic or developmental problems, and timely immunizations to prevent sequelae of typical childhood infections such as measles or chickenpox. Nurses play a key role in providing education to parents about the importance of obtaining immunizations and completing medication therapy to ensure complete resolution of an infection.

Parents also need anticipatory guidance about safety measures to prevent injury, specifically, head and spinal cord injury. Reinforce the need for seat belts and child restraints while riding in automobiles and use of protective gear, such as helmets, for bicycle, motorcycle riding, and contact sports.

For a child with seizures, parents need instructions to prevent injury during a seizure (see later discussion) and to administer anticonvulsants conscientiously.

For a child with a long-term neurologic disorder, rehabilitation and early intervention play a major role in reducing the risk of complications and in promoting the child's and family's optimal level of functioning.

INCREASED INTRACRANIAL PRESSURE

Increased intracranial pressure (ICP) is not a single disorder but a sign that may occur with many neurologic disorders. When caring for a child with a potential neurologic disorder, it is an important sign to detect (Magaziner & Walker, 2007). Increased ICP may occur with an increase in the CSF volume, blood entering the CSF, cerebral edema, or space-occupying lesions such as tumors. Examples of causes of increased ICP include:

- Birth trauma or hydrocephalus
- Head trauma from an accident
- Infection
- Brain tumor
- Guillain-Barré syndrome

The rate at which symptoms develop depends on the cause and the ability of the child's skull to expand to accommodate the increased pressure. Children with open fontanelles can withstand more pressure without brain damage than can older children, whose suture lines and fontanelles have already closed.

Assessment

Assessment of neurologic function may involve only a few quick procedures, such as obtaining vital signs, evaluating pupil response, and determining level of consciousness and motor and sensory function, or it may include more elaborate electronic monitoring. Common signs and symptoms of ICP are shown in Table 49.3.

With increased ICP, symptoms are often subtle at first. The child may report a headache, irritability, or restlessness. Headache is difficult to detect in an infant but most infants with headaches become increasingly fussy or difficult to comfort. Growing pressure on the brainstem, which controls respiration and cardiac activity, causes pulse and respirations to slow. Compression of cranial vessels leads to a compensatory increase in blood pressure (or **pulse pressure,** the gap between the systolic and diastolic blood pressures). Pressure on the hypothalamus, the temperature-regulating center of the body, causes an increase in temperature. These changes may

TABLE 49.3 ✻ Signs and Symptoms of Increased Intracranial Pressure

Sign or Symptom	Indication of Increased ICP
Increased head circumference	An increase >2 cm/month in first 3 months of life, >1 cm/month in the second 3 months, and >0.5 cm/month for the next 6 months
Fontanelle changes	Anterior fontanelle tense and bulging; closing late
Vomiting	Occurring in the absence of nausea, on awakening in morning or after nap; possibly projectile
Eye changes	Diplopia (double vision) from pressure on abducens nerves; white of sclera evident over pupil (setting sun sign); limited visual fields, papilledema
Vital sign changes	Elevated temperature and blood pressure; decreased pulse and respiration rates
Pain	Headache, often present on awakening and standing Increasing with straining at stool (Valsalva maneuver) or holding breath
Mentation	Irritability, altered consciousness such as sleepiness

occur gradually, so a single measurement may not show the extent of the change. Always compare the new information against all recordings taken in the last 24 hours.

Ocular changes may indicate that pressure is increasing posterior to the eye globe. One obvious abnormality is a dilated pupil, which suggests compression of cranial nerve II. Test pupil reactivity by shining a light into each eye. To elicit the most dramatic and sudden response, bring the light to the child's eye from the side or down from the forehead, to make it appear suddenly rather than gradually. Repeat this with the other eye. Each pupil should constrict, and the constriction should be equal bilaterally.

Consensual constriction should also be present. As you shine the light on the right pupil, the left pupil also should constrict, and vice versa.

If a child is alert and able to cooperate, have her follow the light through the six cardinal positions of gaze, and test convergence (ability to follow the light as it approaches closer and closer to the nose). Note any tendency toward strabismus, nystagmus (constant eye movement), "sunset eyes" (white sclera showing over the top of the cornea), or inability to follow the light into any quadrant. Be specific about what you document. "Inability to follow light" is not as informative as "Inability to follow light into left superior field; vertical nystagmus noted as child follows light into other fields."

If a child lies supine and you turn his head gently but rapidly to the right, the eyes will normally turn toward the left, and vice versa (doll's eye reflex). If a child has increased ICP, this phenomenon will be absent (this test is useful in assessing a comatose child who is unable to cooperate by following a light). An older child may be able to report symptoms such as diplopia. On funduscopic examination, papilledema may be detected.

Assess the child's level of consciousness. If the child is alert but unable to comprehend surroundings, time, or place, this may be the first indication of increased ICP. As pressure increases, a pseudoawake state may occur, in which the child is awake but unable to follow light or locate a noise. Finally, the child becomes comatose, unable to be roused by any stimuli. Levels of coma are rated by a Glasgow Coma Scale. This is discussed in Chapter 52 in connection with assessment for head injury.

Children, like adults, generally become disoriented about time first, then place, then self. It is useful, therefore, to assess that the child is alert enough to answer these questions. Explain that you will be asking these seemingly simple questions periodically to make sure the child can answer them accurately each time. Otherwise, a child may quickly become annoyed with your questions and may refuse to answer them or make up silly answers instead. Or a child may pretend to be asleep to avoid being asked.

Be aware that many children, even when healthy, are groggy when they first wake up; until fully awake they may not be able to say who or where they are on first awakening. This happens especially when a child has been dreaming. Make sure children are fully awake before attempting to determine level of consciousness.

Be certain also that you ask questions appropriate to a child's age. Preschoolers do not usually know the day of the week or concepts such as *morning* or *night.* They do not necessarily know their whole name. With children of this age, it is often more helpful to identify an area of knowledge with which they are familiar, such as colors. Every half hour or every hour, show them a colored block and ask them its color. Even if they give the wrong answer, it does not matter. Your concern is that they understood your request, not that they actually recognize the colors. Also remind parents that you are asking these questions to assess their child's level of consciousness, not to quiz for right answers or to be intrusive. Remind them not to answer for the child.

A good way to test an infant's level of consciousness is to determine whether the child responds to sounds such as a music box or voices or reaches for an attractive object.

Motor ability can be assessed by asking a child to perform some simple motor task, such as squeezing your hand, pushing against your hand with both feet or performing rapid, alternating hand movements, such as turning a hand over and back several times. Evaluate cranial nerves grossly by having the child make a face, close the eyes tightly, or smile. With all these assessments, be sure to evaluate whether the responses are equal and symmetric bilaterally.

Test deep tendon reflexes, because these decrease in intensity with decreased level of consciousness. Carefully observe a child's resting posture. When motor control grows weaker because of loss of cell function, characteristic posturing (primitive reflexes) occurs. Cerebral loss is shown mainly by **decorticate posturing.** The child's arms are adducted and flexed on the chest with wrists flexed, hands fisted. The lower extremities are extended and internally rotated, and the feet are plantar flexed (Fig. 49.5A). **Decerebrate posturing,** which occurs

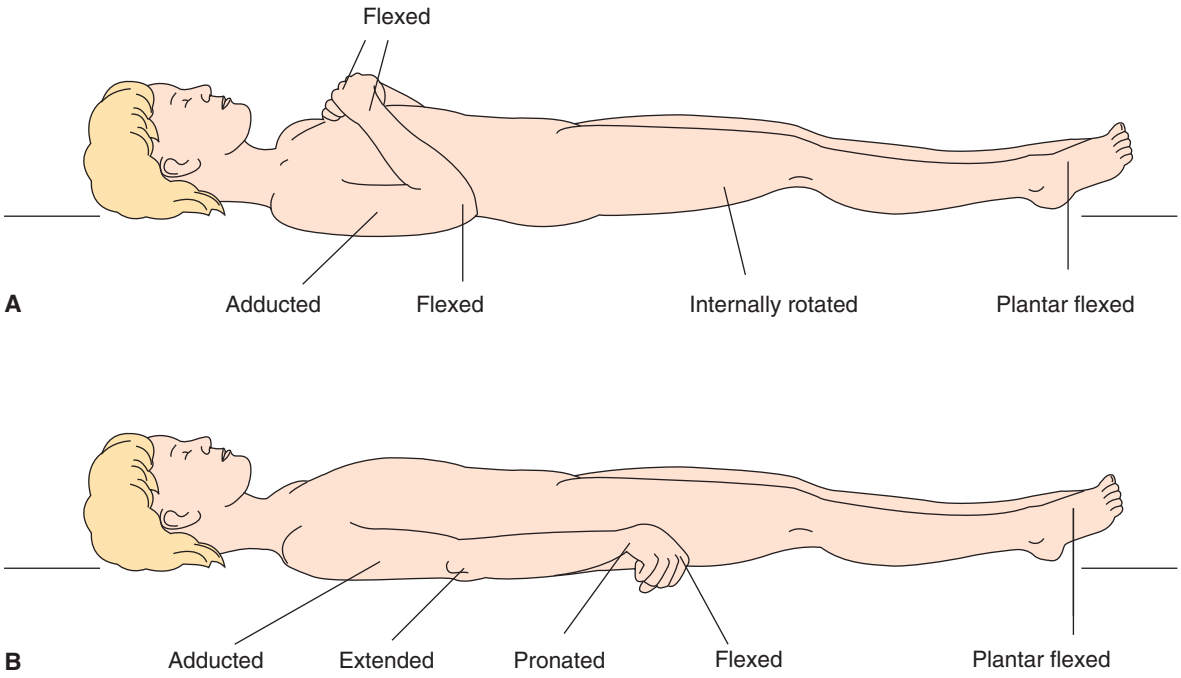

FIGURE 49.5 (**A**) Decorticate posturing. (**B**) Decerebrate posturing.

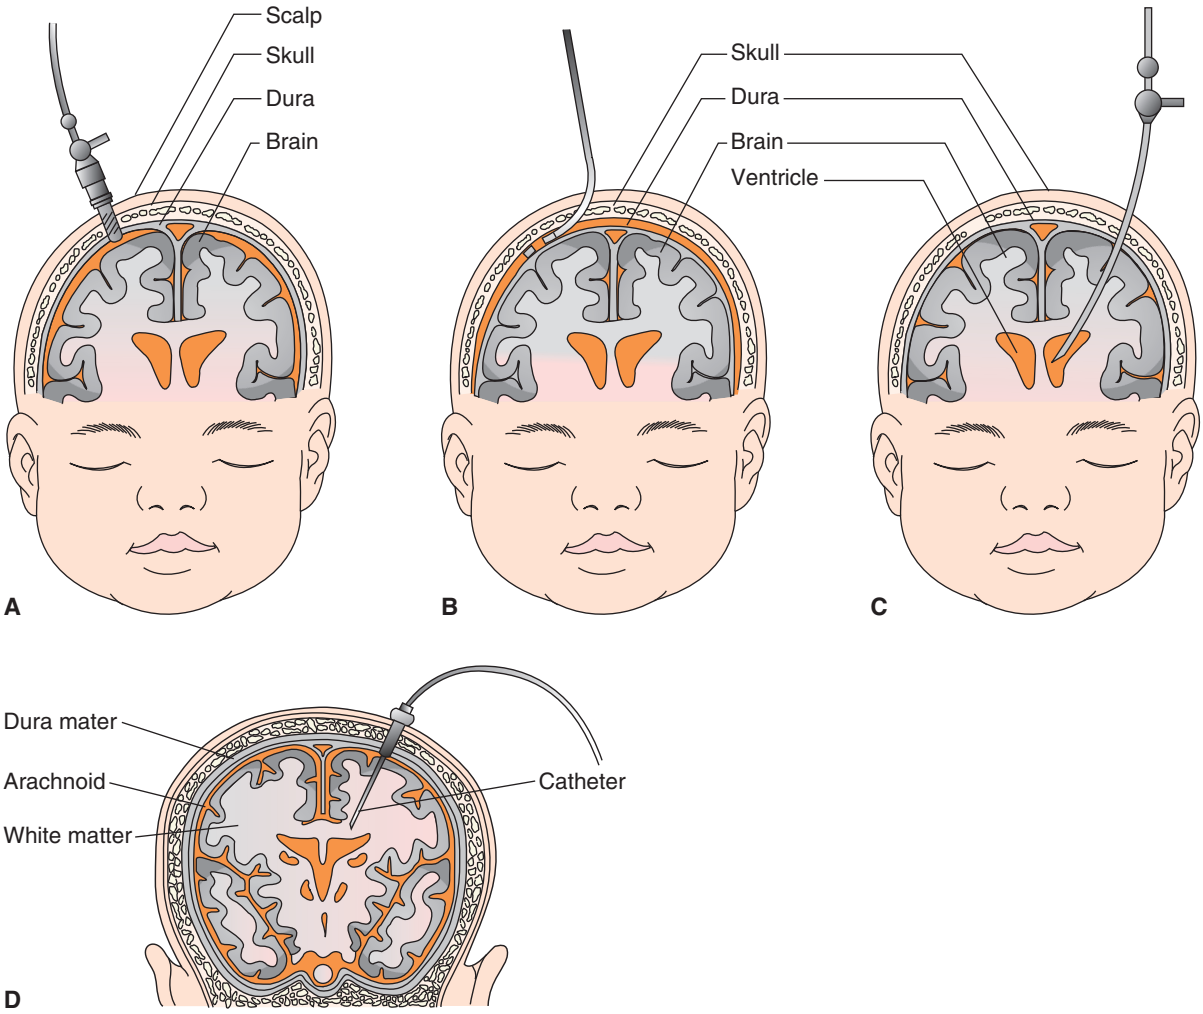

FIGURE 49.6 Devices used to monitor intracranial pressure. (**A**) Subarachnoid screw. (**B**) Epidural sensor. (**C**) Intraventricular catheter. (**D**) Intraparenchymal monitoring.

when the midbrain is not functional, is characterized by rigid extension and adduction of arms and pronation of the wrists with the fingers flexed. The legs are extended, and the feet are plantar flexed (see Fig. 49.5B).

Observe the child carefully for any seizure activity. However, keep in mind that this is a late sign of increased ICP.

Intracranial Pressure Monitoring

ICP can be measured by several methods:

- An intraventricular catheter inserted through the anterior fontanelle
- A subarachnoid screw or bolt inserted through a burr hole in the skull
- A fiberoptic sensor implanted into the epidural space (or the anterior fontanelle in an infant)
- A disposable fiberoptic transducer–tipped catheter inserted through a subarachnoid bolt into the white matter of the brain (Fig. 49.6)

Intraventricular catheters (see Fig. 49.6C) are threaded into the lateral ventricle, filled with normal saline, and then connected to an external pressure monitor (Marota, 2007). As pressure in the ventricle fluctuates, it is registered through the filled catheter on an oscilloscope screen and a written printout. This method is advantageous over simple scanning because it also enables CSF drainage and administration of medication through the catheter.

ICP normally ranges from 1 to 10 mm Hg. A level greater than 15 mm Hg is considered abnormal. As blood pressure rises and falls with the influx of blood through vessels, so does ICP. On a monitor, it appears as A waves (plateau waves), which are transient paroxysmal elevations that last for 5 to 20 minutes with an amplitude of 50 to 100 mm Hg. If brain ischemia is present, these waves increase before other signs, such as a change in blood pressure or pulse rate, become apparent. B waves are short-duration waves (½ to 2 min) with low amplitude (up to 50 mm Hg). C waves are small, rhythmic waves at a frequency of approximately 6 waves per minute. They are related to deviations in the arterial blood pressure (Fig. 49.7). Because A waves appear to reflect brain ischemia, they can be used to signal when a child needs more oxygen.

ICP monitoring also can be used to estimate cerebral perfusion pressure (CPP) or cerebral blood flow (Box 49.3). Normal CPP is at least 50 mm Hg. Cerebral circulation ceases if ICP

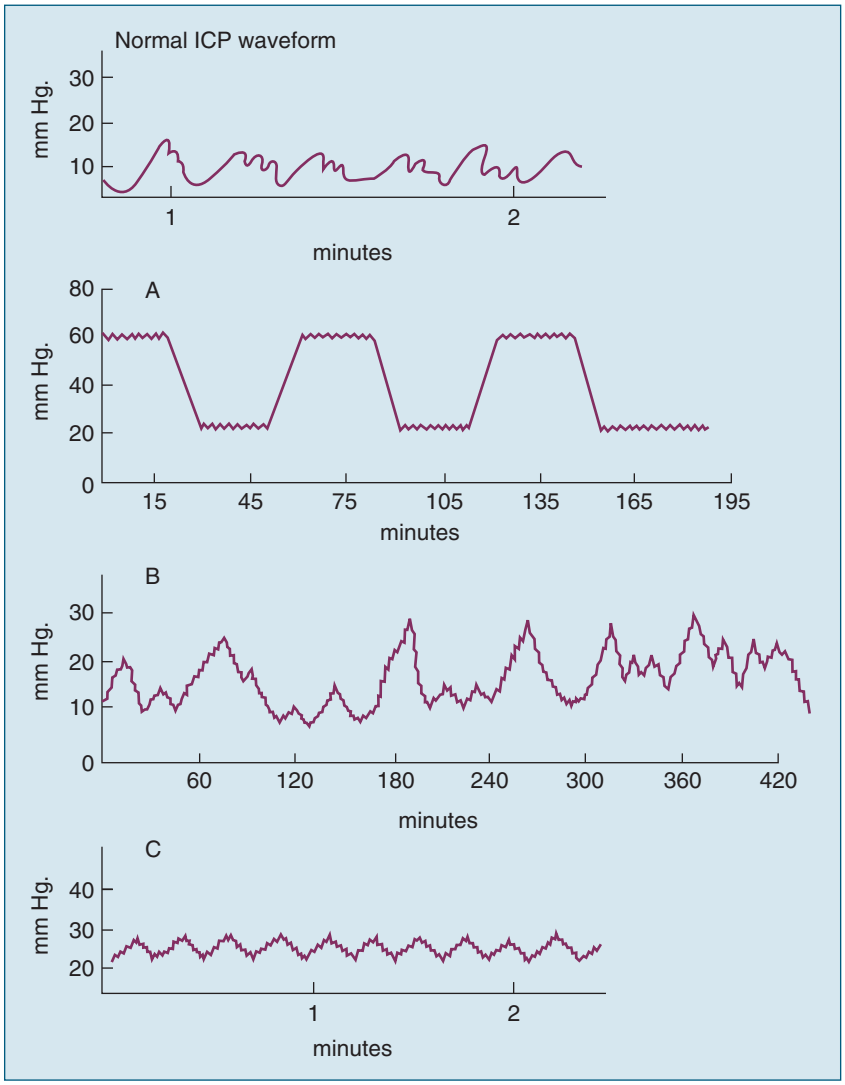

FIGURE 49.7 Normal ICP waveform and generalized shapes of the three types of intracranial pressure waves: A waves or plateau waves, B waves, and C waves.

BOX 49.3 ✻ Calculating Cerebral Perfusion Pressure

Cerebral perfusion pressure (CPP) is calculated by subtracting the mean intracranial pressure (ICP) from the mean arterial pressure (MAP),

$$MAP - ICP = CPP$$

Mean arterial pressure is determined by subtracting the diastolic blood pressure (DBP) reading from the systolic blood pressure (SBP) reading, dividing the result by 3, then adding that sum to 80:

$$MAP = (SBP - DBP)/3 + 80$$

Follow this example: A child has a blood pressure of 100/70 and an ICP of 10 mm Hg. Using the formulas above, first calculate the MAP:

$$(100 - 70)/3 + 80 = 90 \text{ mm Hg}$$

Next calculate the CPP:

$$90 - 10 = 80 \text{ mm Hg}$$

Therefore, a child with a blood pressure of 100/70 and an ICP of 10 has a CPP of 80 mm Hg.

ever exceeds arterial pressure, because this obstructs blood flow through the cerebral vessels (Huether & McCance, 2008).

Parents may have difficulty accepting procedures such as the insertion of intraventricular catheters or screws. Explaining the brain's anatomy will help them see that the catheter or screw does not puncture or tear brain tissue. Be sure to explain that this type of monitoring is advantageous, not only because it enables early detection should problems arise but helps to reduce the risk of further injury or complications.

Therapeutic Management

If ICP increases, the cause of the problem must be identified and remedied as quickly as possible to prevent brain injury. In addition to local injury, severe pressure elevation can compress the brainstem and lead to cardiac and respiratory failure. Actions such as coughing, vomiting, and sneezing increase the ICP and should be kept to a minimum, if possible. When burping infants after feedings, do not put pressure on the jugular veins, because this can increase the ICP. Monitor the rate of IV fluid administration in such children, because overhydration also can increase ICP. Placing a child in a semi-Fowler's position (use an infant seat for babies) can reduce cerebral pressure. A corticosteroid such as dexamethasone (Decadron) may effectively reduce cerebral edema and its accompanying pressure. An osmotic diuretic, such as mannitol, may be given IV to remove fluid from interstitial tissue and reduce pressure. Because mannitol is hypertonic, it causes a shift of fluid from extravascular compartments into the vascular stream, where it can be eliminated by the kidneys. Children usually have an indwelling urinary catheter inserted before starting this therapy, to ensure bladder emptying from the drug-induced rapid diuresis. If excessive fluid accumulates in the brain's ventricles, a ventricular tap may be necessary for immediate reduction of pressure.

NEURAL TUBE DISORDERS

The neural tube is the embryonic structure that matures to form the CNS. Because this structure forms in utero first as a flat plate, then molds to form the brain and cord, it is susceptible to malformation. Neural tube disorders, including spina bifida, are present at birth and so are discussed in Chapter 27.

NEUROCUTANEOUS SYNDROMES

Neurocutaneous syndromes are characterized by the presence of skin or pigment disorders with CNS dysfunction.

Sturge-Weber Syndrome

A child with Sturge-Weber syndrome (encephalofacial angiomatosis) has a congenital port-wine birthmark on the skin of the upper part of the face that extends inward to the meninges and choroid plexus. The skin manifestation follows the distribution of the first division of the fifth cranial nerve (trigeminal nerve). Because the defect is usually unilateral, the port-wine stain ends abruptly at the midline. In many children, only the ophthalmic branch of the nerve is involved, and the lesion is confined to the upper aspect of the face.

Because of involvement of the meningeal blood vessels, blood flow is sluggish, and anoxia may develop in some portions of the cerebral cortex. The child may have symptoms of hemiparesis (numbness) on the side opposite the lesion from destruction of motor neurons. The child may experience intractable seizures, be cognitively challenged, or develop blindness from glaucoma. A CT scan or an MRI of the skull usually shows calcification in the involved cerebral cortex. Such calcification follows a diagnostic "railroad track" or double-groove pattern. An EEG shows areas of decreased voltage.

When this syndrome is first diagnosed, parents may hope that the defect does not extend beyond the skin lesion. They may ask to have the skin lesion surgically removed, in the belief that this will correct their child's condition completely. Ensure that parents understand the need for long-term follow-up, particularly if the child has accompanying seizures that require long-term anticonvulsant therapy (Comi, 2007).

Neurofibromatosis (von Recklinghausen's Disease)

Neurofibromatosis is the unexplained development of subcutaneous tumors. The disorder can occur as a mutation, or it can be inherited as an autosomal dominant trait carried on the long arm of chromosome 17. It occurs in approximately 1 of every 4000 live births and may be diagnosed prenatally (Noll et al., 2007). The famous "Elephant Man" was thought to have had a severe case of neurofibromatosis that also involved skeletal changes. As an infant, a child with neurofibromatosis typically has irregular but excessive skin pigmentation. Later in childhood, pigmented nevi or café-au-lait ("coffee with cream") spots appear that tend to follow the paths of cutaneous nerves. The presence of more than six spots larger than 1 cm in diameter is suggestive of the disorder. By puberty, multiple soft cutaneous tumors begin to form in the child's skin along nerve pathways. Subcutaneous tumors develop by young adulthood. The acoustic nerve (cranial nerve VIII) is

frequently involved, leading to hearing loss. Involvement of the optic nerve causes vision loss. Approximately 15% of children with neurofibromatosis develop neurologic complications such as seizures. Approximately 8% become cognitively challenged as a result of cerebral deterioration. Symptoms and growth of tumors increase at puberty and during pregnancy.

Little therapy is available to halt the tumor growth. Mast cell blockers have some effect. If lesions are causing acoustic or optic degeneration, surgical removal of the tumors may be attempted. Be certain that the parents and child have a source of emotional support through the disease's slow but invariably fatal course.

CEREBRAL PALSY

Cerebral palsy (CP) is a group of nonprogressive disorders of upper motor neuron impairment that result in motor dysfunction. Affected children also may have speech or ocular difficulties, seizures, cognitive challenges, or hyperactivity. Muscle spasticity can lead to orthopedic or gait difficulties (Eilert, 2008).

The exact cause of CP is unknown, but the disorder is associated with low birth weight, premature birth, or birth injury (Moe, Benke, & Bernard, 2008). It apparently is caused by brain anoxia leading to cell destruction of the motor tracts. If intrauterine anoxia occurs for some reason such as faulty placental implantation, placenta previa, or abruptio placentae, this type of brain cell dysfunction may result. Nutritional deficiencies, drugs, and maternal infections such as cytomegalovirus or toxoplasmosis, as well as direct birth injury, may also contribute to the cause.

CP occurs in approximately 2 of every 1000 births, most frequently in very-low-birth-weight infants and those who are small for gestational age. It is increasing in incidence because of the number of very-low-birth-weight infants who survive today. It occurs more frequently in infants born from occipitoposterior rather than anterior birth positions. In these instances, anoxia and resulting brain damage are more likely to occur with birth. In all instances, however, the damage may already have occurred in utero and may be the reason the infant is born abnormally early or presents in an unusual position. Head injury such as can result from child abuse, shaken baby syndrome, trauma, or severe dehydration in the newborn, with resulting venous thrombosis, also may lead to CP symptoms.

Infections such as meningitis or encephalitis in the newborn are yet another cause of CP. In the past, kernicterus resulting from neonatal hyperbilirubinemia was considered a cause of the athetoid type of CP (slow, writhing, involuntary movements). This type is rarely seen today because of improved management of hyperbilirubinemia.

Types of Cerebral Palsy

CP has been classified in various ways. Traditionally, it is divided into two main categories based on the type of neuromuscular involvement: a pyramidal or spastic type (approximately 40% of affected children) and an extrapyramidal type, which is further subdivided into ataxic (approximately 10%), dyskinetic or athetoid (approximately 30%), and mixed (10%) (Jones, Morgan, & Shelton, 2007).

Spastic Type

Spasticity is excessive tone in the voluntary muscles that results in loss of upper motor neurons. A child with spastic CP has hypertonic muscles, abnormal clonus, exaggeration of deep tendon reflexes, abnormal reflexes such as a positive Babinski reflex, and continuation of neonatal reflexes, such as the tonic neck reflex, well past the age at which these usually disappear. If infants with CP are held in a ventral suspension position, they arch their backs and extend their arms and legs abnormally. They fail to demonstrate a parachute reflex if lowered suddenly, failing to hold out their arms as if to break their fall. Children tend to assume a "scissors gait" because tight adductor thigh muscles cause their legs to cross when held upright. This involvement may be so severe that it leads to a subluxated hip. Tightening of the heel cord usually is so severe that children walk on their toes, unable to stretch their heel to touch the ground.

Spastic involvement may affect both extremities on one side **(hemiplegia),** all four extremities **(quadriplegia),** or primarily the lower extremities **(diplegia** or **paraplegia).** Children with hemiplegia usually have greater involvement in the arm than the leg. This may be demonstrated by asking the child to extend the arms and pronate them. When the child is asked to supinate the arm, the elbow flexes on the involved side. The involved arm may be shorter and may have a smaller muscle circumference than the other arm. Most children with hemiplegia have difficulty identifying objects placed in their involved hand when their eyes are closed **(astereognosis).**

In older children, leg involvement may be detected most easily by examining the child's shoes. One heel will be much more worn than the other, because the child does not put the heel all the way down on the involved side. On physical examination, it may be difficult to abduct the involved hip fully, extend the knee, or dorsiflex the foot (Fig. 49.8).

A child with quadriplegia invariably has impaired speech (pseudobulbar palsy) but may or may not be cognitively challenged. Swallowing saliva may be so difficult that the child drools and has difficulty swallowing food. Upper extremity involvement may be limited to an abnormal, awkward hand movement. If there is no involvement of the arms at all, this

FIGURE 49.8 A physical therapist working with a child with cerebral palsy to maximize mobility. (© Lois Silver/Custom Medical Stock Photograph.)

is a true spastic paraplegia, and a spinal cord anomaly rather than a cerebral anomaly is suggested.

Dyskinetic or Athetoid Type

The athetoid type of CP involves abnormal involuntary movement. *Athetoid* means "wormlike." Early in life, the child is limp and flaccid. Later, in place of voluntary movement, children make slow, writhing motions. This may involve all four extremities, plus the face, neck, and tongue. Because of poor tongue and swallowing movements, the child drools and speech is difficult to understand. With emotional stress, the involuntary movements may become irregular and jerking **(choreoid)** with disordered muscle tone **(dyskinetic).**

Ataxic Type

Children with ataxic involvement have an awkward, wide-based gait. On neurologic examination, they are unable to perform the finger-to-nose test or to perform rapid, repetitive movements (tests of cerebellar function) or fine coordinated motions.

Mixed Type

Some children show symptoms of both spasticity and athetoid movements. Ataxic and athetoid movements also may be present together. This combination results in a severe degree of physical impairment.

Assessment of Cerebral Palsy

The diagnosis of CP is based on history and physical assessment. Any episode of possible anoxia during prenatal life or at birth should be documented. Determining the extent of involvement in an infant can be difficult, because a neurologic assessment in infants is difficult. The full extent of the disorder, therefore, may be recognizable only when the child is older and attempts more complex motor skills, such as walking. All infants need careful neurologic assessment during the first year of life so that small signs of impairment can be tracked and also so that a child can be monitored closely for further testing and assessment. Important physical findings that suggest CP are shown in Table 49.4.

Children with all forms of CP may have sensory alterations such as strabismus, refractive disorders, visual perception problems, visual field defects, and speech disorders such as abnormal rhythm or articulation. They may show an attention deficit disorder or autism. Deafness caused by kernicterus occurs in connection with athetoid CP. Cognitive challenge and recurrent seizures also frequently accompany all types of the disorder.

A skull radiograph or ultrasound may show cerebral asymmetry. However, the skull shape usually is normal. A CT or MRI scan usually is negative. The EEG may be abnormal, but the pattern is highly variable. The abnormality may be asymmetry or a spike seizure discharge. An abnormality is noteworthy but is not diagnostic in itself.

Nursing Diagnoses and Related Interventions

Parents who are reacting to the news that their child has multiple physical disabilities often find it difficult to make long-range plans. Therefore, focus expected outcomes on short-term concerns to assist with family functioning.

TABLE 49.4 Physical Findings That Suggest Cerebral Palsy

Finding	Description
Delayed motor development	Children with this disorder usually do not meet motor developmental milestones such as sitting, walking, saying sentences, or changing objects from hand to hand when they should, especially if there is associated cognitive impairment.
Abnormal head circumference	The child's head circumference may be smaller than normal for age, because the head grows as the brain grows. If the brain cortex is severely involved, it grows more slowly than normal.
Abnormal postures	When infants lie on their back, they usually flex their legs; infants with cerebral palsy straighten or "scissor" them; they often hold feet plantar flexed (toes down). Scissoring is also evident when the infant is held upright and you try to make the child bear weight. In a prone position, an infant tends to raise the head higher than normal because of arching of the back. The child may flex arms and legs abnormally under the trunk.
Abnormal reflexes	Newborn reflexes tend to be persistent or last long past the point when they should fade: tonic neck reflex or grasp reflex beyond 5 months, Moro beyond 6 months. Hyperreflexia (extreme reflexes) is also present. Ankle clonus (persistent movement of the ankle after you have repeatedly flexed it) often occurs.
Abnormal muscle performance and tone	These infants often show abnormal use of muscle groups. They often tend to move about not by crawling on their abdomen but by scooting on their back. When they begin walking, they walk by placing their toes down first. Tight adductus muscles at the hip (which also cause scissoring) tend to pull the femoral head out of the acetabulum, so that subluxation of the hip occurs not because of faulty bone formation but because of muscle spasticity.

Nursing Diagnosis: Deficient knowledge related to understanding of complex disease condition

Outcome Evaluation: Parents state they understand that the cause of the disease is unknown and that it is not progressive.

Help parents to understand that CP is a nonprogressive disease. The brain damage that occurred during pregnancy or at birth will not recur, although the child's condition may seem to grow more apparent with age. Motor deficits of the upper extremities, for example, may not be strikingly evident until the child attempts fine motor tasks in school. Without follow-up care, contractures from spasticity may result, further reducing existing motor function.

Caution parents also that CP is a single name for a wide variety of diseases of varying consequence. Although another child may have such severe CP that he has no useful function in his extremities, their own child may not be affected to the same extent. Conversely, although they know someone with CP who is able to hold a full-time job, their child may not be able to do as well. Each child's potential must be evaluated individually.

Nursing Diagnosis: Risk for disuse syndrome related to spasticity of muscle groups

Outcome Evaluation: Child walks with a minimum of support or equipment; skin and tissue remain intact.

Children with CP need promotion of any function that is not already impaired, to prevent further loss of function. Major areas to be addressed include self-care, communication, ambulation, education, safety, nutrition, parental support, and establishment of self-esteem.

Learning to be ambulatory is an important part of self-care, because it helps determine how independent the child can become. This is difficult for the child to achieve because of lack of muscle group coordination. Surgery to lengthen heel tendons may be needed. Assisted ambulation devices such as wheeled walkers may be necessary (Fig. 49.9). Medication to reduce spasticity has little effect, although baclofen (Lioresal) may be prescribed for some children to improve motor function (Hoving et al., 2007). Cerebellar pacemakers may reduce spasticity in some children. Administration of botulism toxin (Botox) has been successful in some children to relieve spasticity and aid in walking (Desloovere et al., 2007).

Preventing contractures is important to maintain motor function. Formerly, children were fitted with extensive braces. The weight of these braces, however, often impeded muscle movement and actually prevented children from learning to walk. Partial lighter-weight leg braces may be prescribed to encourage children to bring their heels down and to keep heel cords from tightening. If leg braces are prescribed, parents may need some encouragement and support to insist that their children wear them. Remind parents that partial leg braces for stretching the heel cords must be worn for long periods during the day to be effective. Just putting them on when the child is going outside is not enough.

FIGURE 49.9 Wheeled walkers give a child added stability for walking and keep heel cords from shortening. (© Barbara Proud.)

Passive and active muscle exercises also are important to prevent contractures. Teach parents passive exercises and games to play with their child that encourage active exercise. At health care visits, remind parents that these exercises are an important part of their child's therapy and must be done consistently each day.

Nursing Diagnosis: Risk for self-care deficit related to impaired mobility

Outcome Evaluation: Child feeds and dresses self and manages elimination independently.

Children need to learn self-care measures such as dressing, toothbrushing, bathing, and toileting, so they can not only gain self-esteem by accomplishing these tasks but achieve optimal independence. Modifications such as straps attached to their toothbrush or feeding utensils may be necessary so they can hold them more securely. Advise parents to always supervise children during bathing. Lack of coordination could cause them to slip underwater and drown. Toileting is often difficult because the child does not have the muscle group coordination necessary to achieve successful bowel evacuation. A high-fiber diet helps prevent constipation and aids bowel evacuation. Voiding may be equally difficult, because the child may lack sufficient voluntary muscle control.

Parents may need considerable support and guidance to allow a child to complete self-care tasks independently, because doing so often requires extreme patience. Letting a child perform these activities, however, helps to instill confidence and self-esteem in the child.

Nursing Diagnosis: Risk for delayed growth and development related to activity restriction secondary to CP

Outcome Evaluation: Child receives environmental stimulation; expresses interest in people and activities around him; attends school setting that is as free of restrictions as possible.

Children with CP may be unable to pursue stimulating activities and surroundings because they are not fully mobile. Therefore, these things must be brought to them. An activity should be neither too difficult nor too easy for the child. Choose toys and activities that are appropriate to the child's intellectual, developmental, and motor levels, not the child's chronologic age. Some children need more stimulating activities than others because they have difficulty concentrating on one activity for any length of time.

A preschool program is important to provide exposure to the outside world. If at all possible, school-age children with CP should be mainstreamed so that they can be among other children. Under federal law, children who are physically or cognitively challenged must be provided an education in the least restrictive setting possible. If they are both cognitively and physically challenged, however, the combined mental and motor deficits may severely limit their abilities, making school placement difficult. You may need to advocate that a child be placed in a school setting that is consistent with intellectual abilities.

Nursing Diagnosis: Risk for imbalanced nutrition, less than body requirements, related to difficulty sucking in infancy or difficulty feeding self in an older child

Outcome Evaluation: Child's weight remains within 5th to 95th percentile on height–weight chart; skin turgor remains good; specific gravity of urine is 1.003 to 1.030.

Providing adequate nutrition to children with CP can be difficult. As infants, they often suck poorly because uncoordinated movements of the tongue, lips, and jaw and tongue thrusting cause them to push food out of their mouth (a retained primitive reflex). Lip and tongue control may be poor, with weak or uncoordinated jaw muscles. Older children may have difficulty holding and controlling a spoon to bring food to their mouth. Spasticity causes children to hyperextend the head when leaning forward to take a bite, so they never feel comfortable while eating. Parents may need guidance in finding a feeding pattern that works for their child. Manually controlling the jaw may help control the head, correct neck and trunk hyperextension, and stabilize the jaw to assist with feeding. If a child cannot chew or swallow well, a liquid or soft diet may be necessary. Some children can handle solids and finger foods but may take longer to eat than the average child. They may need protection for their clothing and the floor. It may take longer for them to eat than the rest of the family, so others need to wait patiently for them to finish.

A hyperactive gag reflex may cause children to vomit after feeding. Be certain that infants are positioned on their side or upright after feeding to prevent aspiration.

Nursing Diagnosis: Impaired verbal communication related to neurologic impairment

Outcome Evaluation: Child can verbally make needs known to strangers and family members.

Most children with CP benefit from speech therapy, which helps them learn to speak slowly and to coordinate their lips and tongue to form speech sounds. Be patient with children, and allow them to form words deliberately. If they try to hurry to please you, their speech will be much less clear, and communication will be impaired. For the child who cannot speak clearly, provide an alternative form of communication, such as flash cards or a picture board. Touch-screen computer programs are often used in school settings to aid communication.

Long-term Care

Because CP is not always diagnosed early in infancy, parents may not learn that their child has a chronic disease until 2 to 4 years later. Help them to encourage their children with CP to reach their fullest potential within the limits of their disorder. Evaluations at health care visits should note not only whether the child is achieving goals but also whether the child and family members find satisfaction and acceptance in the child's achievements. Listen to parents during health care visits and encourage them to discuss the difficulties of daily living, such as feeding problems. They may grieve because their child is not able to accomplish all of the major things they had wished for during pregnancy, and they may feel defeated by the day-to-day strain of caring for their child's multiple special needs. Care of a child with a chronic illness is discussed further in Chapter 56.

✔ Checkpoint Question 49.2

What information would you want parents to know about their child with cerebral palsy?

a. Symptoms of cerebral palsy usually fade by puberty.
b. All children with cerebral palsy are cognitively challenged.
c. Cerebral palsy may be associated with a vaccine reaction.
d. Symptoms may seem to grow worse as fine motor skill is needed.

INFECTION

Nervous system tissue is as susceptible to infection as any other body tissue. Common major infections include meningitis, encephalitis, Guillain-Barré syndrome, Reye's syndrome, and botulism.

Bacterial Meningitis

Meningitis is an infection of the cerebral meninges. It occurs most often in children younger than 24 months of age. Although the disease can occur in any month, its peak incidence appears to be in the winter. In the United States, it is caused most frequently by *Streptococcus pneumoniae* or group B *Streptococcus.* In children younger than 2 months of age, group B *Streptococcus* and *Escherichia coli* are common causes

of meningitis. In children with myelomeningocele who develop meningitis, *Pseudomonas* infection is common. Children who have had a splenectomy are particularly susceptible to pneumococcal meningitis unless they have received a pneumococcal vaccine. *Haemophilus influenzae,* once a major cause of meningitis, is now rarely seen because of routine immunization against this organism (Murphy, 2008).

Pathologic organisms usually are spread to the meninges from upper respiratory tract infections, by lymphatic drainage possibly through the mastoid or sinuses, or by direct introduction through a lumbar puncture or skull fracture. Once organisms enter the meningeal space, they multiply rapidly and spread throughout the CSF. Organisms invade brain tissue through meningeal folds that extend down into the brain itself. The inflammatory response that occurs may lead to a thick, fibrinous exudate that blocks CSF flow. Brain abscess or invasion of the infection into cranial nerves can result in blindness, deafness, or facial paralysis. Pus that accumulates in the narrow aqueduct of Sylvius can cause obstruction leading to hydrocephalus. Brain tissue edema can put pressure on the pituitary gland, causing increased production of antidiuretic hormone, resulting in the syndrome of inappropriate antidiuretic hormone secretion (SIADH). This causes increased edema because the body cannot excrete adequate urine.

Assessment

The symptoms of meningitis occur either insidiously or suddenly. Children usually have had 2 or 3 days of upper respiratory tract infection. They become increasingly irritable because of headaches. They have sharp pain on bending their head forward. They may have seizures. In some children, seizure or shock is the first noticeable sign of illness. As the disease progresses, signs of meningeal irritability occur, as evidenced by positive Brudzinski's and Kernig's signs (Fig. 49.10). Children's backs may become arched and their necks hyperextended (opisthotonos). Cranial nerve paralysis, most typically of the third and sixth nerves, may occur, so that the child is not able to follow a light through full visual fields. If the fontanelles are open, they are bulging and tense; if they are closed, papilledema may develop. If the meningitis is caused by *H. influenzae,* the child may develop septic arthritis. If it is

FIGURE 49.10 (**A**) Brudzinski's sign. The nurse flexes the child's neck forward. (**B**) Positive response. Bilateral hip, knee, and ankle flexion indicates meningeal irritation. (**C**) Kernig's sign. The nurse flexes the child's hip and knee, forming a 90-degree angle. (**D**) Positive response. As the leg is extended, pain, resistance, and spasm are noted, indicating meningeal irritation. (Photographs by John Gallagher.)

caused by *N. meningitidis,* a papular or purple petechial skin rash may occur (Milonovich, 2007).

In the newborn, symptoms such as poor sucking, weak cry, or lethargy are often vague. After this generalized beginning, sudden cardiovascular shock, seizures, nuchal rigidity, or apnea may occur. Because the infant has open fontanelles, nuchal rigidity appears late and is not as useful a sign for diagnosis as in the older child.

Meningitis is diagnosed by history and analysis of CSF obtained by lumbar puncture. A child with a febrile seizure should be assumed to have meningitis until CSF findings prove otherwise. CSF results indicative of meningitis include increased white blood cell and protein levels and a lowered glucose level (because bacteria have fed on the glucose). In a healthy child, the glucose level in the CSF is 60% of that of the serum glucose. Because meningitis often spreads and causes septicemia, a blood culture also is done. A fulminating (overwhelming) meningitis often leads to leukopenia. If the child has had close association with someone with tuberculosis, a tuberculin skin test to rule out tuberculosis meningitis should be done. A CT scan, MRI, or ultrasound study may be ordered to examine for abscesses. Typically, ICP is severely elevated.

Therapeutic Management

Antibiotic therapy as indicated by sensitivity studies is the primary treatment measure. Usually antibiotics are given IV for rapid effect, but intrathecal injections (directly into the CSF) may be necessary to reduce the infection, because the blood–brain barrier may prevent an antibiotic from passing freely into the CSF. If the organism is identified as *H. influenzae*, ampicillin usually is the drug of choice. In other instances, a third-generation cephalosporin, such as cefotaxime (Claforan) or ceftriaxone (Rocephin), may be used for 8 to 10 days. In some children, it takes a month before the CSF cell count returns to normal. A corticosteroid such as dexamethasone or the osmotic diuretic, mannitol, may be administered to reduce ICP and help prevent hearing loss.

In addition to standard precautions, children with meningitis are placed on respiratory precautions for 24 hours after the start of antibiotic therapy to prevent transmission of the infection. Antibiotics also may be prescribed prophylactically for the immediate family members of the ill child or for others who have been in close contact with the child.

Meningitis is always a serious disorder, because it can run a rapid, fulminating, and possibly fatal course. However, if symptoms are recognized early and treatment is effective, a child will recover with no sequelae. Neurologic sequelae, such as learning problems, seizures, hearing and cognitive challenges, and inability to concentrate urine from poor antidiuretic hormone secretion, must be assessed after the infection, because these can be long-term consequences.

Nursing Diagnoses and Related Interventions

If a child has meningitis, the parents may feel responsible for the illness. They knew the child had an upper respiratory infection, and they wonder whether they could have prevented meningitis if only they had taken the child to their primary care provider as soon as the respiratory symptoms started. Reassure them that the symptoms of meningitis occur insidiously. No one could have predicted the full extent of the disease from the first signs.

Encourage parents to care for their child during the illness, both to help make the child more comfortable and to help them manage their own anxiety. Teach them good infection control techniques so that they can perform these tasks safely.

Nursing Diagnosis: Pain related to meningeal irritation

Outcome Evaluation: Child states that pain is tolerable and shows no facial grimacing or other signs of discomfort.

For a child with meningitis, dealing with hospitalization and numerous invasive treatments and procedures is usually difficult. If children had a lumbar puncture on admission, their initial impression is one of people restraining them for a painful procedure. Continuous IV infusions contribute to this impression. Remember that children feel pain when the head is flexed forward so usually are more comfortable without a pillow. Be careful not to flex children's necks when turning or positioning them.

On admission, children may be extremely irritable. Although they would benefit from puppet play or drawing, which would help them express how they feel about so many intrusive procedures, frequently they are too uncomfortable to play and so are not able to be comforted. Be aware that irritation of this nature is part of the disease process so you don't interpret a child's withdrawal as unfriendliness or feel hurt when advances are rebuffed. Parents also need to understand that their child's behavior is caused by the disease and not by anything that they did or are doing. Be certain that the child receives a good explanation of everything that is happening and extra attention from health care personnel consistently, not just when they perform painful procedures. As children recover, irritability lessens and they usually show more interest in communicating feelings. Promote rest by keeping stimulation in the room to a minimum.

Nursing Diagnosis: Risk for ineffective tissue perfusion (cerebral), related to increased ICP

Outcome Evaluation: Child's vital signs return to normal; child is alert and oriented; motor, cognitive, and sensory function are within acceptable parameters for the child's age; specific gravity of urine is 1.003 to 1.030.

Observe the child carefully for signs of increased ICP. Carefully monitor the rate of all IV infusions to prevent overhydration and increased ICP. Measure urine specific gravity to detect oversecretion or undersecretion of antidiuretic hormone because of pituitary pressure. Measure the child's head circumference, and weigh the child daily.

Monitor hearing acuity (reduced if there is compression of the eighth cranial nerve) by asking an older child a question or observing whether an infant listens to a music box or to your voice.

Group B Streptococcal Infection

A major cause of meningitis in newborns is group B streptococci. The organism is contracted either in utero or from secretions in the birth canal. It can spread to other newborns if good handwashing technique is not used.

Group B streptococci colonization can result in either early-onset or late-onset illness. With the early-onset form, symptoms of pneumonia become apparent in the first few hours of life. The late-onset type leads to meningitis instead of pneumonia.

At approximately 2 weeks of age, the infant gradually becomes lethargic and develops a fever and upper respiratory tract symptoms. The fontanelles bulge from increased ICP. Mortality from group B streptococcal infection is approximately 25%; surviving infants may develop neurologic consequences such as hydrocephalus or seizures (Ogle & Anderson, 2008). Treatment is with antibiotics, such as ampicillin and cephalosporins, that are effective against group B streptococcal infections. It can be difficult for parents to understand how their infant suddenly became so ill. They may need considerable support in caring for the infant if the infant is left neurologically challenged.

✔ Checkpoint Question 49.3

Tasha is diagnosed as having bacterial meningitis. How long should she be placed on respiratory precautions for this condition after beginning an antibiotic?

a. 4 hours.
b. 24 hours.
c. 10 days.
d. 30 days.

Encephalitis

Encephalitis is an inflammation of brain tissue and, possibly, the meninges as well (Jacobs, Guglielmo, & Chin-Hong, 2009). It can arise from protozoan, bacterial, fungal, or viral invasion. Enteroviruses are the most frequent cause, followed by arboviruses such as the togavirus. Several encephalitis viruses, such as those that cause St. Louis encephalitis, West Nile encephalitis, and Eastern equine encephalitis, are borne by mosquitoes and are seen most often during the summer months. In endemic areas, mosquito repellents are strongly suggested. Encephalitis also can result from direct invasion of the CSF during lumbar puncture. It may occur as a complication of common childhood diseases, such as measles, mumps, or chickenpox. Therefore, it is crucial that children receive immunization against these childhood diseases.

Assessment

Symptoms of encephalitis begin gradually or suddenly. Symptoms include headache, high temperature, and if meninges are also involved, signs of meningeal irritation, such as nuchal rigidity (positive Brudzinski's sign and Kernig's sign). Symptoms of ataxia, muscle weakness or paralysis, diplopia, confusion, or irritability also may occur. A child becomes increasingly lethargic and eventually comatose.

The diagnosis is made by the history and physical assessment. CSF evaluation shows an elevated leukocyte count and an elevated protein level. An EEG shows widespread cerebral involvement. A brain biopsy, usually from the temporal lobe, may be done to identify the virus.

Therapeutic Management

Treatment for a child with encephalitis is primarily supportive. An antipyretic is given to control fever. Take and record vital signs frequently, because brainstem involvement can affect cardiac or respiratory rates. Mechanical ventilation may be required to maintain the child's respirations during the acute phase. An antiviral agent, such as acyclovir (Zovirax), is usually prescribed. Anticonvulsants, such as carbamazepine (Tegretol), phenobarbital, or phenytoin (Dilantin), may be prescribed for seizures. A steroid such as dexamethasone or an osmotic diuretic such as mannitol may be prescribed to decrease brain edema and ICP.

Encephalitis is always a serious diagnosis because, although a child may recover from the initial attack without further symptoms, there may be residual neurologic damage, such as seizures or learning disabilities. Parents may find it hard to believe that their child is so seriously ill at first because in the beginning of the illness, their child only seemed tired and had a slight headache. They can find it even harder to accept a diagnosis of permanent impairment, such as a learning disability. Follow-up care after hospitalization is important for the child's rehabilitation and to help parents deal with their grief, shock, and possible anger.

Reye's Syndrome

Reye's syndrome is acute encephalopathy with accompanying fatty infiltration of the liver, heart, lungs, pancreas, and skeletal muscle. It occurs in children from 1 to 18 years of age regardless of gender (Stone & Cooney, 2008).

The cause is unknown, but it usually occurs after a viral infection such as varicella (chickenpox) or influenza that was treated with a salicylate such as acetylsalicylic acid (aspirin). Anticipatory guidance to parents and children about avoiding the use of aspirin during viral infections has led to almost total prevention of this syndrome (Schror, 2007).

Assessment

After seeming to recover from an initial viral illness, children become ill again 1 to 3 weeks later, with lethargy, vomiting, agitation, anorexia, confusion, and combativeness. Symptoms in adolescents may be so extreme that they mimic those of drug intoxication. As fatty droplets invade the liver, enzyme abnormalities, hypothrombinemia, hypoglycemia, and elevated blood ammonia levels occur. Although CSF findings except for a slightly elevated opening pressure remain normal, cerebral symptoms progress from confusion to stupor to deep coma, with seizures and respiratory arrest resulting from pressure on the brainstem.

Laboratory diagnosis of Reye's syndrome is confirmed by elevated liver enzyme levels (alanine aminotransferase [ALT or SGPT] and aspartate aminotransferase [AST or SGOT]), elevated serum ammonia, normal direct bilirubin, delayed prothrombin time and partial thromboplastin time, decreased blood glucose, elevated blood urea nitrogen, elevated serum amylase, elevated short-chain fatty acids, and an elevated white blood count. A lumbar puncture is usually done

to rule out other infection. A skull CT scan or ultrasound will be normal at first. Later, these will show cerebral edema and decreased ventricle size. A liver biopsy shows fatty infiltration, establishing a definitive diagnosis.

Therapeutic Management

Left untreated, Reye's syndrome is rapidly fatal. If it is diagnosed early and promptly treated, however, the child usually recovers quickly and without any residual neurologic effects.

Reye's syndrome is not infectious. It is categorized by stages of involvement from 1 to 5, depending on the degree of the child's lethargy or coma. In stages 1 and 2, the child responds to stimuli but may exhibit lethargy or delirium and possibly combativeness. In stages 3 through 5, a child is unresponsive to stimuli with a progressively deepening coma. Frequent neurologic assessments are necessary to evaluate the child's status and possible progression to a more serious stage of involvement. Therapy is directed toward supporting respiratory function, controlling hypoglycemia, and reducing brain edema.

Guillain-Barré Syndrome

Guillain-Barré syndrome (inflammatory polyradiculoneuropathy) is a perplexing syndrome that involves both motor and sensory portions of peripheral nerves. It affects both sexes and occurs most often in school-age children and adolescents (Agrawal, Peake, & Whitehouse, 2007).

The cause of the condition is unknown, but it is suspected that the reaction is immune mediated, occurring after upper respiratory tract or gastrointestinal illnesses or immunizations. Inflammation of the nerve fibers apparently causes temporary demyelinization of the nerve sheaths.

Assessment

Children experience peripheral neuritis several days after the primary infection. Tendon reflexes begin to decrease and then become absent. Muscle paralysis and paresthesia (loss of sensation) begin first in the legs and then spread to involve the arms, trunk, and head. The symmetric nature of the disorder helps to differentiate it from other types of paraplegia. Cranial nerve involvement leads to facial weakness and difficulty in swallowing. As the respiratory muscles become involved, spontaneous respirations are no longer possible. This can lead to respiratory involvement severe enough to warrant mechanical ventilation.

A significant laboratory finding is an elevated CSF protein level. An EEG may show denervation and decreased nerve conduction velocity.

Therapeutic Management

Treatment of Guillain-Barré syndrome is supportive until the process runs its course; paralysis peaks at 3 weeks and is followed by gradual recovery. A course of prednisone to halt the autoimmune response may be tried, but its use is controversial. Plasmapheresis or transfusion of immune serum globulin may shorten the course of the illness.

Care of a child with Guillain-Barré syndrome includes preventing all of the effects of extreme immobility while guarding respiratory function. Cardiac and respiratory function must be closely monitored. An indwelling urinary catheter is usually inserted to monitor urine output. Enteral or total parenteral nutrition may be used to support protein and carbohydrate needs. If the child has discomfort from neuritis, adequate analgesia should be administered.

To prevent muscle contractures and effects of immobility, the child needs passive range-of-motion exercises every 4 hours. Turning and repositioning every 2 hours also is important to protect skin integrity. Providing adequate stimulation for the long weeks when the child is unable to perform any care independently is also important. Fortunately, most children recover completely, without any residual effects of the syndrome, although they may continue to have minor problems such as residual weakness.

Botulism

Botulism occurs when spores of *Clostridium botulinum* colonize and produce toxins in the intestine. The disease cannot be transmitted from person to person. It usually occurs in infants younger than 6 months of age (Underwood et al., 2007). The source of the spores is usually unknown, but honey and corn syrup are frequently contaminated and should be avoided in infants.

Symptoms occur within a few hours after ingestion of the contaminated food. Almost immediately, there is generalized weakness, hypotonia, listlessness, a weak cry, and a diminished gag reflex. This is followed by a flaccid paralysis of the bulbar muscles that leads to diminished respiratory function. The organism can be cultured from stools or serum. Electromyography may be helpful to support the diagnosis.

Treatment is supportive care. The antitoxin for botulism may be administered but also omitted because it is made from a horse serum base, can cause a hypersensitivity reaction, and is usually not necessary for full recovery. Infant botulism may account for some fatalities credited to sudden infant death syndrome.

INFLAMMATORY DISORDERS

Two inflammatory disorders are found frequently in adolescents.

Carpal Tunnel Disorders

Carpal tunnel syndrome is nerve compression of the median nerve that passes through the carpal tunnel at the wrist (Fung et al., 2007). Compression of the nerve causes numbness and sharp pain and burning in the thumb and the second, third, and fourth fingers of the hand. Once thought of as an adult disorder, because of word processing, texting, and video games, it has now become a teenage disorder as well. Pain usually occurs at night and is enough to keep a child awake. It occurs more frequently in children who have a rheumatoid process such as arthritis. The usual therapy is application of a splint to the wrist, which holds the wrist in a neutral (not flexed and not extended) position. An oral anti-inflammatory medication and perhaps a corticosteroid injection into the inflamed wrist both help to relieve pain. If these therapies are not successful, the stricture at the carpal canal can be relieved surgically. Although carpal tunnel syndrome is still rare in children, it is increasing in incidence as more and more teenagers spend hours in

repetitive motion while they play video games, do word processing, or text message.

Facial Palsy (Bell's Palsy)

Facial palsy is facial paralysis of the seventh (facial) cranial nerve, the nerve that innervates the muscles of facial expression. The syndrome occurs abruptly, usually after a herpes or Lyme disease infection. It may occur as a result of cold air from skiing or from riding in a convertible. Therapy consists of prednisone to reduce inflammation and acyclovir if the syndrome is herpes related. If the child is unable to close the eye on the affected side, eye drops 3 or 4 times daily will be needed. Although recovery is slow, usually not until 4 months, most children recover without any permanent disability (Tiemstra & Khatkhate, 2007).

PAROXYSMAL DISORDERS

A paroxysmal disorder is one that occurs suddenly and recurrently. Seizures, headaches, and breath-holding spells are the most frequent types seen in childhood.

Recurrent Seizures

A *seizure* is an involuntary contraction of muscle caused by abnormal electrical brain discharges. Approximately 2% to 3% of children will have at least one seizure by the time they reach adulthood (Moe, Benke, & Bernard, 2008). These episodes are always frightening to parents and other children because of the intensity. Although seizures can be idiopathic (without cause), they also can be attributed to infection, trauma, or tumor growth. Familiar or polygenic inheritance may be responsible. Fifty percent of seizures are unexplained. Because they are not so much a disease as a symptom of an underlying disorder, all seizures need to be investigated carefully. The degree of understanding about the cause of disorders such as recurrent seizures varies in different cultures. Because the cause of recurrent seizures is often unknown (idiopathic), they have, in the past, been attributed to an invasion by evil spirits. Many people today still fear that recurrent seizures will lead to cognitive impairment. Adults with recurrent seizures may be refused jobs because they are viewed as undependable. Being aware of these common misconceptions can help you appreciate parents' anxiety about the diagnosis of recurrent seizures. This anxiety can accentuate the need for parent education and careful planning to maintain self-esteem in the child (Box 49.4).

The term *epilepsy* comes from a Greek word meaning "to take hold of." The preferred term now is *recurrent seizures,* because epilepsy carries the stigma of cognitive challenge, behavioral disorders, institutionalization, or unexplainable strangeness.

The types and causes of seizures vary with age. They are classified into two major categories: partial seizures and generalized seizures (Box 49.5). With partial seizures, only one area of the brain is involved; with generalized seizures, the disturbance involves the entire brain, and loss of consciousness usually occurs. It is important that seizures be differentiated by their degree of severity and type, so that appropriate management and drug therapy can be instituted.

Seizures in the Newborn Period

Seizure activity in the newborn period may be difficult to recognize because it may consist only of twitching of the head, arms, or eyes; slight cyanosis; and perhaps respiratory difficulty or apnea. Afterward, the infant may appear limp and flaccid.

BOX 49.4 ✻ Focus on Evidence-Based Practice

Do children with recurrent seizures have as high self-esteem as others?

For this study, nurse researchers compared 48 families of children with recurrent seizures (ages 8 to 13 years) with 54 families whose child had asthma (same age range) in regard to children's self-concept and parenting stress. Results showed that children with recurrent seizures had significantly lower self-concept scores. Levels of parenting stress were significantly associated with children's self-concept in this group of children (the lower the self-esteem score, the greater the parent stress level). The researchers suggest that parents of children with recurrent seizures could benefit from learning improved coping strategies. This could not only reduce their parenting stress but might positively influence their children's self-concept.

Based on the above study, would you spend more time evaluating the home environment of a child with recurrent seizures or a child with asthma?

Source: Chiou, H., & Hsieh, L. (2008). Comparative study of children's self-concepts and parenting stress between families of children with epilepsy and asthma. *Journal of Nursing Research, 16*(1), 65–74.

BOX 49.5 ✻ Classification of Seizures

Partial (Focal) Seizures

- Simple partial seizures (no altered level of consciousness)
- Simple partial seizures with motor signs (includes aversive, Rolandic, and Jacksonian march)
- Simple partial seizures with sensory signs
- Complex partial (psychomotor) seizures (some impairment or alteration in level of consciousness)

Generalized Seizures

- Tonic–clonic seizures (formerly grand mal)
- Tonic
- Clonic
- Absence seizures (formerly petit mal)
- Atonic seizures (formerly "drop attacks")
- Myoclonic seizures
- Infantile spasms

Whereas older children often have seizures of unknown cause, 75% of seizures in neonates have a known cause. Some of these possible causes are:

- Trauma and anoxia (head trauma involved with the birth process, tight maternal cervix, use of forceps, or placenta previa)
- Metabolic disorders, such as hypoglycemia (glucose level less than 40 mg/100 mL in the full-term infant or 20 mg/100 mL in the preterm infant); infants of diabetic mothers; hypocalcemia; and lack of pyridoxine (vitamin B_6)
- Neonatal infection (CNS infection or prolonged rupture of membranes before birth)
- Kernicterus

Because of the nervous system's immaturity, EEGs in the newborn may be normal despite extensive disease. Therefore, a noticeably abnormal EEG generally means a poor prognosis, indicating that involvement this early in life must be severe. Because almost 20% of all newborns have abnormal CSF values compared with adult standards, lumbar puncture also is not conclusive. Protein is increased, and there may be a few red blood cells from rupture of subarachnoid capillaries from the pressure of birth.

High doses of anticonvulsant medication may be needed to control seizures in newborns because they metabolize drugs more rapidly than older infants. In adults, for example, phenobarbital may be administered in the range of 1.5 mg/kg body weight per day. In newborns, the dose might be as high as 3 to 10 mg/kg per day.

Seizures in the Infant and Toddler Periods

Seizures commonly seen in this age group are **infantile spasms**, a form of generalized seizure ("salaam" or "jackknife"), or infantile myoclonic seizures. These are characterized by very rapid movements of the trunk with sudden strong contractions of most of the body, including flexion and adduction of the limbs. The infant suddenly slumps forward from a sitting position or falls from a standing position. These episodes may occur singly or in clusters as frequently as 100 times a day. They are most common during the first 6 months of life (Moe, Benke, & Bernard, 2008).

In approximately 50% of children affected, there is an identifiable cause such as trauma, a metabolic disease such as phenylketonuria, or a viral invasion such as herpes or cytomegalovirus. In other children, the cause is unknown, but the spasms apparently result from a failure of normal organized electrical activity in the brain. Approximately 90% of infants with this type of involvement will be developmentally delayed as intellectual development appears to halt and even regress after the pattern of seizures begins. Most children with infantile spasms show high-amplitude slow waves and spikes, a chaotic discharge called *hypsarrhythmia,* on an EEG tracing.

The response to treatment with anticonvulsant therapy is poor. Parenteral adrenocorticotropic hormone (ACTH) and pyridoxine (vitamin B_6) therapy is commonly used. High-dose valproic acid or a newer anticonvulsant agent such as topiramate (Topamax) may be used in children who do not respond to usual therapy. The infantile seizure phenomenon seems to "burn itself out" by 2 years of age. The associated cognitive or developmental delay remains, however, so children need good follow-up planning and care.

Seizures Caused by Poisoning or Drugs. The possibility of poisoning must be considered in any child who has a first seizure. Although poisoning is most likely to occur between 6 months and 3 years of age, it must be considered again in adolescence, when drugs may be intentionally self-administered. Seizures also can be a late symptom of encephalopathy caused by lead poisoning (see Chapter 52).

Seizures in Children Older Than 3 Years of Age

Febrile Seizures. Seizures associated with high fever (102° to 104° F [38.9° to 40.0° C]) are the most common type seen in preschool children (5 months to 5 years), although these can occur as early as 3 months or as late as 7 years of age. Febrile seizures may occur after immunization because of an accompanying fever. Seizures show an active tonic–clonic pattern, which lasts for 15 to 20 seconds. The EEG tracing usually is normal. There usually is a history of other family members having had similar seizures.

Febrile seizures usually occur due to a sudden spike of temperature. The seizure only lasts 1 to 2 minutes or less. Such seizures must be taken seriously, however, and investigated for a possible cause, because meningitis often manifests initially with high fever and a seizure (Middleton, 2008).

Prevention of Febrile Seizures. Because these seizures arise with high fever, they are largely preventable. If acetaminophen is given to keep a developing fever below 101° F (38.4° C), seizures rarely occur. They happen most often when a child develops a fever at night, when a parent is not aware of it, or when a parent is reluctant to give acetaminophen in large enough doses to be therapeutic. Although this type of seizure can be prevented by phenobarbital, prophylactic use during an upper respiratory tract infection is not recommended, because phenobarbital takes 2 or 3 days to reach therapeutic blood levels. By this time, the seizures would already have occurred. In addition, phenobarbital is associated with sleepiness, which possibly reduces cognitive function in children. If a second febrile seizure occurs, diazepam (Valium) may be prescribed for the parents to administer the next time the child has a high fever (Moe, Benke, & Bernard, 2008).

Instruct parents that every child who has a febrile seizure must be seen by a health care provider to rule out meningitis. A good rule is to assume that the child in this situation has meningitis until it is ruled out by a complete neurologic workup.

Therapeutic Management. Teach parents that, after a seizure subsides, to sponge the child with tepid water to reduce the fever quickly. Advise them not to put the child in the bathtub, however, because it would be easy for the child to slip under water should a second seizure occur. Applying alcohol or cold water is also not advisable. Extreme cooling causes shock to an immature nervous system; in addition, alcohol can be absorbed by the skin or the fumes can be inhaled in toxic amounts, compounding the child's problems. Parents should not attempt to give oral medications such as acetaminophen, because the child will be in a drowsy, or *postictal*, state after the seizure and might aspirate the medicine. If attempts to reduce the child's temperature by sponging are unsuccessful, advise parents to put cool washcloths on the child's forehead, axillary, and groin areas and transport the child, lightly clothed, to a health care facility for immediate evaluation.

Additional treatment depends on the underlying cause of the fever. A lumbar puncture will be performed to rule out meningitis. Antipyretic drugs to reduce the fever below seizure levels will be administered. Appropriate antibiotic therapy will be started, depending on the type of infection.

Many parents need to be reassured that febrile seizures do not lead to brain damage and that the child is almost always completely well afterward.

What if... Tasha's mother is worried that Tasha will have another febrile convulsion if she develops a cold in the future? She asks if it will be safe to send Tasha to day care. How would you respond to this parent?

Complex Partial (Psychomotor) Seizures. More than half of children who develop recurrent seizures during school age have an idiopathic type—the cause of the seizures cannot be discovered. Nevertheless, medication can control idiopathic seizures in almost all affected children. Other seizures in this age group occur because of organic causes, usually from focal or diffuse brain injury that has left residual damage. The injury may have been caused by laceration of brain tissue in an automobile accident or fall, hemorrhage due to a blood dyscrasia, infection (meningitis or encephalitis), anoxia, or toxic conditions such as lead poisoning. The possibility that a growing brain tumor is causing brain irritation also must be considered.

Complex partial (psychomotor) seizures vary greatly in extent and symptoms and tend to be the most difficult type to control. The child may have a slight aura, but it is rarely as definite as that seen with tonic–clonic seizures. Results of a CT or MRI scan and EEG are invariably normal.

This type of seizure may begin with a sudden change in posture, such as an arm dropping suddenly to the side. Other motor, sensory, and behavioral signs may include **automatisms** (complex purposeless movements, such as lip smacking or fumbling hand movements). The child then slumps to the ground, unconscious. Circumoral pallor may develop due to a halt in respirations. The child usually regains consciousness in less than 5 minutes. He or she may feel slightly drowsy afterward but does not have an actual postictal stage as in tonic–clonic seizures.

Common drugs used to treat this type of seizure include carbamazepine (Tegretol) (Box 49.6), valproic acid (Depakene), phenytoin (Dilantin), and phenobarbital. Carbamazepine can lead to neutropenia, so white blood cell counts need to be monitored during therapy. If these drugs are not effective, surgery to remove the epileptogenic focus or the implantation of a vagus nerve stimulator can significantly reduce seizure frequency.

Partial (Focal) Seizures. Partial seizures originate from a specific brain area. A typical partial seizure with motor signs begins in the fingers and spreads to the wrist, arm, and face in a clonic contraction. If the movement remains localized, there will be no loss of consciousness. If the spread is extensive, the seizure becomes generalized and then is impossible to differentiate from a tonic–clonic seizure. Therefore, it is important to observe children carefully as a seizure begins to distinguish this type. A partial seizure with sensory signs may include numbness, tingling, paresthesia, or pain originating in one area and spreading to other parts of the body. These types of seizures may be caused by a rapidly growing brain tumor. Documenting the spread can help localize the spot in the brain that first initiated the abnormal electrical discharge.

BOX 49.6 ✻ Focus on Pharmacology

Carbamazepine (Tegretol)

Classification: Carbamazepine is an anticonvulsant.

Action: Exact mechanism of action is unknown. It is believed to inhibit polysynaptic responses and block posttetanic potentiation (Karch, 2009).

Pregnancy Risk Category: C

Dosage: Initially in children 6 to 12 years of age, 100 mg orally bid on the first day, increased gradually in 100-mg increments at 6- to 8-hour intervals until best response is achieved, or 10 to 30 mg/kg/day in divided doses tid or qid. Not to exceed 1000 mg/day.

Possible Adverse Effects: Dizziness, drowsiness, behavioral changes, nausea, vomiting, gastrointestinal upset, abnormal liver function tests, bone marrow depression, rash, photosensitivity

Nursing Implications

- Administer the drug with food to minimize gastrointestinal upset. Instruct parents to do the same.
- Obtain serum drug levels as ordered to monitor for effectiveness and to prevent possible toxicity. Keep in mind that the therapeutic range is 4 to 12 μg/mL.
- Monitor liver function studies and blood counts periodically.
- Inform parents about the need for follow-up laboratory tests.
- Suggest that the parents obtain a medical alert bracelet and have the child wear it in case of an emergency.
- Instruct parents and child to avoid alcohol and sleep-inducing or over-the-counter drugs, which could cause dangerous synergistic effects.
- Caution parents not to discontinue the drug abruptly or change the dose unless ordered by the health care provider.
- Instruct parents to notify the health care provider if the child develops bruising, bleeding, or signs of infection. These are signs of possible depression of bone marrow function.

Absence Seizures. Absence seizures, formerly known as petit mal seizures, are classified as generalized seizures (Siren et al., 2007). They usually consist of a staring spell that lasts for a few seconds. A child might be reciting in class when he pauses and stares for 1 to 5 seconds before continuing the recitation; he is unaware that time has passed. Rhythmic blinking and twitching of the mouth or an extremity may accompany the staring. Absence seizures can occur up to 100 times per day. An EEG usually shows a typical 3-Hz wave and slow-wave discharge (Sinclair & Unwala, 2007). Such seizures tend to occur more frequently in girls than in boys. The usual age of occurrence is 6 to 7 years.

Children with absence episodes may be accused of daydreaming in school and may be referred to the school nurse

for behavior problems. These children usually have normal intelligence; however, if they have frequent episodes, they may be doing poorly in school because they are missing instructional content.

Absence seizures can usually be demonstrated in children by asking them to hyperventilate and count out loud. If they are susceptible to such seizures, they will breathe in and out deeply, possibly 10 times, stop and stare for 3 seconds, then continue to hyperventilate and count, unaware that they paused.

No first aid measures are necessary for absence seizures. Downplaying the importance of these episodes helps children maintain a positive self-image.

Seizures can be controlled by ethosuximide (Zarontin), sodium valproate, or lamotrigine (Posner, Mohamed, & Marson, 2009). If seizures are fully controlled by medication, children can participate in normal school activities and ride a bicycle or motorcycle. If seizures cannot be controlled fully, parents need to anticipate potentially hazardous situations during the child's day, such as crossing a busy street on the way to school or learning to drive. This is crucial for adolescents who are eager to get a driver's license, to protect their own safety and that of others.

Approximately one third to one half of all children with absence seizures "outgrow" them by adulthood. This does not mean that treatment is not necessary during childhood, however, in order to keep the child safe and maintain self-esteem. Absence seizures usually occur independently of tonic–clonic seizures, although it is possible for a child to manifest both types. Some children's seizure pattern changes from absence involvement to tonic–clonic involvement as they approach adulthood.

Tonic–Clonic Seizures. Typical tonic–clonic seizures (formerly termed grand mal seizures) are generalized seizures consisting of four stages. There may be a prodromal period of hours or days; an aura, or warning, immediately before the seizure; the tonic–clonic stage; and, finally, a postictal stage. Not all four stages occur with every seizure.

The prodromal period may consist of drowsiness, dizziness, malaise, lack of coordination, or tension. Parents may observe simply that their child is acting differently than usual. As a child reaches school age, the child may be able to predict from these vague preliminary feelings when a seizure is about to occur.

The aura, or second phase, may reflect the portion of the brain in which the seizure originates. Smelling unpleasant odors (often reported as feces) denotes activity in the medial portion of the temporal lobe. Seeing flashing lights suggests the occipital area; repeated hallucinations arise from the temporal lobe; numbness of an extremity relates to the opposite parietal lobe; and a "Cheshire-cat grin" relates to the frontal lobe. Young children, unable to describe or understand an aura, may scream in fright or run to their parent with its onset. Noting exactly what symptoms the child experiences during this time helps to localize the involved brain portion.

The third phase is the tonic stage. All muscles of the body contract, and the child falls to the ground. Extremities stiffen; the face distorts. Although this phase lasts only about 20 seconds, the respiratory muscles are contracted, so the child may experience hypoxia and turn cyanotic. Contraction of the throat prevents swallowing, so saliva collects in the mouth. The child may bite the tongue when the jaws contract. As the chest muscles contract initially, air is pushed through the glottis, producing a guttural cry.

The seizure then enters a clonic stage, in which muscles of the body rapidly contract and relax, producing quick, jerky motions. The child may blow bubbles or foamy saliva and, if the tongue was bitten when the jaw shut with a spasm, saliva will be bloody. A child will be incontinent of stool and urine. This phase usually lasts 20 to 30 seconds.

After the tonic–clonic period, the child falls into a sound sleep, called the *postictal period.* He will sleep soundly for 1 to 4 hours and will rouse only to painful stimuli during this time. When he awakens, he often experiences a severe headache. He has no memory of the seizure.

Seizures may occur only at night. The child wakes in the morning with a bitten tongue, blood on the pillow, or a bed wet with urine. In a child with persistent bedwetting, the possibility of nocturnal seizures must be considered.

Children with this type of seizure usually, although not always, have an abnormal EEG pattern. Other family members may have similarly abnormal EEG patterns although they do not have symptoms.

Therapy includes the daily administration of an anticonvulsant such as valproic acid (Depakene) and carbamazepine (Tegretol). Phenobarbital has the advantage of being an inexpensive anticonvulsant so may be prescribed as well (Box 49.7). However, drowsiness and sleepiness from this may interfere with a child's ability to perform in school. Phenobarbital dosages should be tapered, never stopped suddenly, because the body becomes dependent on it. Rapid withdrawal may precipitate a seizure.

Children with tonic–clonic seizures also may be given phenytoin sodium (Dilantin) for control (Box 49.8). One nontoxic side effect of phenytoin is painless hypertrophy of the gums. Unless the gum hypertrophy is extensive, it is not sufficient reason to discontinue the drug. Medications are usually continued until the child has been seizure free for 2 to 3 years.

Some children are prescribed a ketogenic diet. This diet is high in fat and low in protein and carbohydrate. It causes the child to have a high level of ketones, which is believed to decrease myoclonic or tonic–clonic seizure activity. Because a ketogenic diet is monotonous for children and difficult for parents to prepare, however, it is hard to maintain for very long (Moe, Benke, & Bernard, 2008).

Status Epilepticus. **Status epilepticus** refers to a seizure that lasts continuously for longer than 30 minutes or a series of seizures from which the child does not return to the previous level of consciousness (Novorol, Chin, & Scott, 2007). This is an emergency situation requiring immediate treatment. Otherwise, exhaustion, respiratory failure, permanent brain injury, or death may occur. Oxygen may be necessary to relieve cyanosis. An IV benzodiazepine such as diazepam (Valium) or lorazepam (Ativan) halts seizures dramatically. This may be followed by IV phenobarbital or phenytoin (Dilantin). Diazepam must be administered with extreme caution, because the drug is incompatible with many other medications, and any accidental infiltration into subcutaneous tissue causes extensive tissue sloughing. Parents may administer diazepam by enema at home. Lorazepam (Ativan), a long-acting benzodiazepine used for children older than 2 years of age, provides a longer duration

BOX 49.7 ✻ Focus on Pharmacology

Phenobarbital

Classification: Phenobarbital is a central nervous system (CNS) depressant.

Action: Acts as an anticonvulsant by lowering the seizure threshold (Karch, 2009).

Pregnancy Risk Category: D

Dosage: 3 to 6 mg/kg/day orally, or 4 to 6 mg/kg/day parenterally, for 7 to 10 days until a blood level of 10 to 15 mg/mL is achieved, or 10 to 15 mg/kg/day IV or IM. In status epilepticus, 15 to 20 mg/kg IV administered over 10 to 15 min.

Possible Adverse Effects: Somnolence, sedation, confusion, ataxia, lethargy, hangover, paradoxic excitement, nausea, vomiting, constipation, diarrhea, epigastric pain, bradycardia, hypotension, syncope, hypoventilation, respiratory depression, pain or tissue necrosis at the injection site.

Nursing Implications

- When giving phenobarbital parenterally, administer IV doses slowly, directly into tubing or running infusion. Inject a partial dose and assess the response before continuing. If giving phenobarbital IM, administer it deeply into a large muscle.
- Monitor the IV site carefully for signs of irritation or extravasation.
- Assess vital signs closely—especially pulse, blood pressure, and respiratory rate—during IV administration.
- Administer the oral form of the drug with food to minimize gastrointestinal upset. Instruct parents to do the same.
- Caution the parents and child that the drug will make the child drowsy. Advise the child to change positions slowly and to sit at the edge of the bed for a few minutes before arising. Assist parents with safety measures to protect the child from injury.
- Monitor laboratory tests for liver and renal function and blood counts if the child is on long-term therapy.
- Inform parents about the possible need for follow-up laboratory tests.
- Suggest that the parents obtain a medical alert bracelet and have the child wear it in case of an emergency.
- Instruct parents and child to avoid alcohol and sleep-inducing or over-the-counter drugs, which could cause increased CNS depression.
- Warn parents not to discontinue the drug abruptly or change the dose unless ordered by the health care provider.

BOX 49.8 ✻ Focus on Pharmacology

Phenytoin (Dilantin)

Classification: Phenytoin is an anticonvulsant.

Action: Stabilizes neuronal membranes, prevents hyperexcitability caused by excessive stimulation, and limits the spread of seizure activity without causing general central nervous system depression (Karch, 2009).

Pregnancy Risk Category: D

Dosage: Initially, 5 mg/kg/day in two to three equally divided doses up to a maximum of 300 mg/day with a maintenance dose of 4 to 8 mg/kg/day.

Possible Adverse Effects: Nystagmus, ataxia, slurred speech, confusion, fatigue, irritability, nausea, gingival hyperplasia, liver damage, and blood dyscrasias

Nursing Implications

- Administer the drug with food to minimize gastrointestinal upset and enhance absorption. Instruct parents to do the same.
- Advise parents to have the prescription filled each time with the same brand of drug, because differences in bioavailability have been reported.
- Obtain serum drug levels as ordered to monitor for effectiveness and to prevent possible toxicity. Keep in mind that the therapeutic range is 10 to 20 μg/mL.
- Monitor liver function studies and blood counts periodically.
- Inform parents about the need for follow-up laboratory tests.
- Instruct the child and parents about oral hygiene measures to prevent gum problems. Encourage frequent dental checkups.
- Suggest that the parents obtain a medical alert bracelet and have the child wear it in case of an emergency.
- Caution parents not to discontinue the drug abruptly or change the dose unless ordered by the health care provider.
- Instruct parents to notify the health care provider if the child develops nystagmus, ataxia, or diminished mental capacity. These are signs of possible toxicity.

of action and also less respiratory depression. Newer drugs that also may be included are topiramate (Topamax), lamotrigine (Lamictal), and tiagabine (Gabitril) (Karch, 2009).

Assessment of the Child With Seizures

A thorough pregnancy history must be obtained for any child with seizures. Events that occurred immediately before the seizure and an accurate description of the seizure itself also should be recorded. Investigate the child's overall behavior in the last few weeks. Is the child an A student who has been getting Ds lately? Has the parent noticed bedwetting? These might be signs of absence or nocturnal seizures that have occurred but gone unnoticed.

A complete physical and neurologic examination and blood studies are necessary to rule out metabolic or infectious processes. Prepare a child for a lumbar puncture to rule out meningitis or bleeding into the CSF. A CT scan, MRI, skull radiograph, or EEG may be obtained if indicated. During the EEG, the child may be stimulated with rhythm patterns or flashing lights or asked to hyperventilate to see whether a seizure can be provoked.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for injury related to tonic–clonic seizure

Outcome Evaluation: Child exhibits no signs of aspiration or traumatic injury.

Protecting a child from being hurt during a tonic–clonic seizure is crucial (Box 49.9). Restraining the child's thrashing extremities is not advisable, because it is difficult for an adult to do and could result in injury to the parent or child because of the amount of force needed to keep the child still. In early school-aged children, it is particularly important to avoid inserting a tongue blade between the teeth, because these children often have loose anterior teeth that are on the verge of falling out. Such teeth could be loosened and aspirated.

Remaining calm is important; be aware that people are frightened by the sight of a child having a seizure because the action is so forceful and violent. It is reassuring for them to see someone calm and in control of the situation and to know that there is no reason to be afraid. If the child passes rapidly from one seizure into another (status epilepticus), be prepared to provide supplemental oxygen and administer anticonvulsant therapy as needed.

Nursing Diagnosis: Interrupted family processes related to diagnosis of long-term illness in child

Outcome Evaluation: Child, parents, and other family members express fears and questions about disease to health care team; parents discuss ways to accommodate the illness in their daily life, such as medication schedules, school accommodations, sports activities, plans for vacation, and discipline.

As soon as the diagnosis of a seizure disorder is made, parents and children need to be told that it is likely to signify a long-term disorder as, although seizures can be controlled with medication, these do not cure the underlying cause. If children neglect their medication, seizures are apt to recur (see Focus on Nursing Care Planning Box 49.10). Most children are given tablets rather than liquid medication, because the latter tends to settle at the bottom of the bottle, resulting in overdiluted or overconcentrated doses that can allow seizures to break through. Parents need instruction to plan on always having an adequate supply of medications, especially for a trip away from home or for summer camp. Abrupt discontinuation of seizure medications (particularly phenobarbital) may result in severe seizures.

The child needs to be monitored frequently during childhood to be certain that the medication dosage is adequate. Children need periodic blood sampling to ascertain whether therapeutic blood levels of the medication are being maintained.

Provide parents with as much information as possible about the cause of their child's seizures. This helps them feel that they are dealing with a known disease, not an unexplainable and unpredictable illness.

BOX 49.9 ✻ Focus on Family Teaching

Safety During Seizures

Q. Tasha's mother asks you, "What can we do to make sure she doesn't get hurt during a seizure?"

A. When your daughter has a seizure, here are some tips to help keep her safe:

- Remain calm.
- Move away furniture or any sharp object.
- Turn your child gently on her side, or on her abdomen with her head turned to the side, to prevent aspiration of unswallowed mouth secretions.
- Do not restrain her other than to keep her head turned to the side so that mouth secretions continue to drain. Restraining a child could result in injury because of the amount of force necessary.
- Do not attempt to place a stick or padded tongue blade between the child's teeth. Trying to force a tongue blade into the mouth this way could break the tongue blade or loosen teeth.
- Try to keep onlookers from crowding the area. A convulsing child is an abnormal sight and always attracts a crowd. Ask people who are only interested spectators to move away.
- Be aware that a child having this type of seizure may have some slight cyanosis during the tonic and clonic stages, but these stages are so short that administering oxygen is not needed.
- After any seizure, telephone your primary care facility and notify your primary care provider of the seizure so arrangements for any necessary follow-up care can be made.
- If your child should pass rapidly from one seizure into another (status epilepticus), she may need supplemental oxygen or medicine to stop the seizure. If this happens, telephone your emergency medical service number.

If the cause of the seizures is unknown, parents can be reassured that the treatment is known. Many new anticonvulsant medications are available today and are being introduced into therapy.

General guidelines for safe administration of anticonvulsants include:

- Caution children to be careful around motor vehicles and electrical equipment, because many anticonvulsants cause drowsiness.
- Advise the child and parents to observe for easy bruising, because several anticonvulsants may suppress bone marrow function.
- Caution the adolescent to avoid alcohol while taking anticonvulsants, because alcohol can potentiate the CNS effects of some anticonvulsants.
- Use caution when administering anticonvulsants to children with liver disease. Because many of these drugs are metabolized by the liver, they may not be fully effective in such children.

BOX 49.10 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Child With Recurrent Seizures

Tasha is a 2-year-old girl who was brought to the emergency department by her mother because she had a seizure. Her physician suspects she may have meningitis. Her parent is visibly upset. She says, "Does this mean she'll always have seizures? How will she ever be independent?"

Family Assessment ✻ Parents are divorced. No siblings. Child lives in a 2-bedroom apartment with mother; attends preschool daily 9–3 PM. Neighbor watches her from 3 to 6 PM, when mother returns from work as a research librarian.

Client Assessment ✻ Well-proportioned preschooler sleeping soundly on left side since admission. A second seizure occurred approximately 1 hour ago. Vital signs within age-appropriate parameters. Reacts to painful stimuli only. Deep tendon reflexes depressed. "She was watching television this morning. Suddenly, she just fell to the floor and started shaking. I called 911, and they brought her here." Temperature 103° F. Pain on forward flexion of the neck. Lumbar puncture performed; pressures within normal limits; specimens sent for cell count, glucose, and culture.

Nursing Diagnosis ✻ Risk for injury related to diminished level of consciousness resulting from seizure episode

Outcome Criteria ✻ Child is conscious within the hour. Exhibits no signs of aspiration or traumatic injury.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Assess whether mother was aware child's temperature was elevated. Ask if she has a thermometer for future fevers.	Keep child on side to help ensure an open airway until alert and responsive.	Side-lying position reduces risk for aspiration.	Mother states she understands importance of taking temperature in the future.
Nurse	Assess whether child has continued pain on dorsiflexion of neck.	Determine whether mother feels child is exceptionally irritable.	Pain on dorsiflexion of neck and irritability are symptoms of meningitis.	Mother rates child's emotional state. Unable to assess pain because child is unconscious.
		Consultations		
Physician	Assess in light of this second seizure and spinal tap results whether neurologic service should be consulted.	Consult with neurologic service, if indicated, about management of child.	A second febrile seizure suggests this may be more than a simple febrile seizure.	Neurologic service meets with mother and child as appropriate based on findings.
		Procedures/Medications		
Nurse	Assess whether child has had a spinal tap before.	Assist with spinal tap and specimen collection.	Spinal tap is a frightening procedure for both child and parent.	Mother states she understands reason for procedure and gives consent.
Nurse	Assess whether child has prior experience with intravenous administration.	Begin IV fluid administration as prescribed.	IV line supplies a route for emergency medicine should it be needed for seizure control or treatment of infection.	IV line is established and safeguarded with board for unresponsive child.
Nurse	Assess whether mother understands why respiratory precautions are necessary.	Obtain equipment for respiratory precautions as needed.	Meningitis is contagious by contact with nasal secretions.	Mother states she understands the importance of precautions. Respiratory precautions are readied.

(continued)

BOX 49.10 ✻ Focus on Nursing Care Planning (continued)

		Nutrition		
Nurse	Assess child's level of consciousness using a Glasgow coma scale.	Do not give anything by mouth until the child is fully awake, alert, and oriented and the gag reflex is intact.	Giving oral fluids too early increases risk for aspiration.	Child receives no oral fluid until she is awake and aware.
		Patient/Family Education		
Nurse/nurse practitioner	Assess what mother knows about febrile seizures and meningitis.	Teach that a febrile seizure is more of a symptom of fever than a long-term condition. A meningeal infection could be very serious.	Understanding the basis for febrile seizures and meningitis can help the parent understand the responsibility she needs to take for future care.	Mother states she understands child's current status and possible future implications.
		Psychosocial/Spiritual/Emotional Needs		
Nurse	Assess whether mother needs to contact a support person if her child's diagnosis is serious.	Help mother contact a support person if she feels this would be helpful.	A support person can be vital to help a parent withstand an ominous diagnosis.	Mother contacts support person as needed.
		Discharge Planning		
Nurse	Assess whether parent has any further questions about child's condition before transfer to pediatric intensive care unit.	Answer any remaining questions to make transfer as comfortable for parent and child as possible.	Parents gain confidence in emergency department staff and may find it difficult to change to new health care providers.	Mother states she understands that if meningitis is diagnosed, her child needs further intensive care.

- Caution the child and parents not to discontinue anticonvulsant therapy abruptly, because this may lead to uncontrolled seizures.
- Remind parents about the need for follow-up blood tests to evaluate the drug level.

Maintaining a therapeutic blood level enhances the drug's effectiveness and minimizes the risk for toxicity.

Parents need to be certain to treat children with seizures the same as other family members. Alert them that scolding children, asking them to do household chores, or insisting that they do their homework will not cause seizures. A few children with absence seizures can initiate them by hyperventilating and may try to manipulate those around them by doing this to gain sympathy. The few children who use this extreme form of manipulation may need to be referred for counseling.

Assure parents that occasional seizures in children are not harmful. Unless status epilepticus occurs and the child becomes anoxic, the chance that their child will be injured during a seizure is remote. Knowing this helps parents not to worry about the child becoming cognitively challenged or other misconceptions about seizures. Although some children who have seizures are cognitively challenged, this and the seizures were caused by the same event; the seizures did not cause the impairment. At every health care visit, be certain that parents have time to ask questions about their child's care and to express any concerns they have. There are so many "scare stories" about seizures that every parent is likely to believe some of these stories unless counseled otherwise (Box 49.11).

As a rule, children with seizures should attend regular school and participate in physical education classes and active sports (with possible exceptions such as scuba or sky diving or rock climbing). Many teachers are concerned about the responsibility of having a child with seizures assigned to their classes. Help them learn about the success of modern seizure control. State regulations differ, but most states allow teenagers to apply for a driver's license after they have been seizure free for 1 year.

In many children, seizures increase at puberty. This may be the result of glandular changes or of sudden growth and the need for an increased medicine dosage. It may result in part from adolescent rebellion against following prescribed medication routines. Respect the adolescent's feelings and need for independence, but assist the adolescent with channeling feelings to a more positive area.

All anticonvulsant medications are potentially teratogenic to a fetus. Be certain that adolescent girls are made aware of this so they can choose to delay childbearing until later in life, when their medication can be reduced or even discontinued.

BOX 49.11 ✻ Focus on Communication

Tasha, 2 years old, had a febrile seizure and was diagnosed as having meningitis. You talk to her mother about the seizure.

Less Effective Communication

Nurse: Mrs. Jarman, can you describe what happened?
Mrs. Jarman: She just started shaking all over. It was really frightening.
Nurse: Did she voice any symptoms before the seizure?
Mrs. Jarman: No, she just started shaking.
Nurse: That must have been frightening.
Mrs. Jarman: Thinking about what it did to her is scarier.
Nurse: Well, lucky thing she's fine now.

More Effective Communication

Nurse: Mrs. Jarman, can you describe what happened?
Mrs. Jarman: She just started shaking all over. It was really frightening.
Nurse: Did she voice any symptoms before the seizure?
Mrs. Jarman: No, she just started shaking.
Nurse: That must have been frightening.
Mrs. Jarman: Thinking about what it did to her is scarier.
Nurse: Did to her?
Mrs. Jarman: I know seizures cause mental retardation. Our neighbor's son has them, and he's severely retarded.
Nurse: Mrs. Jarman, let's talk about this a little more.

In the first scenario, although the nurse responds with a therapeutic statement ("That must have been frightening"), she fails to identify a misconception verbalized by the mother. In the second scenario, the nurse identifies the concern and attempts to clarify it, providing an opportunity for teaching.

✔ Checkpoint Question 49.4

Tasha had a generalized or tonic–clonic seizure. What is the usual description of this type of seizure?

a. A momentary halt of about 10 seconds in respirations.
b. Stiffening of the extremities, then shaking of the body.
c. Extreme pain and twitching of one of the extremities.
d. Rapid blinking, then foaming of the mouth.

Breath Holding

Breath holding is a phenomenon that occurs in young children when they are stressed or angry. The child breathes in and, because he is upset, does not breathe out again or else breathes out and then does not inhale again (Goldson & Reynolds, 2008). As brain cells become anoxic, the child becomes cyanotic and slumps to the floor, momentarily unconscious. With loss of consciousness, the child begins breathing again. The child's color returns to normal, and he awakens. Breath holding is frightening but represents the immaturity of the child's neurologic control. This differs from a temper tantrum, in which a child deliberately attempts to hold his breath and pass out (see Chapter 30). The child needs no therapy except reassurance that the episode is over.

Headache

Headache in children younger than school age is rare, although children may report "headache" in imitation of their parents. Headache may occur with a fever because of increased ICP caused by increased cerebral blood flow. As children reach school age, headaches may occur as a result of conditions as simple as eyestrain and sinusitis or as serious as a brain tumor. Headache pain results from meningeal or vascular irritation. The brain itself is insensitive to pain, so a cerebral tumor can be present for a long time before meningeal irritation occurs and pain symptoms become apparent. With a brain tumor, pain becomes evident on changing body position, so a young child who reports a headache after getting up should be carefully evaluated. Pain from a brain tumor is also usually occipital, so asking the child to indicate where it hurts helps determine whether a tumor could be the cause.

Tension or Stress Headache

When children are studying intently or taking a test, contraction of their neck muscles from tension can cause temporary ischemia. This is experienced as a dull, steady pain in the head. Children with these symptoms should have their vision tested, because poor eyesight may be causing them to hunch over their books. Tension or stress is relieved by simple analgesics, such as acetaminophen, or by sleep or application of a cool compress. Advising them to take frequent "stretches" while studying can help avoid muscle tension and stress headaches.

Sinus Headache

Sinus headache usually accompanies sinusitis and is associated with inflammation and possible obstruction of the sinuses. Sinusitis is discussed in Chapter 40.

Migraine Headache

Migraine headache refers to a specific type of headache that may or may not begin with an aura or visual disturbance such as diplopia or a zigzag pattern across the visual field. The pain that follows is usually unilateral and extremely intense, with throbbing that is moderate to severe. The headache is aggravated by routine physical activity, menstrual periods, and may be compounded by nausea and vomiting and intolerance to bright lights and noise (Tobleman & Stone, 2008).

The cause of migraine headache in any age group is not well understood. It probably results from abnormal constriction of intracranial arteries that temporarily reduces cerebral blood supply. This is followed by compensating overdistention of cranial blood vessels. The aura accompanying such headaches is the result of the temporary ischemia, whereas the headache is the result of the overdistention. Some children who have migraine headaches have an abnormal EEG.

Most children with migraine headache have a positive family history. This syndrome may be inherited as a dominant trait.

Assessment. To help assess the cause of a headache, obtain a thorough history, including:

- When the headache usually occurs
- The events preceding it (to detect an aura)
- Its duration, frequency, intensity, description, and associated symptoms
- Any actions taken to treat the headache

The child needs a thorough physical examination, including funduscopic examination, to rule out papilledema. Blood pressure must be measured to rule out hypertension. If an aura is documented, an EEG will be ordered.

Therapeutic Management. A drug commonly prescribed for migraine headache in children is ergotamine tartrate (Cafergot), which constricts cerebral arteries. Propranolol and flunarizine may also be helpful (Victor & Ryan, 2009). Beta-blockers or calcium channel blockers that result in vasodilation may be prescribed prophylactically. At the time of the headache, sleep or lying down may be necessary to relieve the pain and vomiting. Frequent headaches interfere with a child's ability to achieve in school. Children need to be reassured that migraine headaches are benign, although painful and incapacitating, and they are not signs of a developing brain tumor so that they can keep such headaches in perspective. Follow-up visits are necessary to confirm that there is no progressive disease and treatment is remaining adequate (Winner & Hershey, 2007).

If other family members have migraine headaches, counsel them that their reactions to their headaches influence their child's reaction to headaches. If the mother goes to bed for the day when she has a migraine headache, for example, she cannot expect her child to go to school when the child has one.

ATAXIC DISORDERS

Ataxia is failure of muscular coordination or irregularity of muscle action. Ataxic disorders are often manifested by an awkward gait or lack of coordination. Causes of ataxia differ, but degeneration of cerebellar or vestibular function is always involved.

Ataxia-Telangiectasia

Ataxia-telangiectasia, transmitted as an autosomal recessive trait attributable to a defect of chromosome 11, is a primary immunodeficiency disorder that results in progressive cerebellar degeneration. This is a multisystem disease with neurologic and immunologic aspects. In addition, endocrine abnormalities may occur, and there is an increased risk of cancer, particularly brain tumor. Telangiectasia (red vascular markings) appear on the conjunctiva and skin at the flexor creases (Buckley, 2008).

Both immunologic and neurologic symptoms of this disorder vary in severity and onset. Serum immunoglobulin A (IgA) and IgE levels may be low, and there is often evidence of reduced T-cell function. Children develop frequent infections (primarily sinopulmonary) because of the immunologic deficits. Tonsillar tissue in the pharynx is scant.

Neurologic symptoms caused by the degeneration process can usually be detected in early infancy when developmental milestones are not met. Children develop an awkward gait when they begin to walk. **Choreoathetosis** (rapid, purposeless movements), nystagmus, an intention tremor, or scoliosis may develop. Children may be unable to move their eyes on demand or follow movement through visual fields. Eye changes (conjunctival telangiectasia) develop by 5 years of age. There is no effective treatment. Children with this disorder often die in late adolescence of infection, respiratory failure, or a malignant brain tumor.

Friedreich's Ataxia

Friedreich's ataxia, which is carried on the short arm of chromosome 9 as an autosomal recessive trait, involves a variety of degenerative symptoms (Elias, Tsai, & Manchester, 2008). Symptoms such as progressive cerebellar and spinal cord dysfunction occur in late adolescence. Teenagers develop a progressive gait disturbance or a lack of coordinated arm movements. They also develop a high-arched foot (pes cavus), hammer toes, and scoliosis. The combined symptoms of a positive Babinski reflex, absence of deep tendon reflexes in the ankle, and ataxia are strongly diagnostic. Neurologic examination shows difficulty in recognizing foot position (whether the foot is moved up or down). If the ataxia remains untreated, death occurs in young adulthood from myocardial failure. Antioxidant therapy such as high-dose idebenone may help to delay this outcome by reducing ventricular hypertrophy (Di Prospero et al., 2007).

SPINAL CORD INJURY

Because of the resilience of their vertebrae, children have fewer spinal cord injuries than adults. However, the incidence among adolescents is increasing, because more adolescents are involved in motor vehicle accidents, particularly motorcycle accidents, than previously (Achildi, Betz, & Grewal, 2007). Another frequent cause of spinal cord injury is diving into too-shallow water. Any child with multiple traumatic injuries should be assessed for spinal cord damage. Spinal cord injury without radiographic abnormality (SCIWRA syndrome) may occur. Stabilizing the neck is the best protection against further injury in these children (Leonard, Sproule, & McCormack, 2007).

Recovery Phases

Spinal injuries result when the spinal cord becomes compressed or severed by the vertebrae; further cord damage can be caused by hemorrhage, edema, or inflammation at the injury site as the blood supply becomes impeded. Table 49.5 summarizes functional ability after spinal cord injury. The first questions asked by the parents or the child after the injury are: How much damage is there? Will our child be able to walk again? Predictions of useful body function cannot be made at the time of the accident, however. Three phases of recovery must first take place.

First Recovery Phase

Immediately after the injury, the child experiences spinal shock syndrome or loss of autonomic nervous system function (loss of anterior nerve fibers traveling through the anterior horn of the spinal canal). This leads to loss of motor function, sensation, and reflex activity, as well as flaccid paralysis in body areas below the level of the injury. If a cervical injury is present, there is loss of respiratory function because of flaccidity of the diaphragm. In high thoracic lesions, use of accessory muscles of the chest is lost, so the child has difficulty maintaining effective respirations. The child has no ability to sweat or shiver to change body temperature below the level of the lesion because of loss of autonomic nerve control; therefore, hypothermia or hyperthermia becomes a threat.

TABLE 49.5 ✻ Functional Ability After Spinal Cord Injury

Injury Site	Highest Key Functions Still Present	Effects and Possible Interventions
C1–3	Head and neck muscles intact	Respiratory paralysis from loss of phrenic nerve innervation; will need ventilatory assistance No voluntary motion below chin; possibly able to learn to use mouth to control pen for writing and mouthstick to reach objects
C4	Diaphragm intact	Loss of motor function of upper and lower extremities and trunk; able to learn to use abdominal muscles to breathe independently
C5	Shoulder control; biceps, deltoid function	Able to feed self and operate wheelchair if fitted with self-care aids
C6	Forearm pronation; wrist extension	Use of upper extremities for self-care. Can transfer to wheelchair and so have increased independence
C7	Triceps function	Able to transfer to wheelchair readily; increasing independence
C8	Thumb and finger function	Able to do fine motor tasks; increases self-care ability
T1–7	Intercostal muscles (able to breathe with chest, not abdominal, muscles)	Full use of upper extremities but is still dependent on wheelchair Possibly able to drive car with hand controls Possibly able to have high leg braces fitted for standing
T10–12	Abdominal muscles	Use of long leg braces and four-point crutch to ambulate
L2–4	Hip flexion Leg extension	Use of long or short leg braces to ambulate
L5–S1	Gluteus maximus muscle function	Walking without aids
S4	Bladder and anal sphincter control	Controlling bladder and bowel function Penile erection and ejaculation possible

Blood vessels below the level of the injury are no longer able to constrict, so blood tends to pool in the lower body, leading to hypotension, especially if the upper body is elevated. Loss of bladder control occurs (when flaccid, the bladder overdistends and continually empties). The bowel becomes equally distended, and bowel sounds are absent. This phase of spinal cord injury lasts from 1 to 6 weeks. As a rule, the shorter the phase of spinal shock, the better the final outcome.

Administration of a corticosteroid helps to reduce edema and possibly protects function of the spinal cord during this phase. A vasopressor agent such as dopamine may be prescribed to maintain blood pressure and perfusion to the cord.

Second Recovery Phase

During the second phase of recovery, the flaccid paralysis of the shock phase is replaced by spastic paralysis. Normally, motor impulses begin in the brain cortex and are transmitted to the medulla, where they cross to the opposite side of the cord; they then travel down the descending motor tracts of the spinal cord. They synapse in the anterior horn of the spinal cord and travel by way of the spinal and peripheral nerves to the designated muscle group, which they set in motion. The nerve pathways of the brain and the descending tracts are termed *upper motor neurons.* Those in the anterior horn cells and the spinal and peripheral nerves are termed *lower motor neurons.* Whether a motor neuron has upper or lower function, therefore, does not depend on its height in the spinal tract but rather on its position in relation to an anterior horn: between the brain and the anterior horn, it is an upper motor neuron; between the anterior horn and the point of innervation, it is a lower motor neuron (Fig. 49.11).

Spasticity in the second phase is caused by the loss of upper level control or transmission of meaningful innervation to the lower muscles. Lacking upper motor neuron function because of a severed cord, the lower motor neurons or reflex arcs cause the muscles to contract and remain that way. Parents and children are quick to interpret the sudden spastic movement of a lower extremity as meaningful activity. This is particularly easy to believe with an infant, who cannot tell you that she has no control over her leg movement. Differences between upper and lower neuron damage are listed in Table 49.6. If the injury is very low in the spinal tract, affecting mostly lower motor neurons, the muscles will remain flaccid, because the lower motor neurons cannot send impulses for contraction.

During this phase, if the child's bladder is allowed to fill, the resultant sensory stimulation relayed to the damaged cord will initiate a powerful sympathetic reflex reaction **(autonomic dysreflexia),** and the child will show signs of hypertension, tachycardia, flushed face, and severe occipital headache. This is an emergency situation; if the severe hypertension is not relieved, cerebral vascular accident can result (Huether & McCance, 2008). Assess that the child's urinary catheter is not obstructed, so urine can flow freely and reduce the sensory stimulation.

Third Recovery Phase

The third phase of recovery from spinal cord injury is the final outcome, or permanent limitation of motor and sensory function. If the compression of the spinal cord is caused by edema that is then relieved, no permanent motor and sensory disability will occur.

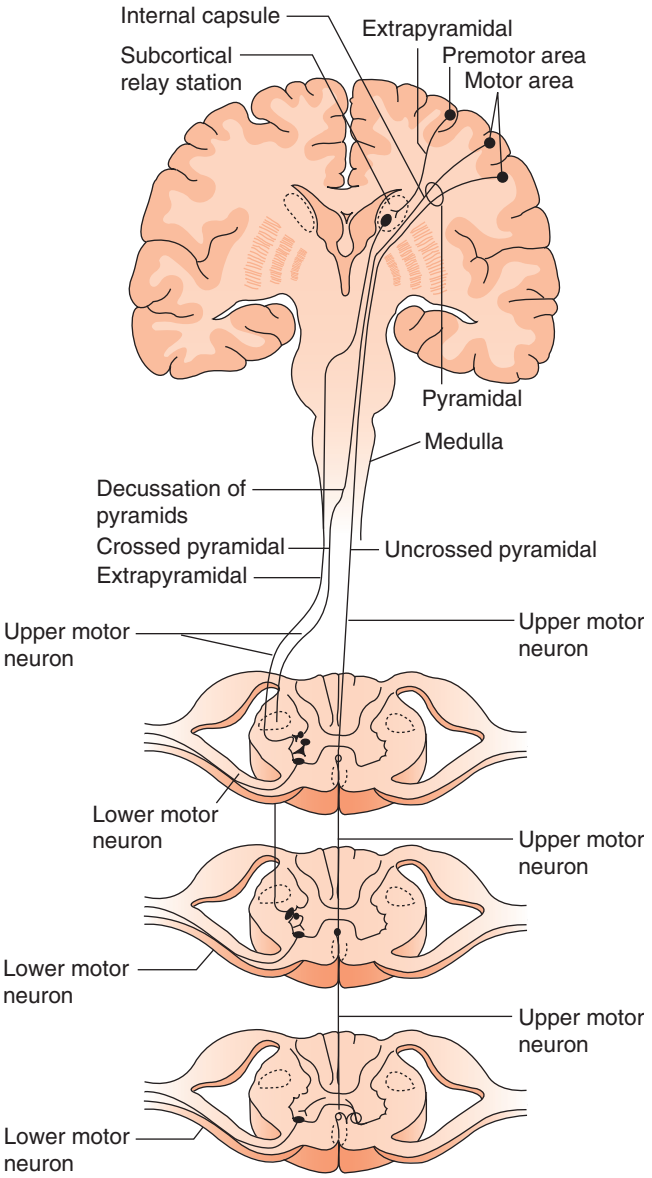

FIGURE 49.11 Diagram of motor pathways between the cerebral cortex, one of the subcortical relay stations, and lower motor neurons in the spinal cord. Decussation (crossing of fibers) means that each side of the brain controls skeletal muscles on the opposite side of the body.

What if... You are caring for a child with a spinal cord injury and he suddenly develops hypertension, tachycardia, diaphoresis, and headache? What would you initially assess for? How would you intervene?

Assessment of Spinal Cord Injury

Cervical and thoracolumbar areas of the spine are the ones most likely to sustain injury. Spinal cord injury should be suspected whenever a child has sustained a forceful trauma of any kind. The signs of spinal cord injury vary according to the level of the injury.

Do not move a child with suspected spinal cord injury until the back and head can be supported in a straight line to prevent further injury to the spinal column from twisting or bending. In the emergency department, do not attempt to move the child from a stretcher to an examining table until spinal x-ray films have been obtained. This reduces any unnecessary movement. When moving the child onto the x-ray table, use a gentle log-rolling technique to avoid additional injury. If resuscitation is necessary, maintain the head in a neutral position; do not hyperextend it. To keep the neck immobilized, do not remove a child's football or motorcycle helmet or neck brace.

The child will need a thorough neurologic assessment to determine the level of injury. Help maintain spinal immobilization during such procedures.

Nursing Diagnoses and Related Interventions

During the first phase of recovery, a child's major problems are those resulting from almost complete immobility: pressure ulcers on bony prominences; loss of appetite and subsequent poor nutrition from depression or being in the supine position; urinary calculi caused by excessive calcium loss from bones; atrophy of flaccid muscle groups; and urinary retention and bladder infection. These effects of immobility are presented in Figure 49.12.

Nursing Diagnosis: Impaired physical mobility related to effects of spinal cord injury

TABLE 49.6 Characteristics of Upper and Lower Motor Nerve Lesions After Spinal Shock Phase

Finding	Upper Motor Lesion	Lower Motor Lesion
Spasticity	Present	Absent (flaccidity present)
Clonus	Present, increased	Absent
Tendon reflexes	Increased	Absent
Babinski reflexes	Present	Absent
Reflexes below level of lesion	Present	Absent
Reflex at level of lesion	Absent	Absent
Atrophy of muscles	Absent or present only to slight degree	Present (muscle fasciculations may be present)

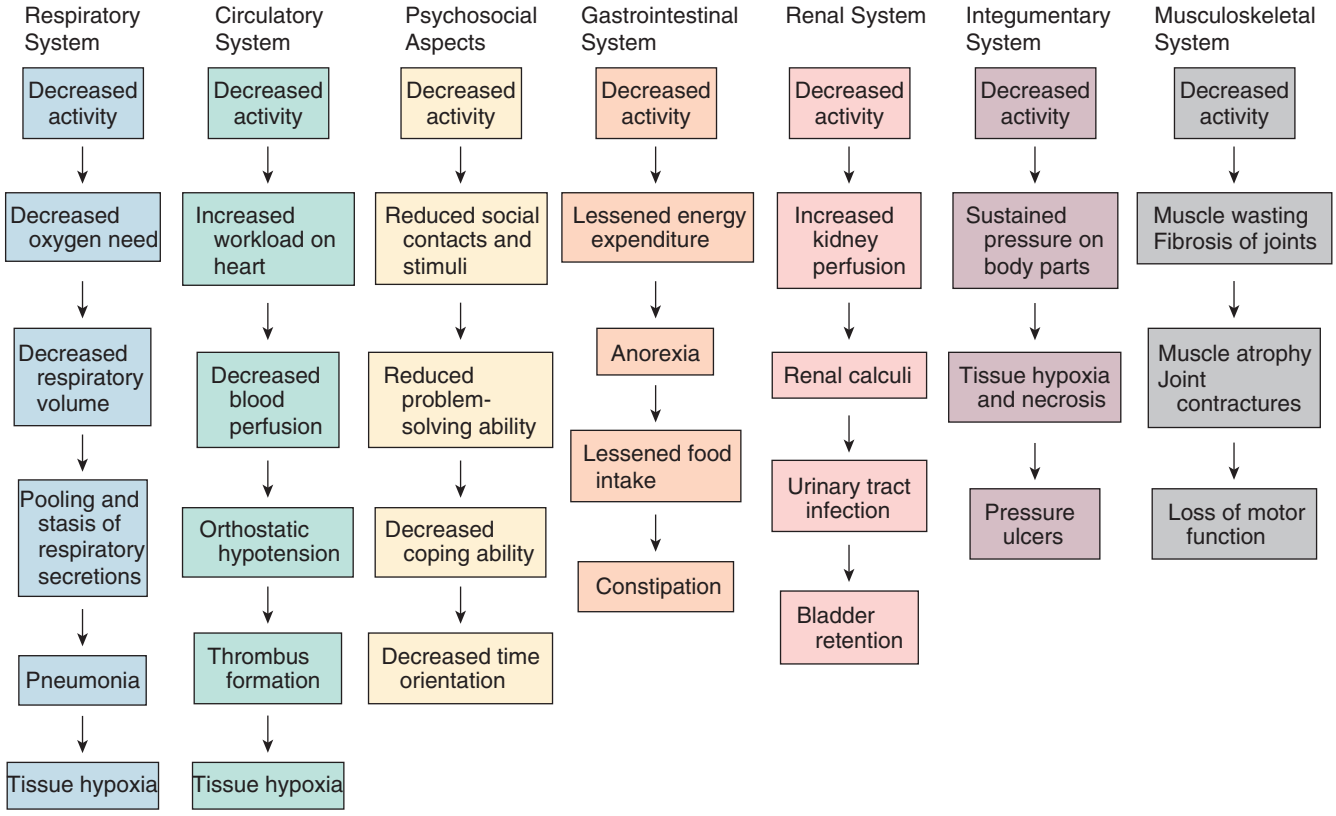

FIGURE 49.12 Effects of immobilization.

Outcome Evaluation: Child demonstrates movement of all extremities with a minimum of artificial support and equipment; participates in exercise program within limitations; exhibits ability to move about environment within limitations.

To relieve edema at the injury site and prevent further injury, IV corticosteroids will be administered. Children may be placed in cervical traction with Crutchfield tongs and a traction belt (Fig. 49.13) or with halo traction (see Chapter 51). Having tongs inserted into the skull is a very frightening procedure for children. They worry that the tongs will burrow into their skull and strike their brain. Children need someone they know and trust to help them lie still during the procedure.

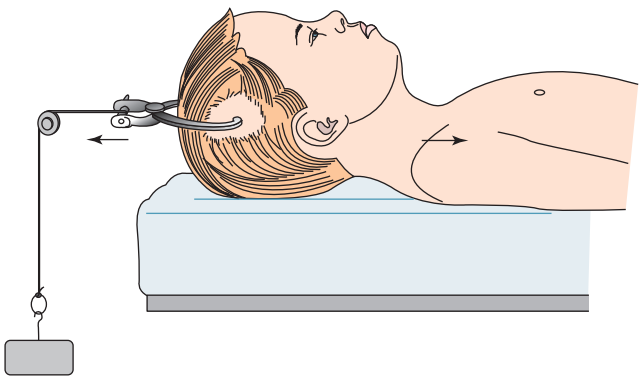

FIGURE 49.13 Crutchfield tongs used to create spinal traction.

To promote circulation and prevent loss of calcium that results from inactivity, full range-of-motion exercises must be done approximately three times per day. These are time-consuming but important in maintaining joint function.

During the second phase of recovery, when spasticity of muscle groups occurs, preventing contractures becomes an important nursing responsibility. Specialized splints, boots, or even hightop sneakers may be used to prevent footdrop (Fig. 49.14). If children have upper extremity mobility but will be left with lower extremity paralysis, exercises to strengthen the upper extremity muscle groups are needed. Strengthening the arms helps children to be able to lift themselves from bed to a wheelchair or raise themselves with a trapeze over the bed when changing positions. Holding legs and arms at the joints while moving them helps reduce muscle spasms.

One major problem of ambulation after spinal cord injury is helping a child's body readjust to a vertical position after being maintained in the supine position for so long. When the child's head is raised, blood tends to pool in dilated blood vessels below the level of the lesion. This pooling of blood results in pseudohypovolemia and hypotension, and the child may faint. Gradually increasing the angle of the bed

FIGURE 49.14 Specialized splints are used for a child with a low spinal cord injury to prevent contractures and foot drop. Here the physical therapist prepares to apply the splint to the child's leg. (Photograph courtesy of Sue Moses.)

helps the child become acclimated to the upright position without experiencing vascular pooling.

Nursing Diagnosis: Self-care deficit related to spinal cord injury

Outcome Evaluation: Child states intention of taking over self-care; practices using equipment for eating, bathing, and toileting; participates in one new aspect of self-care each week.

As soon as possible, children should be introduced to self-help methods for activities of daily living. Most parents need to be encouraged to allow a child to become as self-sufficient as possible and not to take over complete care. The child may well outlive them and will some day need to be able to function as independently as possible.

With autonomic nervous system dysfunction, a child is unable to sweat and becomes hyperthermic if covered too warmly; if not covered warmly enough, the capillaries dilate, and the child loses considerable heat into the environment. If the room temperature cools at night, be careful to dress the child appropriately for sleeping.

Specific measures for bowel evacuation may be necessary, depending on the level of the injury. A bowel program incorporating the use of stool softeners, suppositories, and bowel retraining may be required. The child and parents need support and instructions in accomplishing this task and gaining independence.

For some children and parents, the first day of using a wheelchair is exciting (proof that the child can be partially ambulatory). For others, it is the day on which they must face the reality that they cannot undo the results of the accident and are faced with a lifelong disability. For some parents who have almost overcome their grief and accepted their child's disability, the introduction of a symbol of disability such as a wheelchair or long-leg braces may bring new grieving and a sense of loss.

When the child reaches sexual maturity, limitations in this area may become apparent. If a male has had an upper motor neuron injury, he will not be able to achieve spontaneous erection or ejaculation. However, with manual stimulation of the penis (stimulation of lower motor neuron function), he may be able to achieve an erection and engage in coitus. Ejaculation and fertility remain limited. At the time of injury, lack of lower extremity motor control may seem to be the greatest loss. In adolescence, loss of normal sexual function may become even more disturbing. With most spinal cord injuries, a female is not able to experience orgasm but is able to conceive and bear children.

The limitations caused by a spinal cord injury become especially evident to the child (and the parents) when choosing a vocation and selecting an appropriate school program (children cannot be denied normal schooling by federal law in the United States, even with a severe physical disability).

Counseling and rehabilitation are crucial aspects to achieve an optimal level of functioning and independence.

Nursing Diagnosis: Risk for impaired gas exchange related to spinal cord injury

Outcome Evaluation: Respiratory rate is within acceptable parameters; lungs are clear; airway is patent.

If the cervical level of the cord is involved, a child will need ventilatory assistance. The child may be intubated at first, but orotracheal or nasotracheal intubation is only a temporary measure to maintain a patent airway. A tracheostomy may be done for long-term airway management and to prevent sloughing of pharyngeal tissue from the pressure of the intubation tube. If this is required, parents need instruction about caring for the tracheostomy and working with a mechanical ventilator. A phrenic nerve pacemaker may be used to stimulate the diaphragm to contract and initiate respirations. If the child has a thoracic level injury (which is rare because the rib cage gives extra strength to thoracic vertebrae), the child will be able to breathe independently but will have reduced vital capacity. Periodic positive-pressure breathing treatments may be necessary to encourage increased lung filling. Be careful when positioning a child not to compromise chest movement with equipment or other restricting objects. Other respiratory care measures, such as suctioning and chest physiotherapy, are also important.

Nursing Diagnosis: Risk for impaired skin integrity related to immobility

Outcome Evaluation: Child's skin remains clean, dry, and intact without signs of erythema or ulceration.

To prevent skin breakdown, a child should be turned about every 2 hours (always be sure to log-roll or maintain immobilization with a striker frame or a continuously moving, automatically controlled bed). The

use of an alternating-pressure mattress may be helpful. With loss of sensation in body parts, the child is unable to report skin irritation from a wrinkled sheet or wet clothing. If the child is incontinent, the bedding must be changed immediately to prevent skin breakdown. Once children begin to be ambulatory, their legs and buttocks should be checked regularly to prevent pressure ulcers caused by sitting in a wheelchair or using leg braces.

Nursing Diagnosis: Risk for impaired urinary elimination related to spinal cord injury

Outcome Evaluation: Child's urine output is adequate for intake; child identifies measures to assist with voiding; child demonstrates procedure for self-catheterization.

To prevent urinary retention during the first phase of recovery, a Foley catheter is inserted, or the bladder can be emptied by periodic suprapubic aspiration or intermittent catheterization. Second-stage spasticity causes periodic reflex emptying. This rarely empties the bladder completely, however, so the same problems of stasis and infection continue. To live independently, the child will need to learn self-catheterization to empty the bladder (see Chapter 46).

Nursing Diagnosis: Anticipatory grieving related to loss of function secondary to spinal cord injury

Outcome Evaluation: Child and parents openly discuss their feelings about the injury and its effect on their lives.

The second recovery phase is the time for parents and children to begin thinking about what this degree of disability will mean to them and to face its full extent. Children and parents typically react to the initial diagnosis with grief. They may still be in denial or shock when the second phase begins. With no sudden miracle cure in sight, they may begin to move through stages of anger, bargaining, depression, and then acceptance (the accident happened; we must go on from this point). They need assistance and support to work through these feelings. Both the parents and the child may need counseling to reach acceptance. Incorporation of a rehabilitation program can help in maximizing the child's potential despite the limitations imposed by the injury (Fig. 49.15).

FIGURE 49.15 A 6-year-old girl with a cervical spine injury adapts to her disability by using her mouth to hold a paintbrush and participate in age-appropriate activities. (© Elisa Peterson/Stock Boston.)

✔ Checkpoint Question 49.5

Spinal cord injuries usually occur from accidental injuries. Which is the most common type of injury seen in adolescents that leads to spinal cord injury?

a. Cervical fracture from a diving accident.
b. Sacral fracture from a bicycle accident.
c. Thoracic fracture from a bullet injury.
d. Thoracic/sacral injury from lifting weights.

Key Points for Review

- Nerve cells are unique in that they do not regenerate if damaged. This makes neurologic disease a long-term type of illness. Parents and children alike need support from health care providers to cope with problems that continue to occur over a long period.
- Increased intracranial pressure arises from an increase in the volume of cerebrospinal fluid or from blood accumulation, cerebral edema, or space-occupying lesions. Neurologic changes, such as increased temperature and blood pressure and decreased pulse and respirations, that occur with increased intracranial pressure are subtle. Always compare assessments with previous levels to detect that a consistent, although minor, change is occurring.
- Cerebral palsy is a nonprogressive disorder of upper motor neurons. The exact cause is usually unknown, but the condition is associated with anoxia occurring before, during, or shortly after birth. Four major types are identified: spastic (excessive tone in the voluntary muscles), dyskinetic or athetoid (abnormal involuntary movement), atonic (decreased muscle tone), and mixed (symptoms of both spasticity and athetoid movements).
- Meningitis is infection of the cerebral meninges. It is caused most frequently by bacterial invasion. Children need follow-up afterward to monitor for hearing acuity and impaired secretion of antidiuretic hormone.
- Encephalitis is inflammation of brain tissue. This is always a serious diagnosis, because the child may be left with residual neurologic damage, such as seizures or learning disabilities.
- Reye's syndrome is acute encephalitis with accompanying fatty infiltration of the liver, heart, and lungs; it is associated with the administration of acetylsalicylic acid (aspirin) to children with a viral infection. Its incidence is declining.
- Guillain-Barré syndrome is inflammation of motor and sensory nerves. The reaction may be immune mediated, occurring after an upper respiratory tract illness. Temporary demyelinization of the nerve sheaths causes loss of function.
- Botulism occurs when spores of *C. botulinum* produce toxins in the intestine. Because honey and corn syrup can be sources of the organism, they should not be given to infants.

- Recurrent seizures are involuntary contractions of muscle caused by abnormal electrical brain discharges. Common types seen in children include febrile seizures, infantile spasms, partial (focal) seizures, absence seizures, and tonic–clonic seizures. Therapy is administration of anticonvulsant drugs.
- Spinal cord injury is occurring at increased rates in children involved in sports and motor vehicle accidents. Children pass through a first, second, and third recovery phase after the injury.

CRITICAL THINKING EXERCISES

1. Tasha is the 2-year-old girl you met at the beginning of the chapter, who was diagnosed with bacterial meningitis after a febrile seizure. Her parent is concerned about long-term problems because of the seizure. Would you encourage her to concentrate on this or on more short-term concerns?
2. Tasha is diagnosed with bacterial meningitis. She has severe neck pain when she is moved. Her mother asks you not to worry so much about measuring intake and output, so her daughter can rest. How would you answer her? Suppose you call the child's name and she does not answer you? Why is this a particular cause of concern in a child with meningitis?
4. A spinal cord injury can cause severe disability in adolescents. If you were designing a program to teach measures to prevent spinal cord injury, what topics would you include in your presentation?
5. Examine the National Health Goals related to neurologic disorders in children. Most government-sponsored funds for nursing research are allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to Tasha's family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to neurologic disorders in children. Confirm your answers are correct by reading the rationales.

Chapter

50 Nursing Care of a Family When a Child Has a Vision or Hearing Disorder

KEY TERMS

- accommodation
- amblyopia
- astigmatism
- diplopia
- enucleation
- fovea centralis
- goniotomy
- hyperopia
- light refraction
- myopia
- nystagmus
- orthoptics
- photophobia
- ptosis
- stereopsis
- strabismus
- tympanocentesis

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe the structure and function of the eyes and ears and disorders of these organs as they affect children.
2. Identify National Health Goals related to vision and hearing disorders of children that nurses could help the nation achieve.
3. Use critical thinking to analyze ways that nursing care of children with a disorder of vision or hearing could be more family centered.
4. Assess a child who has a disorder of vision or hearing.
5. Formulate nursing diagnoses related to a child with a disorder of vision or hearing.
6. Establish expected outcomes for a child with a disorder of vision or hearing.
7. Plan nursing interventions for a child with a disorder of vision or hearing.
8. Implement nursing care to meet the specific needs of a child who has a disorder of the eyes or ears such as educating parents about the symptoms of otitis media.
9. Evaluate expected outcomes for achievement and effectiveness of care.
10. Identify areas related to care of children with vision or hearing disorders that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of childhood disorders of the eyes or ears with the nursing process to achieve quality maternal and child health nursing care.

Carla Vander, a 4-year-old child, is brought to a pediatric clinic for evaluation. Her mother states, “She’s always had a lot of problems. She had strabismus as a baby. Now, I think she has another ear infection. It started out as a head cold but now she’s pulling at her ear. Why does she get so many of these?”

Previous chapters discussed the growth and development of well children. This chapter adds information about the changes, physical and psychosocial, that occur when a child develops a disorder of the eyes (vision) or ears (hearing). This is important information because it builds a base for care and health teaching.

How would you answer Ms. Vander? What information does she need to know about ear infections?

Any interference with vision or hearing poses a threat to normal growth and development, because so much of what and how a child learns about the world is achieved through these sensory organs. Infants first learn how to interact with others by watching their parents' faces. They learn to speak by listening to words spoken to them. They continue to depend on sensory input for stimulation and to protect their safety throughout life (Schindler, 2009).

Eye and ear disorders may be transitory. However, they always have the potential for becoming long-term illnesses if they permanently affect vision and hearing. This is an area, therefore, in which health promotion, illness prevention, and health rehabilitation are all important aspects of nursing care. Because of the importance of vision and hearing, National Health Goals have been established in relation to them (Box 50.1).

BOX 50.1 * Focus on National Health Goals

Adequate vision and hearing ability are necessary for normal growth and development. Five National Health Goals address these areas:

- Reduce the rate of otitis media in children and adolescents from a baseline of 344 health care visits yearly per 1000 children to 294 visits yearly.
- Reduce the prevalence of blindness and vision disorders in children and adolescents aged 17 years and under from a baseline of 24 per 1000 to 18 per 1000 children.
- Increase the proportion of newborns who are screened for hearing loss by age 1 month, have audiologic evaluation by age 3 months, and are enrolled in appropriate intervention services by age 6 months from 66% to 90%.
- Reduce the proportion of adolescents who have elevated hearing thresholds, or audiometric notches, in high frequencies (3, 4, or 6 kHz) in both ears, signifying noise-induced hearing loss from a baseline of 46.4 per 1000 adolescents to a target of 34.7 per 1000.
- Increase the proportion of preschool children who receive vision screening from 36% to 52% (http://www.nih.gov).

Nurses can help the nation achieve these goals by screening for vision and hearing at all well-child assessments, paying particular attention to those children who had low birth weight, were cared for in neonatal intensive care units, or were excessively exposed to loud noises such as loud music. Nursing research questions that might yield helpful information include the following: Can infants who are prone to hearing and vision disorders be better identified before discharge from a neonatal intensive care unit? What are effective techniques for teaching adolescents to avoid excessive sound levels, such as those associated with loud music? What are effective ways to teach school-age children to avoid eye injury?

Nursing Process Overview

For Care of a Child With a Vision or Hearing Disorder

Assessment

All newborns should be assessed for their ability to focus on or see an examiner's face and to follow an object from the periphery to the midline. Observe an infant closely to ensure that the newborn's interest is evoked by sight, not by sound. Newborn vision can be further tested by optokinetic nystagmus testing (the infant is shown alternating black and white stripes), visual-evoked potential testing (similar, but checkerboard-appearing pictures are shown), and forced-choice preferential looking testing (the infant is shown a pattern and a plain picture; the seeing child focuses on the pattern).

Assessing newborn infants for hearing loss is an equally important part of newborn care. Newborns should quiet to the sound of a soothing voice (for this, you need to stay out of sight so you are certain the infant is not quieting at the sight of your face). Most hospitals further routinely test newborn hearing with an audible sound before newborns are discharged from the facility.

Throughout childhood, children should be assessed by history for vision problems and hearing loss: Is a parent or teacher concerned about vision? Does a parent worry that the child may not be hearing well? Is the child having any difficulty in school? Vision should also be assessed by inspection: Do the child's eyes follow a moving light into all six fields of vision? Is a red reflex present? Do the child's eyes appear to be in straight alignment? Hearing acuity should be checked periodically at well-child visits. In addition, children also should be assessed for their ability to speak clearly and appropriately for their age, because language development is influenced by hearing. Because hearing and vision assessment are part of routine physical exams, the techniques of these are discussed in Chapter 34.

Nursing Diagnosis

Teaching health promotion measures to safeguard vision and hearing is one of the most important roles in nursing. Examples of nursing diagnoses in this area are:

- Health-seeking behaviors related to prevention of trauma to eyes or ears
- Deficient knowledge related to importance of early diagnosis and treatment of eye infection

Nursing diagnoses for a child with a vision or hearing disorder should focus on the child's and the parents' responses to the loss of sight or hearing, not on the deficit itself (Carpenito, 2007). Such nursing diagnoses include:

- Self-care deficit related to impaired visual acuity
- Risk for injury related to hearing loss
- Risk for situational low self-esteem related to long-term vision deficit
- Impaired verbal communication related to congenital hearing deficit
- Social isolation related to effects of hearing loss
- Dysfunctional grieving related to child's loss of sight
- Readiness for enhanced family coping related to child's traumatic injury and subsequent loss of vision in one eye

Outcome Identification and Planning

Be certain that expected outcomes established are realistic and address areas in which treatment can have some impact. By listening attentively to parents' concerns and providing useful anticipatory guidance, you can help to increase a child's ability to function effectively. Because many eye and ear disorders cause pain, helping parents reduce pain is a major nursing responsibility. Expected outcomes should address preventive aspects of care in all areas of daily living.

When parents learn that a child has a vision or hearing disorder, they usually need help in planning for schooling and activities such as toilet training and self-care. Discuss with them the importance of talking to and touching their infant and the importance of teaching their child how to communicate and learn about the world through touch as well as through other functioning senses.

Children with sensory disorders benefit from very early preschool education programs. This exposes them to interesting and stimulating tasks while their initiative is strongest, allowing them to accomplish learning tasks despite their sensory disorder. It may be difficult for parents to relinquish their children to such programs during the day, especially at an early age. It takes careful planning to enable parents to accept this separation.

Parents of children with hearing disorders may need to be encouraged to talk to their children, even in infancy. Although the infant may not be able to hear what the parents are saying, observing the facial expressions and spontaneous body movements that accompany verbal speech helps a child learn important aspects of communication. For example, although an older child may not be able to hear her mother say, "I'm so proud of you," the child can see the positive reaction displayed on her mother's face.

Referrals to organizations that can provide information and support to parents of children with vision or hearing impairment can be particularly useful, especially if the impairment will be long term. Some of the organizations concerned with sensory impairment are Alexander Graham Bell Association for the Deaf and Hard of Hearing (http://www.agbell.org), American Foundation for the Blind (http://www.afb.org), American Speech-Language-Hearing Association (http://www.asha.org), National Association for Visually Handicapped (http://www.navh.org), National Federation of the Blind, Deaf-Blind Division (http://www.nfb-db.org), Recording for the Blind and Dyslexic (http://www.rfbd.org), and National Association of the Deaf (http://www.nad.org).

Implementation

A disorder of the eyes or ears can range from an acute, one-time illness to a chronic and developmentally debilitating condition if steps are not taken to treat the initial problem quickly and completely. However, even the most rigorous preventive care and attention cannot avert the occurrence of some serious disorders affecting vision and hearing. Nursing care must then focus on helping the child and parents adjust to the condition, ensuring that the child receives the stimulation needed to grow and develop on a normal continuum.

Nursing interventions for a child with a disorder of the eyes or ears range from providing anticipatory guidance and teaching children and parents measures to promote eye and ear health to preparing a child for surgery. Nursing interventions also include helping a child and parents adjust to aids that are used to improve hearing, speech, or sight.

Outcome Evaluation

Continuing follow-up with hearing and vision concerns is essential so self-esteem can be evaluated. Do children think of themselves as well or ill? As people able to do things or as helpless? Plans to promote self-esteem may have to be devised. Some parents may require help with their own feelings of worth (feeling inferior to other parents is common among parents of children with disabilities). They may need help in letting go as their children begin school. The growth of parents in allowing their child to be independent is just as important to evaluate as the child's own progress toward independence.

Examples of expected outcomes are:

- Parent states that she understands antibiotics are no longer prescribed for simple otitis media.
- Parents state concrete plans for enrolling child in preschool program.
- Child wears corrective lenses for major portion of each day.
- Child with hearing disorder communicates effectively with health care providers by lip reading or writing out needs.

HEALTH PROMOTION AND RISK MANAGEMENT

All newborns should be screened for hearing in the first few days of life (U.S. Preventive Services Task Force, 2008). Vision can be assessed in these early days by eliciting a blink reflex and the ability to follow a moving object. Such tests give reassurance to worried parents that their child's vision and hearing is adequate or set the stage for early interventions if their child is visually or hearing challenged (Box 50.2).

From preschool through adolescence, children should continue to be screened routinely for vision and hearing problems, so that these problems can be detected and management begun as early in life as possible (Zaba et al., 2007) (Box 50.3). A history and physical examination performed at each health maintenance visit can provide important clues to possible problems and need for further evaluation. Pay special attention to any questions or concerns voiced by the parents at these visits, because children's needs change as they grow (Sweetow, Henderson, & Sabes, 2008). As a child grows older and attends school, often the school nurse assumes a major responsibility for vision and hearing testing. General guidelines for evaluation are listed in Table 50.1.

Providing anticipatory guidance to parents about safety measures to prevent accidental injury is another major nursing responsibility. Box 50.4 summarizes safety measures for preventing eye injuries and hearing loss in children.

If a child has a vision or hearing impairment, safety measures take on even greater importance. Assist the parents with

BOX 50.2 ✻ Focus on Evidence-Based Practice

Do parents who receive false-positive results on newborn hearing exams continue to worry about their child's hearing?

Because amniotic fluid must drain from the ear canal of newborns before hearing becomes optimal, some newborns will be reported as not hearing well (a false-positive result) on a newborn screening hearing exam. To determine if this results in long-lasting concern, 154 parents whose child tested positive or inconclusive in at least one of three newborn tests but afterward proved not to have hearing impairment and 288 parents whose child passed the first test filled out a questionnaire designed to measure their anxiety level 6 months after the screening test. Results revealed that 4% of parents whose newborns passed a test the first time, 10% of parents whose children were tested twice, and 15% of parents whose children were tested three times were worried about their child's hearing. The researchers concluded that false-positive test results do not cause long-term parental anxiety, but 6 months after screening, a considerable proportion of parents continue to experience hearing-specific worries regarding their child.

Based on the above study, would it be unusual for a father to ask you to retest his son's hearing at a 6-month health care visit?

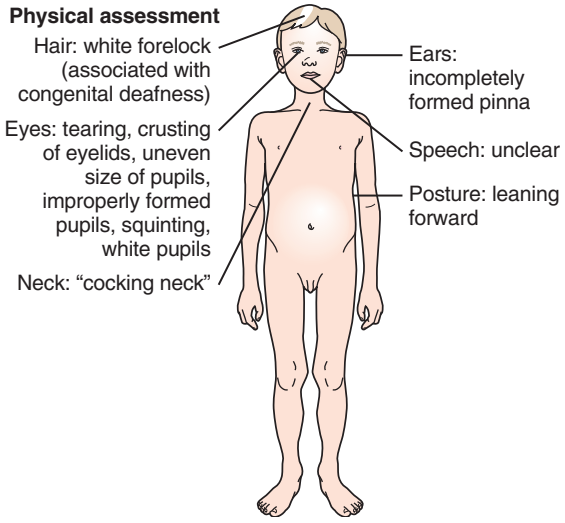
Box 50.3 Assessment
Assessing a Child for Vision or Hearing Disorders

History

Chief concern: Are symptoms of vision or hearing difficulty present—blurriness of vision, squinting, turning head, leaning toward speaker, ignoring instructions?
Past health history: Has child had any exposure to loud noises? Eye trauma? Ear infection?
Family medical history: Do any family members have a hearing disorder? What is the vision level of parents?

Physical assessment



measures to adapt the child's environment to meet safety needs while promoting growth and development and independence as much as possible. Supplement verbal explanations with tactile and visual aids as appropriate, and allow the child to use drawings, writing, or gestures to respond and communicate. Encourage the use of specialized devices, such as a talking picture board or e-mail, if the child is hearing challenged with limited speech. Assess whether parents are interested in investigating cochlear implants for a hearing-challenged child. Provide ample time for interaction, and incorporate the use of therapeutic play. Children with vision or hearing disorders need to attend regular classrooms in school, if possible, so that they can have contact with seeing and hearing children to promote normal growth and development. School nurses or preschool nurse consultants need to advocate for such placements. In addition to safety measures,

TABLE 50.1 ✻ Assessment Parameters for Vision and Hearing Screening

Age	Vision Assessment Parameters	Hearing Assessment Parameters
Infant	Ability to follow objects Corneal reflex Ability to turn to light stimuli	Startle reflex (at birth) Ability to track sounds (3–6 months) Ability to recognize sounds (6–8 months) Ability to locate sounds (8–12 months)
Toddler	Corneal light reflex Cover test Smooth ocular movements Hand–eye coordination	Ability to react to soft sounds (whispers) Ability to track source of sounds Ability to form a noun–verb sentence by 2 years Ability to follow simple directions Awareness of pitch and tone
Preschooler	Corneal light reflex Cover test Snellen E chart (or modification)	Pure tone audiometry (starting at age 4 years) Understandable language with increasing vocabulary
School age	Visual acuity testing every 1–2 years	Pure tone audiometry at ages 6, 8, and 11 years
Adolescent	Visual acuity testing every 1–2 years	Pure tone audiometry at ages 14 and 18 years

BOX 50.4 ✻ Focus on Family Teaching

Protecting Vision and Hearing

Q. Carla's mother says to you, "What can we do to protect our children from having problems with their eyes and ears?"

A. Here are some helpful tips to protect your children's vision and hearing:

To protect vision:

- Place infants and small children in a car seat (for older children, use a seat belt) when in a car to keep them from hitting the dashboard or front seat in case of an accident.
- Do not allow infants to hold sharp objects. If an infant is holding such an object in his hand, there is the danger that the object could strike his eye as he brings his fist to his mouth to suck his thumb.
- Do not allow toddlers to carry sharp objects such as lollipop sticks in their hands while walking. They fall readily because of their unsteady gait.
- Do not allow older children to run with sharp objects in their hands, because they can fall while running and puncture an eye.
- Caution older children to use eye-protection measures, such as goggles, when working with projects, such as soldering metal, in school.
- Encourage the use of face masks for hockey players.
- Teach children not to place any medication in their eyes that is not prescribed by a health care provider; do not use outdated eye medication, because it may become contaminated with bacteria or may change in composition with time.
- Caution children that chemicals can cause burns to the eye; alert them to the emergency shower installations in science rooms that are used to wash away any spilled chemical from their eyes. Chemical burns may be worse in children who have contact lenses in place, because chemicals can flow under the lens and remain in contact with the cornea longer.
- Teach children not to wear contact lenses for longer intervals than recommended by the manufacturer, to prevent drying and lack of oxygen supply to the cornea.

To prevent hearing loss:

- Teach children to avoid chronic exposure to loud noises, such as can occur with radios and earphones.
- Secure prompt treatment for pharyngitis (fever and sore throat), because this condition can lead to otitis media (middle ear infection).
- Caution children not to put anything in their ear canals, because they could puncture their eardrums.
- Be certain children's immunizations are up to date, because illnesses such as parotitis (mumps) or bacterial meningitis can lead to hearing loss.

parents may need instruction about measures to prevent eye and ear infections, so that they do not lead to long-term problems. Mild vitamin A deficiency, for example, leads to loss of night vision, and severe vitamin A deficiency that could occur from an adolescent eating disorder can lead to blindness (keratomalacia) (Cooney, Johnson, & Elner, 2007).

VISION

Vision occurs because light rays reflect from an object through the corneas, aqueous humors, lenses, and vitreous humors to the retinas (Fig. 50.1). If any of these structures have defects, light rays may not be able to reach the retinas or focus correctly there, resulting in a vision disturbance. The retinas are studded with *rods*, which are instrumental for night vision and movement in the visual field, and *cones*, which register daylight and color vision. Rods and cones join in a major network to register at the optic nerve. The **fovea centralis** (the center of the macula) is an area of closely packed cones on the retinas where color is best perceived.

Each eye globe must develop good central and peripheral vision. However, in addition, *fusion* must occur—that is, both eyes together must interpret a visual image as one image, fusing visual perception into a single image. This is called *single binocular vision.* Infants with poor eye alignment

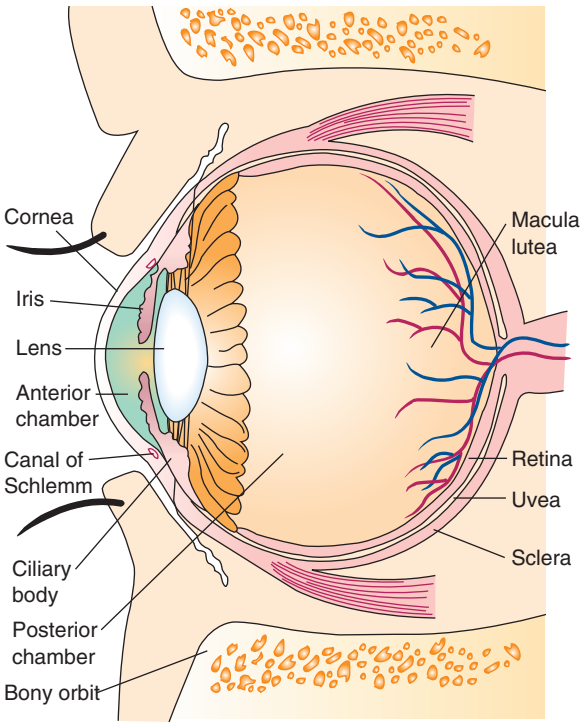


FIGURE 50.1 Anatomy of the eye.

cannot establish single binocular vision but have **diplopia,** or double vision.

Stereopsis

Stereopsis is depth perception, or the ability to locate an object in space relative to other objects. The right eye sees more of the right side of an object, whereas the left eye sees more of the left side. This makes the object appear to be three-dimensional. Children with vision loss in one eye do not develop stereopsis and, consequently, tend to reach farther than or closer than the actual distance to an object when attempting to grasp it. They have difficulty learning to ride a bicycle and have great difficulty driving a car safely. Children without stereopsis do not realize that their sight is different from that of other people. The *Stereo-Fly* or random dot test, a simple test for depth perception, is a specially constructed picture of a large fly made of colored dots. When asked to touch the fly's wings, a child with good depth perception touches them accurately. A child with poor depth perception touches a spot 2 or 3 inches above the pattern.

Accommodation

Accommodation is the adjustment the eye makes when focusing on a close image. To focus on a close object, the ciliary bodies of the eye contract, changing the curvature of the lens. The action of the ciliary body allows accommodation but also causes the eye to converge (look medially) and the pupil to constrict. To test accommodation, ask a child to follow a penlight as it moves in toward the nose. Children should be able to do this by 6 months of age. Actually, convergence is what is demonstrated with this test, but because convergence does not occur without accommodation, the test indirectly measures accommodation. Children who cannot accommodate have double vision (diplopia), are unable to focus on objects near their eyes, and have difficulty reading.

DISORDERS THAT INTERFERE WITH VISION

Eye disorders in children are always potentially serious because if permanent vision impairment occurs, a child's functioning at many everyday tasks can be severely compromised.

Refractive Errors

The largest category of vision defects in children is refractive errors (Heidary & Kazlas, 2008). **Light refraction** refers to the manner in which light is bent as it passes through the lens. Normally, this bending causes a ray of light to fall directly on the retina (Fig. 50.2A). Because the depth of the eye globe in infants and children increases with age, the light rays do not always focus onto the retina accurately as the child grows older, but at a point behind the retina. This results in **hyperopia** (farsightedness), in which vision is blurry at a close range and clear at a far range. The normal hyperopia of a preschooler needs no correction. It is important to keep this in mind when performing vision screening with children of this age. At about 5 years of age, as a result of developmental changes, hyperopia begins to diminish. Some children, however, remain hyperopic. Focusing on close objects requires such strong accommodation that these children often have

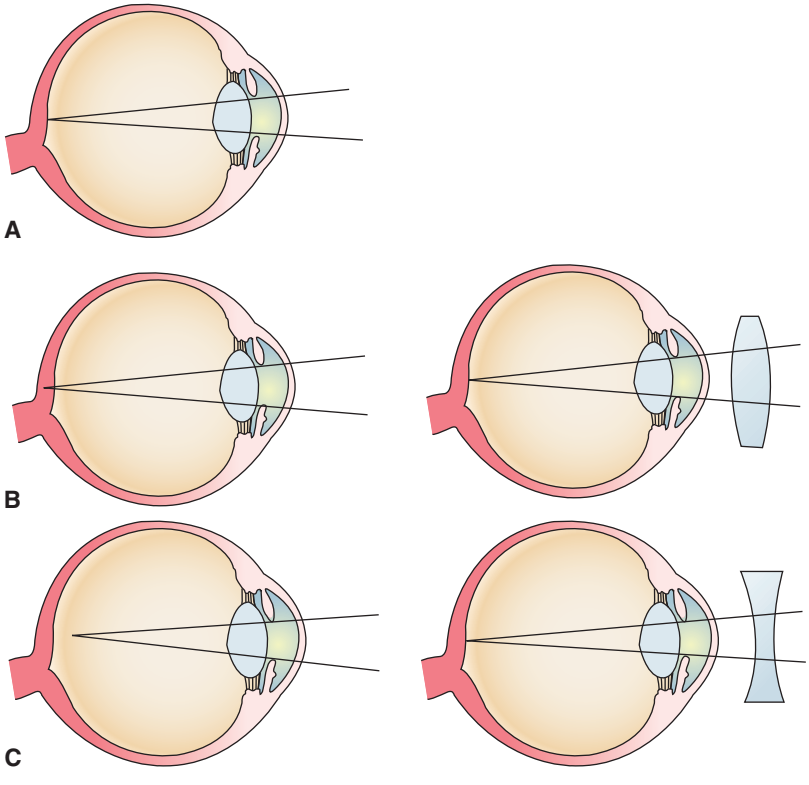

FIGURE 50.2 Corrective lenses for refractive errors of vision. (**A**) Normal vision. (**B**) Convex lens for hyperopia (farsightedness). (**C**) Concave lens for myopia (nearsightedness).

headaches or dizziness after completing schoolwork. A finding of hyperopia in a school-age child is cause for referral so that the child can get a prescription for glasses with a convex lens.

Approximately 10% of school-age children have eye changes that result in **myopia** (nearsightedness), meaning that the light rays focus at a point in front of the retina (Beyer & Pavan-Langston, 2008). These children can read a book or a computer screen immediately in front of them but are unable to read the blackboard clearly in a classroom. They have difficulty reading signs across the street or playing baseball. Once myopia begins, it often progresses into the teen years, when it plateaus and remains for life. Children with myopia need corrective (concave) lenses to enable them to see at a distance.

Myopia tends to be familial. If both parents are myopic, their children should be screened yearly during the early school years. Children with myopia try to focus on objects by squinting and rubbing their eyes, which changes the shape of the eye globe. Any child who reports difficulty seeing or who shows mannerisms suggestive of refraction errors—rubbing the eyes, tearing, red-rimmed eyes, blinking, squinting, or pressing on the eyes—should be screened for visual difficulty.

In the past, the only correction for refractive errors of vision was by eyeglasses or contact lenses (Fig. 50.2B,C). Today, adolescents can have laser surgery (LASIK) to permanently change the contour of the cornea and correct refractive vision errors.

Although wearing glasses is more acceptable today, children still may encounter name calling if they wear these. If these are needed, however, encourage them to give glasses a fair try. In most instances, glasses improve vision to such an extent that after trying them children will continue to wear them. However, throughout their development, they may need continued encouragement to keep wearing glasses until they are old enough for contact lenses or surgical correction.

If parents are going to purchase eyeglasses, advise them to choose frames fitted with plastic or safety glass (shatterproof) lenses so that, if the lenses accidentally break, the child's eyes will not be injured. It is possible for contact lenses to be fitted for even young infants. Children as young as 5 years of age are capable of putting them in and taking them out if taught properly. Contact lenses are a big responsibility, however; they require conscientious cleaning or changing to prevent eye irritation or infection. Children are usually about 12 years of age before they can be relied on to take appropriate care of contact lenses totally independently.

Laser in Situ Keratomileusis (LASIK)

Laser in situ keratomileusis (LASIK) is laser surgery for correction of myopia (Azar, 2008). It involves making an incision under the cornea to change the contour of the eye globe so that light rays fall more accurately on the retina. Postoperatively, children frequently have disturbed tear function for 1 or more months and need to be managed with artificial tears or ointments to prevent surface damage. Because having the procedure carried out before the child's eye globe has reached its adult size would require that the surgery be repeated with maturity, the youngest age at which LASIK therapy is appropriate is controversial. The technique is a major method of correcting refractive vision errors in adults and in the future is expected to also be applicable to children.

Astigmatism

Astigmatism is congenital or acquired unevenness of the curvature of the cornea (Sands & Drack, 2008). This causes light rays coming to the retina to not be all refracted in the same way; the result is an uneven quality of vision. When children with astigmatism look at the letter T, for example, they may see the crossbar but not the letter stem. If they focus on the stem, they cannot see the crossbar. On any given page of print, therefore, they may see only half the letters. For this reason, they can have difficulty reading or following written instructions. They may report headache and vertigo after doing close work. Their vision may appear deceptively normal on vision screening tests because they are able to see all of the numbers on a chart by tilting their head. These children need to be referred to an ophthalmologist, however, on the basis of their other problems such as vertigo, headaches, and difficulty with reading. Corrective lenses for close work relieve the symptoms and restore functional vision. Contact lenses may be even more helpful, because they actually smooth out the curvature of the cornea.

Nystagmus

Nystagmus is rapid, irregular eye movement, either vertically or horizontally. It is not a disease in itself but rather a symptom of an underlying disease condition. It is seen in children with vision-impairing lesions such as congenital cataracts. It also occurs as a neurologic sign if there is a lesion of the cerebellum or brainstem. Children with nystagmus must be referred to a physician so that the underlying cause of the symptom can be determined.

Amblyopia

Amblyopia is "lazy eye," or subnormal vision in one eye; the child may be using only one eye for vision while "resting" the other eye. If this process continues too long, central vision fails to develop (or the central vision that had developed fades), and the child becomes functionally blind in one eye. This can occur in children who have a refractive error in one eye that is significantly different from that of the other eye or in children with astigmatism. Because one eye focuses more readily than the other, they come to depend on only the easily focused eye (Harvey et al., 2007).

Amblyopia can also develop from strabismus (crossed eyes). With strabismus, one eye looks straight ahead while the other eye "wanders." Children who have an eye that wanders are constantly looking at two separate images rather than one fused image. To make sense out of what they see, they suppress one visual image; this leads to suppression of central vision in that eye, or amblyopia. The same phenomenon occurs if the vision in one eye is obscured by a lid that does not open fully (ptosis).

Assessment

All preschool children should be screened for amblyopia by vision testing with a preschool E chart at routine health visits (see Chapter 34). A child with amblyopia has 20/50 vision (normal for preschool age) in one eye, and the other eye shows lessened vision (perhaps 20/100).

Therapeutic Management

Amblyopia is correctable if treated during the preschool period. Although there are reports of success with older children and adolescents, the prognosis for correction is considerably diminished after 6 years of age. It may not be possible after 9 or 10 years of age (Heidary & Kazlas, 2008). For treatment, the good eye is covered by a patch held firmly in place. This forces the child to use the poor eye, thus developing vision in that eye. Usually, children have some difficulty initially adjusting to a patch; being unable to see well from the unpatched eye, they may develop headaches or dizziness and notice poor depth perception. Only constant attempts to see with the weaker eye, however, will improve binocular vision. The patch is removed for 1 hour each day to prevent amblyopia from developing in the nonamblyopic eye. Administration of levodopa in addition to occlusion therapy may also be prescribed as this almost immediately improves vision in the poorer eye. Atropine, which causes pupil dilation and blurred vision when dropped into the better eye, may be yet another solution.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Deficient knowledge deficit related to need for consistent wearing of patch

Outcome Evaluation: Parents state that the reason their child must wear a patch over the functioning eye is to improve vision in the poorly functioning eye. Child wears patch over functioning eye for all but 1 hour per day.

Children with an eye patch in place may have more difficulty with motor coordination than others so need careful supervision with activities such as bicycle riding or crossing a street safely (Engel-Yeger, 2008).

Parents need support to be firm with their child about keeping the patch in place. A child may beg to remove the patch for special occasions, such as a birthday party or a family wedding, or just for an hour, because the child finds the patch embarrassing and uncomfortable. Soon, however, the "special occasions" become so frequent that a child is wearing the patch only half the time. Remind parents how important it is to adhere to occlusion therapy so that their child will achieve good vision. If amblyopia occurs secondary to another disorder (strabismus, ptosis, or refraction error), the primary problem also needs to be corrected. Otherwise, the amblyopia will recur after the patching is completed.

✔ Checkpoint Question 50.1

What if Carla had amblyopia? What is a common assessment for amblyopia?

a. Doing a cover test.
b. Assessing for a red reflex.
c. Preschool E chart testing.
d. Palpation for tenseness.

Color Vision Deficit (Color Blindness)

Color deficit is the inability to perceive color correctly. It occurs because one of the sets of cones of the retina that perceive red, green, or blue is absent. It is inherited as a sex-linked disorder and occurs in about 8% of boys. There is a high incidence of color vision deficit in children with hemophilia, congenital nystagmus, or glucose-6-phosphate dehydrogenase deficiency. It may be associated with exposure to occupational solvents during pregnancy (Paallysaho et al., 2007).

The vision problem may involve the inability to distinguish red from green or blue from yellow. A small proportion of children are unable to see any colors. Color plates or discs can be used to detect color deficit in children as young as preschool age. Children with normal vision see numbers or patterns on these plates, whereas children with a color vision deficit see only a jumble of dots or unclear images.

There is no therapy for color vision deficit, but the condition should be detected early so the child is not asked to complete color identification assignments in school and can be educated about traffic signals and other color-dependent signs necessary for safety.

Some children associate color blindness with total "blindness" and fear that they will eventually lose their eyesight. Reassure them that, although color blindness means that they have a loss of color discrimination, their loss is limited to that one area.

STRUCTURAL PROBLEMS OF THE EYE

Structural problems of the eye tend to be congenital or present at birth.

Coloboma

A *coloboma* is the congenital incomplete closure of the facial cleft. The incomplete closure may involve only the lower eyelid (there is a notch in the lid); it may involve the iris, giving it the shape of a keyhole, rather than a circle (Fig. 50.3). It may involve the ciliary body, the lens, the choroid, the retina, and the optic nerve. Children with any degree of coloboma should be referred to an ophthalmologist for further investi-

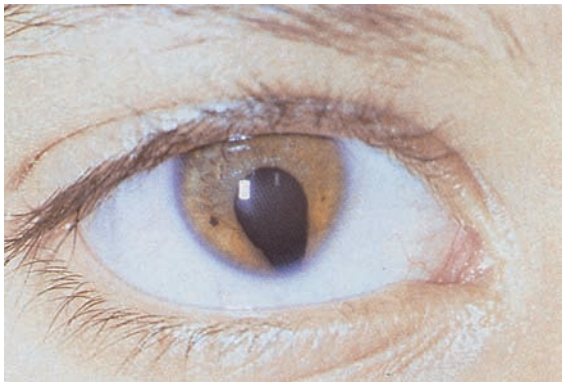

FIGURE 50.3 Coloboma involving the iris, showing a "keyhole" appearance. (From Tasman, W., & Jaeger, E. A. [1996], *Willis Eye Hospital atlas of clinical ophthalmology.* Philadelphia: Lippincott-Raven Publishers.)

gation to determine the extent of the condition. Children with retina and optic nerve coloboma will have some vision impairment in the affected eye.

Hypertelorism

Hypertelorism is a congenital condition involving abnormally wide-spaced eyes. Children with wide epicanthal folds by the inner canthus may appear to have wide-spaced eyes, but, when the distance between the pupils is measured and compared with standards for the child's age, the true condition is revealed. Detecting true hypertelorism in children is important, because this condition is associated with chromosomal abnormalities, most notably Waardenburg's syndrome, which also involves congenital hearing impairment. Children with this syndrome also have a white forelock of hair, different-colored irises, and eyebrows that tend to grow together in the center line. These signs may not be noticeable in newborns. Therefore, wide-spaced eyes, because of a broad-bridged nose, are the chief clue in a newborn that the child can hear no sound and will need close follow-up to determine whether cochlear implants or hearing aids can provide ability to hear.

Ptosis

Ptosis is the inability to raise the upper eyelid normally so the eyelid always remains slightly closed. The condition may be congenital (frequently hereditary and bilateral) or acquired (usually unilateral). It may be a result of injury to the third cranial nerve (neurogenic) or to the lid or levator muscle. Usually, with injury to the third cranial nerve, paralysis of one or more of the other muscles supplied by that nerve is also present. In addition, children may exhibit:

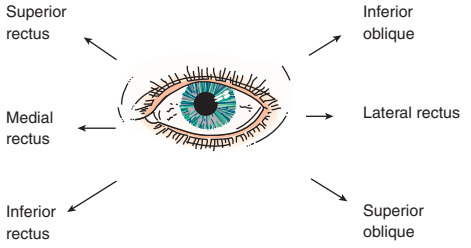
- A dilated pupil
- Inability to rotate the eye globe upward, medially, or downward
- Weakness of accommodation (looking at near objects)

Myasthenia gravis, which produces generalized muscle weakness, must always be ruled out as a cause of bilateral ptosis. Children with ptosis tend to wrinkle their forehead and raise their eyebrows more than usual in an attempt to lift the eyelid further. Also, they may cock their heads back to see under the lowered lid.

After careful investigation of the cause has been completed, ptosis is corrected surgically. The correction is usually important to the child from a cosmetic standpoint. More important, if the lid obstructs vision, early surgery is necessary to prevent the development of amblyopia (from lack of use of the eye). Be sure that parents understand the importance of surgical correction. Otherwise, they may insist on delaying a corrective procedure "until the child is older." When the child is older, although the ptosis can be corrected, the amblyopia cannot.

Strabismus

The movement of each eye globe is controlled by extraocular muscles. These can be compared in movement to the handling of reins of a horse (Fig. 50.4). **Strabismus** is unequally aligned eyes (cross-eyes) caused by unbalanced muscle control.



Eye muscle	Action	Innervation
Superior rectus	Turns eye up and medially	Oculomotor (third cranial) nerve
Medial rectus	Turns eye inward	Oculomotor (third cranial) nerve
Inferior rectus	Turns eye down and medially	Oculomotor (third cranial) nerve
Lateral rectus	Turns eye out	Abducens (sixth cranial) nerve
Superior oblique	Turns eye down and laterally	Trochlear (fourth cranial) nerve
Inferior oblique	Turns eye up and laterally	Oculomotor (third cranial) nerve

FIGURE 50.4 Extraocular eye muscles.

Approximately 1% to 2% of children have some degree of strabismus. The condition occurs without regard to gender, social status, or geographic area. Approximately 30% of children with strabismus have a history of a similar strabismus in the family. If there is a family history of strabismus, the child needs to be observed and examined yearly for this problem (Donahue, 2007).

Normally, with good eye alignment, the resting position of the eyes is straight, largely as a result of neuromuscular influences the child cannot control. In strabismus, the resting position of one eye may be *divergent* (turned out) or *convergent* (turned in). One pupil may be higher than the other (vertical strabismus). The strabismus may be monocular, in which the same eye deviates constantly, or it may be an alternating strabismus, in which one eye and then the other deviates.

Both the resting position of eyes and the amount of turning necessary to read small print depend on the eyes' ability to fuse and see only one image. This ability is minimal in infancy but becomes stronger with practice. In adulthood, it is automatic. If children cannot fuse vision effectively early in life because of strabismus, they may be unable to achieve fusion later on or be unable to maintain good eye position.

Assessment

Infants' eyes may cross occasionally until 6 weeks of age. If infants demonstrate strabismus past this age, they should be referred for diagnosis and treatment. Infants who demonstrate a constant strabismus before 6 weeks of age need referral right away.

Definite deviations are obvious (Fig. 50.5). These can be *exotropia* (eye turning out), *esotropia* (eye turning in), or *hypertropia* (eye turning up). If the deviation is not so obvious

FIGURE 50.5 Strabismus (esotropia) in an infant.

and occurs only when the child is fatigued or ill and, therefore, less able to maintain fixation, the terms used are *exophoria, esophoria,* and *hyperphoria.* If the parents report that the deviation occurs only when the child is tired or sick, attempt to assess the strabismus at such a time, because then the deviation will be most striking.

Strabismus may be detected best when children examine a nearby object. It takes muscular effort to look medially (turn an eye in toward the nose). When children read small print, they turn both eyes medially, or *converge,* to focus at the short distance. If they are farsighted in one eye, they will have to turn the affected eye in more than the other, causing strabismus. If one eye is nearsighted, they will not need to turn that eye in as far as the other one; this results in divergence of the nearsighted eye. Although these children have good eye alignment at rest, they "cross their eyes" when attempting to focus at a reading distance.

Some children have a latent strabismus, but, because they are able to maintain fusion, the strabismus is not overt. They maintain this fusion at the expense of eyestrain, however. They may experience headaches; tired, irritated eyes; and perhaps even nausea and vomiting.

Children who have flat, broad-bridged noses, a narrow interpupillary distance, and an epicanthal fold or oval-shaped palpebral fissures may appear to have strabismus when they truly do not (pseudostrabismus). These children have less white sclera visible in the inner margin of the eye than normally, so the eye appears to be turned in (*pseudoesotropia*). A cover test reveals the true condition. If pseudostrabismus is present, the covered eye will not move after being uncovered. It only appears to be turned medially because of the obscured sclera at the inner canthus. Hirshberg's test is another method of detecting true strabismus (see Chapter 34).

Once strabismus is detected, it is important to attempt to discern whether it is concomitant (measures the same in all directions of gaze) or nonconcomitant (greater in one direction than in another; often called *paralytic strabismus*).

Concomitant (nonparalytic) strabismus is the most usual type found in children. All the muscles of the eye are capable of function, but they are not functioning together. The deviation is equally apparent in all directions of gaze.

Paralytic strabismus is caused by paralysis of a muscle or nerve, perhaps from an injury, such as a birth injury, or an invading lesion. The eyes appear straight except when they are moved in the direction of the paralyzed muscle. Then double vision occurs, and the crossed eye is evident. Such children often close one eye or tilt their head to decrease the double vision. They may tilt their head so much they appear to have a torticollis, or "wry neck"—an orthopedic rather than an eye problem. They are often fussy or clumsy because of the diplopia. They cannot see well and may be too young to describe what is happening to them through any means other than fussiness.

Therapeutic Management

The therapy for strabismus depends on the cause of the problem. If the fusion mechanism is weak, eye exercises **(orthoptics)** may be necessary. If eyes are diverging with attempted convergence because of farsightedness or nearsightedness, the child needs glasses to correct the basic visual defect. If the misalignment is caused by unequal muscle strength, eye-muscle surgery usually is necessary to correct the problem, although injection of botulinum toxin into the eye muscle may be tried first as temporary therapy or as an adjunct to surgery (Pavan-Langston & Azar, 2008). This paralyzes the muscle, temporarily aligning vision.

Because strabismus causes the eyes to be viewing two different fields of vision, diplopia occurs. To prevent this, the child suppresses the vision in one eye or looks with one eye (amblyopia). Even if diplopia is not present, the lack of fusion leads to the same consequence. For this reason, eye correction for strabismus must be done early in life, before 6 years of age. Some children whose eyes are crossing because of an accommodation problem caused by hyperopia in one eye outgrow the condition as the normal hyperopia of the preschooler lessens. This does not always occur, however. Even if the child's eyes appear to be straighter later, an amblyopia may be present that could have been prevented by earlier treatment.

Nursing care for the child having eye surgery is discussed later in this chapter. After strabismus surgery, eye patches are not required. Postoperatively, antibiotic ointment is applied to the eye for 2 or 3 days. The child may experience some pain on eye movement for the first day.

Follow-up visits after surgery are necessary to determine the success of the surgery. Retest children who have had this surgery periodically at health maintenance visits to be certain that their vision remains equal and eye alignment remains straight.

INFECTION OR INFLAMMATION OF THE EYE

Many different types of eye infection or inflammatory conditions can occur in children (Table 50.2). Newborns are susceptible to eye infection contacted from vaginal secretions (Pavan-Langston & Colby, 2008). Regardless of the condition, parents need specific instructions about instilling eye drops or applying ointment, preventing the transmission of infection, applying compresses, and completing systemic antibiotic therapy. Having eye medication applied can be frightening for older children, because they worry that the health care provider's or parent's hand might slip and cut their eye. If they have pain, they may be especially reluctant to let anyone touch their eye.

TABLE 50.2 ✻ Infectious and Inflammatory Eye Disorders

Disorder	Description/Cause	Signs and Symptoms	Treatment
Stye	Infection of a ciliary gland (a modified sweat gland) that enters into the hair follicle at the lid margin; most commonly caused by *Staphylococcus*	Pain and redness at a localized point on the lid margin Possible edema of the lid out of proportion to the severity of the disease Preauricular lymph node swelling and tenderness	Hot, moist compresses for 15–20 minutes four times daily Antibiotic ointment application after the compresses (possible); incision and drainage (when the stye points [develops a head]) Nose and throat cultures for *Staphylococcus* Follow-up evaluation for repeated episodes to rule out other debilitating diseases such as diabetes mellitus or anemia Visual acuity assessment (although styes are not associated with refraction error, they occur when children rub their eyes excessively because of problems with visual acuity)
Chalazion	Low-grade granulation tissue tumor of the *meibomian*, or tarsal, gland on the eyelid; cause unknown, but may be a result of a low-grade infection produced by retained secretion in the gland	Small, slow-growing, hard but painless nodule on the lid Skin freely movable over it; absence of inflammation or edema	None; may resolve itself spontaneously, evacuating itself onto the conjunctival surface of the lid Incision and drainage if no spontaneous remission, followed by antibiotic ointment application to prevent secondary gland infection If ptosis is present in a child younger than 8 years of age, surgical removal is performed to prevent possible subsequent amblyopia
Blepharitis marginalis	Inflammation of the eyelid margin; usually a local infection caused by *Staphylococcus*; possibly an extension of seborrheic dermatitis (cradle cap)	Eyelid margin reddened, possibly covered by hard, dirty-yellow crusts that stick tenaciously to the lid margin and lashes Styes possibly present secondary to the presence of *Staphylococcus*	Application of an antibiotic ointment six to eight times a day to the lower conjunctival rim Removal of crusts with a moistened cotton applicator after the lid margins have been covered by wet compresses for 10–15 minutes If condition persists, systemic antibiotic therapy to reduce the presence of *Staphylococcus* on the skin surface
Conjunctivitis	Inflammation of the conjunctiva; causes are numerous, including bacterial (most serious—ophthalmia neonatorum [exposure to gonococcus bacillus]; see Chapter 26), viral, and fungal	Eyes watery with reddened conjunctiva and sensitivity to light Sticking of eyelids with pustular drainage	Application of an antibiotic ointment Follow-up visit mandatory to be certain infection clears

Disorder	Description/Cause	Signs and Symptoms	Treatment
Inclusion blennorrhea	*Chlamydia* organism	Acute inflammation usually occurring on the 5th to 14th day after birth Conjunctiva reddened with tearing Eye discharge	Systemic antibiotic such as erythromycin
Acute catarrhal conjunctivitis	Commonly called "pinkeye," usually caused by a virus or irritation from a foreign body; most frequently caused by *Haemophilus influenzae, Streptococcus pneumoniae*	Conjunctiva fiery red with tearing Mucopurulent or purulent discharge	Antibiotic ointment or drops three to four times daily for 7 days (redness usually disappears within 48 hours) Avoid rubbing and transmitting infection to unaffected eye Cool, moist compresses to affected eye
Herpetic conjunctivitis	Herpes simplex viral infection (may occur along with development of facial herpes lesion)	Series of pinpoint vesicles on the conjunctiva On fluorescein stain, vesicles stain bright green and are readily evident	Referral to ophthalmologist (can spread easily and become a corneal infection with resultant opacity and permanent scarring) Antibiotics ineffective; steroids avoided Idoxuridine (Herplex) specific for herpesvirus, possibly effective in limiting corneal involvement
Allergic conjunctivitis	Hypersensitivity to specific allergen; usually seasonal	Eyelid edema Profuse tearing and severe itching	Treatment of underlying allergy Cool, moist compresses
Keratitis	Inflammation and infection of the superficial layers of the cornea; may accompany or be a complication of conjunctivitis. May result when a foreign body strikes the cornea, with the invading organism fungal, bacterial, or viral	Acute pain, tearing, photophobia (intolerance to light), and redness	Referral to ophthalmologist for therapy (infection could lead to corneal scarring, resulting in vision impairment [light rays unable to enter the eye normally])
Periorbital cellulitis	Cellulitis (infection of subcutaneous tissue) most often caused by extension of a superficial infection after an open break in the skin, such as a mosquito bite or scratch near the eye	Swelling around and in the eye with possible damage to eye globe or optic nerve	IV antibiotic therapy
Dacryostenosis	Blockage of the nasolacrimal duct; primarily in newborns because of a membrane obscuring distal end of duct or plugging by epithelial debris	Painless lump in the inner canthus Tearing Usually unilateral	Gentle pressure to inner aspect of each eye at each feeding in attempt to "milk" secretions down into duct Ophthalmologic probing of gland duct if condition not corrected spontaneously after age of 6 months
Dacryocystitis	Inflammation of nasolacrimal duct; possibly secondary to dacryostenosis (from fluid stasis) or from nasal mucosal swelling and infected mucus being forced back into duct	Acute pain in inner canthus (from presence of infected sac); complaints of pain in back of eye or possibly in the eye itself	Local and systemic antibiotics Possible probing of duct to free obstruction and allow for free drainage Antihistamines for children with chronic allergies or sinusitis to reduce nasal congestion

TRAUMATIC INJURY TO THE EYE

The primary cause of vision disorders in children today is ocular trauma, caused by missiles such as dirt or sand, baseballs, pieces of broken plastic toys, or flying glass in car accidents that strike or even enter the eye globe. Fights with other children, cigarette burns, sports injuries, fingernail scratches, and burns from fireworks are also causes (Whitcher, 2008).

Assessment

Children who have eye injuries are usually in acute pain immediately after the accident. Their eyes tear and are sensitive to light, and they blink rapidly. Vision may be blurred or lost in the affected eye. Because of the pain and the fear of not being able to see clearly, most children are very reluctant to let anyone examine or touch their injured eye. A few drops of a topical anesthetic instilled into the eye may be necessary to relieve the pain and allow the eye to be opened for examination. Even after the anesthetic is applied, the child needs a thorough explanation of what is happening and that an examiner is "just looking" (provided this is true). Even after anesthetic application, a child may not be able to open the eye readily for inspection, because the acute pain of the injury can cause the eyelid to close by reflex spasm. Eyelid edema also may form quickly, interfering with the eye's ability to open. Do not confuse these physical problems with unwillingness to open the eye (Prentiss & Dorfman, 2008).

To visualize the inner surface of the lower lid and the bottom half of the eye globe, press firmly on the lower lid with your fingertip until it turns out. The inner surface of the upper lid and the upper portion of the eye globe can best be visualized if the upper eyelid is everted. Ask the child to look downward. Grasp the eyelashes and gently stretch the upper eyelid downward. Place the stick of a cotton-tipped applicator horizontally against the center of the upper lid. While still grasping the eyelashes, pull the eyelid upward and over the applicator until it is everted (Fig. 50.6). Gently press the everted eyelid against the eyebrow to maintain the everted position. Be careful not to exert pressure on the eye globe during the procedure, in case a penetrating injury from a foreign body is present. Pressure would further embed the object into the eye globe.

A foreign body, such as a speck of dirt or a fragment of glass, often clings to the inside of the upper lid and can be readily removed by touching it with a moistened, sterile, cotton-tipped applicator while the lid is everted. Keep an eyelid everted no longer than is necessary, because the eye globe tends to become dry when it is exposed. Magnetic resonance imaging (MRI) is an excellent method for documenting internal eye damage after an injury.

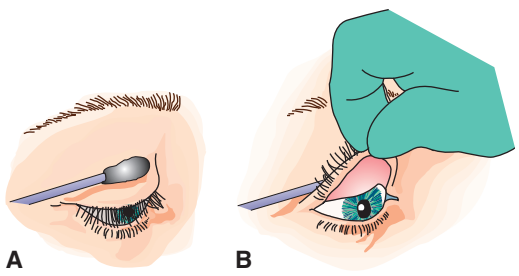


FIGURE 50.6 Technique for everting the upper eyelid for examination and foreign body removal. (**A**) Place a cotton applicator across the upper eyelid. (**B**) Pull the eyelid outward and upward over the applicator.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Parental role conflict related to feelings of guilt about accident affecting child's vision

Outcome Evaluation: Parents accurately state child's treatment plan and expected outcome; child and parents talk openly about the accident and ways to prevent future ones; parents participate actively in child's care and in decision making with health care providers regarding follow-up and long-term care.

Eye injuries are almost always serious in children because of the pain and the potential threat to vision. Both parents and children are apt to feel guilty about the accident. Parents may have difficulty handling this emergency because they are angry at their child and even more angry at themselves for not supervising the child or teaching the child more about eye safety. Children remember being told many times to be careful of their eyes. Children may need help in understanding that, although this accident might have been prevented, accidents do happen. Doing so helps them to maintain a sense of self-esteem. Parents also may need counseling to understand that accidents can happen even under the most watchful care; this helps them reestablish their feelings of worth as parents (Box 50.5).

After eye trauma, the degree of vision in the child's affected eye, as well as the status of the parent–child relationship, needs to be evaluated. Guilt about the accident, in either parent or child, can interfere with the parent–child relationship. After an eye injury, most children do not need future warnings about protecting their eyes.

Foreign Bodies

Foreign bodies such as sand or dirt that are loose on the conjunctiva can be removed by irrigation with a sterile normal saline solution or by gentle wiping with a well-moistened, sterile, cotton-tipped applicator after the eyelid is everted. After the removal, if the conjunctiva is touched with a strip of filter paper impregnated with fluorescein stain, any corneal ulceration or abrasion from the foreign body will stain green and be readily apparent. If the foreign body is easily removed and no corneal ulceration or injury is present, no further treatment is necessary. The child will blink a few times after the upper lid is returned to its place, but, in a matter of minutes, the child will report feeling "fine" again. If the fluorescein stain shows any corneal ulceration, refer the child to an ophthalmologist for follow-up care.

If a foreign body adheres to the cornea, it needs to be removed by an ophthalmologist. If the foreign body is metallic and has been in contact with the cornea for a period of hours, a rust ring can form around the particle. This rust ring must also be removed, or it will continue to act as a foreign body.

BOX 50.5 * Focus on Communication

Carla's older brother, Jon, a 7-year-old, is brought to the emergency department by his mother after he was hit by a baseball on the right side of his face at his right eye.

Less Effective Communication

Nurse: Hello, Mrs. Vander. How did this injury happen?
Ms. Vander: He was playing catch with his cousin in the backyard.
Nurse: Was he hurt anywhere else?
Ms. Vander: No, but I didn't see exactly what happened. I should have been watching him more closely.
Nurse: Does he have pain?
Ms. Vander: Just a little, but I didn't see what happened. I shouldn't have left him out there with his cousin. He's too young to play baseball.
Nurse: Okay, wait here. The doctor will be in shortly to examine Jon.

More Effective Communication

Nurse: Hello, Mrs. Vander. How did this injury happen?
Ms. Vander: He was playing catch with his cousin in the backyard.
Nurse: Was he hurt anywhere else?
Ms. Vander: No, but I didn't see exactly what happened. I should have been watching him more closely.
Nurse: Watching him more closely?
Ms. Vander: Yes, I was inside checking on them through the kitchen window. I should have been outside supervising them.
Nurse: It sounds like you're blaming yourself.
Ms. Vander: It's my fault. I should have been out there instead of inside making dinner. He's too young to be playing baseball.
Nurse: Let's talk a little more about this.

In the first scenario, the nurse focuses on assessing the events surrounding the injury. Although this is important information, the nurse fails to identify the mother's feelings. In the second scenario, the nurse actively listens to the mother to elicit more information about her feelings.

After corneal injury, corneal tissue regenerates. To allow for this, the eye is washed with an antibiotic solution and then closed and patched. The patch must be secure enough to keep the eyelid closed yet not put undue pressure on the eye. Caution the child that the patch must be left in place to prevent the delicate regenerating corneal epithelium from being rubbed off until it is well healed and secure once more.

If a foreign object is relatively large, such as a BB bullet, lollipop stick, or piece of broken glass, the fact that it has punctured the eye globe is usually apparent on first inspection (Augsurger & Asbury, 2008). In these instances, also, the child needs to be examined by an ophthalmologist. Surgery may be necessary to explore the depth of the puncture and save the child's sight in that eye. Iron or copper fragments must be removed to prevent rust formation and continued irritation.

An extremely serious complication called *sympathetic iritis,* or inflammation of the opposite eye, may result if the ciliary body was involved in a penetrating injury. As a result, blindness in the noninjured eye may occur. This complication can be prevented by administration of a corticosteroid and antibiotics to reduce inflammation. If this is unsuccessful, removal **(enucleation)** of the injured eye may be necessary. If the vision in the injured eye appears to be destroyed, a decision for removal is not difficult for parents to make. If the vision is not totally destroyed, however, deciding to remove the injured eye is extremely difficult for parents. Fortunately, immediate treatment with corticosteroids and antibiotics has significantly reduced the incidence of this complication.

Contusion Injuries

Many eye injuries happen not from a sharp object striking the eye but from blunt trauma such as being hit in the eye by a baseball, a fist, a soccer ball, or an automobile dashboard. With this type of injury, the eyelid and the surrounding tissue, including the intraorbital tissue, hemorrhages and becomes edematous.

The simplest form of contusion injury is a "black eye." When this occurs, inspect the eye globe (including a funduscopic examination) and assess vision in the eye. If a vision chart is not available, vision can be assessed by having children tell you how many fingers they can count at a distance of about 6 feet (assuming they are old enough to count accurately) or by having them read a printed page at reading distance (assuming they are old enough to read). Ask children if they are having any difficulty seeing. Evaluate extraocular eye movements for adequate function. Children should be able to look up and down, left and right, upward obliquely, and downward obliquely—the six cardinal positions of gaze (West & Asbury, 2008).

If there is no apparent eye injury, ocular movement is good, and vision is normal (for that child), the only treatment necessary is an ice pack applied to the eye to minimize swelling (20 minutes on, 20 minutes off, and repeat). Reabsorption of hemorrhage in the tissue surrounding the eye will take place over the next 1 to 3 weeks. Often, tissue hemorrhage extends across the nose and surrounds the other eye the day after the injury. Assure both parents and child that this is not a worsening of the condition but mainly evidence of the severity of the initial blow.

Limited eye movement or reports of diplopia (double vision) are strong evidence that a "blowout" fracture of the floor of the orbit (the maxillary bone) has occurred. This fracture line is trapping intraorbital tissue and preventing the eye globe from moving freely. Refer these children to an ophthalmologist. Surgery is needed to free the entrapped tissue, prevent interference with vascular flow, and restore normal eye movements.

After a blunt contusion to the eye globe, several serious findings in addition to limited motion may be present. These include disturbances of the pupil, such as a dilated, fixed, or cloudy pupil; cloudy lens or cornea; loss of vision in the eye; and visible blood in the anterior chamber (hyphema). These conditions may indicate dislocation of the lens or retinal detachment requiring immediate evaluation by an ophthalmologist.

Eyelid Injuries

Eyelid injuries may accompany eye globe injuries, or they may be the only finding present after a foreign body has struck the

eye. Although such injuries appear to be trivial, don't dismiss them lightly. Refer the child to an ophthalmologist for care. A deep laceration of the eyelid can cause a permanent ptosis. A laceration to the inner canthal area can disrupt the lacrimal drainage system (dacryostenosis).

What if... Carla's father tells you he always buys fireworks to celebrate the 4th of July and sets them off in his backyard? What type of safety teaching does he need?

INNER EYE CONDITIONS

Inner eye conditions are those that affect the lens, the retina, or the aqueous humor.

Congenital Glaucoma

Glaucoma is increased intraocular pressure (IOP) in the eye globe caused by inadequate or blocked drainage of aqueous humor (Girgis & Frantz, 2007). Normally, aqueous humor, produced by the ciliary body, flows from the posterior chamber through the pupil to the anterior chamber and is excreted through the canal of Schlemm at the lateral angle into the venous circulation (Fig. 50.7). In congenital glaucoma, a developmental anomaly in the angle of the anterior chamber prevents proper drainage into the canal. Later in life, glaucoma occurs when the canal becomes blocked. The increased fluid content that accumulates causes the globe of the eye to increase in size. After it has increased in size to the extent that it can, the pressure in the eye globe continues to rise, compressing and ultimately destroying the optic nerve. Glaucoma (meaning "gray") gets its name from the color of the retina or red reflex (which appears gray to green) in the eye after the sight has been lost. The condition occurs in as many as 1 in every 10,000 live births.

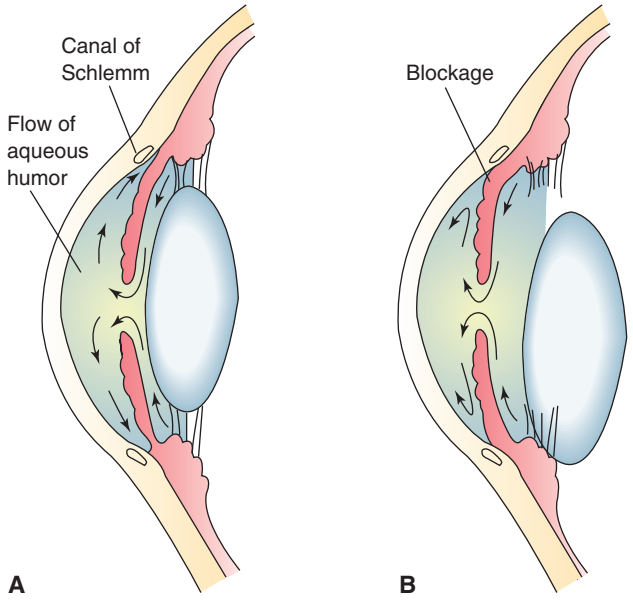

FIGURE 50.7 (**A**) Circulation of aqueous humor. (**B**) Blockage of canal of Schlemm in congenital glaucoma.

Assessment

Although congenital glaucoma is a rare disease, all infants should be assessed for it because the disease accounts for vision disorders in 5% to 13% of children in schools for the visually challenged. In most infants, the condition is bilateral and is caused by inheritance of a recessive gene. Symptoms begin to be noticeable shortly after birth; readily noticeable symptoms are apparent at 1 year of age. The condition occurs more often in girls than in boys (Sands & Drack, 2008). Glaucoma can occur after eye trauma in older children if there is scarring at the canal of Schlemm.

The cornea, which appears enlarged, may be edematous and hazy. In addition, there may be tearing, pain, and **photophobia** (sensitivity to light), all difficult to identify in a newborn. The eye globe may feel tense to finger palpation.

Eye pressure is measured by means of a *tonometer,* a pressure-sensitive device that is placed against the anterior eye globe and measures eye pressure by a beam of light directed toward the eye. Tension greater than the normal range of 12 to 20 mm Hg is suggestive of glaucoma. If local anesthesia is needed for tonometry, caution parents that children should not rub their eyes after the procedure (an infant's arms may need to be gently restrained to prevent eye rubbing for about 4 hours after such an examination). Otherwise, corneal abrasions may occur because of the cornea's lack of sensitivity.

Therapeutic Management

Immediate surgery—a **goniotomy,** or trabeculotomy, in which a new opening to the canal of Schlemm is constructed—is scheduled for the infant (Yalvac et al., 2007). A drug such as acetazolamide (Diamox), a carbonic anhydrase inhibitor that suppresses the formation of aqueous humor, may be used temporarily to reduce eye pressure before surgery can be scheduled. Newer surgical techniques include laser therapy (Pavan-Langston, Brauner, & Grosskreutz, 2008).

Before surgery, the infant should not receive any drug, such as atropine sulfate, that dilates the pupil, because this will further occlude the canal of Schlemm. After surgery, rough play activities should be restricted for 1 week.

Surgery may need to be repeated before the new opening for drainage of fluid is adequate to keep eye globe tension at a usual level. Inform parents of this possibility when surgery is first proposed, so that they will not think the additional surgery is needed because the first operation was inadequate or was done incorrectly.

Children who have eye injuries are usually scheduled for a follow-up appointment in 1 month for eye pressure assessment. Stress the importance of this visit without alarming the parents or child about the possible complication.

Cataract

A *cataract* is marked opacity of the lens. This may be present at birth, or it may become apparent in early childhood. Some children have cataracts as a dominantly inherited condition. They also can be caused by galactosemia, or inability

to metabolize the lactose in milk (Rubio-Gozalbo et al., 2007). A few children develop cataracts as a result of steroid use or radiation exposure. It can be caused by trauma to the eye if the lens is injured. If the opacity occurs on the anterior surface of the lens, the cause is thought to be birth injury or possibly contact between the lens and the cornea during intrauterine life. If the opacity is located at the edge of the lens, it may be a result of nutritional deficiency during intrauterine life, such as rickets or hypocalcemia. Infants who contract rubella prenatally may develop opacity throughout the lens (Chak et al., 2007).

Assessment

When you inspect the pupil of a child with a cataract, the pupil opening appears to be white (leukocoria). The red reflex elicited by shining a light into the pupil appears white. Older children may report blurred vision because of cataract formation. In the infant, this can be detected by lack of response to a smile or inability to reach and grasp a nearby object. The infant may also demonstrate nystagmus, being unable to focus the eye on objects. A few other conditions, such as retinoblastoma, retinopathy of prematurity, or an abscess of the posterior chamber, simulate this appearance. In congenital glaucoma, the lens may be opaque because of edema. This can be differentiated from simple cataract by the accompanying enlargement of the eye and pupil opening.

Therapeutic Management

Treatment of childhood cataract is surgical removal of the cloudy lens, followed by insertion of an internal intraocular lens. If the total lens is involved, this may be done as early as 3 months of age. If this is not done before 6 months of age, amblyopia may result.

With modern surgical techniques, the incision is so small that eye patching is not necessary. Infants may be given a sedative to help them rest for 24 hours. Introduce fluids cautiously after eye surgery so nausea and vomiting do not occur as vomiting increases IOP, which could injure the suture line. Encourage parents to stay with their infant, helping with care so that the infant does not cry after surgery, because crying also increases IOP. Infants can be expected to have some discomfort but, in general, they should not have acute pain after surgery. If they are unusually restless, fussy, or crying and seem to be in pain, notify the physician immediately. Although this could be unrelated to the surgery, it may be a sign of increased IOP from hemorrhage or from occlusion of the canal of Schlemm, causing a developing glaucoma.

As a rule, children will be given a mydriatic agent to dilate the pupil and steroids to prevent postoperative development of pupillary adhesions. If the eye that had the cataract is now amblyopic, patching of the normal eye (as with usual amblyopia correction) may be necessary to restore vision.

Parents of children with congenital cataracts need support to carry out the procedures necessary and to give the long-term medication and corrective measures needed. Outcome evaluation should include children's current vision status and also how they view themselves in light of this early vision problem.

THE CHILD UNDERGOING EYE SURGERY

Surgery for cataracts or glaucoma in childhood is usually performed during the infant period. Preparation for surgery, therefore, primarily consists of helping a baby to adjust to a strange environment and encouraging parents or a primary care person to spend as much time with the infant as possible. This is particularly important if the eyes will be patched after surgery. Surgery for strabismus is often done during the preschool period. The operation can be explained to the preschooler through the use of puppets or dolls. As with all surgical procedures, talk about the child's affected parts (in this case, the eyes) being "fixed" or "made better," never "cut." Even a very young child knows how important eyes are and will agree to having them made better but not cut.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Anxiety related to lack of knowledge about eye surgery and postoperative experience

Outcome Evaluation: Child asks questions and expresses fears about surgery; child states plans for postoperative period and practices putting on eye patches, if appropriate.

Most eye surgery is completed as ambulatory surgery. A major nursing role is preparing the parents to support the child through the procedure.

If the child's eyes are going to be patched after surgery, it is helpful to allow the child to become accustomed to the feeling of patches beforehand. Even when only one eye is going to be operated on, it is not unusual for both eyes to be patched, because the eyes move conjugately—that is, when the right eye looks to the right, so does the left eye. The repaired eye, therefore, will stay immobile under a bandage only if both eyes are patched.

Parents could show the child a doll with eye patches and let the child practice wearing them. They could play a game such as "pin the tail on the donkey" or "blindman's bluff" to adjust to the sensation of the eyes being covered. Another helpful game is to have the child pull out familiar objects from a paper bag—a key, an orange, a spoon, and a penny—and, with eyes covered, try to guess what they are.

When you meet children before surgery, be certain to speak with them enough so they are able to recognize your voice afterward. Practice having the child identify a parent's voice by covering the eyes and then guessing whether you or the parent is speaking.

Postoperatively, check that the young child's favorite toy is within reach if eyes are patched. If a child will require arm restraints to prevent him from pressing on his eyes or removing the patches, urge the parents to introduce these preoperatively as well. Children who awaken from conscious sedation and find their arms tied down can be extremely frightened or believe they are being punished.

✔ Checkpoint Question 50.2

After cataract surgery, why should vomiting be prevented if at all possible?

a. Vomitus could be splashed into the eye.
b. Loss of sodium discolors the new lens.
c. Vomiting increases intraocular pressure.
d. Loss of fluid causes the globe to shrink.

THE HOSPITALIZED CHILD WITH A VISION DISORDER

The World Health Organization defines severe vision impairment as testing 20/60 to 20/200 in the better eye on a standard eye examination. Blindness is defined as vision less than 20/200 or peripheral vision less than 10 degrees. It occurs for a multitude of reasons, including vitamin A deficiency, inadequately treated eye infections, corneal scarring, and diabetes (Pavan, Burrows, & Pavan-Langston, 2008). Children may be hospitalized because of their primary vision disorder. As, like other children, those with vision disorders experience diseases such as appendicitis or pneumonia, they may also require hospitalization for other reasons. Severe vision impairment or blindness can cause increased difficulty adjusting to a hospital environment.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Powerlessness related to difficulty adjusting to strange environment, secondary to vision disorder

Outcome Evaluation: Child identifies specific fears and concerns; child is able to make age-appropriate decisions regarding self-care

Vision problems can range from very mild disorders to total blindness. Assess children carefully for the degree of their vision impairment to better gauge their abilities, so you help them neither too much nor not enough. Some children with severe vision disorders rock back and forth excessively, an action that apparently gives them additional stimulation (Campbell, 2007). Also, keep in mind that severe vision disorders can lead to chronic depression as children grow older and realize more and more the many ways that lack of vision affects their life. Help children who are blind to feel secure in a strange hospital environment. Be sure to thoroughly orient them to the experience and their surroundings. Remember that they may become frightened if they think a parent has left them when the parent has only moved a few feet away.

Before you approach children who are blind, speak first to avoid startling them. Children who are blind are very aware of another person's presence in the room and may be frightened if you slip in quietly to straighten another child's bed or pick up some equipment without speaking to them.

The sounds of a hospital are strange sounds to any child. The whirring noise of a floor-polishing machine or another child's oxygen equipment, the hissing of a ventilator, and the clanking of waste baskets being emptied can be frightening sounds if you do not know what they are. Stand by the child's bed and explain the sounds you both hear. Sound is a major way in which visually challenged children experience their environment.

Children who are blind need to learn self-care like other children; they can be taught to bathe themselves, brush their teeth, brush their hair, and put on their clothes like other children their age. Toilet training may come later, because they cannot see the excretions that parents are asking them to dispose of in a special place. They must be able to understand cognitively what is expected of them.

Blind children often want to be told what is on their food tray when it is first presented to them. Name the foods so that they can identify tastes with names. Do not hesitate to use food colors: "Those are green beans; this is an orange; those are red beets." These words are names as well as colors. Visually challenged preschoolers enjoy the same finger foods as sighted children do. Children with severe vision disorders have difficulty getting food from spoons or forks to their mouths neatly. However, they should not be spoon-fed just because it is neater and faster: eating is an important self-care skill that a blind child must learn to be independent as an adult.

Be certain to offer frequent descriptions of what is happening or planned for these children. They cannot see their surgical dressing, for example, so encourage them to feel it. They cannot see the intravenous infusion, but they can feel the tubing and the arm board that is holding their arm in place.

Parents of a severely visually challenged child usually plan to room-in with their child during a hospitalization experience. Demonstrate competence and consistency when caring for their child by using good techniques and by relating to the child warmly. Ask the parents about their child's routines at mealtime and bedtime, their child's favorite toy, what word is used for voiding, and so on, and pass this information on to the entire nursing staff. Only when parents have confidence in you and the other staff members will they be able to leave their child in your care to meet their own needs, such as eating.

STRUCTURE AND FUNCTION OF THE EARS

Ear anatomy is shown in Figure 50.8. Most diseases of the ear in children involve the external and middle portions.

Physiology of Hearing Loss

Hearing loss is termed a *conduction loss* if there is interference with sound reaching the inner ear (difficulty with the external canal, the tympanic membrane, or the ossicles). It is termed *nerve* or *sensorineural loss* if the inner ear or the eighth cranial nerve is affected. Conduction loss can occur if the ex-

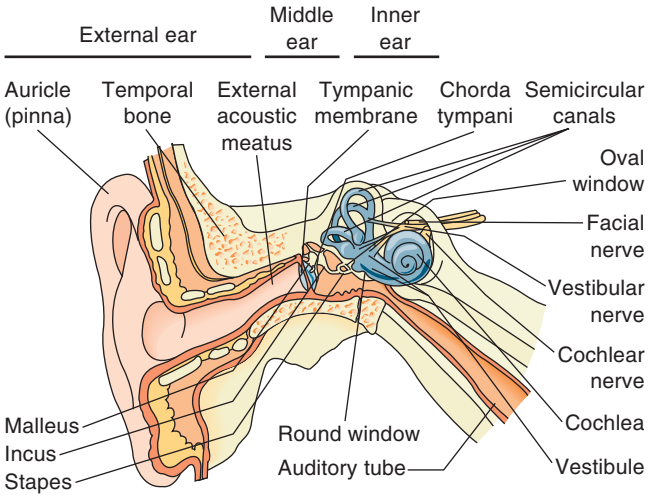

FIGURE 50.8 Structures of the ear.

ternal canal is obstructed with cerumen (wax) or a foreign object, if the tympanic membrane is damaged or immobile, or if the middle ear is filled with fluid, as occurs in *serous otitis media.* Sensorineural loss results from diseases that affect the transmission of sound sensation to the cerebral cortex or from a pathologic condition of the cochlea. In children, this condition is usually congenital, although it can occur after drug therapy or an infection such as meningitis. It also can occur from exposure to loud sound (Vogel et al., 2008).

TABLE 50.3 ✻ Levels of Hearing Impairment

Decibel Level	Hearing Level Present
Slight (<30)	Unable to hear whispered words or faint speech No speech impairment present May not be aware of hearing difficulty Achieves well in school and home by compensating (e.g., leaning forward, speaking loudly)
Mild (30–50)	Beginning speech impairment may be present Difficulty hearing if not facing speaker; some difficulty with normal conversation
Moderate (55–70)	Speech impairment present; may require speech therapy Difficulty with normal conversation
Severe (70–90)	Difficulty with any but nearby loud voice Hears vowels more easily than consonants Requires speech therapy for clear speech May still hear loud sounds, such as jets or train whistles
Profound (>90)	Hears almost no sound

Because the diseases that lead to inherited hearing challenge tend to be autosomal dominant, there is a strong chance that they will occur in future siblings of the hearing-challenged child. Genetic counseling can aid in increasing parental awareness.

Hearing Impairment

Hearing impairment occurs in many different degrees and is rated by level of severity. Usual classifications are shown in Table 50.3. Approximately 1 in 1000 children in the United States are profoundly hearing challenged; 17 in 1000 children have a moderate to severe hearing impairment. Congenital sensorineural hearing loss occurs in 2 to 3 of every 1000 live births (National Institute on Deafness and Other Communication Disorders, 2008). Treacher Collins syndrome, otosclerosis, osteogenesis imperfecta, and Waardenburg's syndrome, all transmitted by autosomal dominant inheritance, are examples of disorders that result in congenital deafness. Prenatal rubella infection accounts for another large percentage. Causes of slight hearing impairment include serous otitis media, trauma from such things as inflating airbags, and untreated acute otitis media with rupture of the tympanic membrane.

Discovery that a child is hearing challenged is almost always a shock to parents. Children with congenital hearing impairment should be enrolled in special programs for hearing-challenged children as soon as the hearing loss is discovered (Pierson et al., 2007). This early exposure is necessary so that the child can learn effective speech (Fig. 50.9). For children who have conductive losses, an improvement in hearing usually can be achieved by use of a hearing aid (which intensifies the level of sound waves). Children who have inner ear or nerve deafness cannot expect this kind of improvement.

FIGURE 50.9 A hearing-challenged young girl learning to use the computer with the aid of a speech therapist. (© Bob Daemmrich/Stock Boston.)

Acupuncture, often recommended to parents by friends as therapy for nerve deafness, has no documented effect. Parents of children with neural deafness need an explanation of the difference so that they do not continue to search for a "cure" for their child or spend a great deal of money for hearing aids, hoping that a different brand or model will help their child.

Hearing Aids and Cochlear Implants

Hearing aids pick up sound through a microphone, convert the sound waves into electrical impulses, and amplify them across the tympanic membrane. They are powered by batteries that must be changed periodically.

Hearing aids are designed to be as inconspicuous as possible so that children will not feel self-conscious wearing them. The receiver of the hearing aid may be incorporated into eyeglasses, molded into a plastic form that fits behind or in the ear, or housed in a small box (the size of a cellphone or iPod) that children wear on a cord around their neck or carry in a blouse or shirt pocket. Teach children to remove hearing aids before washing their hair, showering, or swimming. Hearing aids should be turned off when removed, to preserve the life of the batteries.

Children with a hearing impairment may grow self-conscious about wearing a hearing aid during school years. Encourage such children to view themselves as whole persons despite their need for their device, rather than as someone with something to hide.

Cochlear implants are mechanical devices consisting of a microphone, a speech processor, a transmitter/receiver, and an arrangement of electrodes that send impulses from the receiver to the auditory nerve. The auditory nerve then transmits the impulses to the brain where they are interpreted as words or common noises. Cochlear implants have the potential to replace a nonfunctioning inner ear and create the ability to receive and interpret sounds in an ear that has sustained nerve damage (Berg et al., 2007). The implant consists of an external portion that sits behind the ear and a second portion that is surgically implanted under the skin.

After implantation, hearing is often reported as "muffled" but adequate. Months of training are necessary to help a child interpret these distorted impulses correctly. Hearing-challenged adults may be reluctant to consent to a cochlear implant for their child, believing that the change from hearing-challenged to non–hearing-challenged status will remove their child from their deaf culture. Children who spoke with an impediment before implantation usually need speech therapy afterward to improve their speech pattern.

Speech Therapy

If children who are hearing challenged are to interact as fully as possible with the world around them, they need an intensive program of speech therapy. Some therapists believe that learning sign language early is helpful because it allows children to express their needs early. Others believe that, by learning sign language, children decrease their need to learn to articulate speech sounds or to lip read and, for this reason, learning sign language should not be encouraged. It is true that, for real independence and to perform in regular school classes, children need to communicate by means other than sign language. For children with a profound impairment, however, learning speech sounds may be a long-term process, making sign language necessary for contact with the world around them until they can learn to speak.

What if... You discover that Carla, who is hearing challenged, refuses to wear her hearing aid because another child in her nursery school made fun of it? What suggestions could you make to her parents to help her accept her hearing aid better?

DISORDERS OF THE EAR

Ear disorders are always serious in children, because hearing is such an important function for the growing child. Assessment of hearing is discussed in Chapter 34.

External Otitis

External otitis (otitis externa) is inflammation of the external ear canal. Although external ear inflammation rarely threatens hearing or causes permanent damage, it does cause discomfort in the form of itching and sometimes extreme pain.

Assessment

The history of children with external otitis usually reveals that they have recently been swimming, which is why this condition is popularly called *swimmer's ear.* It also can occur if a young child pushes a foreign object, such as a peanut, into the ear canal. Unlike middle ear infection (otitis media), there is no history of a recent respiratory infection. Children first notice itching of the canal, then pain. When the external ear is touched, the pain becomes acute. The moisture in the canal left from swimming has caused inflammation; a secondary infection then occurs in the closed space. *Pseudomonas* and *Candida* are agents frequently involved in these infections. Otoscopic examination may indicate only the sharply localized, tender swelling of a furuncle, or the entire canal may be swollen shut and tender to the touch. If a fungal infection is present, the entire canal may appear brown or black. If the inflammation is from a foreign body, such as a peanut or the tip of a cotton applicator, white or gray debris may surround the object; the skin under the object will be moist, red, and eroded.

In otitis externa, the tympanic membrane must be visualized to ensure that there is no extension of the external otitis into the middle ear (Stone, 2007). In some instances, the eardrum is so inflamed from the external infectious process that it is difficult to tell whether the middle ear is free of disease. Before the tympanic membrane can be visualized, it is often necessary to remove superficial debris from the canal. A Weber test (discussed in Chapter 34) should show that hearing is equal in both ears. A tuning fork vibration that sounds louder in the affected ear suggests that otitis media (middle ear infection) is present.

Removal of debris from an infected external canal requires patience and skill. Foreign material should not be irrigated until it is shown that the tympanic membrane is intact. Otherwise, infected material could be washed through a rupture into the middle ear. Material should be removed by an ear curette using extremely gentle pressure. Children must be

securely restrained for the procedure to prevent them from suddenly turning their head, causing the curette to puncture the tympanic membrane. If the debris is hard and difficult to remove, it can be softened and loosened by touching it with a hydrogen peroxide–soaked, soft, cotton applicator; alternatively, 2% acetic acid can be instilled into the canal and allowed to stand for a few minutes.

Therapeutic Management

The treatment of otitis externa differs according to the organism causing the infection. If the canal is so swollen that ear drops cannot flow back into the canal, a cotton wick moistened with Burow's solution may be threaded into the canal. The cotton extending out into the auricle is kept moistened by rewetting it for 24 hours with Burow's solution. This usually reduces the swelling of the canal to a point where further treatment can be initiated.

The parents are then instructed to use ear drops containing hydrocortisone and an antibiotic or an antifungal mixture. Hydrocortisone reduces inflammation; the antibiotic or antifungal preparation reduces the infection. Some ear drops have an additional alcohol base, which serves to dry the external canal further. If ear pain is present, an analgesic, such as acetaminophen or ibuprofen, may be necessary to control discomfort. Children must keep the ear canal dry, avoiding swimming and hair washing during this time. If they shower, they should first insert ear plugs into the external meatus, to keep out moisture.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Deficient knowledge related to technique for ear drop instillation and preventive care measures

Outcome Evaluation: Parents demonstrate proper instillation of ear drops; parents state the importance of continuing prescribed treatment to completion.

Administering ear drops can be a challenging task. Show parents how this is done (see Chapter 38) before they leave the health care facility. Encourage them to give the medication for the full period prescribed. Otherwise, because the drops are difficult to administer, they may give them only until the pain subsides (24 to 48 hours). As a result, the infection may recur a week later. Caution parents and the child not to put anything but the ear drops into their child's ear.

Evaluation after external otitis should include not only whether the inflammation and pain have decreased but also whether the child and the parents are aware of how to prevent the condition in the future. This includes knowing not to put any object into the ear canal and using ear plugs during swimming. Instillation of a dilute alcohol or acetic acid solution by dropper after swimming is a prophylactic measure that helps keep the ear canal dry. This is often recommended for children who swim competitively or spend a great deal of time in water.

Impacted Cerumen

Cerumen (earwax) serves the important function of cleansing the external ear canal as it gradually moves outward, bringing with it shed epithelial cells and any foreign objects. Parents are often concerned that earwax will lead to loss of hearing (or they view it as dirty) and ask to have it removed. Wax accumulation rarely is extensive enough to interfere with hearing. Cerumen serves a protective function, however, so should not be removed routinely. Caution parents not to clean the child's ears with cotton-tipped applicators as a regular practice, because they may scratch the ear canal, causing an invasion site for a secondary infection. This practice may also push accumulated cerumen farther into the ear canal, causing a true plugging of wax.

Commercial softeners are available if cerumen accumulates to such an extent that hearing is affected. Some physicians advise a dilute solution of hydrogen peroxide to dissolve cerumen. This may be done once in a while but, again, should not be done regularly because this will keep the ear canal constantly moist, an environment that leads to external otitis. For most children, the basic rule—never put anything smaller than an elbow in a child's ear—is the best rule.

Acute Otitis Media

Inflammation of the middle ear (otitis media) is the most prevalent disease of childhood after respiratory tract infections (Kelley, 2008). It occurs most often in children 6 to 36 months of age and again at 4 to 6 years. It is seen most frequently in males, in Alaskan and Native American children, and in children with cleft palate. There is a higher incidence of otitis media in formula-fed infants than those who are breastfed, because formula-fed infants are held in a more slanted position while feeding, and this allows milk to enter the eustachian tube. Otitis media is also associated with constant pacifier use. The incidence of otitis media is highest in the winter and spring and is higher in homes in which a parent smokes cigarettes (Yates & Anari, 2008).

Otitis media is an extremely serious disease of childhood, because permanent damage can occur to middle ear structures, leading to hearing impairment.

Assessment

Acute otitis media usually occurs after a respiratory tract infection. Children have a "cold," rhinitis, and perhaps a low-grade fever for several days. Suddenly, they have a fever of about 102° F (38° C) and a sharp, constant pain in one or both ears. Older children can verbalize reports of pain. Infants become extremely irritable and frequently pull or tug at the affected ear in an attempt to gain relief from pain. The external canal is usually free of wax because the warmth of the inflammation and fever melts the wax and moves it more readily out of the canal. In contrast to an external ear canal infection, the discomfort does not increase on manipulation of the auricle. It is important that the mastoid process behind the ear does not feel tender to touch. If it does, the infection probably has spread out of the middle ear into the mastoid cells, a very serious complication.

The appearance of a normal eardrum shows the outline of the malleus (see Chapter 34). With infection, the tympanic membrane appears inflamed or reddened on otoscopic

examination. It may be seen bulging into the external canal. The light reflex of the otoscope will not be as definite as usual because of the convex shape of the eardrum. The landmarks of the tympanic membrane, the malleus and incus, can be visualized only poorly or not at all. There is decreased mobility on pneumatic examination. A **tympanocentesis** (withdrawal of fluid from the middle ear through the tympanic membrane) may be performed by a physician to obtain fluid for culture at the time of assessment.

Therapeutic Management

Most middle ear infections are caused by *Streptococcus pneumoniae, Haemophilus influenzae* (especially in children younger than 5 years), or streptococcus pyrogenes. Most otitis media infections resolve spontaneously without therapy, but, to avoid the possibility of complications, most children in the past were prescribed an antibiotic such as ampicillin or amoxicillin (antibiotics that eliminate *H. influenzae* organisms). Today, it is recognized that antibiotic therapy is unnecessary and may add to bacterial resistance, so it is no longer routinely prescribed (Johnson & Holger, 2007).

Children need an analgesic and antipyretic such as acetaminophen (Tylenol). Some health care providers may prescribe decongestant nose drops to open the eustachian tubes and allow air to be admitted to the middle ear. Although not proved, this may be helpful in preventing the infection from becoming a serous or long-term otitis media. Nasal decongestant drops usually are given for only 3 days. If they are given longer, a rebound effect may occur, causing edema and a subsequent increase in mucous membrane inflammation.

During the course of otitis media, most children have a conductive hearing loss; this may last up to 6 months after an acute infection. Caution parents about this, so they will not think the infection is growing worse if they first notice the impairment after they arrive home from the health care facility. They also need to know about the possible hearing loss so that, if the child is routinely screened for hearing in school during the next 6 months, they can account for the loss. If a child still has a conductive hearing loss after 6 months (or has other symptoms), the child should be examined again to see whether a new infection or serous otitis media is present (see Focus on Nursing Care Planning Box 50.6).

Chronic or persistent otitis media may be caused by *Staphylococcus,* which would require treatment with an antibiotic, such as a cephalosporin, that is effective against *Staphylococcus.*

BOX 50.6 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Child With Otitis Media

Carla Vander, a 4-year-old child, is brought to a pediatric clinic for evaluation. Her mother states, "She's always had a lot of problems. She had strabismus as a baby. Now, I'm sure she has an ear infection. Can you get me the antibiotic prescription in a hurry, before the drug store closes?" How would you answer Ms. Vander? What information does she need about ear infections?

Family Assessment ✻ Child lives with parents and 7-year-old brother in three-bedroom suburban cottage. Father works as a travel agent; mother is a grade school librarian. Father describes finances as "middle class."

Client Assessment ✻ Child has had two previous ear infections in the past 8 months. Child had a clear, watery nasal discharge and slight cough for 2 days. Now, thick, purulent, white nasal drainage is noted from both nostrils. Last evening, she developed a fever of 102.2° F (39.0° C). Temperature now 100.8° F (38.2° C). Observed tugging vigorously on right ear. On examination, right tympanic membrane erythematous and bulging, with poor mobility on pneumoscopy. Left ear examination unremarkable. Child is diagnosed with otitis media of the right ear.

Nursing Diagnosis ✻ Pain related to inflammation and erythema secondary to ear infection

Outcome Evaluation ✻ Child no longer tugs at right ear; tympanic membrane no longer reddened or bulging; child rates pain as no higher than 2 on a FACES pain scale.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Assess whether child is able to sleep or wakes with pain.	Suggest mother give antihistamine at bedtime. Urge child to sleep with affected ear up.	Antihistamines can make children sleepy. Sleeping on affected ear can put pressure on eustachian tube and increase pain.	Mother reports child is able to sleep through the night.

		Consultations		
Physician	Assess whether child has susceptibility to ear infections or whether this could be reoccurrence of a former infection.	Meet with ear, nose, and throat service to consult on cause of frequent otitis media.	Otitis media can be so persistent it needs an antibiotic to cure it.	Consultant meets with mother to discuss cause of frequent ear infections.
		Procedures/Medications		
Nurse	Assess whether child has experience with taking oral medicine. Rate child's level of pain by FACES pain scale.	Instruct the mother to administer acetaminophen q4h or ibuprofen q8h.	Acetaminophen and ibuprofen are effective analgesics and antipyretics for this degree of pain.	Child is able to take oral medicine cooperatively. Rates pain level as not above 2 on FACES pain scale.
Nurse	Assess whether child has ever had nasal medicine administered and whether mother knows technique.	Instruct mother in use of saline nose drops or nasal spray as prescribed.	Saline nose drops or nasal spray helps to relieve nasal inflammation and subsequent pressure on the eustachian tube.	Child cooperates with administration of nose drops or spray.
		Nutrition		
Nurse	Assess what soft foods and fluids child likes to eat.	Encourage mother to offer liquids and soft foods.	Movement of the eustachian tube, such as with chewing, may increase pain.	Child names some foods and fluid she is willing to eat. Eats less than usual, but adequate amount.
		Patient/Family Education		
Nurse	Assess how much mother and child understand about the cause of otitis media and the newer, no-antibiotic approach to treatment.	Educate the mother about the common characteristics of otitis media. Reassure mother that the infection will resolve without an antibiotic.	Education promotes better understanding of the problem, alleviating some of the stress and anxiety associated with it.	Mother states her prime goal is to get child well again. Will follow clinic physician's recommendation for care.
		Psychosocial/Spiritual/Emotional Needs		
Nurse	Assess how much experience mother has with care of ill child.	Praise the mother for her ability to recognize signs and symptoms and seek treatment.	Praise enhances mother's self-esteem, helping to promote feelings of control.	Mother states she feels capable of caring for child with acute otitis media without antibiotic prescription.
		Discharge Planning		
Nurse	Assess whether child or parents have any questions about care that they still need answered.	Instruct the mother to contact the clinic or health care provider if there is no improvement within 24 to 48 hr or if the child exhibits increased pain or a sudden relief of pain.	Lack of improvement within 24 to 48 hr indicates the need for further evaluation. Increased pain may indicate excessive fluid accumulation, which could lead to tympanic rupture, evidenced by a sudden relief of pain.	Mother states she feels prepared to care for child at home. Has clinic telephone number. Will telephone if symptoms of complications occur.

Otitis Media With Effusion

Otitis media with effusion is a result of chronic otitis media. Normally, the middle ear is an air-filled cavity, with air being supplied to it by the eustachian tube. The tube opens with swallowing, yawning, or chewing. If this source of air to the middle ear is shut off, the epithelial cells of the middle ear change in function, becoming secretory cells. The middle ear fills with these secretions. Over time, the fluid becomes so thick and tenacious that it is described as "gluelike." Some children notice a feeling of fullness or the sound of popping or ringing in their ears. There may be a drop in hearing of 20 to 40 dB because of the fluid content. Because the loss is gradual, parents and children may not be aware of it until it is noticed on a routine hearing screening. Involvement is usually bilateral. The condition occurs most frequently in children 3 to 10 years of age (Yates & Anari, 2008).

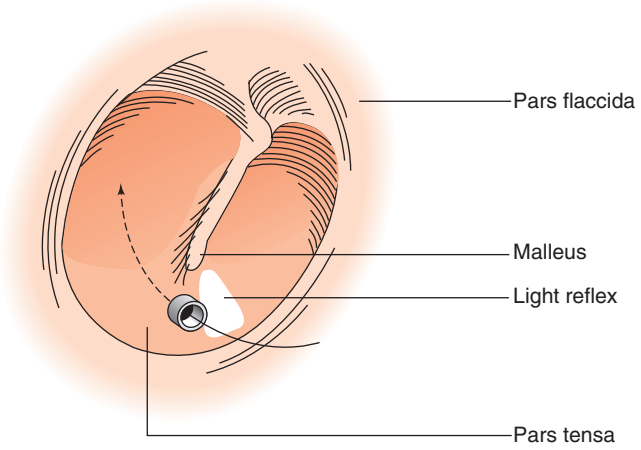

FIGURE 50.10 A myringotomy tube provides air to the middle ear to prevent otitis media with effusion.

Assessment

With otitis media with effusion, a child experiences muffled hearing and a feeling of pressure in the ear. Examination of the ears may show a level of fluid behind the tympanic membrane. However, a fluid line will be visible only if there is also a quantity of air in the middle ear to contrast with it. As the collected fluid becomes thick, it tends to retract the eardrum. This makes the malleus more prominent and perhaps displaced to a horizontal angle as the membrane is retracted around it; the light reflex from the otoscope light becomes distorted. If a pneumatic otoscope is used, gentle introduction of air against the eardrum produces no movement of the tympanic membrane (as there would be normally).

Therapeutic Management

Therapy for otitis media with effusion may be long term. If the condition appears to be intensified by inflammation from an allergy, measures to control the allergy must be initiated. These may include avoidance of the allergen, hyposensitization, or pharmacologic alteration of the allergic response. Treatment of children with allergies is discussed in Chapter 42.

Definitive medical treatment is aimed at supplying air to the middle ear. For mild involvement, the daily administration of an antihistamine or a nasal decongestant to shrink the mucous membrane of the eustachian tube may be enough to achieve an air supply. In a few children, the eustachian tube is blocked by enlarged adenoids, and their removal is indicated. Fluid from the middle ear can be removed by tympanocentesis (needle inserted through the tympanic membrane); this usually returns, however, unless some intervention to introduce air to the middle ear (tubal myringotomy) is undertaken.

Tubal Myringotomy. A source of air can be supplied to the middle ear by the insertion of small plastic (Teflon) tubes inserted through the tympanic membrane (tympanostomy). The insertion of such tubes is done after a myringotomy at a point in the tympanic membrane that is not instrumental for hearing, so they do not interfere with hearing (Fig. 50.10). Myringotomy tubes can be placed in one or both ears as an ambulatory procedure after the local injection of lidocaine (Xylocaine). Tubes tend to be extruded after 6 to 12 months. For many children, this period is long enough to halt the secretory process of the middle ear. In others, tubes must be reinserted to continue the aeration.

When myringotomy tubes are in place, water should not be allowed to enter the child's ears. Most physicians prefer children to bathe rather than shower, but showering may be allowed if ear plugs are used. Hair washing should be done with ear plugs in place. Similarly, swimming is either contraindicated or allowed only with ear plugs in place.

Otitis media with effusion runs a long-term course in many children. Teach parents to continue giving medications as prescribed. They often need a great deal of support to accept the insertion of myringotomy tubes as these seem so intrusive (Schindler et al., 2009).

Parents are afraid that cutting of the eardrum will do more harm than if they just leave the situation alone. Because the course of the process is long term, the hearing impairment associated with it may also be long term. Urge parents to notify the school nurse that their child is hearing challenged. Children may need to be changed to a front seat in a classroom so they do not miss important class content or discussion. They need support through this puzzling and annoying condition.

Cholesteatoma

Cholesteatoma is a lesion of the pars flaccida or upper portion of the tympanic membrane. A retraction cyst forms, and there is necrosis of the pars flaccida with foul-smelling drainage from the ear. If the retraction cyst is not discovered and surgically removed at this point, it grows gradually deeper and deeper, until it eventually invades the mastoid cells. It can progress to mastoiditis, meningitis, and possibly facial nerve paralysis if it is not surgically removed.

Any child with foul-smelling drainage from the ear should be referred to a primary care provider for further investigation to rule out this problem. If you are inspecting children's tympanic membranes during health maintenance visits, be certain to inspect the pars flaccida and pars tensa to detect cholesteatoma (Fischbein & Ong, 2008).

THE HOSPITALIZED CHILD WITH A HEARING IMPAIRMENT

A hearing loss greater than 49 dB is sufficient enough to interfere with hearing normal conversation and developing language. Like visually challenged children, children with hearing loss may be hospitalized for other health problems. It can be difficult for parents to prepare children who cannot hear for hospitalization. Words such as *surgery, tonsils, hurts, operating room,* and *recovery room* are new to them. Showing the child a book with good pictures demonstrating what is going to happen is helpful. Allowing children time to play with dolls or puppets can help them understand hospital routine. Because children who are hearing challenged may not be as well prepared for hospitalization as those without a hearing impairment, make an extra effort on admission to ensure that they receive such instruction.

Always allow hearing-challenged children to see you before you touch them as they will not find this nearly as intrusive as being touched without warning. If children are sleeping when you approach them, use a light touch to waken them gently. Some children turn off their hearing aid or remove it while they sleep. You may need to turn it on before you call them to wake them, or they may need to replace the hearing aid as soon as they awaken. Children as young as 2 years of age are effective lip readers as long as you are facing them. Position yourself at eye level, so the child can view your face. In a group, help the child follow conversation by directing him to the person who is speaking. Assign consistent staff members to decrease the number of people with whom the child must attempt to communicate. Have a staff person accompany the child and stay with the child in all departments to help with communication.

Do not underestimate the intelligence level of hearing-challenged children. Because they do not speak clearly, others may assume that hearing-challenged children are cognitively challenged. As a result, they may not be given information that the average hearing child receives, such as explanations of how things work. On a hospital unit, hearing-challenged children, locked in a silent world, are unable to express how they feel about procedures. They need help from health care personnel who understand this and take more than the usual amount of time to offer them explanations and support.

Ask parents of children who are hearing challenged to draw pictures or demonstrate the sign language symbols their children use for important words such as *pain, drink,* and *bathroom.* Encourage children to use or draw pictures of what they want if they are still too young to write words and you cannot understand what they are saying.

Hearing-challenged children have the right to be provided with a sign language interpreter during care. Advocate for this, especially if the parents will not be present during care.

✔ Checkpoint Question 50.3

Carla has acute otitis media. How does this differ from otitis externa?

a. Otitis media manifests as a sudden disease; externa tends to be a chronic disease.
b. Otitis media is infection of the middle ear; externa is infection of the outer canal.
c. Otitis media occurs on the eardrum; externa occurs on the cochlear nerve.
d. Otitis media is treated with antibiotics; externa is treated with antifungal agents.

Key Points for Review

- Teaching preventive measures to avoid eye and hearing injuries (using proper eye protection during sports or play and wearing goggles or ear protection as appropriate) and screening children for sensory impairments are important nursing roles.
- Refractive errors of vision such as myopia and hyperopia are the most common eye disorders in children. Amblyopia (lazy eye) is subnormal vision in one eye. Children with these disorders need correction at the time the disorder is recognized to prevent further vision distortion.
- Coloboma is congenital incomplete closure of the pupil or lower eyelid. Ptosis is the inability to open the upper eyelid normally. Ptosis needs correction to avoid development of amblyopia. Strabismus is unequally aligned eyes. Like ptosis, it can lead to amblyopia if not corrected.
- Infections of the lids, such as styes or chalazions, can occur in children. Conjunctivitis (inflammation of the conjunctiva) often manifests with acute symptoms. An antibiotic is necessary for therapy.
- Eye injuries such as penetration by a foreign body need follow-up after treatment to be certain that vision remains adequate.
- Children who are either vision or hearing challenged need special preparation and orientation for a hospital or ambulatory health visit, so that they can fully understand what is going to happen during the visit.
- Help children who are vision challenged to work through new experiences by letting them feel equipment as much as possible. Guide their hands through the steps of a new procedure you are teaching them.
- Otitis media (middle ear infection) is a common childhood illness. Some children who have otitis media with effusion have myringotomy tubes inserted to relieve pressure and supply air access to the middle ear.
- Use photographs, drawings, or demonstration with hearing-challenged children to help them learn new skills. Contact a signing interpreter as appropriate to be certain that children understand instructions.

CRITICAL THINKING EXERCISES

1. Carla is the 4-year-old girl with an ear infection whom you met at the beginning of the chapter. Her mother states, "She's always had a lot of problems. She had strabismus as a baby. Now, I think she has another ear

infection. It started out as a head cold but now she's pulling at her ear. Why does she get so many of these?" How would you answer Ms. Vander? What information does she need to know about ear infections?

2. Carla will be having surgery to remove a chalazion from her eyelid. What special steps do you want to take to prepare her for this surgery? Is she old enough to appreciate the importance of seeing?
3. You are going to teach a first-grade class on ways to prevent eye and hearing injuries. What would you include in your class? How would your teaching plan be different if the class was for 16-year-old students?
4. Examine the National Health Goals related to sensory disorders in children. Most government-sponsored funds for nursing research are allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to the Vander family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to vision and hearing disorders in children. Confirm your answers are correct by reading the rationales.

Chapter 51

Nursing Care of a Family When a Child Has a Musculoskeletal Disorder

KEY TERMS

- apposition
- arthroscopy
- cartilage
- compartment syndrome
- diaphysis
- distraction
- epiphyseal plate
- epiphysis
- fracture
- malleoli
- metaphysis
- myopathy
- periosteum
- remodeling
- resorption
- sequestrum
- sprain
- strain
- traction

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe common musculoskeletal disorders in children.
2. Identify National Health Goals related to musculoskeletal disorders and children that nurses can help the nation achieve.
3. Use critical thinking to analyze ways that care of a child with a musculoskeletal disorder can be more family centered.
4. Assess a child with a musculoskeletal disorder.
5. Formulate nursing diagnoses related to a child with a musculoskeletal disorder.
6. Establish expected outcomes for a child with a musculoskeletal disorder.
7. Plan nursing care for a child with a musculoskeletal disorder.
8. Implement nursing care, such as supplying age-appropriate diversional activities, for a child with a musculoskeletal disorder.
9. Evaluate expected outcomes for achievement and effectiveness of care.
10. Identify areas related to care of a child with a musculoskeletal disorder that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of musculoskeletal disorders with nursing process to achieve quality maternal and child health nursing care.

Jeffrey, a 13-year-old boy, is brought to a clinic today because he has pain in his left lower leg. He has a fever, and his leg is warm to the touch and edematous. His mother tells you he had an infected mosquito bite in that area 2 weeks ago. After further evaluation, Jeffrey is diagnosed with osteomyelitis. His mother asks, "How could he get an infection all the way into his bone from such a simple thing? I thought he was just having growing pains."

Previous chapters described the growth and development of well children and the nursing care of children with a disorder of other body systems. This chapter adds information about the dramatic changes, both physical and psychosocial, that can occur when a child develops a musculoskeletal disorder.

What does Jeffrey's mother need to know about bone infections? How would you explain to her what has happened?

The skeletal system, composed of more than 200 bones connected by the joints and tendons, provides a structural casing or protective armor for the internal organs of the body. Skeletal muscles, which are attached to the bones by connective tissue, tendons, and ligaments, allow for voluntary movement, including gross motor activity, such as running, and fine motor activity, such as writing. Together, the skeletal and muscular systems support the body and make coordinated movement possible.

Because their bones and muscles are still growing, children suffer from disorders of the musculoskeletal system more frequently than do adults. On the other hand, because bones are still growing, fractures (breaks in the continuity or structure of bone) heal much more quickly in children than in adults. However, if a growth plate is injured and bone growth halts, an injury that might be simple in an adult becomes serious in a child. Because many musculoskeletal system disorders lead to problems with locomotion and possibly limitations of activity, they can threaten a child's ability to develop optimally in other ways. Children gain much of their knowledge by interacting with people and exploring the environment around them so any self-limiting problem of locomotion can become a serious impairment during childhood. Nurses, along with occupational therapists and physical therapists, play a key role in teaching parents ways to expose their children to the same sorts of stimuli that might be experienced if a child were able to move around independently. Much of this can be achieved by early intervention programs. Maintenance of musculoskeletal function is addressed by the National Health Goals (Box 51.1).

BOX 51.1 ✻ Focus on National Health Goals

To maintain a healthy musculoskeletal system, proper exercise is necessary. Several National Health Goals address this issue:

- Increase the proportion of the nation's public and private schools that require daily physical education for middle or junior high students from a baseline of 6.4% to 9.4%.
- Increase the proportion of adolescents who participate in moderate physical activity for at least 30 minutes per day on 5 days a week from a baseline of 27% to at least 35%.
- Increase the proportion of adolescents who view television 2 or fewer hours on a school day from 57% to 75%.
- Increase the proportion of trips that children and adolescents make by walking from 31% to 50% (http://www.nih.gov).

Nurses can help the nation achieve these goals by educating children about the importance of physical activity, serving as consultants for school systems in designing physical education programs, and being certain to ask children about their usual activity level at health maintenance visits.

Nursing research that would help add to nursing knowledge includes investigating whether children sustain interest longer in group or single-person exercise programs; whether adolescents are accurate in reporting the time and intensity of exercise in which they engage; and whether designing exercise programs for well children and for those with chronic illness can be a nursing role.

Nursing Process Overview

For Care of a Child With a Musculoskeletal Disorder

Assessment

Unlike many other diseases in children, disorders of the skeletal system usually manifest with specific, localized symptoms so parents usually bring children to health care facilities early in the course of such illnesses. On the other hand, disorders of the muscles or joints such as juvenile rheumatoid arthritis (JA) may manifest insidiously; when the disorder is diagnosed, parents may feel guilty for not having sought health care earlier.

The way that parents and children react to the diagnosis of a musculoskeletal disorder can be culturally influenced. Because an adolescent culture is often one that respects athletics, beauty, and conformity, it can be a very difficult time for an adolescent to maintain body image and self-esteem when a musculoskeletal disorder is present.

One condition whose seriousness parents may underestimate is a childhood limp. A limp is never normal, and it may be the first manifestation of a serious hip or knee problem. When weighing or measuring children at health care visits, take the opportunity to assess gait (whether a child walks naturally or stiffly, on tiptoes or on the whole foot; whether the feet are in good alignment; whether the back is held straight). Such assessments may detect that a child brought to a health care center because of an upper respiratory condition, for example, has another, perhaps more important, musculoskeletal problem requiring evaluation. Because scoliosis is a common spinal deformity requiring early detection, school nurses have direct responsibility for instituting scoliosis screening programs in their schools. Because skeletal injuries can be a sign of abuse, careful history taking is necessary to rule out this possibility.

Nursing Diagnosis

The nursing diagnoses most frequently identified for children with musculoskeletal disorders include those that deal with pain, lack of mobility, and, because of immobilization, a need for diversional activities. Children, especially adolescents, who require a walker or other equipment to aid in skeletal support or locomotion may encounter problems with self-esteem. Examples of some typical nursing diagnoses are:

- Pain related to chronic inflammation of joints
- Impaired physical mobility related to cast on leg
- Deficient diversional activity related to need for imposed activity restriction for 4 weeks
- Situational low self-esteem related to continuous use of body brace

Outcome Identification and Planning

Many musculoskeletal problems in children require long-term care. Despite current therapies, some disorders may leave a child with a permanent disability. Before a child is discharged from an ambulatory or inpatient setting, help the parents plan how they will care for the child at home. At first, a cast on an arm seems exciting to a school-age child: it is something to show off, an injury to describe, an excuse not to write in school. After a few days, the cast may become more frustrating than enjoyable. Take the time to review what wearing the cast will mean to the child in everyday situations. For example, the cast may not fit through school uniform shirts with tight cuffs. Planning transportation may be a problem if the child has a large cast and is not able to fit in a car seat. If the child must stay home from school, plans for tutoring need to be made. If both parents work outside their home, child care may be necessary.

Depending on the child's and family's circumstances, the answers to these problems differ. However, taking the time to sit down with the parents and asking them whether these concerns will pose problems initiates problem solving. Doing so helps parents prepare solutions with a concerned person rather than by themselves at home.

Referrals to appropriate organizations may be helpful. Organizations that can be used for referral include Arthritis Foundation (http://www.arthritis.org), Muscular Dystrophy Association of America, Inc. (http://www.mdausa.org), National Institutes of Health, Osteoporosis and Related Bone Diseases—National Resource Center (http://www.osteo.org), Osteogenesis Imperfecta Foundation, Inc. (http://www.oif.org), and Scoliosis Foundation (http://www.scoliosis.org).

Implementation

Many nursing interventions for children with musculoskeletal disorders involve care of a child in a cast or in traction (treatment involving pulling on a body part in one direction against a counterpull exerted in the opposite direction) or teaching about common concerns, such as posture or children's shoes. Parents and children who are kept well informed in these matters are much more likely to be able to cope with changing circumstances.

Outcome Evaluation

Children with musculoskeletal disorders invariably need follow-up care after discharge from an ambulatory visit or inpatient care, because bone healing can be a slow process.

Both parents and children may need support at re-evaluation visits when learning that a cast or brace must stay on longer or that they must continue exercises. Praise for their management thus far is an effective intervention for helping parents realize that they can cope with the situation in the future.

During re-evaluation visits, spend time assessing children's body image and self-esteem. Do children view themselves as basically well persons who, oh, by the way, have a right leg shorter than the left leg, or as deformed persons who are inferior to others? Success of treatment is incomplete if a child's self-concept is diminished.

Some examples indicating achievement of outcomes are:

- Child states he feels no pain or numbness in extremity after application of a cast.
- Child demonstrates allowable weight-bearing activities with casted lower extremity.
- Parents accurately state child's care needs both in and out of the hospital.
- Child states positive aspects of self, participates in activities, establishes friendships with peers.

THE MUSCULOSKELETAL SYSTEM

Bones and Bone Growth

Bones are generally classified by their shape as long, short, flat, or irregular. Long bones are the bones of the extremities, including the fingers and toes, in which most childhood bone disorders are found. The short bones are those found in the ankle and wrist. Flat bones are found in the skull, ribs, scapula, and clavicle. Irregular bones are found in the vertebrae, the pelvis, and the facial bones of the skull.

Long bones are composed of a long central shaft (the **diaphysis),** a rounded end portion (the **epiphysis),** and a thin area between them (the **metaphysis)** (Fig. 51.1). Increase in the length of long bones occurs at the cartilage segment (the **epiphyseal plate),** between the epiphysis and the metaphysis. As **cartilage** (connective tissue) cells grow away from the shaft, they are replaced by bone, thereby increasing bone length. Injury to this area in a growing child is always potentially serious, because it may halt growth, stimulate abnormal growth, or cause irregular or erratic growth. The central shafts of long bones are covered by an outer sensitive layer of **periosteum.** Bone width increases by growth at the inner surface of the periosteum. Injury to the periosteum, such as may occur with osteomyelitis, can also threaten bone growth (Helmann & Imboden, 2009).

Although it is easy to think of bones as rigid, solid structures, they are, in fact, living tissue, to which nutrients must be supplied for growth. Calcium, one of the main components of bone, is an important element for bone formation, **remodeling** (replacement of old by new bone tissue), and

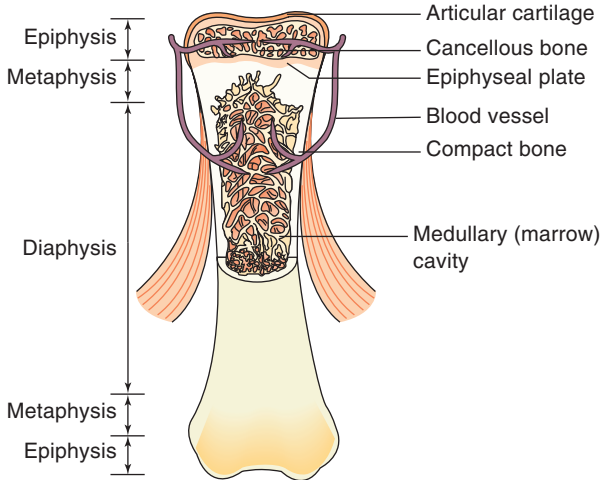

FIGURE 51.1 Structure of a bone.

resorption (bone breakdown). These processes are influenced by parathyroid hormone, calcitonin, vitamin D, other minerals, nutrients, and enzymes. "Bone age" can be determined by a radiograph of the wrist that shows the ossification level of the bones.

The inner core of long bones is filled with yellow and red marrow and is responsible for the formation of platelets, red blood cells, white blood cells, and adipose (fat) cells. Red marrow is primarily involved in blood component production, whereas yellow marrow is chiefly involved in adipose cell formation. The blood supply to bones is abundant, so that the marrow can actively supply enough blood components for the body. As with other tissues, if the blood supply is cut off, bone cells die.

The bones of children tend to be more resilient than those of adults. This means that accidents that might result in severe breaks to adult bones are apt to result in lesser breaks or only torsional twists in children. Because bones heal more quickly in children than in adults, children usually are incapacitated for a shorter time after an injury.

Muscle

The skeletal muscular system is composed of one type of muscle, called striated muscle, which is the predominant muscle in the body (differentiated from smooth muscle, which is responsible for, among other things, gastrointestinal peristalsis). Activation of skeletal muscle occurs with innervation from a motor nerve and is under voluntary control. **Myopathy,** or disease of the muscular system, can be inherited (as in muscular dystrophy) or acquired (as in myasthenia gravis).

ASSESSMENT OF MUSCULOSKELETAL FUNCTION

In addition to a history and physical examination, diagnostic tests frequently are necessary to detect musculoskeletal dysfunction in children. These may include x-ray and bone scans, bone and muscle biopsies, electromyography, and arthroscopy. Ultrasound and magnetic resonance imaging (MRI) studies are used to reveal soft tissue disease.

Radiography

Because bones are opaque, they outline well on radiography. Information can be provided about a specific bone, groups of bones, or a joint. Radiographs can also provide information about soft tissue structure, swelling, or calcification around bones. However, other tests are indicated to confirm problems with cartilage, tendons, and ligaments.

Bone Scan

A bone scan is a study of the uptake by bone of intravenously (IV) injected radioactive substances (Nadel, 2007). The distribution and concentration of the substance are evaluated to determine the exact problem. For example, areas of increased metabolic activity cause the substance to concentrate in that area. A bone scan provides information on very early stages of bone disease and healing, often before they are visible on radiographs.

Electromyography

Electromyography studies the electrical activity of skeletal muscle and nerve conduction. It can determine the location and cause of disorders such as myasthenia gravis, muscular dystrophy, and lower motor neuron and peripheral nerve disorders.

For the test, needle electrodes are inserted into muscle masses; the electrical activity of the muscle at rest and in motion is detected by audioamplification and recorded on an oscilloscope screen. Normally, resting muscle is quiet. If defects such as fasciculations are present, abnormal noises or oscilloscope spikes will be observed.

Although the needle electrodes are small, the test may be frightening for children because they are pricked by needles. They need support from someone they know during the procedure. Before and after the procedure, provide opportunities for therapeutic play so a child can express anxiety and feelings.

Muscle or Bone Biopsy

A muscle or bone biopsy involves removal of a tissue sample for examination of its microscopic structure. It can provide evidence about infection, malignant bone growth, inflammation, or atrophy of the area. Either type may be done during surgery or as an ambulatory procedure.

Muscle biopsy is usually done using conscious sedation and a local anesthetic. If local anesthesia is used, caution children that they will feel the initial prick of an anesthetizing needle; as the actual biopsy needle enters the muscle mass, they will feel an additional momentary pressure. They can be assured that the amount of tissue taken from them is no larger than the inner bore of the biopsy needle, comparable to the size of the lead in a pencil.

Arthroscopy

Arthroscopy involves direct visualization of a joint with a fiberoptic instrument. It is usually done under local anesthesia in an ambulatory care setting. Arthroscopy allows a joint, most commonly the knee, but also the hip, shoulder, elbow, or wrist, to be examined without a large incision. It is most often used to diagnose athletic injuries and to differentiate between acute and chronic joint disorders (Urquhart & Wilckens, 2007).

HEALTH PROMOTION AND RISK MANAGEMENT

Health promotion focuses on thorough assessment at all health maintenance visits. A child's ability to achieve developmental milestones, specifically gross and fine motor abilities, provides important information about the child's musculoskeletal function because the ability of a child to be fully mobile directly influences the child's exploration of the environment and exposure to stimuli. If mobility is impaired, it can interfere with growth and development to a high degree. Screening for musculoskeletal disorders, such as for scoliosis in the prepubescent child and adolescent, is an extremely important health promotion measure.

Parents may ask to have x-ray studies done frequently to evaluate healing progress. They may need to be reminded that

radiographs are never taken on children unless there is a documented need for them, because excessive radiation at epiphyseal plates can lead to uneven growth. Although controversial, extensive radiation has also been associated with the development of malignancies, such as sarcomas, carcinomas, or brain tumors in the field of radiation (Maloney et al., 2008).

Safety is paramount for any child to prevent injury. Anticipatory guidance for parents is essential to minimize the risk of injury, specifically to the extremities, in all aspects of everyday life. As a child grows and becomes active in sports, parental and child education about the importance of using bike helmets for bike riding, or protective gear for football, takes on an even greater role.

Nutrition education is important to ensure adequate calcium intake for bone growth and healing. However, if a child requires bed rest, calcium intake should be moderated to reduce the risk of renal calculi formation resulting from immobilization. The teenage years are an important time for both males and females to build calcium stores to protect against osteoporosis later in life (Pepper & Saint-Phard, 2007).

If a child experiences a musculoskeletal disorder, education helps to prevent complications, maximize the child's ability to function, and minimize the risk of residual impaired physical mobility. Both parents and children need instruction about aspects of treatment and follow-up—for example, caring for a child who requires a cast, traction, a body brace, or drug therapy such as antibiotics for osteomyelitis, or nonsteroidal anti-inflammatory drugs (NSAIDs). Teaching provides a basis for maximizing the effectiveness of treatment and minimizing the possible long-term risk for complications.

THERAPEUTIC MANAGEMENT OF MUSCULOSKELETAL DISORDERS IN CHILDREN

Various methods may be used as therapy for children with musculoskeletal disorders, including casts, traction, distraction, and open reduction. Amputation, a rare necessity, is discussed in Chapter 53.

Casting

Casts may be used to treat a variety of musculoskeletal system disorders, from simple fractures in the extremities to correction of congenital structural bone disorders.

Cast Application

Casts are created from either plaster of Paris or fiberglass. Fiberglass is an attractive material to use for children's casts because it is light in weight; comes in attractive colors; and, when a special waterproof liner is used, can be immersed in water. Unfortunately, it is more expensive and may not be practical for casts that need frequent changing, such as those used to correct talipes disorders, a common congenital disorder that requires serial casting.

Children need an explanation of what to expect with casting. To maintain alignment of body parts, a physician gently exerts a pull on the body part being casted during the cast application. If a large body cast is being applied, children may be positioned on a special cast table with traction apparatus at the chin and pelvis to initiate tension. These are stark, steel tables and may resemble torture racks children have seen in horror movies. Allow a support person to accompany children to a cast room to hold their hand or talk to them during the application. Most children (and adults) are unaware that casts are formed from strips or rolls of material impregnated with the casting material. The normal curiosity of children as they watch a cast grow and mold to their body part makes casting a pleasant procedure. Some children look forward to having a cast applied, regarding it as a badge of courage or a conversation piece.

Before a cast is applied, a tube of stockinette is stretched over the area, and soft cotton padding is placed over bony prominences. This stockinette is pulled up and over the raw edges of the cast as it is applied to create a smooth, padded surface (Fig. 51.2). If a plaster cast is to be applied, caution children that, at first, the wet strips of plaster of Paris feel cool. Almost immediately, the strips begin to generate heat as evaporation begins, and body parts feel warm. If the cast is a full-body cast, children may become uncomfortably warm, with perspiration possibly running from their forehead. Assure them that this feeling of warmth is transient and is never enough to cause a burn.

A plaster cast takes 10 to 72 hours to dry, depending on its size. Fiberglass casts usually dry within 5 to 30 minutes. A

FIGURE 51.2 Cast application. (**A**) A cast is applied to a young boy's arm over a stockinette already in place. (**B**) Casts do not cover the fingers so these can be assessed for color and warmth. (© Shout Pictures/Custom Medical Stock Photographs.)

window may be placed in a cast if an infection is suspected, so that the area can be observed. A window also may be used with an open fracture, to permit observation and care of the wound site. If the child has a body or hip spica cast, windowing may prevent uncomfortable abdominal distention.

Compartment syndrome is a phenomenon that occurs when a cast or tight constrictive dressing puts pressure on an enclosed space such as the forearm. This pressure results in severely decreased blood flow that potentially threatens damage to and necrosis of surrounding soft tissue or nerves. Assess fingers or toes carefully for warmth, pain, and function after application of a cast to be certain a compartment syndrome is not developing. If signs of compartment syndrome are present, the cast needs to be released immediately to prevent permanent nerve and tissue damage. A fasciotomy (surgically opening the compartment) may be necessary to further prevent nerve damage.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for ineffective peripheral tissue perfusion related to pressure from cast

Outcome Evaluation: Child states she feels no pain or numbness in extremity; distal nail bed blanches and refills in less than 3 seconds; pedal pulses are palpable.

If an extremity has been casted, keep it elevated to prevent edema in the part. Check circulation frequently, such as every 15 minutes during the first hour, hourly for the next 4 hours, and then every 4 hours through the first day. Assess for color, warmth, presence of pedal pulses, and sensations of numbness or tingling. Signs of impaired neurovascular function include pallor (including blueness or coldness of a distal part), pulselessness, pain in the casted part, paresthesia (numbness or tingling in the part, as if it were "asleep"), and paralysis. Children younger than 6 or 7 years of age have difficulty describing paresthesia; however, they may whine or cry with the discomfort of the sensation. Edema that does not improve with elevation is also an important sign. Any of these symptoms requires immediate attention, because neurovascular impairment can lead to nerve ischemia and destruction, possibly causing permanent paralysis of an extremity.

Preventing the flow of urine under the edges of a cast can be a problem with full body or high leg casts. If a cast surrounds the genital area of a non–toilet-trained child, cover the edges of the cast with plastic or waterproof material. Keeping children in a semi-Fowler's position by using pillows or raising the head of the bed helps to direct urine and feces downward away from the cast. Because a cast is heavy, infants tend to slip down in bed a great deal, so they need frequent repositioning to remain in a raised position.

Make certain that children who are being fed or feeding themselves have a bib or cover over the top edge of their cast so that crumbs and fluid do not spill inside. Toys should be chosen carefully for the same reason. A piece of food inside a cast will mold and macerate the skin; a small part of a toy dropped inside a cast can cause irritation and a pressure ulcer. Casts can be cleaned with a damp cloth if food or fluid is spilled on the outside of a cast.

Nursing Diagnosis: Parental health-seeking behaviors related to care of child with cast at home

Outcome Evaluation: Parents state plans for adapting home environment and lifestyle to accommodate child with cast; parents demonstrate measures to check neurovascular status.

If the child has an upper-extremity cast, be sure the parents understand how to position the extremity properly, such as with a sling. If the cast is on a lower extremity, instruct the child and parents on the amount of weight bearing allowed to the affected extremity and the use of crutches, if prescribed.

Handling a child in a large cast is a major task for parents. For many, it seems so overwhelming that they do not see how they will be able to care for the child at home. Assure them that the child is quite comfortable in the cast, despite its awkward, constricting appearance. Role model moving the child to give them direction. Be sure to caution them that, if an abduction bar is used with a cast, it must never be used as a handle for lifting the cast. Such use can break the bar from the cast or weaken its support.

A body cast is heavy, so caution parents to use good body mechanics (lift with the thighs instead of the back) when turning or positioning the child. Parents may also appreciate suggestions on ways to help move the child from room to room, such as using a toy wagon with a flat board on top or using a skateboard for the child to propel herself forward. It is important to point out that all children thrive on being touched. Children in large body casts need their head and arms stroked (or any areas of the body that are not covered by the cast). Demonstrate how even a child in a large hip spica cast can be held, cuddled, and supported for feeding.

Many children report a sensation of itching inside a cast at about the end of the first week. If the area is immediately under the edge of the cast, the itching is probably the result of dry skin caused by the drying effect of the cast. Reaching a hand under the edge of the cast and massaging the area usually relieves the itching. Applying hand lotion may relieve the dryness. If the area is unreachable, blowing cool air through the cast with a fan or a hair dryer set on cool air may relieve the uncomfortable feeling. Caution the child and parents not to use implements such as a coat hanger or knitting needle to scratch the area. These can injure the skin, causing infection under the cast (Box 51.2).

Transporting the child in a car, particularly fitting a bulky cast into an infant car seat, can be a major problem. Before a child is discharged from the health care facility, give parents a telephone number to call if they have any questions about cast care or their child's condition.

BOX 51.2 ✻ Focus on Family Teaching

Cast Care at Home

Q. Jeffrey's sister has a fiberglass cast on her arm. Her parents ask you, "How do we care for this?"

A. Here are some helpful tips to care for your child's cast at home:

- Keep the casted body part elevated on a pillow for the first day, to decrease swelling.
- Observe the hands and fingers (the body part distal to the cast) for swelling or blueness, and ask your child to move the part about every 4 hours for the first 24 hours. If she is unable to move distal parts or if swelling, blueness, or pain is present, telephone your health care provider. These signs could mean the cast is pressing on a nerve or constricting a blood vessel.
- Monitor strenuous activities, such as rough-housing, while the cast is in place, but urge usual activities, so your child remains active.
- Ask your child to think through how wearing a cast will change her day, such as making it difficult to eat in the school cafeteria or carry books to classes, and brainstorm how to solve these problems.
- Be certain your child knows not to put anything inside the cast. If itching occurs inside the cast, blowing some cool air into it from a hair dryer can be comforting.
- Be sure that your child keeps the cast dry (cover it with a plastic bag to shower); no swimming is allowed. Remind her that autographs are not allowed, because fiberglass is a porous material.
- Be certain to keep your return appointment for follow-up care. Because children grow so quickly, they can outgrow a cast rapidly. Outgrowing the cast could put pressure on nerves and lead to permanent disability.

Cast Removal

Most casts remain in place for 4 to 8 weeks and are then removed, using an electric cast cutter with a rapidly vibrating, circular disk (Fig. 51.3). Cast cutters are frightening, because the disk makes a very loud noise as it cuts through the cast material and also generates heat. To the child, the disk appears capable of cutting through not only the plaster but an arm or leg as well. The person removing the cast usually demonstrates that the disk does not cut skin by touching a thumb to the edge of it. Not all children are totally convinced by the demonstration, however, and may require additional support while the disk moves from one end of a cast to the other, such as saying, "It's all right to cry; I know this looks scary" or by holding your hands over the child's ears to lessen the noise.

The skin of the child's extremity looks macerated and dirty after a cast is removed; a good bath usually washes away most of this. If an arm has been casted in flexion, the elbow may feel stiff and even sore as the child is asked to extend it for the first time. Children often use extremities with caution after a cast has been removed. Advise parents to allow children to begin using extremities again this way at their own pace. As children naturally play and reach for objects, they gradually forget to favor the arm or leg, and full function then returns. Once healing has taken place, the extremity is as strong as it was before the fracture. The child does not need to continue to favor the extremity to protect it from a second fracture.

Crutches

Crutches are prescribed for children for one of three reasons: to keep weight off one or both legs, to support weakened legs, or to maintain balance. Usually, a physical therapist measures crutch length and gives beginning instruction in crutch walking. Be familiar with measuring and supervising crutch walking, so that you can offer emotional support to children as they learn to use crutches and can assess progress at follow-up visits.

Fit and Adjustment

If crutches are properly fitted, there should be a space of 1 to 1 and ½ inches between the axilla crutch pad and the child's axilla. When the child stands upright and places his hands on the hand rests of the crutches, the elbows should flex about 20 degrees. This degree of flexion ensures that, when the child bears weight on the crutch, the body weight will be borne by the arm, not the axilla. Pressure of a crutch against the axilla could lead to compression and damage of the brachial nerve plexus crossing the axilla, resulting in permanent nerve palsy. Teach children not to rest with the crutch pad pressing on the axilla but always to support their weight at the hand grip.

Always assess the tips of crutches to see that the rubber tip is intact and not worn through as the tip prevents the crutch from slipping. Be certain that the child is walking with the crutches placed about 6 inches to the side of the foot. This distance furnishes a wide, balanced base for support.

Explore with children any problems crutches may cause with their daily activities. If they carry books to school, for example, they may prefer to wear a backpack until they are free of crutches so their hands are free for the hand rests. Caution parents to clear articles such as throw rugs and small footstools out of the paths at home. If there are small children at home, parents will need to keep traffic areas free of toys to prevent an accident.

Crutch Walking

Two main crutch-walking patterns are used (Fig. 51.4). A two-point gait is used when a child needs support for weakened muscles or balance but may bear weight on both lower extremities. The child places the right crutch and left foot forward, then left crutch and right foot forward, and so on. Using the crutch opposite a foot provides a wider base of support than using the crutch next to the foot. Caution children to take small steps until they feel confident.

A three-point swing-through gait is used when no weight bearing is allowed on one foot. For this, the crutches are both brought forward. The weight of the body is then shifted forward as both legs are swung through the crutches. The child bears weight on the unaffected (good) leg and moves the crutches forward again. It takes strong arm support to bear full weight on crutches this way. Be certain the child is bearing weight on the hands and not on the axillae when swinging through. Some children use a swing-through gait rather recklessly and need to be advised to slow their pace to a safer one.

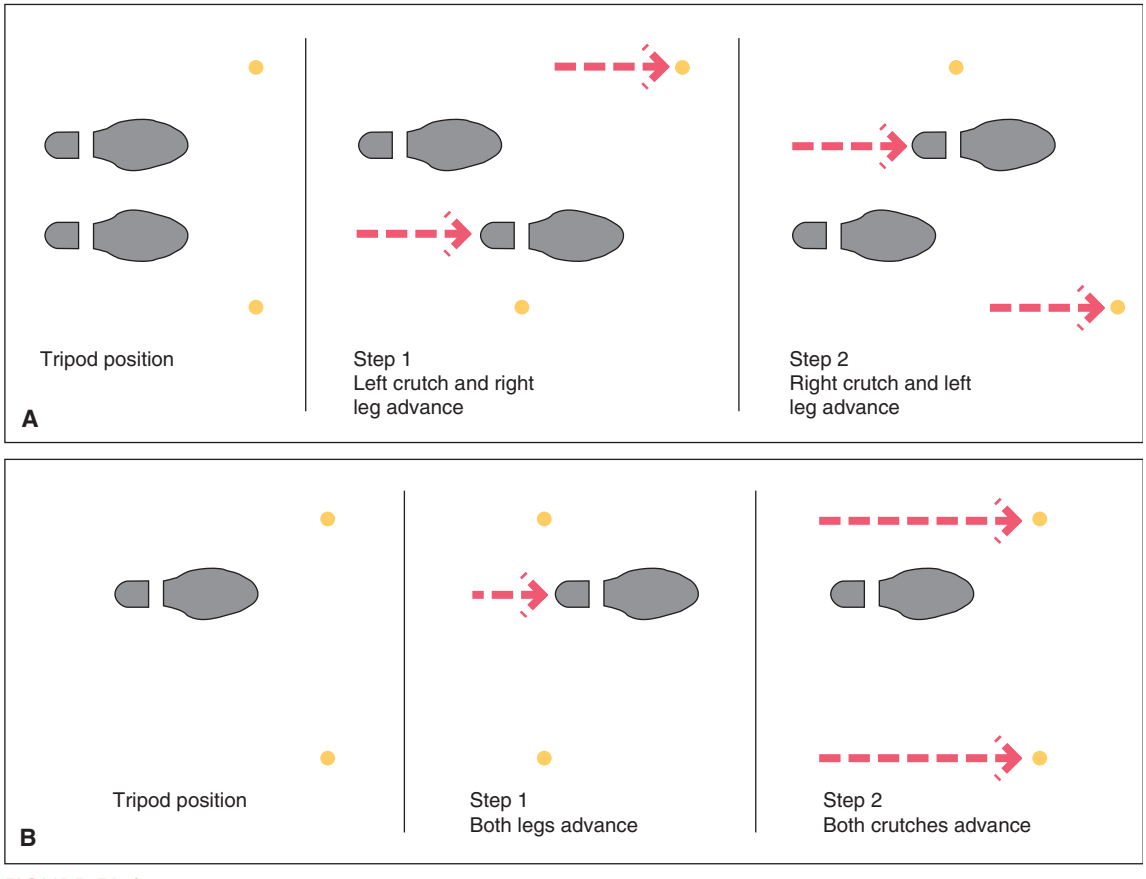

FIGURE 51.4 Crutch-walking patterns. (**A**) Two-point gait. (**B**) Swing-through gait.

To walk downstairs using a swing-through gait, children place their crutches on the lower step, then swing the unaffected (good) foot forward and down to that step. To go upstairs, they place their unaffected (good) foot on the elevated step, then raise the crutches onto the step and lift themselves up. To help children remember this pattern, a saying—"angels" (the good foot) go up; "devils" (the bad foot with the crutches) go down—is traditionally used.

✔ Checkpoint Question 51.1

You are teaching a child to walk with crutches. Which is the best instruction?

a. He should bear weight on his armpits to keep stress off his arms.
b. He should lean forward at a 45-degree angle while walking.
c. He should bear weight on his arms to avoid pressure on his axillae.
d. It is unsafe to walk downstairs with crutches; upstairs is all right.

Traction

Traction, which is used to reduce dislocations and immobilize fractures, involves pulling on a body part in one direction against a counterpull exerted in the opposite direction. Although still necessary for some conditions, the use of intermedullary rods is making its use unnecessary in many instances. In straight (running) traction, the child's body weight serves as the counterpull. In suspended or balanced traction, the body part is suspended by a sling, and the counterpull and primary pull are accomplished by pulleys and weights. Either skin traction (in which skin provides the counterpull) or skeletal traction (in which bone provides the counterpull) may be used. Skin traction is used if only minimal traction is necessary; the child's skin must be in good condition for this procedure. Skeletal traction is used if a longer period of traction or a greater strength of traction pull is needed. Types of traction are illustrated in Figure 51.5. Use of traction in the home shortens hospital stays and enables a child to interact with family members, so it should be encouraged.

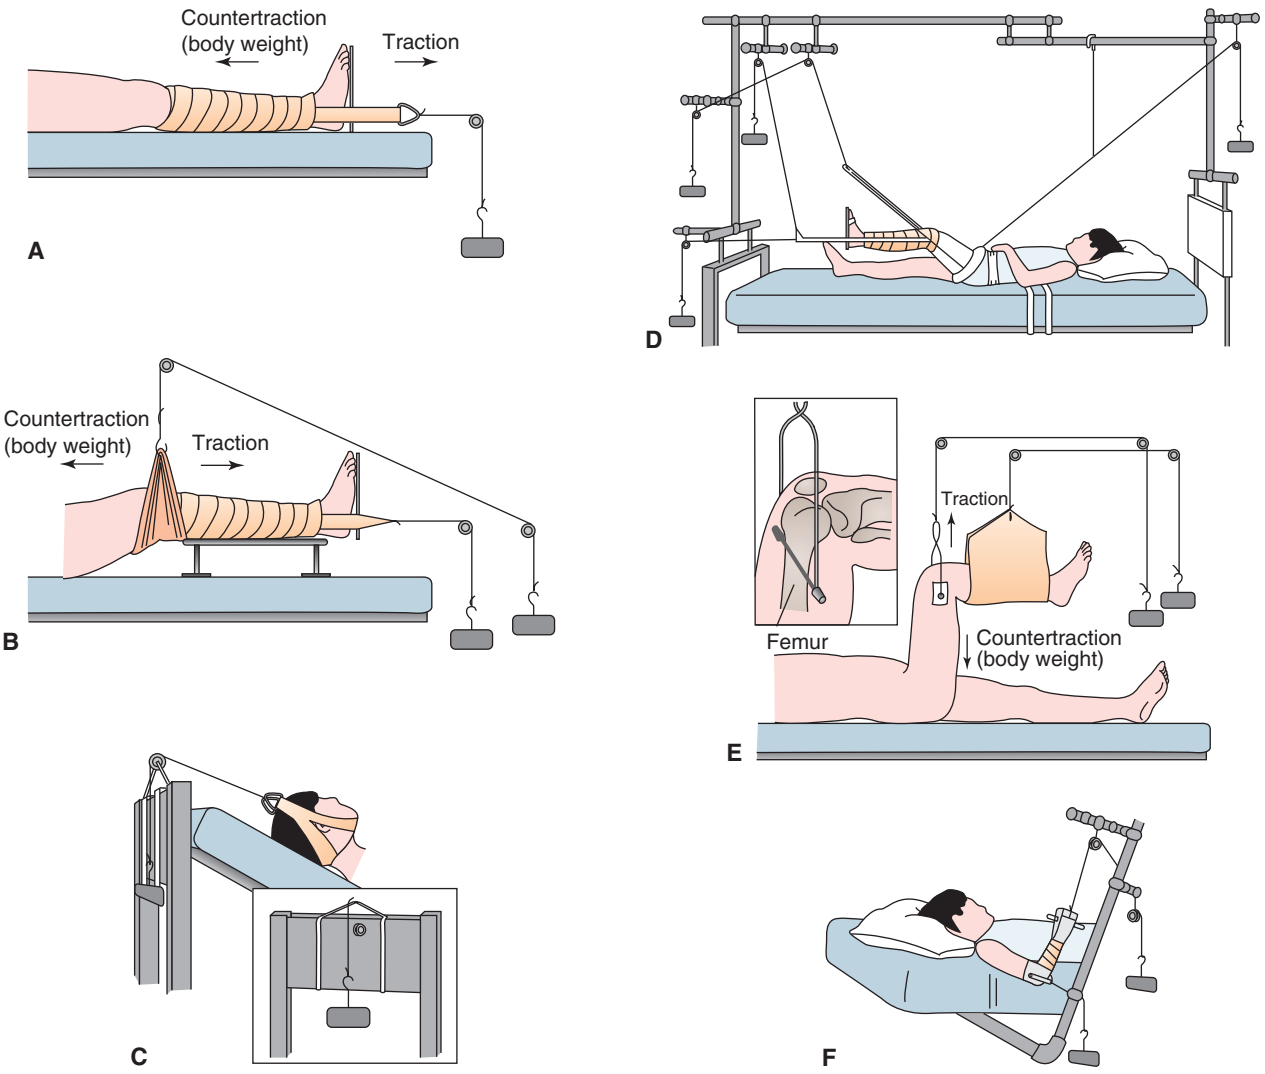

FIGURE 51.5 Types of skin traction: (**A**) Buck's extension, (**B**) Russell, (**C**) Cervical skin traction. Types of skeletal traction: (**D**) Balanced suspension, (**E**) 90-degree, (**F**) Dunlop's traction with pin insertion.

Skin Traction

Skin traction means a child's extremity is wrapped in a material such as an Ace bandage and then suspended from a nearby pole or frame so the weight of the body part produces traction (Esenyel et al., 2007). Bryant's traction, used for fractured femurs in children younger than 2 years of age, is an example of skin traction (Fig. 51.6). It also may be used in preparation for surgical repair of congenital developmental disorders, such as developmental hip dysplasia (see Chapter 27). This type of traction is used less frequently now because the elevation of the extremities causes blood to pool at the hips. This and the possible tourniquet effect of the traction strips, bandages, and traction itself increase the risk for vasospasm and avascular hip necrosis.

Buck's extension is an example of skin traction used for immobilizing lower-extremity fractures in older children. Dunlop's traction is used to immobilize an upper extremity. Cervical skin traction may be used to decrease muscle spasms in the back. This type of traction uses a halter-type device attached to weights. With this type of traction, the head of the bed is elevated to provide some countertraction.

Skeletal Traction

Skeletal traction involves the use of a pin, such as a Steinmann pin, or a wire, such as a Kirschner wire, that is passed through the skin into the end of a long bone. The pin or wire can be inserted in an emergency department under local anesthesia if the child can hold absolutely still, but usually it is done under general anesthesia in the operating room. With skeletal traction, ropes strung over pulleys and attached to weights exert a pull on the extremity at the pin site. Cotton gauze squares usually are placed around the ends of the pin on the outside. Be sure to observe the pin sites daily for drainage. Odorous or excessive drainage or erythema may be a sign of infection at the pin site.

Traction-Related Care

Children in traction need to be assessed carefully for neurovascular impairment, as do children in casts. The extremity in traction should be checked every 15 minutes during the first hour, hourly for 24 hours, and every 4 hours thereafter for signs of pallor (or blueness), lack of warmth (coldness), tingling, absent peripheral pulse, edema, or pain. Traction can lead to hypertension because the head typically is positioned lower than the lower extremities. Assess once a day for this possibility.

FIGURE 51.6 An infant in Bryant's traction. Here, the father feeds the infant while the infant is maintained in traction. (© BSIP/Custom Medical Stock Photograph.)

FIGURE 51.7 A child in skeletal traction engages in therapeutic play. (© Gary Wagner/Stock Boston.)

Be careful when changing a child's bed linens or carrying out nursing functions that you do not move the weights or interfere with the traction. Provide good skin care on the child's back, elbows, and heels, which may become irritated. A trapeze bar suspended over the bed provides a great deal of mobility and assists children in using a bedpan and positioning themselves in bed.

Being in traction is not as dramatic for children as being placed in a cast. There is an unspoken feeling from other children that "if what you have is really serious, you'd have a cast." Explain to children why this type of treatment is best for them. Keep them informed of radiograph assessments (perhaps: "The fracture is being held in just the right position; the bone is beginning to re-form"). Although they cannot see progress, this information can help assure them that progress is occurring.

Children in traction usually are not "ill" children. They feel well except for the leg or arm being held in correct position. Therefore, they have the energy and the need for stimulation of well children. Child life specialists or volunteers can be helpful to keep them occupied. Being certain that they are involved in activities (perhaps using a wireless computer or texting) is a major part of nursing care (Fig. 51.7).

Help children to maintain contact with their school friends through cards, letters, or tape-recorded messages. If hospitalized, their bed should be located so that they can see unit activities. Whether at home or in the hospital, encourage frequent visitors of their own age, to help maintain peer relationships.

Distraction

Distraction involves the use of an external device to separate opposing bones, which encourages new bone growth. It can be used to lengthen a bone if one limb is shorter than the other. It also can be used to immobilize fractures or correct defects if the bone is rotated or angled.

A device such as the Ilizarov external fixator is used to achieve distraction (Fig. 51.8). It consists of wires that are

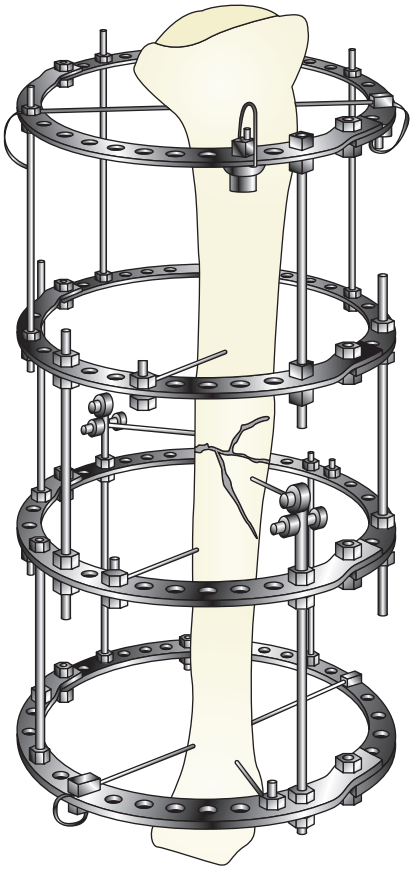

FIGURE 51.8 Ilizarov device in place to treat comminuted fracture.

inserted through the bone. The wires are attached to either full or half rings, which are secured to telescoping rods. For bone lengthening, the rods are adjusted approximately 1 mm each day to stimulate bone growth until the desired length is achieved. The device remains in place until consolidation is complete and there is no pain, limp, or edema. At this time, the bone is healed and can bear weight.

The child and parents need thorough preparation for the surgery and application of the device. Because the device is external, large, and awkward, they need to be prepared for its appearance and the reactions of others to it. Provide suggestions for ways to minimize the device's appearance, such as wide-legged pants with adjustable closures. Parents also need instructions about adjusting the telescoping rods, if ordered; providing care to the wire insertion sites; assessing for signs and symptoms of infection; and instituting activity restrictions. Follow-up care is essential to ensure the optimal outcome for the child.

Open Reduction

Open reduction is a surgical technique that is used to align and repair bone. If there is a spinal fracture or both bones of a forearm or lower leg are fractured, open reduction and insertion of a rod or screw may be necessary to stabilize the bones.

Once an open reduction is completed, the area usually is casted to provide support. Invariably, serosanguineous fluid oozes from an open-reduction site. Outline with a ballpoint pen any stain on the cast that suggests oozing from a surgical incision, so that an increase in the size of the mark can be detected. Do not use a magic marker for this, because the fluid tends to penetrate through the cast. Noting the time at which you make the pen mark on the cast allows you to tell how rapidly the spot is increasing. Children with an open-reduction incision are prone to incision infection, as is any child after a surgical incision. Be aware of systemic symptoms (increased pulse, increased temperature, lethargy) and local signs (edema, pain, tingling, blueness or coolness of the distal extremity) of infection.

DISORDERS OF BONE DEVELOPMENT

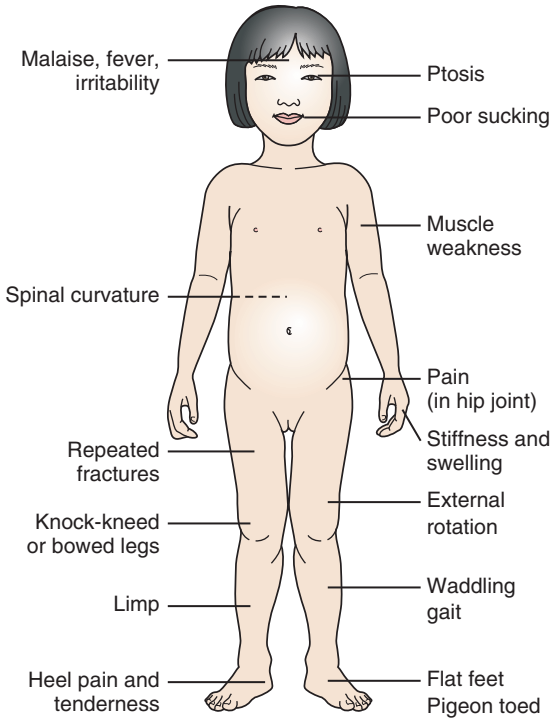
Many common musculoskeletal disorders in children are first noticed during routine physical exams (Box 51.3).

Flat Feet (Pes Planus)

The term *flat feet* refers to relaxation of the longitudinal arch of the foot. Although it is rare, many parents worry that their children have this problem. Parents become concerned because a newborn's foot is normally flatter and proportionately wider than an adult's. A transverse arch rarely is visible and a longitudinal arch may not be present until the child has been walking for months. Parents notice that when their child leaves footprints in the sand or makes wet tracks on the bathroom floor, the track makes an impression of a "flat foot."

Box 51.3 Assessment

Assessing a Child for Possible Signs and Symptoms of a Musculoskeletal Disorder



Evaluate children's feet by having them stand on tiptoe. In this position, a longitudinal arch should be visible. If they can stand on their heels with the soles of the feet off the ground, the feet probably are normal. Examine the ankle joint to be certain a full range of motion is present and to demonstrate that the Achilles tendon is not shortened. Tarsal and metatarsal joints should also show a full range of motion.

Some children experience foot pain at the end of the day. This probably occurs not from lack of a longitudinal arch, but from poor arch development. The arch can be strengthened and the pain usually can be eliminated if the child walks on tiptoe for 5 to 10 minutes daily or practices picking up marbles with the toes. For an older child, standing pigeon toed (toes pointed in) and throwing the weight forward onto the lateral aspect of the feet tends to strengthen arches.

Teach parents that children do not need a hightop or rigid shoe for foot development. If the child notices leg pain from poor arch support, a sneaker is usually adequate to correct the problem.

Bowlegs (Genu Varum)

Genu varum is lateral bowing of the tibia. If genu varum is present, the **malleoli** (rounded prominence on either side of the ankles) will be touching and the medial surfaces of the knees will be more than 2 in (5 cm) apart (Fig. 51.9A). Children develop this condition as part of normal development; it is seen most commonly in 2-year-olds. Record the extent of the bowing at health maintenance visits by approximating the medial malleoli of the ankles and measuring the distance between the patellas (knees) for changes.

Genu varum gradually corrects itself by about 3 years of age or, at the latest, by school age. If the problem is unilateral, is becoming rapidly worse, or persists beyond this time, the child needs referral to an orthopedist for further evaluation.

Knock Knees (Genu Valgum)

Genu valgum, or knock knee, appears as the opposite of genu varum. The medial surfaces of the knees touch, and the medial surfaces of the ankle malleoli are separated by more than 3 in (7.5 cm) (see Fig. 51.9B).

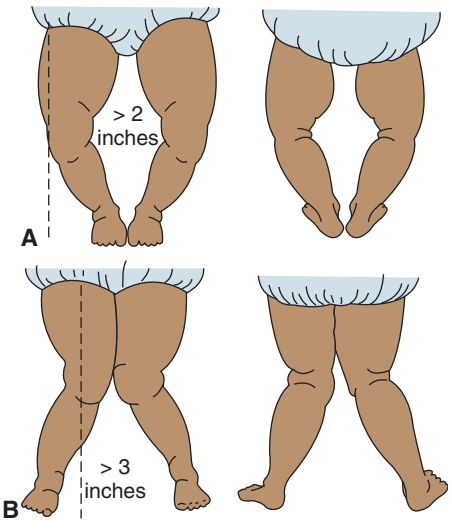


FIGURE 51.9 (**A**) Genu varum. (**B**) Genu valgum.

This is seen most commonly in children 3 to 4 years old. No treatment is necessary for genu valgum. The problem tends to correct itself as the child grows. By school age, few children continue to have the problem. Those who do, and those in whom the abnormality is unilateral or becoming more pronounced, need a referral to an orthopedist for further evaluation. The severity of the deformity can be measured at regular health maintenance visits by approximating the medial aspects of the knees and measuring the distance between the medial malleoli of the ankles.

Blount's Disease (Tibia Vara)

Blount's disease is retardation of growth of the epiphyseal line on the medial side of the proximal tibia (inside of the knee) that results in bowed legs. Unlike the normal developmental aspect of genu varum, Blount's disease is usually unilateral and a serious disturbance in bone growth that requires treatment (Gary & Richards, 2008).

Because it is not possible to rule out Blount's disease by appearance alone, almost all children with bowed legs have an initial radiograph. In those with Blount's disease, the medial aspect of the proximal tibia will show a sharp, beaklike appearance on the radiograph.

Bracing or osteotomy may be necessary to correct this deformity or prevent it from becoming more severe (Wilson, Scherl, & Cramer, 2007). Explain to the parents why their child requires treatment or surgery when another child on the block with a similar appearance (developmental genu varum) is expected to outgrow the problem.

Toeing-In

Toeing-in (pigeon toe) in children may occur as a result of foot, tibial, femoral, or hip displacement. Assess for these conditions if parents describe their child as "always falling over his feet" or "awkward."

Metatarsus adductus is turning in of the forefoot. The heel is in good alignment; only the forefoot is turned in. This condition may develop or become more pronounced in infants who sleep prone with the feet adducted and in older children who watch television by kneeling, resting on their feet, and turning their feet in. If you stand the child on a copying machine and make a print, the turning in of the foot can be well demonstrated.

Most instances of metatarsus adductus resolve without therapy. Those that persist beyond 1 year can be corrected by passive stretching exercises. A few infants with extremely rigid, incorrect foot posture may require casts or splints for correction. Early detection of these extreme instances is important, because treatment for metatarsus adductus is most effective if it is begun before an infant walks. With early treatment, the prognosis is excellent.

Inward tibial torsion also may be evidenced as toeing-in. This condition is diagnosed when a line drawn from the anterior superior iliac crest through the center of the patella intersects the fourth or fifth toe (or a position even more lateral) (Fig. 51.10). Ordinarily, such a line should intersect the second toe.

Tibial torsion usually improves as the tibia grows and requires no treatment. Parents need a good explanation of why no treatment is necessary. Reassure them at periodic health

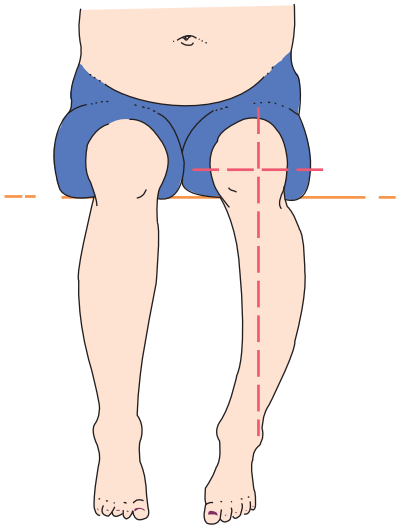

FIGURE 51.10 Toeing-in caused by inward tibial torsion. In good alignment, a line drawn from the anterosuperior iliac crest through the patella should intersect the second toe.

maintenance visits that patience and time will correct tibial torsion (Nguyen & Shultz, 2007).

Inward femoral torsion can be detected if you ask a child to lie supine and attempt to rotate the leg internally and then externally at the hip. Normally, internal rotation is about 30 degrees, and outward rotation is about 90 degrees. With inward femoral torsion, the internal rotation is closer to 90 degrees. In some children, the femur rotates so far that the patellar bones face each other. As with tibial torsion, no treatment is necessary. Inward femoral rotation will not correct itself, but a compensating tibial torsion will develop and make feet appear straight.

A fourth cause of toeing-in may be improper hip placement or developmental hip dysplasia, a problem that is very serious and needs early therapy for correction (see Chapter 27).

Limps

Observation of a child's gait is part of every health assessment. Gait is a variable characteristic; however, limping is never normal. Although limping may reflect a simple problem such as a recently stubbed toe or a shin splint from excessive running, it may also reflect serious bone or muscle involvement, such as occurs with osteomyelitis or cerebral palsy.

History is important in determining the cause of a limp. When children have pain in a lower extremity, they protect the extremity by limping—stepping gingerly and quickly on the affected leg. Although children may seem to be favoring an ankle or a knee, ask them specifically what hurts. Because a hip hurts, they may be walking gingerly on the leg and causing pain in a knee (Abbassian, 2007).

The lower extremities need careful, thoughtful examination, including inspection, measurement of leg length, range of motion, palpation, and a neurologic examination. Radiography or bone scan may be necessary to rule out a pathologic process.

Growing Pains

Listen to parents carefully when they state that their child has "growing pains." What they are reporting may be symptoms indicative of rheumatic fever or JA rather than a simple, transient phenomenon. Growing pains occur most frequently in the muscle of the calf, never in a joint. They occur in preschool and school-age children, who wake at night because of the pain. Such cramping usually is associated with a day of vigorous activity or wearing new shoes with a heel of a different height than before. Children with genu varum (bowlegs) tend to have more of such pain than do other children. Some children reported to have growing pains may actually have restless leg syndrome (Picchietti et al., 2007). Restless leg syndrome (insomnia associated with involuntary leg movements) is associated with decreased dopamine production. As iron is an essential component of dopamine, a daily vitamin pill with iron may help relieve the phenomena (Patrick, 2007).

Osteogenesis Imperfecta

Osteogenesis imperfecta is a connective tissue disorder in which fragile bone formation leads to recurring (pathologic) fractures (Martin & Shapiro, 2007). It occurs in two main forms: a severe autosomal dominant form that is recognized at birth (osteogenesis imperfecta type 1) and an autosomal recessive form where symptoms develop later in life (osteogenesis imperfecta type 3).

Children with type 1 disease are born with countless fractures already present from the force of birth. They develop many more fractures during childhood. Radiographs reveal a particular ribbonlike or mosaic pattern in bones, which aids in diagnosis. The sclera of the eye is unusually blue because of poor connective tissue formation. Children with the type 3 form may have associated deafness and dental deformities. In both instances, the major clinical manifestation is a tendency for bones to fracture easily because of poor collagen formation. In some children, the bones are so fragile that fracture can result not only from trauma, such as a fall, but from simple walking. Because the child has such frequent injuries, parents may be accused of child abuse before the child's condition is diagnosed and documented.

As the child grows older, the multiple breaks tend to cause limb and spinal column deformities, interfering with alignment or growth. Several therapies, such as growth hormone to stimulate growth, calcitonin to aid bone healing, and bisphosphonates such as pamidronate to increase bone mass, may be prescribed, although no therapy is curative (Astrom, Jorulf, & Soderhall, 2007). Parents need to protect children from trauma; fractures need to be aligned and casted; and children need to be educated about a lifestyle that is productive yet minimizes the risk of trauma. Lightweight leg braces or new intermedullary rod insertion techniques are available to strengthen bones (Esposito & Plotkin, 2008).

Always be careful when caring for a child with this disorder not to cause any trauma to bones. Be sure to raise side rails on cribs or beds. Keep floors dry, and remove objects that could cause falls. Always lift children gently and avoid lifting them by a single arm or leg, to avoid placing strain on a bone.

Legg-Calvé-Perthes Disease (Coxa Plana)

Legg-Calvé-Perthes disease is avascular necrosis of the proximal femoral epiphysis. Although the cause is not proven, the condition is associated with incomplete clotting factors (Gough-Palmer & McHugh, 2007). The disorder occurs more often in boys than in girls and has a peak incidence between 4 and 8 years of age. It usually occurs unilaterally but may occur bilaterally.

The child notices pain in the hip joint accompanied by spasm and limited motion. X-ray studies are used to distinguish between Legg-Calvé-Perthes disease and simple synovitis (inflammation of the hip joint), which begins with the same symptoms. Radiographic changes may not be apparent when a child is first seen, but they appear after about 3 weeks. For this reason, most children seen for synovitis of the hip joint are asked to return in 3 weeks for a repeat film.

Children with Legg-Calvé-Perthes disease pass through four stages. First is the synovitis stage, or period of painful inflammation. Next is a necrotic stage, during which bone in the femur head shrinks in size and shows increased density on radiography. This stage lasts 6 to 12 months. The third stage is a fragmentation stage; resorption of dead bone occurs over a 1- to 2-year period. The fourth stage, a reconstruction stage, marks final healing, with deposition of new bone.

Treatment for Legg-Calvé-Perthes disease focuses on pain reduction with NSAIDs and on keeping the head of the femur within the acetabulum, which acts as a mold to preserve the shape of the femoral head and maintain range of motion.

Initially, rest is used to reduce inflammation and restore motion. To keep the head of the femur correctly positioned within the acetabulum, "containment" devices, such as abduction braces, casts, or leather harness slings, or non-weight-bearing devices, such as abduction ambulation braces or casts (after bedrest and traction), may be used although reconstructive surgery techniques (an osteotomy to center the femur head in the acetabulum followed by cast application) is most often used today. This technique returns the child to normal activity within 3 to 4 months in contrast to many months of restricted activity required by non-weight-bearing-devices (Jawish, Ghorayeb, & Khalife, 2007).

Parents and children need thorough education about treatment and care, because most of it occurs on an ambulatory basis. It can be difficult for children to accept the extended treatment period involved with this disorder. Be certain that parents and children both understand the long-term consequences. Without treatment, the femur head tends to remold in a mushroom shape, making the hip unstable thereafter. Because this shape does not conform well to the acetabulum, degenerative changes may occur later in life, leading to chronic pain, reduced mobility of the hip joint, and possibly permanent disability. Parents may need assistance with devising appropriate activities for the child during the time that activity is limited and weight bearing is not allowed.

Osgood-Schlatter Disease

Osgood-Schlatter disease is thickening and enlargement of the tibial tuberosity resulting from microtrauma. Children notice pain and swelling over the tibia tubercle that is aggravated by running and squatting. The disorder tends to occur in early adolescence or preadolescence in children who are athletic, probably because of rapid growth at these times (Gholve et al., 2007).

Therapy depends on the extent of the bone changes. Administration of NSAIDs, ice, and limiting strenuous physical exercise may be all that is necessary. Occasionally, immobilization of the leg in a walking cast or immobilizer for about 6 weeks may be required.

Slipped Capital Femoral Epiphysis

Slipped epiphysis (coxa vera) is, as the name implies, a slipping of the femur head in relation to the neck of the femur at the epiphyseal line. The proximal femoral head displaces posteriorly and inferiorly. An avascular necrosis similar to that observed in Legg-Calvé-Perthes disease may occur. The cartilage covering the femur head may be destroyed by necrosis, resulting in permanent loss of motion of the femoral head (Hart, Grottkau, & Albright, 2007). Surgical reconstruction of the hip joint is necessary to correct the problem.

This disorder occurs most frequently in preadolescence. It is twice as frequent in young African Americans than in children of other races, and twice as frequent in boys as in girls. It is most common in obese or rapidly growing children. This suggests that it occurs because of the influence of growth hormone and excessive weight bearing in the preadolescent child. It may occur originally in one hip and then at a later date in the other (Takahashi et al., 2007).

The onset of symptoms is gradual. On inspection, children often are observed to be limping and holding their leg externally rotated to relieve stress and pain in the hip joint. They may report pain first in the knee, because favoring the hip joint puts abnormal stress on the knee. On physical examination, internal rotation of the hip is difficult and painful. Radiographs reveal the slipped epiphysis at the femoral head.

Early detection is important, because correction is easiest if it is attempted before the condition has progressed to epiphyseal destruction. Surgery with pinning or external fixation, such as with skeletal traction, is used to stabilize the femur head. After surgery, the child may have activity restrictions or be confined to bed. Because the disease is most common in preadolescence, these children need continued support. Help them to understand the potential seriousness of the condition. Although they may not like being restricted or confined in this way, supportive communication and education can help them accept this treatment as necessary to maintain good healing and function of the hip joint. Encourage frequent visits and telephone calls with friends to provide optimal growth and development.

Although this condition usually is unilateral, some affected children later develop the same condition in the opposite hip. All children with a slipped epiphysis, therefore, need follow-up care, with careful attention to the condition of the opposite hip.

What if... Jeffrey's parents report that he has been waking up at night because of "growing pains"? Is there such a thing?

INFECTIOUS AND INFLAMMATORY DISORDERS OF THE BONES AND JOINTS

All bone infections are potentially dangerous because bones have rich blood supplies, so infection can easily spread and become septicemia.

Osteomyelitis

Osteomyelitis is infection of the bone. It is most often caused by *Staphylococcus aureus* in older children and by *Streptococcus pyogenes* in younger children. Children with sickle cell anemia have a special susceptibility to *Salmonella* invasion in long bones. Organisms are carried to the bone site by septicemia (blood infection). It may occur after extensive impetigo, burns, or something as simple as a furuncle (skin abscess). It also may occur directly by outside invasion from a penetrating wound, open fracture, or contamination during surgery (Hevroni & Koplewitz, 2007).

Osteomyelitis begins typically as a metaphyseal infection, because the blood supply is sluggish in that portion of the bone. An abscess forms and spreads along the shaft of the bone under the periosteum, possibly extending to and penetrating the bone marrow. Sinuses may form between the marrow and the periosteum, or between the infected bone and the skin above. If the epiphyseal plate is infected, altered bone growth may result.

Assessment

Osteomyelitis usually begins with acute symptoms. Children show systemic malaise, fever, and irritability. They may have sharp pain at the bone metaphysis. By the second day, the area of skin over the infected bone feels warm to the touch; edema is present. Edema reduces the blood supply to vast expanses of bone, causing death of bone tissue. This dead bone tissue, which appears dense on radiographs, is called **sequestrum**.

Blood studies reveal an increased white blood cell count, C-reactive protein level, and sedimentation rate; blood culture results usually are positive. Computed tomography may demonstrate early-stage bone changes. Simple radiographs, however, may not reveal bone changes (formation of sequestrum) until 5 to 10 days after the beginning of the infection. Some children with osteomyelitis are not seen at health care facilities as soon as they should be, because parents account for the pain as "growing pains." Children with systemic symptoms, such as fever, malaise, and joint pain, must be evaluated carefully so that developing osteomyelitis, if present, can be detected early.

Therapeutic Management

Medical therapy includes limitation of weight bearing on the affected part, bedrest, immobilization, and administration of an IV antibiotic such as oxacillin (Bactocill), as indicated by the blood culture. This therapy is usually initiated in the hospital and then continued at home for as long as 2 weeks; often an intermittent infusion device or peripherally inserted central catheter is used. After this, the child will be prescribed an oral antibiotic for 3 to 4 more weeks. Additional therapy may include administration of bisphosphonates to help reduce bone loss (Simm, Allen, & Zacharin, 2008).

If pus forms under the periosteum, it may be aspirated using a technique similar to bone marrow aspiration. After the procedure, a tube may be inserted into the area for instillation of an antibiotic solution. A drainage tube may be inserted and attached to suction to evacuate the subperiosteum area.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Parental health-seeking behaviors related to care of the child with osteomyelitis

Outcome Evaluation: Parents accurately identify child's care needs in the hospital and at home; parents demonstrate procedure for IV antibiotic administration.

When planning for a child with osteomyelitis, be certain that the long-term immobilization necessary for care is considered. Parents may need to make major changes in their lifestyle if their child remains in a hospital or if they need to give care at home for an extended period.

Parents have many questions when osteomyelitis is diagnosed, because the defect does not show on radiographs initially. They may be startled to hear their physician talking about the need for 6 weeks of antibiotic therapy. They may be suspicious, anxious, and afraid that hospitalization and administration of IV antibiotics are really unnecessary. Often, at the point at which radiographs reveal the process, they become more supportive and understanding of the care needed for their child.

Handle the extremity gently when giving care because the child has pain. Provide instructions to the parents about good food sources of calcium and protein for bone healing. Keep in mind that young children are active, even if they are on bedrest. If a child had surgery and drainage tubes are in place, institute infection-control precautions, because the drain evacuates infected material.

Most children with osteomyelitis recover without long-term effects (Girschick et al., 2007). When the child is discharged from the hospital, be sure to instruct the parents about the importance of follow-up antibiotic care at home, even though the child's symptoms may have completely disappeared. Review with them measures to care for a PICC line and techniques for antibiotic administration. Also review the signs and symptoms of reinfection, measures for wound care and infection control, and possible adverse effects of antibiotic treatment (see Focus on Nursing Care Planning Box 51.4). A referral for home care follow-up is important to ensure continued support and education.

If osteomyelitis is not entirely eradicated with the initial treatment, it will return and result in a chronic infectious process with open, draining sinuses and bone deformity in years to come. Growth plates can be destroyed, leading to shortening of an extremity (Connolly et al., 2007).

BOX 51.4 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Child With Osteomyelitis

Jeffrey, 13 years old, is a boy with scoliosis. He is brought to a clinic today because he has pain in his left lower leg. He has a fever, and his leg is warm to the touch and edematous. His mother tells you he had an infected mosquito bite in that area 2 weeks ago. After further evaluation, Jeffrey is diagnosed with osteomyelitis. His mother asks, "How could he get an infection all the way into his bone from such a simple thing? I thought he was just having growing pains."

Family Assessment ✻ Child lives with 7-year-old sister and two parents. Father works as a family court judge. Mother works part-time as a court reporter. Child rates finances as, "Okay. Although I'd like a better bicycle."

Client Assessment ✻ Child has worn orthopedic brace for scoliosis for last 6 months. Today, left lower extremity is pale but warm; pedal pulses are present. Capillary refill time in toes is 3 seconds. States he had pain on admission, rating it a 4 on a numerical scale of 1 to 10 (no pain to severe pain). Relieved with codeine and acetaminophen as prescribed. During morning assessment, child states, "I'm so bored. If I have to stay in bed for a whole week, I'll go stir crazy." Child normally enjoys playing baseball with friends and video games.

Nursing Diagnosis ✻ Risk for peripheral neurovascular dysfunction related to the effects of bone infection

Outcome Criteria ✻ Child's extremity remains pink and warm with palpable pedal pulses and capillary refill time of 3 seconds or less. Pain is no more than 2 on a scale of 1 to 10.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Assess whether child understands he should not bear weight on affected leg.	Review with child importance of not bearing weight on infected leg.	Infected bone is weakened, so it could fracture more easily than usual.	Child states he understands he can not walk to bathroom, greet visitors, etc.
		Consultations		
Physician	Assess whether orthopedic service is needed to consult on antibiotic therapy.	Consult with orthopedic service if needed to assure antibiotic regimen is adequate.	Because bone infections are deep-seated, antibiotics must be carefully selected for specific organisms and tissue penetration.	Orthopedic service consults as necessary to reduce threat of chronic illness.
		Procedures/Medications		
Nurse	Assess whether child has past experience with IV therapy.	Orient child to IV therapy and importance of armboard to guard against infiltration.	Infiltration interferes with antibiotic infusion and can cause tissue necrosis.	Child states he understands importance of continuous IV therapy and will work to guard site.
Nurse	Assess whether child is allergic to any antibiotic he has received in the past.	Administer antibiotics as prescribed by intravenous route.	IV antibiotic therapy is necessary so the antibiotic can be carried deeply into the bone.	Parent reports child has no known allergy to antibiotics; child cooperates with medication infusions.
		Nutrition		
Nurse/ nutritionist	Meet with child to discuss what his favorite foods are.	Discuss importance of not gaining weight while on bedrest.	Child wears orthopedic brace. Gaining weight interferes with correct fit.	Child states he understands importance of not gaining weight; will cooperate with nutritionist's recommendations.

(continued)

BOX 51.4 ✻ Focus on Nursing Care Planning (continued)

		Patient/Family Education		
Nurse	Assess what child understands about the cause of bone infections.	Review association between skin infection and osteomyelitis.	Osteomyelitis is often caused by extension of a skin infection such as impetigo.	Child states he understands that infection can occur to anyone and that outcome should not result in loss of function.
		Psychosocial/Spiritual/Emotional Needs		
Nurse	Assess what activities child would enjoy during bedrest.	Talk to child about importance of keeping busy because he will not feel systemically ill during this time.	Bedrest is difficult for children when they feel well except for one body part.	Child names at least two activities besides schoolwork he could do to keep busy and help relieve boredom.
		Discharge Planning		
Nurse	Assess whether child has had experience taking oral medication at home.	Explain necessity to continue antibiotics even though symptoms are lessening.	If child does not understand purpose of long-term therapy, he may neglect to take antibiotic once symptoms fade.	Child and parents both state they understand importance of continuing antibiotic; parents state they will monitor child.
Nurse	Assess whether child and parents understand importance of follow-up visit.	Schedule follow-up appointment as physician prescribes.	A follow-up visit is necessary to ensure that infection is completely eliminated.	Child and mother both state they understand importance of return visit and will keep the appointment.

✔ Checkpoint Question 51.2

When caring for Jeffrey, who has osteomyelitis, which of the following would be your most important intervention?

a. Maintain an intravenous antibiotic therapy infusion.
b. Alert his parents the infection was caused by food poisoning.
c. Restrict fluid to encourage red blood cell production.
d. Assist the child with moderate weight-bearing activities.

Synovitis

Synovitis, an acute, nonpurulent inflammation of the synovial membrane of a joint, occurs most commonly in the hip joint in children. The peak age of incidence is between 2 and 10 years (Gough-Palmer & McHugh, 2007). Children notice pain in the groin, in the lower portion of the thigh or knee, or in the buttocks. Pain is intense and is most noticeable in the morning, when they first awaken. Children may wake at night or in the morning, crying from the pain of turning over. Pain again becomes worse later in the day, when the child becomes tired.

Aside from the localized pain, children feel well except that they usually hold the joint flexed in a position of comfort. On physical examination, range-of-motion exercises cause pain. A radiograph or MRI may reveal capsular swelling at the involved joint.

The treatment of synovitis is prescription of an NSAID such as ibuprofen (Motrin) and limited activity until muscle spasm from pain has passed. In most children, 3 days of rest reduces the synovitis. However, some children may need 10 to 14 days, and a short course of oral corticosteroids as well.

Synovitis must be differentiated from septic arthritis that is restricted to one joint (Kwack et al., 2007). With septic arthritis, a child tends to be systemically ill, and blood studies reveal an increased white blood cell count. This condition requires an antibiotic for therapy.

It is important that children and parents understand that synovitis is a simple inflammation process that will heal without sequelae. Rest is important for this recovery, however, and must be enforced.

Apophysitis

Adolescents who are growing rapidly and physically active are prone to apophysitis, or inflammation of the epiphysis of a heel bone. It may be caused by a micro heel fracture (Weiner, Morscher, & Dicintio, 2007). The heel feels tender, and pain on walking may be acute.

Pain usually can be relieved by adding a lift to the heel of the adolescent's shoe, reducing the tension on the heel cord and bone. After the pain has subsided, the adolescent may need to practice exercises to stretch the heel cord. This can be accomplished by standing on a slanting board that elevates the foot and toes above the level of the heel, for 20 minutes about three times a day.

Apophysitis is an annoying condition, particularly for adolescents who feel a need to excel in sports to win peer

approval. They need assurance that, although this annoying pain may persist for weeks, it is not a serious disorder. It helps to put the slant board by the telephone or in front of the television, somewhere where the child will be reminded of it daily. Many adolescents believe that they are too busy and do not have the time for such an exercise three times a day, unless they can combine it with another activity such as talking on the telephone or watching television.

DISORDERS OF SKELETAL STRUCTURE

Spinal disorders in children may include kyphosis (an outward curvature of the spine) or lordosis (an inward curving of the spine) but scoliosis (a sideways curve) is the most commonly seen disorder.

Functional (Postural) Scoliosis

Scoliosis is a lateral (sideways) curvature of the spine. It may involve all or only a portion of the spinal column. It may be functional (a curve caused by a secondary problem) or structural (a primary deformity).

Functional scoliosis occurs as a compensatory mechanism in children who have unequal leg lengths, in children with ocular refractive errors that cause them constantly to tilt their head sideways, or children with accompanying neuromuscular disorders such as cerebral palsy (Sarwark & Sarwahi, 2007). The pelvic tilt caused by unequal leg length or muscle strength results in a spinal deviation because this is necessary for the child to stand upright. The curve that occurs in functional scoliosis tends to be a C-shaped curve, whereas that in structural scoliosis tends to be S-shaped (composed of two separate curves). With functional curves, there is little change in the shape of the vertebrae on radiography.

Children with noncorrectable neuromuscular conditions may need spinal fusion but to rectify the most simple forms of functional scoliosis, the difficulty causing the spinal curvature can be corrected, eliminating the difficulty. Leg length is measured from the anterior iliac spine to the bottom of the medial malleolus; a lift inserted in one shoe corrects unequal leg length. Correction of ocular refractive errors improves problems caused by head tilt. In addition, children must be reminded to maintain good posture during everyday activities. Walking with a book on the head for 10 minutes, three times a day, or hanging by the hands from a door frame (chinning themselves) stretches the back and is often helpful. Sit-ups and push-ups are good exercises. Swimming also is good exercise, because the reaching involved stretches the spine.

Parents and children need to be reassured that functional scoliosis is a disorder that can be corrected. Children need to be aware of this to prevent problems with self-esteem and body image. Caution parents about nagging children of this age to do exercises or maintain good posture. Puberty is an age of rebellion and exertion of independence. Excessive reminders can lead to the child ignoring the parents' requests. Let children know that you understand that children of their age believe they do not have to do everything their parents want them to do. Help them to find alternative, more positive ways to exert their independence, such as not making their bed.

Structural Scoliosis

Structural scoliosis is idiopathic, permanent curvature of the spine accompanied by damage to the vertebrae. The spine assumes a primary lateral curvature. To allow the child to hold the head level, a compensatory second curve develops, giving the spine an S-shaped appearance (Fig. 51.11). The primary curve is often a right thoracic convexity. As the original curve

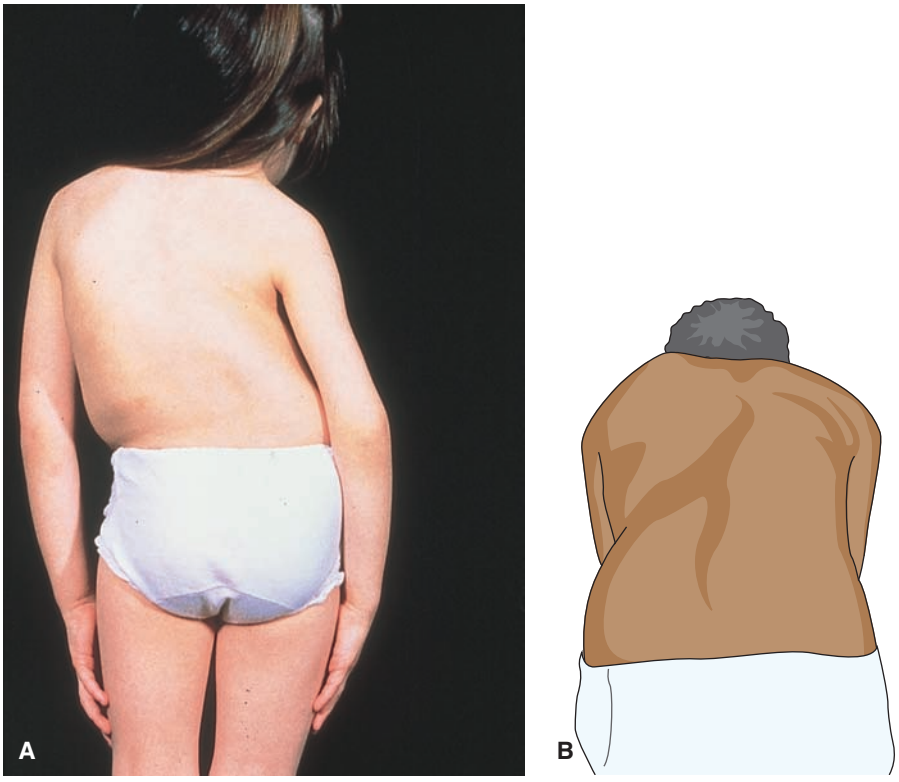

FIGURE 51.11 Assessing scoliosis. (**A**) Child with scoliosis (standing). (**B**) Child with scoliosis (bending over). (SIU Biomedical Communications/ Custom Medical Stock Photograph.)

becomes severe, rotation and angulation of vertebrae occur. The thoracic rib cage rotates to become very protuberant on the convex curve. Vertebral growth may halt because of extreme pressure changes.

A family history of curvature of the spine is found in up to 30% of children with scoliosis, although no specific inheritance pattern has been documented. It is five times more common in girls than in boys and has a peak incidence at 8 to 15 years of age. As long as the child is growing, the spinal curves will become more severe. This is why the symptoms become most marked at prepuberty, a time of rapid growth.

Assessment

All children older than 10 years of age should be assessed for scoliosis at all health assessment visits. Often, the condition develops insidiously and is prominent before it is noticed because of the preadolescent's and adolescent's need for privacy and the lack of pain that accompanies the condition. A parent might notice when doing laundry that a daughter's bra straps are adjusted to unequal lengths. A girl may find it difficult to buy jeans that fit correctly because of uneven iliac crests, or she may notice that her skirts and dresses hang unevenly. If the child bends forward, the curve becomes even more noticeable.

A scoliometer is a commercial device that can be used to document the extent of a spinal curve. With this device (a type of protractor), a reading greater than 7 degrees equals a 20-degree scoliotic curve detected by radiography.

Radiographs and photographs are helpful in estimating the extent of the deformity and provide a baseline description. If the child has a vertebral rotation causing rib imbalance, pulmonary function studies and a chest radiograph may be obtained to provide further baseline information. Children's bone age is established by radiography of the wrists or iliac bones. If bone growth is complete or almost complete, little more deformity will result, so no correction may be necessary. If the child has 1 to 2 years of bone growth remaining, some correction most likely will be undertaken.

Therapeutic Management

Usually, if the spinal curve is less than 20 degrees, no therapy is required except for close observation until the child reaches about 18 years of age. If the curve is greater than 20 degrees, treatment may consist of a conservative, nonsurgical approach using a body brace or traction, or it may include surgery or a combination of both surgical and nonsurgical measures. Curves greater than 40 degrees require surgery with spinal fusion. Regardless of the type of treatment chosen, a child must be prepared for long-term treatment. The goal of both surgery and mechanical bracing is to maintain spinal stability and prevent further progression of the deformity until bone growth is complete.

During prepuberty and adolescence, children are very concerned about body image and are very impatient with scoliosis correction, often wanting their problem to be corrected immediately. They need a great deal of support at health care visits to help them cope with the time needed for correction.

Bracing. If the spinal curve is greater than 20 degrees but less than 40 degrees and the child is still skeletally immature, bracing, one of the oldest forms of correction, is still a prime intervention (Maruyama, 2008). The Milwaukee brace was the first type used for this purpose so, although today's braces look much different, they may still be referred to by this name. Originally these braces extended to the neck and were almost impossible to conceal under clothing; today, they are underarm thoracolumbar supports that are worn under clothing (Fig. 51.12). The brace is worn for 23 hours per day to be removed only for showering or participation in a structured athletic program. At night, the child may wear a Charleston Bending Brace that confines the spine to an overcorrected position.

FIGURE 51.12 A teenage girl is fitted with a thoracic-lumbar-sacral orthotic device for treatment of scoliosis. (© Aaron Haupt/Science Source/Photo Researchers.)

Children and parents need thorough instruction on how to apply these braces. Frequent follow-up health care visits are necessary to check the fit of the device, making sure that it fits snugly without rubbing on bony prominences, such as the iliac crests. Caution children and parents to notify their health care providers if rubbing occurs. Also caution them not to loosen straps to decrease the discomfort. This makes the brace fit loosely, and it will not exert adequate compression and traction this way.

During the first couple of weeks of wearing a brace, children may notice slight muscle aches resulting from the new alignment. If neck and pelvic traction were applied beforehand, this aching is minimized. A mild analgesic such as acetaminophen (Tylenol) will decrease the discomfort in most children. Rest also provides considerable relief. Caution children not to remove the brace during this time, because taking it off will compound the problem of discomfort by prolonging the period of adjustment. Braces should be worn over a T-shirt to prevent the plastic pads from touching skin surfaces and causing skin excoriation. Children should remove the brace to bathe or shower.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Situational low self-esteem related to obviousness of the brace used for scoliosis correction

Outcome Evaluation: Child states positive aspects of self; participates in activities; establishes friendships with peers.

It is easier for children to accept bracing today than it once was, because the braces are more compact and because teenage clothing now tends to be more casual and looser. Although choosing clothes is easier than it once was, it may still be a major problem for some children. They need time at health care visits to voice concerns about their appearance. Encourage children to voice what it feels like to have to wear a brace of this size constantly. Help them to concentrate on things they can do, such as having a friend over or going to the movies, rather than those things they cannot do because of the brace (play a contact sport) (Box 51.5).

Encourage children wearing scoliosis braces to remain as socially active as possible. They may comment at first that they feel awkward or "so much taller" that they are afraid they will fall. The only way to get comfortable with a brace is to walk and get used to the new sensation of actually being a little taller. Braces may be awkward at school if chairs are attached to desks. Advocate for the child with the school nurse for seating arrangements that are comfortable.

Friends typically ask questions about what happened to a child. The sooner children expose themselves wearing a brace to friends and family, the sooner these questions will cease. A brace may need adjustment about every 3 months to accomplish more alignment, and frequent visits may be required so that children can express the problems they are having with social and school adjustment. However, do not underestimate an adolescent's ability to adjust to new situations. Children can see by looking in a mirror that their spine is curved, and they want this corrected. They will endure necessary discomfort if they have hope that they will emerge at the end of the correction period without an obvious physical deformity.

In some instances, parents must be firm about insisting that the child wear the brace continuously. If bracing does not work, the child must have spinal alignment and fusion surgery. Be certain that children do not think spinal surgery is a simple, quick procedure, similar to an appendectomy, and therefore preferable to bracing. If they think this, they may avoid wearing the brace, hoping that surgery will then be prescribed. However, do not depict surgery as horrible. In some children, the scoliosis continues to worsen despite good bracing, and surgery will still be necessary.

A scoliosis brace typically is worn until the child's spinal growth stops (at about 14½ years of age in girls, 16½ years in boys), as demonstrated by spinal radiographs. Bracing is not discontinued abruptly, however. The child is weaned from the brace gradually, because some demineralization of vertebrae may have occurred during the long period of bracing. Gradual resumption of activity allows remineralization and continued spinal support. Adolescents may continue to wear the brace at night for an additional period (6 months).

BOX 51.5 ✻ Focus on Communication

Jeffrey is a 13-year-old boy diagnosed with structural scoliosis after a routine screening. He is being fitted with a scoliosis brace.

Less Effective Communication

Jeffrey: Look at this thing. I can't wear this!
Nurse: It is awkward, but it's not too bad.
Jeffrey: All my friends are going to laugh at me!
Nurse: You need to wear this brace to help correct your spine.
Jeffrey: I know, but . . . I'm going to look like a freak!
Nurse: End of conversation. You need to wear it. Otherwise, your spine will be deformed.

More Effective Communication

Jeffrey: Look at this thing. I can't wear this!
Nurse: It is awkward, but it's not too bad.
Jeffrey: All my friends are going to laugh at me!
Nurse: You need to wear this brace to help correct your spine.
Jeffrey: I know, but . . . I'm going to look like a freak!
Nurse: You'll feel like a freak?
Jeffrey: Yeah, how can I go to school? What can I wear?
Nurse: Let's talk about this. Now, what do you usually like to wear to school?

In the first scenario, the nurse focuses on stressing the need for wearing the brace but fails to identify and acknowledge the adolescent's concerns about how he will look. In the second scenario, the nurse picks up on the adolescent's cues about body image and self-esteem and works with him to develop possible strategies to enhance these areas and promote cooperation with wearing the brace.

Halo Traction. Halo traction is the use of opposing forces to straighten and reduce spinal curves that are severe when first diagnosed (over 80 degrees) or that progress despite bracing. Halo traction is achieved using a ring of metal (a halo) held in place with about four stainless steel pins inserted into the skull bones (D'Astous & Sanders, 2007). Countertraction is applied by pins inserted into the distal femurs or iliac crests (Fig. 51.13). A halo traction apparatus is bulky and looks frightening. Children may be afraid that, when the pins are inserted into their skull (under general anesthesia), they will slip and penetrate their brain. They may worry that the apparatus will be so heavy that it will strain or break their neck.

Halo traction is typically used for children who have such severe scoliosis they experience respiratory involvement, cervical instability, a high thoracic deformity, or decreased vital capacity from severe spinal curvature and rotation. Children need to see photographs of the apparatus or talk to children who have the apparatus in place before having it applied. They need time to express their feelings about being placed in such a cumbersome device. Children may react to the apparatus physically, such as with nausea or diarrhea, or emotionally, such as with chronic sadness, until they see that they can adjust to it. Orientation must be as thorough for the parents as it is for the child. Parents may show symptoms similar to those of the child for the first few days after the application of such traction. During the first week, they usually feel unsure about how to care for their child. Therefore, they need support to parent during this time.

FIGURE 51.13 A 9-year-old girl in halo traction. (© Caroline Brown, RNC, MS, DEd.)

Halo traction is prescribed for about 3 months' time. Careful explanations about the child's care before it is given helps to reduce anxiety. Stressing positive aspects, such as what the child can do, and explaining that the traction will help the spinal curvature, may encourage children to accept such extreme traction.

For the first 24 hours after the apparatus is applied, most children experience a nagging level of pain at the pin insertion sites. A generalized headache may occur, requiring analgesia. Accepting halo traction is difficult, even without this pain. Offer adequate analgesia for comfort.

Children in halo traction need frequent hair care to keep the pin sites clean. Crusting around the pin sites can be reduced by cleaning the pin insertion sites daily with half-strength hydrogen peroxide or another appropriate solution. Encourage children to be as self-sufficient as possible. Be certain that parents or children have a telephone number they can call for advice or if they have questions once they return home.

After optimal spinal correction has been achieved, halo traction equipment is easily removed. The pin sites in the skull heal within 1 week without obvious scarring.

Surgical Intervention: Spinal Instrumentation. Surgical correction usually is necessary if the spinal curvature is greater than 40 degrees. Instruments, such as rods, screws, and wires, are placed next to the spinal column to provide firm reduction of the curvature; the spine is then fused in the corrected position. Bone from the iliac crests may be used to strengthen the fusion procedure (Hedequist, 2007). Newer procedures involve fusionless interventions such as malleable rods, intervertebral stapling, and a vertical expandable prosthetic titanium rib (Torre-Healy & Samdani, 2007).

Preoperative Nursing Care. Before spinal instrumentation, extensive radiographs are taken to plan the exact location of the rods or staples. Introduce children to the postoperative deep-breathing exercises and incentive spirometry they will need to perform. Deep-breathing exercises are particularly important for children whose scoliosis has caused chronically reduced lung capacity.

Ensure that children have a good explanation of what they can expect after surgery. This surgery involves bone destruction and major muscle and tendon shifts, so they can expect to have pain. It is a major operation, so they can expect to feel tired and "not themselves" for several days. Teaching young adolescents about these events helps them adjust to the postoperative period, and they appreciate being treated like adults. Be aware, however, that early adolescents are not adults, and, although they seem eager to breathe deeply and cooperate with routines before surgery, these requests may be overwhelming for them postoperatively, and their behavior may not be nearly as mature as they anticipate. Epidural anesthesia offers a great deal of pain relief. Allowing children to use an IV or epidural patient-controlled analgesia system offers both pain relief and a feeling of control.

The type of rods used depends on the degree of spinal curvature and the age of the child. Harrington rods were the first such rods manufactured, so the surgery is frequently referred to as Harrington rod placement, although newer types of rods are now more commonly used. Luque rods and Wisconsin segmental spinal instrumentation use a segmental approach. Cotrel-Dubousset rods also are commonly used. These are attached to the vertebrae using hooks or screws (Fig. 51.14A).

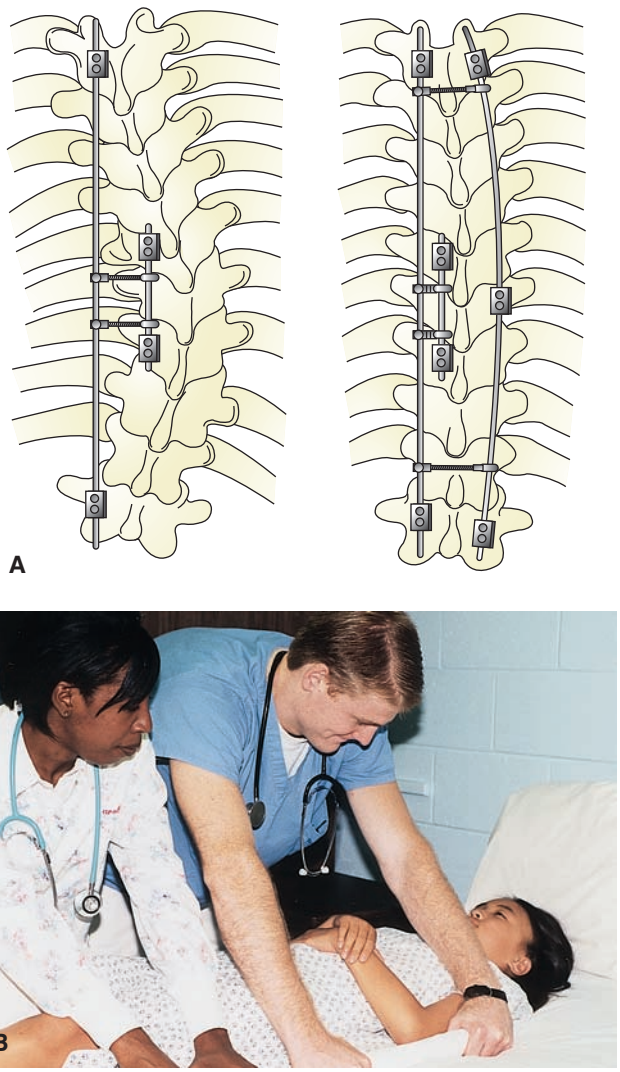

FIGURE 51.14 (**A**) Cotrel-Dubousset rods to correct scoliosis. A short distraction rod is linked to a longer one to correct the major curve. A convex rod is then applied. (**B**) Preparing to log roll. Two nurses use a drawsheet to roll the child in one coordinated movement to the side-lying position.

Postoperative Care. After surgery, the head of the child's bed must not be raised because, once rods are in place and the spinal fusion has been done, the child's back must not be bent. Tape the latch of the bed in place or unplug electric controls so the head of the bed cannot be raised by accident by a parent or by uninformed auxiliary personnel. A nasogastric tube usually is inserted before surgery to prevent abdominal distention, because major surgery may cause temporary paralytic ileus and lack of bowel tone.

Depending on the type of rods inserted, when the child returns from surgery, the child may need to lie flat and be log-rolled (always by two people) to a side-lying position every 2 hours to enhance respiratory status (see Fig. 51.14B). Neurologic dysfunction may result from bleeding or compression caused by a bone particle dislodged during the spinal fusion. Perform neurovascular assessment of lower-extremity function every hour for the first 24 hours by assessing lower extremities for warmth, whether the child can feel you touch a foot, and wiggle the toes. Circulatory pressure changes resulting from realignment of the chest cage and reduced rotation of the spine may result in circulatory impairment so assess and record vital signs carefully. There is usually extensive blood loss during spinal fusion surgery. The procedure itself or the blood loss may cause shock and hypotension. A drainage system, such as a Hemovac, may be inserted next to the incision to evacuate any accumulating drainage.

The child will be prescribed nothing by mouth until bowel sounds return (usually 12 to 24 hours). An indwelling urinary catheter is usually left in place for 24 hours, because voiding may be difficult because of the horizontal position that must be maintained and the edema at the lower spinal cord innervation points.

Although the child's parents have been prepared for the fact that spinal fusion is major surgery, they may be shocked by the child's appearance after surgery. This can cause them to be afraid to touch the child to provide comfort, at a time when the child would probably enjoy being touched because of feeling so ill and frightened. Explaining that major surgery is frightening for everyone can help the parents feel more comfortable.

As soon as bowel sounds are present, a child can take fluids and then solids. Remaining flat can result in rapid release of calcium from bones. Calcium intake should, therefore, be moderate at first rather than extensive, to prevent renal calculi.

By 24 to 48 hours after surgery, children are allowed out of bed to sit up with a brace in place. They may feel dizzy at first and must get used to sitting by attempting it for short periods at a time. Then activity is increased to a normal level with few restrictions.

Because removing rods is as extensive a procedure as inserting them, instrumentation rods are left in place permanently unless they cause irritation later. The average child becomes unaware that the rods are in place. However, the child must always be conscious of good posture such as not slumping in chairs and stooping and not bending to pick up objects from the floor. Extremely active gymnastics, football, or trampoline work is contraindicated. The rods do not interfere with other sports.

Children may be afraid to move freely after spinal fusion because, if they have had a brace applied beforehand, they have been in some type of restraining device for a long time. They may need to be reassured frequently that, with the spinal fusion, their problem finally is corrected. No further curvature can occur after this point, so it is safe for them to be without support.

Correction of scoliosis may have taken years. After surgery, children need an opportunity to talk at health care assessments about how they feel to be free of this problem. If the correction was not as complete as the child wished (children with severe scoliosis cannot expect 100% correction), they need time to talk about their disappointment and to adjust to their new appearance. They may believe their disorder has caused them to miss adolescence or "the best time of their lives." Emphasize positive experiences and point out positive attributes to help the adolescent gain self-esteem. Assure a child that with a straightened back, the best years are still to come.

What if... Jeffrey who has scoliosis says to you, "Will I ever get better, or will I be a cripple the rest of my life?" How would you answer him?

Osteoporosis

Osteoporosis is loss of bone mass that leaves bones brittle and easily fractured. Stress on weakened spinal vertebrae can result in a severe kyphosis. Osteoporosis tends to occur most often in postmenopausal white women as their estrogen levels decrease with aging. Although osteoporosis is not a disease of adolescents, adolescents need education about it because adolescence is the time when most bone density is massed (von Scheven, 2007). Urge adolescent girls to begin a program of weight-bearing physical exercise, a dietary calcium intake of 1200 mg/day, and an adequate vitamin D intake to prevent osteoporosis.

DISORDERS OF THE JOINTS AND TENDONS: COLLAGEN-VASCULAR DISEASE

Collagen is composed of bundles of protein-rich fibers and forms the connective tissue of the tendons, ligaments, and bones. Because this tissue is found throughout the body, collagen diseases are systemic. They also tend to be painful, involve inflammation, and are long term.

Juvenile Arthritis (JA)

JA primarily involves the joints of the body, although it also affects blood vessels and other connective tissues (Guell, 2007). To be classified as JA, symptoms must begin before 16 years of age and last longer than 3 months. The peak incidence occurs at two times in childhood: 1 to 3 years and 8 to 12 years. It can occur in children as young as 6 months of age and is slightly more common in girls than in boys. Acute changes rarely continue past 19 years of age.

The cause of JA is unknown, although it is probably an autoimmune process in which a child develops circulating antibodies (immunoglobulins) against body cells. This is revealed by the presence of antinuclear antibodies (ANA). A genetic predisposition may increase the risk in some children.

Three separate subtypes of JA exist. Major distinctions of these types are outlined in Table 51.1. Types differ mainly by the type of joint affected and the severity of systemic effects.

TABLE 51.1 ✻ Comparing Different Types of Juvenile Arthritis

Characteristic	Polyarticular	Pauciarticular	Systemic Onset
Number of joints involved	Five or more	Four or less	Any number
Joints affected	Usually small joints of fingers and hands Also possibly weight-bearing joints Often same joint on both sides of body	Usually large joints, such as knees, ankle, or elbow Usually particular joint on one side of body	Any joint
Gender affected	More girls than boys	More girls than boys (most common type)	Boys and girls equally
Body temperature	Low-grade fever	Low-grade fever	High spiking fever lasting for weeks or months
Other symptoms	Stiffness and minimal joint swelling, leading to limited motion Rheumatoid nodules or bumps on elbow or other body area receiving pressure from chairs, shoes, or other object (+)Rheumatoid factor (in approximately 20% of children) (+)ANA titer (possible) Elevated white blood cell count, complement, and sedimentation rate	Iridocyclitis (eye inflammation) Painless joint swelling with little redness (+)ANA titer (possible) (+)HLA antigen (possible in boys)	Macular rash on chest, thighs Inflammation of heart and lungs Anemia Enlarged lymph nodes, liver, and spleen Rarely + rheumatoid factor and ANA titer Elevated white blood cell count

Assessment

Children with systemic JA may be brought to a health care provider because of a persistent fever and rash, symptoms that are present even before joint involvement. When arthritis is diagnosed, parents may be surprised, believing that arthritis is a disease of older adults only. Regardless of the type of JA, assess children for the effect their disease is having on self-care. Do they need help eating, dressing, ambulating, or toileting? An activity such as sitting on the toilet may be uncomfortable if hip and knee joints are painful. An elevated toilet seat can be helpful because it reduces bending. Children may be unable to dress themselves independently because they cannot manage buttons or zippers with painful finger joints. Modifying these activities by using loops or Velcro strips not only helps children feel good about themselves but increases their overall level of activity.

Also assess the child's and parents' understanding of the illness and planned therapy, because children and parents typically bear the major responsibility for carrying out therapy at home and evaluating symptoms (Fig. 51.15).

Children with pauciarticular arthritis need screening with a slit-lamp examination every 6 months for uveitis (inflammation of the iris, ciliary body, and choroid membrane of the eye), because severe uveitis can lead to blindness (Grassi et al., 2007).

Therapeutic Management

Because JA is a long-term illness, therapy includes a balanced program of exercise, rest, and medication administration to relieve pain, restore function, and maintain joint mobility.

Exercise. There is little documentation that exercise makes long-term differences, but to preserve muscle and joint function, children are prescribed a set program of daily range-of-motion exercises to strengthen muscles and put joints through their full range of motion (Takken et al., 2009). It is best if these exercises can be incorporated into a dance routine or a game, such as "Simon Says." This not only makes exercises enjoyable, but it also can make the exercise a family participation time to be anticipated rather than a dull routine

FIGURE 51.15 The knees of a child with juvenile arthritis. Note the degree of joint enlargement and swelling. (Photograph courtesy of A. I. duPont Institute, Children's Hospital, Wilmington, DE.)

that must be followed. Swimming and tricycle or bicycle riding are excellent activities because they provide smooth joint action. Also encourage children to do as much self-care as they can, because the natural motions of activities such as dressing and brushing teeth exercise joints. In contrast, to reduce joint destruction, activities that place excessive strain on joints, such as running, jumping, prolonged walking, and kicking, should be avoided. School-age children can cooperate to avoid these activities. Parents of preschool children need to create interesting alternative activities so that the child avoids such motions.

Children should continue to attend school, because active children tend to show fewer contractures and less decalcification of bones than do inactive children. Children with JA fatigue easily, however, so they may need a shortened school day. If the school day is to be shortened, it is often better if the starting time is moved to midmorning. This allows a child time for a warm bath in the morning before school, an activity that reduces the pain and increases movement of involved joints.

Heat Application. Heat reduces pain and inflammation in joints and increases comfort and motion. Heat can be applied by the use of warm water soaks for 20 to 30 minutes. Paraffin soaks can be useful for wrist and finger inflammation.

Splinting. Splinting, once used extensively to immobilize inflamed joints in good body alignment, is rarely prescribed today because NSAIDs are effective and efficient in reducing joint inflammation.

Nutrition. Children with JA, like those with other chronic diseases, may eat poorly because of joint pain and fatigue. Some children experience mild gastric irritation from NSAID therapy. Help parents plan mealtimes for "best times" of the day to overcome these problems.

Medication. NSAIDs such as ibuprofen (Motrin) or naproxen (Naprosyn) are the drugs of choice for children with JA. They are prescribed one to four times a day. They not only control pain and inflammation, thereby reducing joint swelling, joint discomfort, and morning stiffness, but they may contribute to improvement in malaise and irritability. NSAIDs must be taken for at least 6 to 8 weeks to ensure effectiveness.

Because NSAIDs can cause gastrointestinal upset and bleeding, advise parents always to give the medication with food. Most parents think of NSAIDs as a drug to give children only when they have pain. Teach that they should continue to give the drug even if the child has no noticeable pain at the time of administration, because the drug's anti-inflammatory action is just as important as preventing pain.

Slow-acting antirheumatic drugs (SAARDs), also called disease-modifying antirheumatic drugs (DMARDs), are used if NSAIDs are ineffective. In contrast to the immediate pain relief or anti-inflammatory effect of NSAIDs, these drugs modify the natural progress of the disease over weeks to months. Examples include gold salts, penicillamine, and hydroxychloroquine.

Steroids, such as prednisone, may be added to the drug therapy if the disease is severe or is an incapacitating systemic disease that has not responded to other anti-inflammatory agents. Although steroids are potent anti-inflammatory drugs, they are avoided if at all possible because of their numerous adverse effects. When they are prescribed, usually the lowest possible dose given for the shortest time is the rule. Immunosuppressants or tumor necrosis factor-alpha blocking agents such as infliximab or etanercept may be helpful to reverse the progression of uveitis and protect vision as well as decease joint symptoms (Lovell, 2008; Rabinovich, 2007). Cytotoxic drugs, such as cyclophosphamide, azathioprine, chlorambucil, and methotrexate, may be used for children who have severely debilitating joint disease that has not responded to other therapy.

Newer therapy for JA is the use of anticytokines. Cytokines are protein particles produced by the immune system that play a role in destruction of body joints (de Jager et al., 2007). Thalidomide may be effective but because of its documented teratogenic effects, this is not the drug of choice for a sexually active adolescent girl (Karch, 2009).

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Deficient knowledge related to care necessary to control disease symptoms

Outcome Evaluation: Parents and child follow instructions regarding exercise and medication.

Help parents and children to understand the necessity for them to take an active role in therapy. Help them plan exercise and medication programs around school and other activities. Children with JA commonly experience irritability and fatigue, which may interfere with plans. Assist them with devising a schedule that allows for a balance of rest periods with exercise to maximize the possibility of success.

Children with JA need ongoing follow-up care to evaluate the disease and how they view themselves. Assist them with measures that allow them to view themselves as well again after such a long period of pain and illness. The few children who are left with joint contractures may require soft-tissue surgery, such as contracture release, tendon reconstruction, and synovectomy, or orthopedic surgery, such as equalization of leg length and orthoplasty, at a later date. Surgery may be delayed until growth is complete so that further growth will not influence the outcome.

About half of children with JA recover without chronic joint involvement. The others continue to have the disease into adulthood. Until the disease does reach remission, children need a great deal of support to perform exercises and take daily medication as prescribed.

✔ Checkpoint Question 51.3

Jeffrey's sister has juvenile arthritis. What is a common method used to reduce pain with this disorder?

a. Apply ice to painful joints to reduce inflammation.
b. Have the joints scraped during an arthroscopy.
c. Apply hydrocortisone ointment to affected joints.
d. Take a nonsteroidal anti-inflammatory drug daily.

DISORDERS OF THE SKELETAL MUSCLES

Myasthenia Gravis

For nerve conduction to cause muscles to contract effectively, a neurotransmitter, acetylcholine (ACh), must be released at synaptic junctions. ACh release is governed by the enzyme cholinesterase. With myasthenia gravis, there is interference in ACh processing, which leads to symptoms of progressive muscle weakness. The fault may be impaired synthesis or storage of ACh, insufficient ACh release, inadequate ACh receptors present at motor end plates, opposition of ACh by an ACh factor, or excessive cholinesterase. In adults, the defect is probably most often a motor end plate insufficiency (decreased number of ACh receptors present). In children, the disorder probably occurs most often from an autoimmune process (autoantibodies may block receptor sites for ACh). It occurs in three forms in childhood: neonatal transient myasthenia, congenital myasthenia, and juvenile myasthenia.

Assessment

With neonatal transient myasthenia, the mother has myasthenia gravis and the infant demonstrates transient disease symptoms at birth because of the transfer of antibodies from the mother. The newborn appears "floppy," sucks poorly, and has weak respiratory effort. Ptosis (drooping eyelids) may be present. The symptoms disappear within 2 to 4 weeks, but if they are not recognized when present, they could prove fatal because of respiratory muscle dysfunction.

Congenital myasthenia appears to be an inherited disorder that results in faulty ACh transmission or reception. Juvenile myasthenia gravis is an autoimmune process; it occurs most typically at 10 to 13 years of age and in girls more frequently than boys. Most children with this form have thymus hypertrophy; this sign helps document the autoimmune process.

With all forms, children gradually begin to develop double vision (diplopia). Ptosis is present because of weakness of the extraocular muscles. Symptoms grow more intense as facial, neck, jaw, swallowing, and intercostal muscles become affected. Fatigue is extreme, becoming more noticeable as a day progresses. Symptoms increase with emotional stress, fatigue, menstruation, respiratory infections, and alcohol intake. In the most severe form, all muscles, including those of respiration, become unable to contract.

Obtaining an accurate history, especially documenting whether a child can perform repetitive movements, is important. Ask a child to look upward and hold that position. Children with myasthenia gravis, unlike others, will gradually demonstrate ptosis. Other repetitive motions such as walking up stairs may also be tested although the time spent doing this should not be prolonged as it is tiring and does not reveal much more information (Rubin & Hentschel, 2007). Most children have myography performed to document their poor muscle function. Chest radiography and computed tomography demonstrate the enlarged thymus gland. Administration of edrophonium (Tensilon), which prolongs the action of ACh and therefore increases muscle strength, renews exhausted muscles in a few minutes. If this occurs, the diagnosis is positive for myasthenia gravis.

Therapeutic Management

Myasthenia gravis is treated by the administration of neostigmine (Prostigmin) or pyridostigmine bromide (Mestinon), acetylcholinesterase inhibitors that prolong the action of ACh (Box 51.6). The dosage of these agents must be individually determined. If toxicity occurs, symptoms similar to those of the original disease reoccur as excessive ACh leads to continued neurotransmitter stimulation and inability of muscles to repolarize for a new contraction. In some children, prednisone may be added to their medication regimen to decrease the amount of anticholinesterase medication required. In other children, plasmapheresis to remove immune

BOX 51.6 ✻ Focus on Pharmacology

Neostigmine (Prostigmin)

Classification: Neostigmine is a cholinesterase inhibitor that acts as an antimyasthenic agent.

Action: Neostigmine increases the concentration of acetylcholine at nerve endings, prolonging and exaggerating its effects and facilitating neuromuscular transmission (Karch, 2009).

Pregnancy Risk Category: C

Dosage: Orally, 2 mg/kg daily in divided doses every 3 to 4 hours; or 0.01 to 0.04 mg/kg per dose intramuscularly, intravenously, or subcutaneously every 2 to 3 hours, as needed

Possible adverse effects: Salivation, dysphagia, nausea, vomiting, increased peristalsis, abdominal cramps, cardiac arrhythmias, increased respiratory secretions, urinary frequency, pupil constriction, and diaphoresis

Nursing Implications

- If the drug is to be given intravenously, administer the dose slowly, directly into a vein or into the tubing's injection port of an intravenous infusion.
- Assess the child for increased muscle weakness, indicating possible cholinergic crisis. Keep atropine sulfate readily available as the antidote.
- If giving neostigmine orally, administer the drug with food or milk to minimize gastrointestinal upset. Instruct parents to administer the drug exactly as prescribed.
- Plan to administer larger portions of the divided doses approximately one half hour before anticipated times of greater fatigue.
- Review possible adverse effects with parents and child. Advise parents to watch for signs of excessive salivation, emesis, or frequent urination and to notify the health care provider if any occur.
- Encourage parents to control the child's environmental temperature as much as possible, to prevent diaphoresis from too hot or too humid an environment.
- Inform parents that an increase in muscle weakness may be related to drug overdose or exacerbation of the disease. Urge them to report any signs of increased weakness to their health care provider.

complexes from the bloodstream or administration of intravenous immunoglobulin to provide immune suppression is effective in reducing symptoms (Gajdos, Chevret, & Toyka, 2009). Excision of the thymus gland may also reduce symptoms, although this may leave the child open to additional autoimmune disorders.

Teach parents and children that symptoms become worse under stress, so parents need to prepare children well for new experiences such as menstruation, high school, a parental divorce, or surgery to minimize stress. Help children plan their day to include rest periods, possibly advocating for a special school schedule if necessary. If chewing and swallowing are difficult, ensure a rest period before meals. Children may need to eat a soft diet and learn to eat slowly and cautiously to avoid choking and aspiration. Scheduling medication administration for about 1 hour before mealtime is often helpful. If symptoms of muscle weakness suddenly become very severe, the child should be seen at a health care facility, because loss of function of intercostal muscles may lead to respiratory arrest. Atropine, an anticholinergic agent and the antidote for an overdose of anticholinesterase drugs, should be available to administer as necessary.

Dermatomyositis

Dermatomyositis occurs from degeneration of skeletal muscle fibers. The cause of the disorder is unknown, although an autoimmune basis is suspected. It is more common in girls and occurs between the ages of 5 and 14 years.

Symptoms usually begin insidiously, with muscle weakness that prevents children from performing tasks that they could manage previously, such as competing in gym classes, lifting objects, or climbing onto a high stool. Muscle pain is infrequent. Skin symptoms such as swollen upper eyelids, a confluent rash on the cheeks that increases to become telangiectatic, and scaling begin to develop. Subcutaneous calcifications may appear, making the skin feel unusually firm. Muscle breakdown leads to the appearance of creatinine in the urine. A muscle biopsy reveals lack of electrical activity in muscle fibers (Morinishi et al., 2007).

High-dose corticosteroids or methotrexate are prescribed to improve muscle strength. Specific immunosuppressants may also be helpful (Cooper et al., 2007). Children who survive beyond the first year after diagnosis have a good prognosis for prolonged remissions.

Muscular Dystrophies

Muscular dystrophies are a group of inherited disorders that lead to progressive degeneration of skeletal muscles, apparently from lack of a protein (merosin) that is necessary for muscle contraction (Aminoff, 2009).

Types

Muscular dystrophies seen in children are classified into three types: congenital myotonic dystrophy, facioscapulohumeral muscular dystrophy, and pseudohypertrophic muscular dystrophy (Duchenne's disease).

Congenital Myotonic Dystrophy. Congenital myotonic dystrophy is inherited as an autosomal dominant trait. Because the disease process begins in utero, the infant may already have severe myotonia (muscle weakness) at birth. Muscle degeneration continues until adequate respiratory muscle movement becomes difficult. Diagnosis is by serum enzyme analysis and muscle biopsy. Most of these infants die before they are 1 year old because they cannot sustain respiratory function.

Facioscapulohumeral Muscular Dystrophy. Facioscapulohumeral muscular dystrophy is inherited as a dominant trait, carried on chromosome 4. Symptoms begin after the child is 10 years old. The predominant symptom is facial weakness. The child becomes unable to wrinkle the forehead and cannot whistle. Serum enzyme analysis and muscle biopsy are used in diagnosis. The symptoms usually progress so slowly that a normal life span is possible.

Pseudohypertrophic Muscular Dystrophy (Duchenne's Disease). Duchenne's disease, the most common form of muscular dystrophy, is inherited as a sex-linked recessive trait. Therefore, it occurs only in boys. Symptoms are usually apparent by 3 years of age (Gaudreault et al., 2007).

Assessment

Children with Duchenne's muscular dystrophy usually have a history of meeting motor milestones, such as sitting, walking, and standing, but they reach these milestones later than does the average infant. By about 3 years of age, symptoms become acute and obvious as boys develop a waddling gait and have difficulty climbing stairs. They can rise from the floor only by rolling onto their stomachs and then pushing themselves to their knees. To stand, they press their hands against their ankles, knees, and thighs (they "walk up their front"); this is Gower's sign. They may walk on their toes, which leads to the development of a short heel cord. Speech and swallowing become difficult. It can be difficult to lift a young child with this condition by placing your hands under the axillae as the child seems to slip through your hands because of the lax shoulder muscles. In contrast, calf muscles are hypertrophied (measure larger than normal) because the muscles become so degenerated that they are replaced by fat and connective tissue.

As the disease progresses, muscle weakness becomes more pronounced. Scoliosis of the spine and fractures of long bones may occur from abnormal muscle tension and lack of muscle support. By junior high school age, most boys become wheelchair dependent. Tachycardia occurs as the heart muscle weakens and enlarges. Pneumonia develops easily as the child's cough reflex becomes weak and ineffective. Death from pulmonary dysfunction tends to occur at about 20 years of age (Brown, Amato, & Mendell, 2008).

The diagnosis is based on the history and physical findings, a muscle biopsy showing fibrous degeneration and fatty deposits, electromyography showing a decrease in amplitude and duration of motor unit potentials, and an increased concentration of serum creatine phosphokinase.

Therapeutic Management

Encourage boys with muscular dystrophy to remain ambulatory for as long as possible. To do this, help the child and family plan a program of active and passive daily range-of-motion exercises. Splinting and bracing may be necessary to maintain lower-extremity stability and avoid contractures. If children become overweight, remaining ambulatory becomes more

difficult for them. Therefore, encourage a low-calorie, high-protein diet to avoid excessive weight gain. In addition, to prevent constipation, encourage a high intake of fiber and fluids. Advocate for a stool softener if necessary. Corticosteroid therapy may be helpful to increase function and strength at least for a short term basis (Manzur et al., 2009).

Because the disease is progressive, assist the child and family with achieving the optimal level of activity within the child's limitations. Provide support for parents, to assist them with coping, because they can become depressed as disease symptoms progress (Chen & Clark, 2007).

Help children and parents locate a parent support group such as the Muscular Dystrophy Association (http://www.mdausa.org).

✔ Checkpoint Question 51.4

What is an important nursing intervention for children with muscular dystrophy?

a. Urge them to rest most of the day to avoid fatigue.
b. Guide them to avoid weight gain so they can be mobile longer.
c. Caution them not to eat meat and legumes at the same meal.
d. Encourage a diet rich in calcium to prevent osteoporosis.

INJURIES OF THE EXTREMITIES

Finger Injuries

It is not uncommon for a child to sustain a finger injury from a slammed car door. This injury, which causes a crushing blow to the tip of the finger, is excruciatingly painful. The fingernail may be lacerated and detached. As blood accumulates under an attached fingernail, pain continues to increase. An incision under the distal end of the nail or a stab wound through the attached nail helps to relieve pain. Fingernails often are lost after these injuries, but they grow back readily with little scarring. Reassure parents that, although the fingernail may be lost, the cosmetic effect will invariably not be a problem.

Parents may feel embarrassed and guilty when they bring a child to a health care facility for this type of injury. The accident usually occurred because they closed a door without looking for the child's finger. They appreciate how much this hurts and are angry with themselves for being so careless. Reassure parents that this is a common childhood injury.

A radiograph of the fingertip may be obtained to make certain that the tip of the distal phalanx is not broken. The rule, "If the child can bend it, it's not broken," does not apply to this injury, because the fracture is distal to the last phalangeal joint. Any open wound must be cleaned well. If the distal phalanx is fractured, a splint is applied to the finger. A follow-up visit is necessary to ensure that healing has occurred.

Bicycle-Spoke Injuries

Children who ride in child bicycle seats or over the back wheel of a bicycle can catch a foot or ankle between the spoke and the frame of the bicycle, resulting in a crushing, lacerating injury that quickly becomes edematous. Children can also injure their fingers in bicycle spokes. A radiograph is needed to rule out a fracture.

The wound, which usually is contaminated with spoke grease, needs cleaning with an antiseptic. It may be necessary to soak the area first with a solution of lidocaine, a local anesthetic, because of the amount of pain that quickly occurs from edema and ecchymosis. Sutures and a splint may be necessary. If it is a foot injury, the child may need to limit weight bearing by using crutches.

Soft-tissue injuries continue to be painful. Elevating the body part on pillows helps to reduce both the pain and edema. Such a major tissue injury may take up to 6 weeks to heal. Advise parents of this at the time of the injury. Otherwise, they may worry that the child's injury is not healing well. Because of the increase in the use of helmets, concussion or skull fracture from bicycle injuries are coming to be seen less frequently (Pardi et al., 2007).

Fractures

A **fracture** is a break in the continuity or structure of bone. Because children experience falls during their growth years, fractures of long bones are common childhood injuries. Various types are described in Table 51.2. Fractures in children tend to be different than in adults because:

- Bone in childhood is fairly porous allowing bones to bend rather than break.
- The periosteum is thick so the bone may not break all the way through.
- Epiphyseal lines may cushion a blow so that the bone does not break.
- Healing is rapid as a result of overall increased bone growth.

Because of the high resilience of immature bone, many fractures in early childhood are the greenstick variety (one side of a bone is broken; the other is only bent). These fractures cause minimal pain, swelling, or deformity, the usual hallmarks of fracture.

Many fractures in children, however, occur at the epiphyseal line. These are always serious because bone growth occurs at this point. Damage to the area can lead to undergrowth, overgrowth, or uneven growth, resulting in angulation. If a fall occurred from a high distance or was caused by a violent force, such as a speeding automobile, breaks may be complex, or the formation may be compounded (the bone pierces the skin) or comminuted (parts of the bone are fragmented). These injuries are always serious as well, because the severed bone may lacerate nerves or blood vessels. The open wound may become infected, and correction will most likely involve surgery with the risks of anesthesia.

Fractures heal relatively slowly compared with other body injuries. Immediately after a fracture, a hematoma forms at the site of the break; over the next several days, granulation tissue is laid down. Over the next several weeks, osteoblasts invade this new tissue, and calcium is deposited (termed *callus*) to form new bone. By the time callus formation is extensive (enough for movement at the fracture site to be impossible), clinical healing or clinical union has occurred. Complete healing does not occur until all the temporary callus formation has been replaced by mature bone cells and the bone has once more regained its normal shape and contour.

Several complications may occur during this process. One is fat embolus—the release of fat from the marrow of the bro-

TABLE 51.2 ✻ Common Fractures in Children

Type of Fracture	Description
Plastic deformation (bend) 	Bone bends, causing a microscopic fracture line that does not cross the bone; most common in the ulna and fibula
Buckle (torus) 	Fracture on the tension side of the bone near softened metaphyseal bone, causing a buckling and raised area on the harder diaphyseal bone (opposite side)
Greenstick 	Bone bent with fracture beginning but not crossing through the bone
Complete 	Bone divided (either transversely [crosswise at right angle to long axis of bone], obliquely [slanted but straight], or spirally [slanted and circular]); bone remnants possibly attached by a periosteal hinge

ken bone into the bloodstream. This embolus can travel to the cerebral vessels and cause symptoms of confusion or hallucinations as the oxygen supply to brain cells is shut off. It also could become a pulmonary embolus, producing dyspnea, tachycardia, and cyanosis. A second problem is *compartment syndrome*. This occurs when excessive swelling around the injury site causes increased pressure on nerves or blood vessels. Color and warmth of the extremity may remain normal, but the child has severe pain at the site that is aggravated by passive stretching. Any constricting device such as a cast needs to be removed to reduce this pressure in the compartment. If there is a great deal of edema present at the time of an accident, a body part may not be casted immediately but contained in a splint to avoid compartment syndrome. A long-term complication of fracture may be interference with growth if the growth plate was involved. Some children need bone-lengthening or bone-shortening procedures later in life to correct this problem.

Assessment

When children are seen in an emergency department for multiple trauma, the extremities should be observed closely for the hallmark signs of fracture (deformity, edema, and pain). If a fracture is suspected, splint the extremity to avoid further trauma. Splinting also reduces pain, because it prevents further movement of the bone. Splints should extend from a joint above to a joint below the suspected fracture site. For example, for a fracture of the forearm, the splint should reach from above the elbow to below the wrist. Immobilizing the joints above and below the injury this way prevents movement and muscle tension with further dislocation of the fracture. If the extremity is so seriously deformed by the break that it will not conform to the contour of a splint, do not attempt to move it into a splint position. Immobilize the extremity by placing sandbags on the sides of the arm or leg and leave it in that position. Take a thorough history of the accident. Some fractures in childhood occur from child abuse. This must be ruled out with all accidents.

Therapeutic Management

All children with a suspected fracture will need a radiograph to confirm the diagnosis and to determine the alignment and **apposition** (the amount of end-to-end contact of the bone fragments) of the fractured segments of bone. Apposition is not as important in children as it is in adults. Bayonet or side-to-side apposition may be established or left in children up to 10 to 12 years old, because, as the child grows and remodeling occurs, the bone will develop with normal contour and length. Side-to-side apposition results in a rapid, strong union and actually is the preferred position for some fractures.

If skin has been broken, the child may need tetanus prophylaxis. A hematocrit determination to estimate blood loss and cross-matching for replacement therapy may be necessary. An IV line is usually established to provide a route for fluid or blood replacement or for administration of an IV antibiotic to reduce the possibility of infection through the open wound.

All children with fractures are in some pain. Usually, they are frightened not only from the pain, the appearance of the fracture, and their inability to use the extremity, but also from the frightening situation that led to the fracture such as a fall from a bunk bed or an automobile accident. Spend time comforting and helping children to realize that they are now safe and will not be injured further. If they can relax enough to lie still and not move the fractured extremity, the pain will decrease. Children who have a compound fracture are as frightened by the sight of blood as they are by the deformity and pain. However, reassure children and parents that, unless the bone has been crushed, the bone fragments can be brought back into line. Afterward, the bone will heal with the same strength as before.

Types of Fractures

Forearm Fractures. Because children often fall on an outstretched arm, fractures of the forearm are common. In children, most fractures of the forearm involve the distal third; a smaller number of such accidents occur in the middle or proximal third. The injury may involve a fracture of the radius, a fracture of both the radius and ulna, or a displacement of the epiphyseal plate of the radius. In young children, the injury usually is a greenstick fracture. Sometimes greenstick fractures are broken completely before casting to prevent the bone's resuming its "bent" position within the cast. Refer to this as "straightening" the bone, rather than "breaking" the bone. If a greenstick fracture is slight so that the degree of angulation is not great, it may not be reduced or brought into a straight line; as callus is formed and the bone remodels itself, it will naturally straighten into good alignment.

If the fracture is complete and overriding is excessive, traction to the fingers may be used as a part of the cast. This "banjo" traction is cumbersome and limits the child's use of that hand. The hand is covered up to the first phalangeal knuckle to prevent the child from moving the hand excessively and damaging the edge of the cast, which would loosen it and pull the arm into poor alignment.

Elbow Fractures. If a child falls and stops the fall with a hand, the elbow may hyperextend, transmitting the force of the blow to the distal humerus and causing a supracondylar fracture of the humerus. Fractures of the humerus are reduced and stabilized with an arm cast, a splint, or traction, depending on the position of the fracture (Sadiq, Syed, & Travlos, 2007). Elevating the cast on pillows or suspending the hand by a strip of gauze or traction apparatus reduces edema. Although the fracture may be minor, the child needs to be assessed carefully for signs of blood vessel or nerve compression (Volkmann's contracture).

Volkmann's Ischemic Contracture. When an arm is flexed and put into a cast, the radial artery and nerve may be compressed at the elbow, causing nerve injury or severe impairment of circulation. If the fracture is in the proximal third of the radius, parents need to assess for signs of circulatory or nerve impairment for 24 hours.

If symptoms of compression are present but not detected within 6 hours, Volkmann's contracture and possible permanent damage to the arm will result. The arm is left permanently flexed at the elbow. The wrist is hyperextended, and the fingers assume a flexed, clawlike, useless position. If a child is going to be discharged after application of a cast, inform parents about the symptoms of compression so that its development can be detected. If a child is admitted to the hospital for 24 hours, the radial pulse (if palpable at the edge of the cast) should be taken hourly, along with checks for coldness, blanching, and color of the fingers, for the first 8 hours. In some instances, a cast is applied incompletely for 24 hours, the elbow portion being simply splinted and wrapped with elastic bandages. After 24 hours, when edema has subsided and the chance of compression is less, the rest of the arm is casted.

Epiphyseal Separations of the Radius. If a child breaks a fall with an outstretched arm, a separation of the epiphysis of the distal radius may result. When this occurs, the wrist must be casted to restabilize the epiphysis. Although epiphyseal injuries are always serious, distal radial injury rarely causes serious sequelae in children. However, advise parents that it is important to keep appointments for follow-up visits, so that growth disturbances can be detected early and correction started. Stapling the epiphysis may be done to arrest abnormal growth if it occurs. Stimulation of the epiphyseal line may increase growth if growth restriction occurs.

Clavicle Fractures. When young children fall and catch themselves with an outstretched arm, the force of the blow may be transmitted to the clavicle, causing fracture of the clavicle or dislocation at the sternal joint (Stewart & Van Klompenberg, 2008). Clavicles also may be fractured during birth or be a mark of child abuse.

Swelling is often present at the site of the break. In the newborn, a Moro reflex can only be demonstrated on the unaffected side. An older child refuses to use the arm, leaving it hanging at the side. Crepitus (crackling) can be felt over the clavicle. After radiographic diagnosis, the child is placed in a commercially manufactured or figure-of-eight splint of stockinette placed over the shoulders and under the axilla, keeping the arm adducted and flexed across the chest. This is left in place for about 3 weeks, during which time the wrap tends to look soiled. The child should keep the splint dry—no swimming or showering during this time. The parent often needs to tighten the splint every morning to keep it firmly in place. Parents are usually apologetic about the appearance of the stockinette when they return for a repeat radiograph after 3 weeks. They may be worried that the soiled appearance of the splint reflects the quality of their housekeeping or child care. Assure them that the soiled splint proves that they followed instructions well and left the splint in place for 3 weeks.

Parents may need reassurance that this splint is adequate therapy. They may ask, "The bone is broken, after all—why is my child not being placed in a cast?" Acknowledge their concern with a statement such as, "Most people think that when there is a broken bone, a cast is needed, but this is an exception." Doing so allows parents to voice their concern and receive necessary assurance.

Fracture of the Femur. Children who are involved in automobile accidents or who fall from considerable heights and land on their feet may suffer a fractured femur (Sturdee et al., 2007). Child abuse should be considered in an infant who sus-

tains a fractured femur, because there are few normal instances when a fracture of this magnitude should occur in an infant.

Even with closed femoral fractures, blood loss can be extensive because of the size of the bone broken. As the child lies on the examining table in the emergency department, the child tends to hold the leg externally rotated; the thigh may appear abnormally short or deformed. Often, the child is in a great deal of pain, possibly with signs of shock from pain and blood loss. Children are frightened as well by the force of the accident that caused such a severe injury.

In the past, fractured femurs were not casted immediately because strong tendon spasm causes poor alignment and overriding of the femur segments. Only after muscle spasm had been reduced enough by skeletal or Bryant's traction to allow close approximation of the bone edges (7 to 14 days), was the child removed from traction and placed in a hip spica cast. Today, a child may be taken to surgery immediately to have an intramedullary rod placed to align and stabilize the fracture. No cast may be required.

Help the child and family identify ways for the child to continue contact with friends during any time of restricted activity.

Dislocation of the Radial Head. If a small child is lifted by one hand, as happens when a parent pulls on one arm to lift the child over a curb or up a step, the head of the radius may escape the ligament surrounding it and become dislocated (nursemaid's elbow). The child holds the arm flexed at the elbow with the forearm pronated. The child winces with pain when the radial head is palpated.

A simple dislocation of the radial head can be reduced by a physician, using gentle pressure on the radial head while the arm is flexed and supinated. Relief of pain is immediate, and the child begins to use the arm again.

Parents feel guilty because they caused this dislocation. Reassure parents that this is a common injury in small children. They rarely need to be cautioned that lifting a child in this manner is not wise. Be aware, however, that a dislocation of the radial head can occur from extremely rough handling, as is seen in child abuse. Investigate the circumstances of the injury closely.

Athletic Injuries

Although participating in athletics promotes growth and development, it can also lead to injury. Playing on backyard trampolines, in particular, is a dangerous sport for children (Hurson et al., 2007). Strategies to prevent sports injuries include preparticipation health examinations; medical coverage at sporting events; proper coaching; adequate hydration; proper officiating; and proper equipment and field or surface playing conditions (Rennie et al., 2007).

Knee Injuries

Participation in sports such as football, skiing, soccer, and track are frequent causes of knee injuries in children (Box 51.7). These injuries usually involve the ligaments surrounding the knee—the medial, lateral, posterior, or cruciate ligaments (figure-eight ligaments that stabilize the knee). After the injury, the child has severe pain in the knee with localized edema. A radiograph or MRI will be taken to rule out fracture (Giugliano & Solomon, 2007).

BOX 51.7 ✻ Focus on Evidence-Based Practice

Are male or female high school athletes most apt to experience a knee injury?

Knee injuries are the leading cause of high school sports-related surgeries. To assess the chance of a high school athlete suffering a knee injury, all of which are potentially life changing, researchers studied athletes from 100 high schools selected randomly across the United States. The rate of knee injury at these schools was 3.89 per 10,000 athletic events. Boys had a higher overall rate of knee injury but girls were twice as likely to sustain knee injuries requiring surgery and also twice as likely to incur the knee injury during a noncontact moment or sport. Illegal play was identified as a cause in only 5.7% of injuries. Injuries from illegal play, however, tended to be more severe than others as 20% of injuries resulting from illegal play required surgery.

Based on the above study, would you advise high school students not to play contact sports?

Source: Ingram, J.G., et al. (2008). Epidemiology of knee injuries among boys and girls in U.S. high school athletics. *American Journal of Sports Medicine, 36*(6), 1116–1122.

If the injury is mild (only a few torn fibers), bedrest with ice applied to the knee is often the only therapy needed. Local infiltration of an anesthetic may be necessary to minimize pain. After 24 hours, heat is applied to the knee to hasten healing.

If the injury is more severe, the knee joint may fill with fluid. The child will need bedrest and ice applied to the joint. The abnormal synovial fluid will be aspirated, and a compression dressing will be applied to discourage accumulation of further fluid. After 24 hours, heat treatments will be started to hasten healing.

If the injury is severe, arthroscopy may be done to visualize and surgically repair the knee ligaments. Arthroscopic surgery makes repair of ligaments or cartilage a minor procedure and limits the necessity for immobilization and a cast.

A severe twisting motion to the knee can cause a dislocation of the kneecap (it moves to the posterior surface of the knee). The knee appears deformed, and the child is in acute pain. Immediate treatment for a dislocated kneecap is to slide it again to the front of the knee. After this realignment, the child usually has to use a leg immobilizer for 1 week. If the problem is chronic or occurs frequently, surgery to strengthen the ligaments may be necessary. Quadriceps exercises (straight-leg raising) are important to prevent the dislocation from occurring again.

Throwing Injuries

Throwing places repeated stress on an upper extremity, particularly the elbow joint. The injury tends to occur during the forward motion of the arm or during the follow-through. After the injury, the child is unable to extend the

elbow completely because of minute tears and fibrous contractures in the muscle. The child notices pain and tenderness and has loss of complete elbow extension for 24 to 48 hours after the injury. Resting the arm and applying ice packs for 15 to 20 minutes three times a day relieves the pain. An anti-inflammatory agent may be helpful. A limited number of cortisone injections into the elbow musculature may be helpful. Exercises to strengthen flexor muscles help to prevent this type of injury.

"Little Leaguer's elbow" is epiphysitis of the medial epicondylar epiphysis. Throwing curve balls and breaking pitches increases the stress in this area because of the forceful flexion and pronation required. A radiograph of the elbow may reveal increased growth, separation, and fragmentation of the medial epicondylar epiphysis. Children need extra protection against this type of injury until the epiphyseal growth centers at the elbow have fused at 14 to 17 years of age (Magra, Caine, & Maffulli, 2007).

Children who participate in Little League sports need time for proper warm-up. They should be encouraged to refrain from throwing curve balls or breaking pitches and should be limited to pitching about six innings per week with a 3-day rest between games. Treatment for Little Leaguer's elbow is rest and immobilization until pain, tenderness, and limitation of movement have passed. If the injury is not treated adequately, permanent damage to the epiphyseal line and elbow deformity can occur.

Strains and Sprains

A **strain** is a muscle-tendon injury. A **sprain** is a ligament injury. Strained or sprained ankles are common but difficult childhood injuries. The joint is painful and swollen. Such injuries typically occur from inline skating or snow- or skateboarding. When radiography reveals no fracture, a child may feel as though someone has said that the injury is not serious but "just a sprain." This makes the extent of the swelling and pain baffling. Some children may be accused by parents of "putting on" pain, because the injury is "only a sprain."

Help the child and parents to understand that strains and sprains are truly painful. Because a cast is not used and the ankle is not immobilized completely, strains and sprains can be more painful than fractures, which are casted.

If the injury is recent, an ice pack should be applied for approximately 20 minutes at a time to reduce edema at the site. An elastic bandage may be applied for firm support. The child may be given crutches to limit weight bearing for the next 3 or 4 days. Make certain that the parents of the child understand how the elastic bandage is applied so that it can be rewrapped if it loosens, and be sure that the child is using the crutches properly before being discharged from the emergency department.

✔ Checkpoint Question 51.5

Why is casting an elbow a potentially dangerous type of cast application?

a. It prevents the ulna and radius from continuing to grow.
b. Edema at the elbow can cause permanent nerve damage.
c. Holding the arm bent at the elbow causes low-grade pain.
d. These casts get dirty and so lead to humeral osteomyelitis.

Key Points for Review

- Bone and muscle disorders tend to be long-term disorders. Help children and their families to think about how the disorder will affect tasks of daily living, to help a child better adjust to interventions such as a cast or brace. Help children plan self-diversional activities as necessary, so they continue to grow developmentally while confined to a cast or traction.
- As a rule, children with a broken bone need additional calcium in their diet to aid bone healing. If they are on strict bedrest, however, this should only be a moderate addition to their diet, to prevent renal calculi from forming.
- Many children have casts applied to allow broken bones to heal. If broken bones are not easily aligned, children are placed in traction.
- Developmental disorders that occur in children include flat feet (pronation), genu varum (bowlegs), and genu valgum (knock knees). The majority of these disorders are corrected naturally by normal growth.
- Slipped epiphysis is slipping of the femur head in relation to the neck of the femur at the epiphyseal line. It occurs most frequently in obese or rapidly growing boys.
- Osteomyelitis is infection of the bone. It can result in extensive destruction of the bone. Antibiotic therapy is necessary to combat the infection.
- Scoliosis is a lateral curvature of the spine. It is treated by bracing or surgery.
- Juvenile arthritis occurs in several different forms: polyarticular, pauciarticular, and systemic onset. Therapy includes exercise, heat application, and administration of medications such as NSAIDs or methotrexate.
- Myasthenia gravis can occur in three types: neonatal transient myasthenia, congenital myasthenia, and juvenile myasthenia. Anticholinesterase drugs such as neostigmine, which prolong acetylcholine action, are used.
- Muscular dystrophies are a group of disorders that lead to progressive degeneration of skeletal muscles. Different types can occur, including congenital myotonic, facioscapulohumeral, and pseudohypertrophic. Children and parents need support throughout this long-term illness.
- A fracture or bruise of soft tissue can result from any trauma, including child abuse. Be certain to secure a detailed history of an injury, to be sure that the history is consistent with the degree of injury.
- Volkmann's ischemic contracture is a complication that occurs when an arm is casted in a bent position and the radial artery and nerve are compressed at the elbow. Frequent assessments of finger color and warmth are safeguards to detect if this is occurring.

CRITICAL THINKING EXERCISES

1. Jeffrey is the 13-year-old boy with osteomyelitis you met at the beginning of the chapter. How would you explain to his mother what has happened to him?

2. Suppose Jeffrey who has scoliosis and was prescribed a brace to wear 23 hours a day for treatment a month ago. During the last month, he dropped out of the school band and the one after-school club to which he belonged. He tells you he is dropping activities "to have more time to study." Would you be concerned about him? What areas would you need to assess, and how would you intervene?
3. Jeffrey's sister has juvenile arthritis. You notice when she returns for a follow-up visit to the arthritis clinic that the inflammation in her joints is worse than at her last visit, and she says she has more pain. Her mother tells you she has been giving her acetaminophen instead of her prescribed NSAID because she read that NSAIDs cause stomach irritation and heart disease. Was she wise to substitute another medication this way? How would you suggest she proceed at this point?
4. Examine the National Health Goals related to musculoskeletal disorders in children. Most government-sponsored funds for nursing research are allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to Jeffrey's family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to musculoskeletal disorders in children. Confirm your answers are correct by reading the rationales.

Chapter

52 Nursing Care of a Family When a Child Has an Unintentional Injury

KEY TERMS

- allografting
- autografting
- contrecoup injury
- débridement
- drowning
- escharotomy
- heterografts
- homografting
- near drowning
- otorrhea
- plumbism
- rhinorrhea
- stupor

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe the causes and consequences of common accidents and injuries in childhood and measures to prevent them.
2. Identify National Health Goals related to children who have experienced trauma that nurses can help the nation achieve.
3. Use critical thinking to analyze ways that care of children with unintentional injuries can be more family centered.
4. Assess a child who is unintentionally injured from an accident.
5. Formulate nursing diagnoses related to an unintentionally injured child.
6. Establish expected outcomes for an unintentionally injured child.
7. Plan nursing care related to an unintentionally injured child.
8. Implement nursing care for a child with an unintentional injury, such as providing pain relief.
9. Evaluate expected outcomes for achievement and effectiveness of care.
10. Identify areas related to care of children with unintentional injuries that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of unintentional injuries in childhood with nursing process to achieve quality maternal and child health care.

Jason, a 5-year-old boy, is seen in the emergency department after an automobile accident. He is crying and upset, although the only visible signs of trauma are a reddened and edematous area on the middle of his forehead. Vital signs reveal the following: temperature, 99.4° F (37.5° C); respirations, 18 breaths/minute; pulse, 62 beats per minute; and blood pressure, 110/62 mm Hg. His left pupil is more dilated than his right and it reacts sluggishly to light. His Glasgow Coma Scale score is 10. His mother tells you, "I'm sure he's not injured badly. He was wearing his seat belt." Previous chapters described the growth and development of well children and care of children with disorders of specific body systems. This chapter adds information about the characteristic changes, both physical and psychosocial, that occur when children experience an unintentional injury.

Suppose you are a triage nurse. Would you rate Jason as a child to be seen immediately, or could he be given second priority?

Accidents, such as those involving motor vehicles, falls, burns, and water immersions, cause more deaths in the 1- to 4-year age group than the next six most prevalent causes combined. In the 15- to 24-year age group, they cause half of the deaths of the age group (NCHS, 2009). If unintentional injuries such as these could be prevented, therefore, a major cause of childhood morbidity and mortality could be eliminated. However, total accident elimination may not be possible. Children commonly believe that accidents will not happen to them and, as a result, fail to take sensible precautions against them. Some parents may predispose their children to accidents by overestimating their development and giving them responsibility beyond their capabilities.

The frequency of various types of accidents varies according to age group (Table 52.1). Because the anatomy and physiology of children are different from those of adults, they are not only involved in different types of accidents than adults, but accidents affect them differently.

Family stress plays a large role in childhood poisoning accidents because these types of accidents tend to occur when parents are preoccupied. Many medicine poisoning ingestions occur on the same day that the medicine was purchased, implying that the stress of family illness plays a major role. Eliminating accidents in children, therefore, is not a simple procedure, because it involves reducing family stress as well. National Health Goals related to children and trauma are shown in Box 52.1.

Nursing Process Overview

For Care of a Child With an Unintentional Injury

Assessment

When children are seen at health care facilities because of unintentional injuries, neither they nor their parents may be functioning at their optimal level because of the stress of the situation. Both may be apprehensive and frightened not only about what *has* happened, but also about what could have happened. Children often feel guilty and fear that they will be scolded or punished. Their parents may feel equally guilty; they may feel that if they were really "good" parents, they would have been watching more closely. They may feel defensive because they are worried about being criticized. People under stress do not hear well and may not perceive the information given to them correctly. Information they receive in the emergency department, therefore, may be grossly misinterpreted or not heard at all.

Children are likely to be in pain. They are frightened not just from the pain of the injury but also from the circumstance of the injury. Children count on their parents to keep them safe, yet they have been hurt. The trust is broken momentarily. How can they be safe here if their parents are no longer protecting them?

TABLE 52.1 ✻ Most Common Accidents in Children by Age Group

Age (yr)	Type of Accident
0–1	Falls, inhalation of foreign objects, poisoning, burns, drowning
2–4	Falls, drowning, motor vehicles, poisoning, burns
5–9	Motor vehicles, bicycle accidents, drowning, burns, firearms
10–14	Motor vehicles, drowning, burns, firearms, falls, bicycle accidents
15–18	Motor vehicles, drowning, firearms

National Center for Health Statistics. (2009). *Health Data for All Ages.* Hyattsville, MD: Author.

BOX 52.1 ✻ Focus on National Health Goals

Because prevention of unintentional injuries could have immediate and long-term effects on the nation's health, several National Health Goals are concerned with preventing accidents and unintentional injuries in children:

- Reduce the number of drownings each year from a baseline of 1.5 per 100,000 to 0.7 per 100,000 children.
- Reduce the rate of firearm-related deaths from a baseline of 10.3 per 100,000 to 3.6 per 100,000 children.
- Reduce the number of nonfatal poisonings from a baseline of 348 per 100,000 to 292 per 100,000 children.
- Reduce the number of deaths caused by suffocation from a baseline of 4.2 per 100,000 to 3.3 per 100,000 children.
- Reduce the rate of deaths caused by unintentional injury from a baseline of 35.3 per 100,000 to 17.1 per 100,000 children.
- Reduce the number of deaths caused by motor vehicle crashes from a baseline of 14.7 per 100,000 to 8 per 100,000 children.
- Increase the use of child automobile safety restraints from a baseline of 92% to 100%.
- Increase the proportion of bicyclists, 1 to 15 years of age, who regularly wear a bicycle helmet from a baseline of 69% to 76%.
- Reduce the number of residential fire deaths from a baseline of 1.2 per 100,000 to 0.2 per 100,000 children (http://www.nih.gov).

Nurses can help the nation achieve these goals by providing counseling on safety precautions to parents and children. Nursing research in these areas that would be helpful is: What are effective ways to communicate safety information to parents at well-child visits when time is at a premium? In what ways should safety teaching given after an accident to prevent a further accident be different from that given as primary prevention? Is there an association between children setting fires and their exposure to fire experiences with fireplaces or candles?

Because the emergency department nurse is often the first person who sees a child after an injury, be ready to make a preliminary assessment of the extent of a child's injuries before a physician arrives. Remember that children may be seriously hurt but not crying because they are in shock. They may be hemorrhaging, but, if they are bleeding internally, the blood may not be visibly evident. Accidents become fatal when lung, heart, or brain function becomes inadequate. These three body systems, therefore, must be evaluated first (Airway, Breathing, Circulation and Disability, or an ABCD evaluation). Table 52.2 lists signs and symptoms to assess when determining the respiratory, cardiovascular, and neurologic status of an injured child.

While conducting a preliminary assessment of a child's major body systems, take a brief history of the accident. What happened? How long ago did it happen? Was the child using protective equipment such as a helmet or a secured seatbelt? What have the parents done? If the child fell, how far was the fall? On what body part did the child land? (A head injury is more likely to be serious than an ankle injury, although a child may be in more pain and may have more obvious symptoms with the lesser injury.) Ask the parents what they think are their child's major injuries. Children may report one body part hurts at first, but then a small cut elsewhere begins to bleed, and they focus on the minor bleeding as their major injury. If parents say, "At first, he acted as if his stomach hurt," this may be the first suggestion that he has a serious abdominal injury such as splenic rupture.

TABLE 52.2 ✻ Important Assessments on Initial Examination of an Injured Child

Body System	Assessment
Respiratory system	Quality of respirations
	Rate of respirations
	Sound of obstruction (wheezing, stridor, retractions, coughing?)
	Color (cyanotic?)
	Oxygen hunger (restlessness, inability to lie flat?)
Cardiovascular system	Color (pallor from hemorrhage or cardiovascular collapse?)
	Gross bleeding
	Pulse rate (increases with hemorrhage)
	Blood pressure (decreases with hemorrhage)
	Feeling of apprehension from altered vascular pressure
Nervous system	Level of consciousness (child answers questions coherently, infant attunes to parent's voice?)
	Pupils (equal and reacting to light?)
	Bumps or bruises on head or spinal column
	Loss of motion or sensory function in a body part

Evaluating children in an emergency department is difficult, because they may be too young to communicate or unconscious or they are so frightened that they cannot stop crying to report which body parts are painful or to indicate which parts should be assessed first. Spend a few minutes attempting to calm children and get them past this initial fright, unless symptoms of major body system disturbances require that you direct your immediate efforts elsewhere. Parents need frequent explanations of care given or planned, because as long as they are worried and tense, children cannot be calmed easily.

A proportion of unintentional injuries in children result from child abuse. Conflicting histories or a parent and child recounting different stories is a hallmark of this. Always ask yourself if this could be a possibility (see Chapter 55).

Nursing Diagnosis

The nursing diagnosis used most frequently with injured children is Pain. Depending on the particular injury, several other nursing diagnoses are relevant, as are those that relate to the suffering that parents experience when their child is injured. Examples of possible nursing diagnoses are:

- Pain related to fractured tibia from sports injury
- Ineffective airway clearance related to burned esophageal tissue
- Impaired physical mobility related to severe burn injury
- Disturbed body image related to change in physical appearance from thermal injury
- Parental fear related to outcome after head injury in child
- Interrupted family processes related to child's unintentional injury
- Anxiety related to apprehension and lack of knowledge regarding medical treatment of child

Outcome Identification and Planning

Parents in an emergency department are rarely ready for long-term planning. They often have great difficulty in coming up with answers to the most straightforward immediate questions. Therefore, long-term planning may have to be delayed until the immediate concern of the injury has passed.

On discharge from the emergency department, parents need printed instructions about the child's care at home and the name and number of the person to call if they have questions about care or progress. They also need an appointment (or the number to call for a return appointment) for follow-up care. If a child is admitted to the hospital from the emergency department, it is helpful if the nurse who cared for the child in the emergency department can accompany the child to the hospital unit. The first person who cares for a child after an injury becomes very important to the child and parents, because that person was the first one to recognize their distress. Parents have difficulty letting this person go and accepting a new caregiver. A transition period, a "passing on of care," helps a parent accept the child's new caregivers as being as dependable and trustworthy as the emergency department staff.

A key component of nursing intervention in an emergency department is to help parents understand why an

injury happened and plan ways to make their immediate or community environment safe for children. An organization that might be appropriate for referral is the American Association of Poison Control Centers (http://www.aapcc.org).

Implementation

The extent of a child's injury depends on the injuring agent, the part of the body that was injured, and often the immediate care, including both physical and psychological management, that a child receives.

The diameter of the airway in children is smaller than in adults, so an injury to this body area almost always results in a greater danger of airway closure than in adults. This could happen from the child's inhaling a substance, such as water, that directly obstructs the airway or from inhaling toxic fumes that cause inflammation along the lining of the airway, resulting in obstruction. A blow to the neck can result in edema of surrounding tissues, causing the airway to close.

Injuries may involve some blood loss. Fortunately, a child's circulatory system is capable of rapid compensation for blood loss by vasoconstriction. Because the total volume of blood in a child is reduced, however, blood loss in children is always potentially serious. Because of this, many health care agencies have standing orders that allow emergency care nurses to begin intravenous normal saline boluses on children with obvious blood loss.

Often, in the emergency department, large portions of the child's body must be exposed to view so that care can be given easily. This means that rapid cooling can occur. Because of the large body surface area of children in relation to weight, always be conscious of body temperature and take active measures to decrease cooling by keeping a child covered as much as possible during examination times.

Standard infection precautions must be maintained in emergency situations, the same as at any other time. Parental consent must be obtained for treatment procedures even in an emergency, except for life-saving actions, such as cardiopulmonary resuscitation. In these instances, action can and should be taken to save a child's life with or without parental permission (it is assumed that parents would consent to life-saving procedures). Delaying emergency procedures until parents can be located may result in permanent disability or death.

Outcome Evaluation

After an injury, children need follow-up care to be certain that the immediate interventions were adequate and that healing is taking place. Evaluation visits are also the time to determine whether the child's environment has been changed and is safer now than at the time of the accident (if applicable). At the time of the accident, parents may have been too anxious to hear health supervision information. Now, with the accident behind them, they are ready for such information and prepared to make changes.

If an injury could not have been anticipated, parents appreciate hearing one more time that such an accident could not have been avoided and that they are good parents. This helps them maintain adequate self-esteem to continue to function well as parents.

Examples of expected outcomes suggesting achievement of goals are:

- Child swallows fluids without distress after esophageal burns.
- Child states pain is at tolerable level within 30 minutes.
- Child demonstrates full range of motion in hand after thermal injury.
- Child states he understands that wearing a seat belt is an important safety measure.
- Child states she will wear helmet when riding bicycle in the future.

HEALTH PROMOTION AND RISK MANAGEMENT

In every care setting, nurses have the unique opportunity among health care professionals to provide child and family teaching concerning the prevention of accidents. Even in the acute care setting when an accident has already occurred, nurses can provide valuable instruction to families about safeguarding their children against future accidents. In a community setting, nurses have a great opportunity for assessment of the unique threats that are present in particular environments such as lead-based paint or kerosene heaters in older homes, risk of drowning in a home with an unfenced swimming pool, or the danger for children riding in the back of pickup trucks. To teach effective accident prevention, nurses need to be knowledgeable about common measures that prevent injury.

Poisoning is an important cause of serious injuries in children younger than 6 years of age; more than 1 million episodes occur every year (Dart & Rumack, 2008). Common household agents are often the cause. Since passage of the Poison Prevention Packaging Act of 1970, potentially hazardous products must be sold in child-resistant containers. Passage of this act initiated a decrease in the incidence of childhood poisonings from common medicines.

The home environment may still contain products that can be hazardous and poisonous to children if handled improperly. Plants, cosmetics, and cleaning products can be dangerous to children if ingested or absorbed through the skin. Teach parents to be aware of these dangers and of strategies for maintaining a safe home environment, including learning basic first aid procedures.

Measures for a safe home environment include actions such as installing child-resistant locks on low cabinets where household products are stored, moving plants to a higher surface or removing them from the home until the child is older, keeping matches in safe places, and teaching street safety. In addition, parents should anticipate that, even in the safest environment, a child can be injured. Along with knowledge of basic first aid, the telephone number of the local poison control center should be posted by the telephone.

HEAD TRAUMA

Children receive head injuries when they are involved in multiple-trauma accidents, such as automobile crashes. Falls from swing sets, porches, and bunk beds also cause many head in-

juries. Other children are injured by being struck on the head by an object, such as a baseball, rock, or hockey puck, or by falling from a bicycle (Faries & Battan, 2008).

Head injuries are always potentially serious not only because they can cause an immediate threat to the life of the child, but also because several complications may follow. With a depressed skull fracture, for example, recurrent seizures can occur. Many of these children show focal abnormalities on an electroencephalogram (EEG) because of scar tissue formation. Some children with seizure involvement have normal EEGs, however, so, by itself, the EEG is of limited value in predicting whether posttraumatic seizures will occur.

Some children experience memory deficits or minor personality changes after head injury (Fazio et al., 2007). Symptoms such as headache, irritability, and postural vertigo (sensation of feeling faint or the inability to maintain normal balance—also known as posttrauma syndrome) also may occur. Behavioral manifestations may include aggressiveness or poor school performance. It often is difficult to determine whether these symptoms are organic or the result of being treated differently than usual by anxious parents.

Immediate Assessment

All children with head trauma require a neurologic assessment as soon as they are seen and again at frequent intervals to detect signs and symptoms of increased intracranial pressure (ICP). Increasing pressure puts stress on the respiratory, cardiac, and temperature centers, causing dysfunction in these areas. With increased pressure, the pupils become slow or unable to react immediately. Level of consciousness and motor ability decrease, pulse and respiratory rates decrease, and temperature and pulse pressure increase.

Assess vital signs to detect these changes and observe children's pupils to be certain that they are equal and react to light. Assess children's level of consciousness and motor function. Stabilize the neck with a brace until cervical trauma has been ruled out.

Immediate Management

After a head injury, brain edema is likely because fluid rushes into the inflamed and bruised area. Both central venous and central arterial lines may be inserted. ICP monitoring may be initiated (see Chapter 49). A computed tomography (CT) scan or magnetic resonance imaging (MRI) will be ordered to determine areas of edema or bleeding. An attempt may be made to decrease brain edema by intravenous (IV) administration of a hypertonic solution, such as mannitol. This will increase intravascular pressure and shift the edema fluid back into the blood vessels. Steroids such as dexamethasone may be added to decrease inflammation and edema. Keeping the head elevated is also effective in reducing ICP.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for excess fluid volume related to administration of hypertonic solution

Outcome Evaluation: The child's respiratory rate remains between 16 to 24 breaths/minute; specific gravity of urine is between 1.003 and 1.030; pulse remains between 60 to 100 beats per minute; blood pressure remains consistent for age group; lungs are clear to auscultation.

When hypertonic solutions are being infused intravenously into children, assess vital signs frequently to be certain that the fluid load being pulled into the intravascular system does not overtax it. This fluid must be excreted by the kidneys to keep the vascular system from becoming overloaded. Keep accurate intake and output records to ensure that the kidneys are functioning, and test the specific gravity of urine to detect the development of pituitary compression and resultant overproduction or underproduction of antidiuretic hormone from the posterior pituitary.

Nursing Diagnosis: Risk for delayed growth and development related to late sequelae of head injury

Outcome Evaluation: Child shows no evidence of any alteration in thought processes, seizure activity, or memory at follow-up visits. Cognitive and physical development are appropriate for age.

Helping care for a child with a head injury can be difficult for parents because they are so worried. Offer information on the child's progress as it becomes available to you. Urge parents to help care for the child to increase their sense of control.

During the acute phase of illness, ensure that parents are informed about the dangers of increased ICP. If they ask about the possibility that personality changes or seizures will develop later in life, their questions should be answered truthfully. At the same time, do not give unnecessary warnings about observing the child carefully in the months to come. Head injuries by themselves are worrisome enough to parents and children without adding to their burden.

Skull Fracture

A skull fracture is a crack in the bone of the skull (Aminoff, 2009). Recognizing skull fractures in children is important, because associated cerebral injury often occurs under the fracture. Many skull fractures are simple linear types, most often involving the parietal bones. In some children, the skull does not fracture, but the suture lines separate. This occurs more commonly in the lambdoid suture line; a coronal suture separation is rare and, if present, indicates severe trauma (Fig. 52.1).

Assessment

If the base of the skull is fractured, a child usually exhibits orbital or postauricular ecchymosis. **Rhinorrhea** or **otorrhea** (clear fluid draining from the nose or ear, respectively) may be present. This is escaping cerebrospinal fluid (CSF)—a serious finding, because it means that the child's central nervous system is open to infection. Test the fluid discharge with a glucose reagent strip if there is doubt about the source of the drainage. CSF will test positive for glucose, whereas the clear, watery drainage from an upper respiratory tract infection will not.

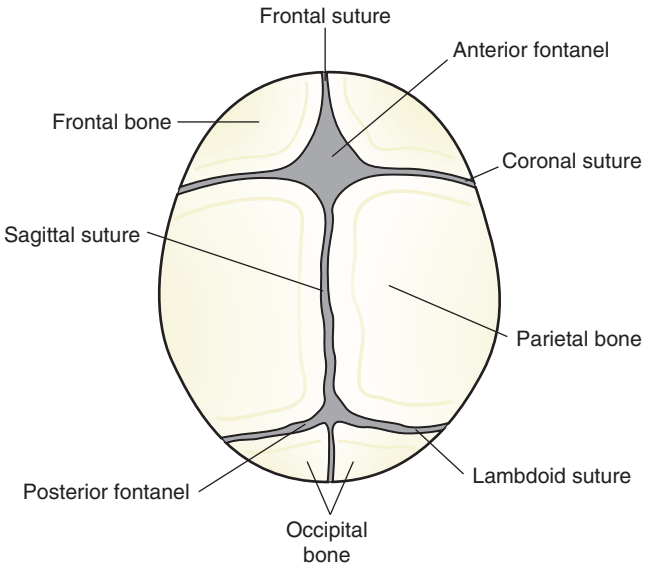

FIGURE 52.1 Location of suture lines of the skull.

Take a careful history of the accident, so that the strength of the blow to the head can be judged. Shock with hypotension rarely occurs with an isolated head injury. If a child is in shock, investigate for bleeding points other than the head injury. Skull fractures are confirmed by skull radiography.

If a skull fracture is linear with no underlying pathology, no treatment except observation and prescription of an analgesic is necessary. In about 3 weeks, a repeat radiograph will be needed to confirm that healing has taken place. Parents can be reassured that a second radiograph this soon is not harmful but necessary.

If a fracture is depressed (a bone fragment is pressing inward) or compounded (bone is broken into pieces), surgery will be necessary to remove or repair broken fragments. Cranial surgery of this type is discussed in Chapter 49.

Therapeutic Management

If CSF is draining from the nose, a child will be admitted to the hospital for observation. Keep the child in a semi-Fowler's position so that fluid drains out, not inward, to reduce the possibility of introducing infection. Make certain that children do not attempt to hold their nose or pack their nostrils with something to halt the drainage. Because coughing and sneezing may allow air to enter the meningeal space, coughing may be suppressed by medication. If the drainage is excoriating to the upper lip, coat the space with petrolatum. Children may be prescribed a prophylactic antibiotic to reduce the risk for meningitis. If the drainage does not stop within a few days, surgery will be necessary to repair the fracture and reduce the danger of meningitis. Air that enters intracranial spaces usually is absorbed rapidly. If radiographs at 72 hours still show air in the cerebral spaces, it implies that a skull defect remains, and surgery may be indicated to close the defect.

Potential Complications

A long-term complication of even a linear fracture may be a *leptomeningeal cyst.* This results from projection of the arachnoid membrane into the fracture site. With the interfering tissue, bone cannot heal and actually erodes, so that the fracture site becomes progressively larger, not smaller. This becomes evident on a follow-up radiograph. It may be suspected if a child develops focal seizures or symptoms of increased ICP. The defect may be palpated on the skull as an underlying indentation. Surgical resection is necessary to remove the cyst.

Subdural Hematoma

Subdural hematoma is venous bleeding into the space between the dura and the arachnoid membrane (Fig. 52.2A). It occurs when head trauma lacerates minute veins in this area (Amirjamshidi et al., 2007). The collection of blood is usually bilateral.

Subdural hematomas tend to occur in infants more often than in older children. Symptoms may occur within 3 days or as late as 20 days after trauma. Infants usually have symptoms of increased ICP. Seizures, vomiting, hyperirritability, and enlargement of the head may occur. Anemia caused by the substantial blood loss is a prominent sign. Angiography or ultrasound reveals the extent of the hematoma.

In infants, accumulated subdural blood may be removed by a subdural puncture through the lateral aspect of a patent anterior fontanelle. The procedure is similar to a lumbar puncture. Infants receive conscious sedation or must be held extremely still during the procedure so that they do not move and cause the aspiration needle to be inserted incorrectly. Without conscious sedation, half of the success of subdural puncture depends on the ability to hold the child still.

Subdural punctures may need to be repeated daily to empty the subdural space. Once the space is empty, expanding brain tissue will naturally occlude it. If the space has not been occluded after 2 weeks of daily punctures, active bleeding is still present, and surgery usually is necessary to reduce the space and halt bleeding.

In older children, surgery usually is necessary, because the anterior fontanelle is closed and the space cannot be reached by puncture.

Epidural Hematoma

Epidural hematoma is bleeding into the space between the dura and the skull (Fig. 52.2B). This happens when head trauma is severe. Subdural hemorrhage is usually venous bleeding, but epidural hemorrhage is usually a result of rupture of the middle meningeal artery and is, therefore, arterial bleeding. It usually is intense and causes rapid brain compression.

At the time of the injury, children become momentarily unconscious. They then regain consciousness and, to the untrained eye, appear to be well for minutes or hours. Then signs of cortical compression—vomiting, loss of consciousness, headache, seizures, or hemiparesis (paralysis on one side)—are observed. On physical examination, unequal dilation or constriction of the pupils may be present. Decorticate posturing (see Chapter 49) may be seen, indicating extreme pressure on upper cortical centers. If the pressure is allowed to continue unchecked, cortical compression may be so great that brainstem, respiratory, or cardiovascular function becomes impaired.

As a rule, the closer to the time of the injury that symptoms of compression occur, the more extreme is the amount of blood loss. The treatment is surgical removal of

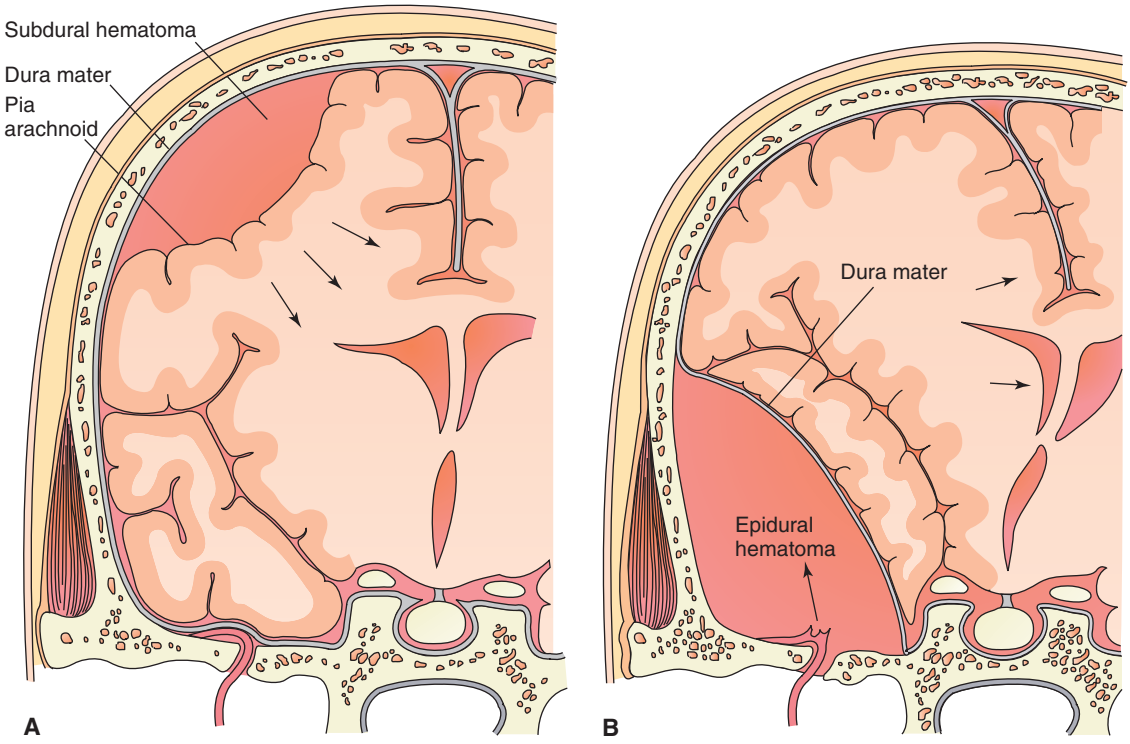

FIGURE 52.2 (**A**) Subdural hematoma. The red area in the upper left area of the drawing is the hematoma. Note the shift of structures. (**B**) Epidural hematoma. The red area in the lower left area of the drawing is the hematoma. Note the broken blood vessel and the shift of midline structures.

the accumulated blood and cauterization or ligation of the torn artery. The earlier the process is recognized and treated, the less the chance of residual damage from extreme pressure or anoxia to the involved portion of the brain.

Concussion

Concussion is the temporary and immediate impairment of neurologic function caused by a hard, jarring shock (Wilson & Matthews, 2008). It may occur on the side of the skull that was struck (a *coup injury*) or on the opposite side of the brain (a **contrecoup injury;** Fig. 52.3). As the brain recoils from the force of the blow and strikes the posterior surface of the skull, this second injury occurs. Children have at least a transient loss of consciousness at the time of the injury. They may vomit and may show irritability after regaining consciousness. They typically have no memory (amnesia) of the events leading up to the injury or of the injury itself. For

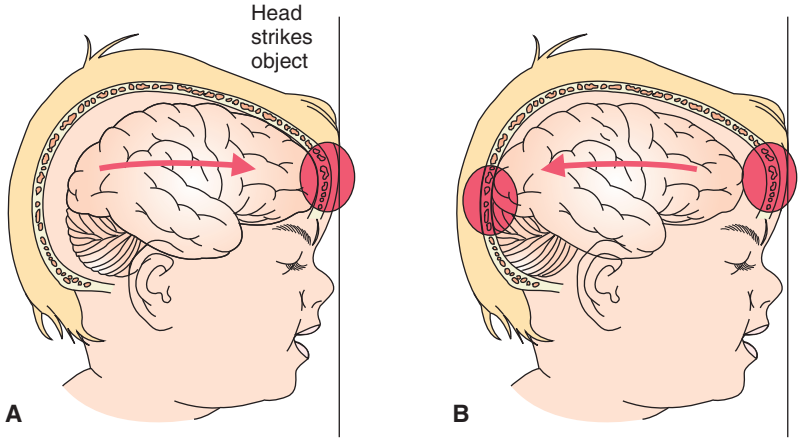

FIGURE 52.3 Etiology of (**A**) coup and (**B**) contrecoup injuries.

some children, this makes being asked questions about the accident extremely upsetting because they do not remember anything that happened and feel a frightening loss of control. The child requires a skull radiograph to rule out skull fracture and observation for 24 hours to rule out severe brain trauma, edema, or laceration. A child usually can be observed at home by the parents, who are instructed to check the child's level of consciousness every 1 to 2 hours while the child is awake. Parents usually are instructed not to keep waking children during the night, because multiple wakings are disorienting and can be confused with unconsciousness. Parents should wake the child at least once during the night, however, and assess that the pulse rate is greater than 60 beats per minute.

To be certain that children are alert, parents can ask them to name a familiar object, such as a favorite toy, or to name the color of some object shown to them. Telling parents their name or where they live is equally revealing.

Give parents the telephone number to call if they have any questions about their child's care. Advise them to call if their child's behavior changes in any way that seems worrisome. Many parents need to set an alarm clock to wake themselves during the night to assess their child's status. There is an old belief that, if children fall asleep after a head injury, they will die in their sleep; this belief causes some parents to keep shaking children awake or making them walk continually. Be certain they understand that it is all right for children to sleep, but they must wake them at least once to assess their status (see Focus on Nursing Care Planning Box 52.2).

Contusion

A brain contusion occurs when there is tearing or laceration of brain tissue (Fig. 52.4). The symptoms are the same type as for concussion but more severe. In addition, there are specific symptoms related to the lacerated brain area such as a focal seizure, eye deviation, or loss of speech. Surgery may be necessary to halt bleeding. The child's prognosis depends on the extent of the injury and effectiveness of therapy.

What if... In the emergency department, Jason's parents state that since his head injury he has been vomiting? Is it more likely that the vomiting is a result of the head injury, or that he has contracted a gastrointestinal infection?

Coma

Coma (unconsciousness from which a child cannot be roused) or **stupor** (grogginess from which a child can be roused) may be present in children after severe head trauma. Coma and stupor are both symptoms of underlying disorders; a history of the injury must be obtained so that treatment can be directed specifically toward the cause.

Assessment

Obtain a history to determine the circumstances immediately before the time the child became comatose. Assess children in coma carefully and completely, so that the cause of the decreased consciousness can quickly be determined.

Undress the child completely so that all body parts can be inspected. Although head injury is most likely to be the underlying cause of coma or seizure, metabolic disturbances such as diabetes mellitus, dehydration, severe hemorrhage, or drug ingestion, also must be considered as possible causes. Count respirations and pulse and measure blood pressure to establish baseline values, because changes in these values often provide good clues regarding the cause of coma. A child with increased ICP, for example, will show decreased pulse and respiratory rates and increased blood pressure. Diabetes, in contrast, leads to increased respirations. Hemorrhage leads to an increased pulse rate and decreased blood pressure. Drug ingestion may lead to either increased or decreased measurements, depending on the drug ingested.

If bulbar (brainstem) compression is present, a child cannot swallow effectively or safely. If this is suspected, turn the child on the side to prevent aspiration. Observe the eyes for signs of increased ICP. If both pupils are dilated, irreversible brainstem damage is suggested, although such a finding may also be present with poisoning from an atropine-like drug. Pinpoint pupils suggest barbiturate or opiate intoxication. One pupil dilated more than the other suggests third cranial nerve compression. An eye may be deviated downward and laterally as well. This also may be caused by a tentorial tear (laceration of the membrane between the cerebellum and cerebrum) and herniation of the temporal lobe into the torn membrane. This situation requires immediate surgery to correct temporal compression.

The retina of the eye should be examined for papilledema, which will be present if increased pressure is long-standing (more than 24 to 48 hours). Lack of a doll's eye reflex suggests that compression of the oculomotor nerves (third, fourth, or sixth) or of the brainstem is involved. Observe for posturing, such as decerebrate posturing, which suggests cerebral compression and dysfunction.

Many laboratory studies are helpful in determining the cause of coma. Blood glucose, blood electrolytes, blood urea

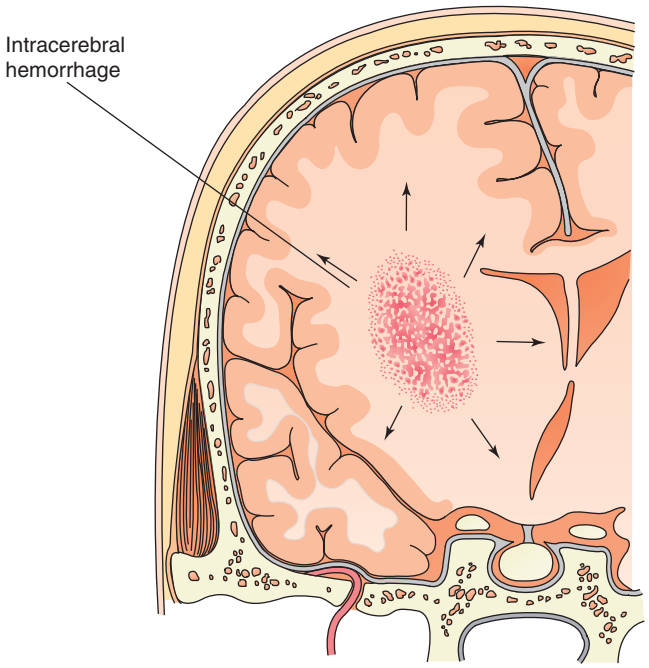

FIGURE 52.4 Intracerebral hemorrhage. The central large dark area represents the hemorrhage. Note the midline shift.

BOX 52.2 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Child With a Concussion

Jason, a 5-year-old boy, is seen in the emergency department after an automobile accident. His family is here on vacation. Child is crying and upset, although the only visible signs of trauma are a reddened and edematous area on the middle of his forehead. His twin sister, in a car seat beside him, was not injured. His mother tells you, "I'm sure he's not injured badly. He was wearing his seat belt."

Family Assessment ✻ Child is staying with twin sister and two parents in motel room while on 10-day vacation. Father normally works as a salesman. Mother clerks in department store. Father describes finances as "good." Father concerned because rented car was totally destroyed in accident and his insurance may not cover this.

Client Assessment ✻ A 5-year-old boy visibly upset and crying. Height and weight at 75th percentile for age. Child unable to report or recall anything about the incident. Mother reports he was restrained by a seat belt but not a car seat. Head hit side window when a car struck their vehicle.

Vital signs: temperature, 99.4° F (37.5° C); respirations, 18 breaths/minute; pulse, 62 bpm; and blood pressure, 110/62 mm Hg. Left pupil is more dilated than his right; it reacts sluggishly to light. Glasgow Coma score is 10. Alert enough to name toy racing car brought in with him. Pupils equal, round, reactive to light and accommodation bilaterally. 1.5-cm raised area noted on forehead. Skin intact without evidence of bleeding. Child cries when area is touched. Negative otorrhea or rhinorrhea. Small 2-cm abrasion noted on right knee; 3-cm abrasion noted on right hand. No other injuries noted. Able to move all extremities through range of motion.

A diagnosis of mild contrecoup concussion is made, and child is to be discharged to motel in parents' care.

Nursing Diagnosis ✻ Risk for injury related to effects of concussion

Outcome Criteria ✻ Child remains alert and oriented; easily arousable. Pupils equal, round, react to light and accommodation; vital signs within age-acceptable parameters; exhibits no signs or symptoms of neurologic dysfunction.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Take history of accident, speed car was traveling, and position of child in vehicle.	Assess child's vital signs, level of consciousness, and neurologic function initially, and then every 30 min until discharge.	Changes in vital signs, level of consciousness, or neurologic function indicate a worsening of the child's condition and possibly increasing intracranial pressure.	Parent describes accident and reactions of child since accident.
		Consultations		
N/A	N/A	N/A	N/A	N/A
		Procedures/Medications		
Physician/nurse	Assess whether child's demeanor (crying) is from fright or pain.	Institute measures to calm the child. Encourage the parents to hold and reassure him.	Crying increases intracranial pressure. Involving the parents provides them with a concrete activity, helping to provide some sense of control over the situation.	Parents are able to calm child to allow for better evaluation of condition.
Physician/nurse	Assess whether child has had experience with x-ray examination.	Schedule a skull radiograph or other diagnostic tests as ordered, such as CT scan or MRI.	Skull radiograph rules out a possible skull fracture secondary to the trauma. CT scan or MRI helps determine any areas of bleeding or edema if present.	Child cooperates with diagnostic procedures; results are available for physician review.

(continued)

BOX 52.2 ✻ Focus on Nursing Care Planning (continued)

		Nutrition		
Nurse	Assess whether child has vomited since head injury.	If not NPO, feed small amount of a favorite food to be certain child does not have vomiting.	Vomiting is a symptom of increased intracranial pressure.	Child eats some food without vomiting.
		Patient/Family Education		
Nurse	Assess what parents understand about concussion in children.	Teach parents how contrecoup injuries occur and symptoms they cause.	A contrecoup injury causes injury or edema to the posterior brain.	Parents state they understand why their child has posterior (eye control) cranial symptoms, such as unequal pupils.
		Psychosocial/Spiritual/Emotional Needs		
Nurse	Assess whether child or parents have any questions about care.	Orient the child to his surroundings. Offer explanations about any treatments or procedures that are to come.	Children often have no memory of events with concussion. Parents are in strange community. Orientation and explanation help to minimize a child's fear of the unknown and of his situation.	Parents and child state they understand procedures being carried out. Voice confidence in new situation.
Nurse	Attempt to identify the meaning and effect of the child's accident for the parents (e.g., father upset over rent-a-car liability).	Encourage parents to express their feelings about themselves as parents and their role in the child's accident.	Identification of the meaning and effect of the child's accident assists in determining the degree to which the situation is affecting the parents.	Parents state they were not responsible for accident, or at least did everything possible to avoid their child's injury.
		Discharge Planning		
Nurse/physician	Assess whether parents will be staying in city or traveling back home during next 24 hours.	Instruct parents to rouse the child approximately every 2 hours during daytime hours and at least once during the night, asking the child to name a familiar object or color.	Frequent waking can be disorienting to a child and can be confused with altered levels of consciousness, but occasional waking is a good way to assess whether complications are occurring.	Parents state they will remain in motel for 24 hours, rather than fly home immediately, so they can observe child.
Nurse	Assess whether parents will be able to keep a follow-up appointment for additional care.	Schedule a return appointment to clinic for 24-hour follow-up visit. Supply clinic telephone number if needed before then.	A follow-up visit is necessary to be certain child can travel safely.	Parents state they understand importance of follow-up visit and will keep appointment with child.

nitrogen (BUN), liver function tests, blood gas studies, lumbar puncture, and toxicology tests may be ordered to rule out possible causes such as bacterial meningitis or hemorrhage. Computed tomography (CT) or MRI will be done if a head injury is the most likely cause (Claret-Teruel et al., 2007).

Coma is usually graded according to a standard scale so that changes in the level of consciousness can be evaluated accurately. Figure 52.5 shows the Glasgow Coma Scale, a commonly used evaluation system (Morris, 2008). Because this system was devised as an adult assessment scale, it must be modified for use with children or infants. Such a modification is shown in Box 52.3.

A score of 3 to 8 on the scale suggests severe trauma (a number less than 5 suggests a very severe prognosis); a score of 9 to 12, moderate trauma; and 13 to 15, slight trauma.

Therapeutic Management

If children are unconscious for longer than a transient period, they usually are admitted to an observation unit for further assessment. As a general rule, place a child who is comatose on the side to reduce the risk of aspiration. Oral suctioning to remove mucus from the mouth and pharynx may be necessary. If a child has acute signs of respiratory difficulty, endotracheal intubation may be necessary to ensure respiratory function.

An IV route is established so that, when specific measures such as blood replacement, electrolyte replacement, or fluid replacement are needed, a route for immediate administration will be available. Blood will be drawn for a complete blood count, electrolyte determination, toxicology tests, and cross-matching. If the cause of the coma is unknown, a lumbar puncture and EEG may be done. Skull radiography, CT scan, or MRI may be done.

Lumbar puncture has little value at first in predicting the severity of a head injury, because any degree of cerebral contusion usually leads to increased CSF pressure. Lumbar puncture is contraindicated if increased ICP is present as release of fluid with the puncture can cause brainstem compression into the cord. Obtain the child's vital signs and assess neurologic status, such as state of consciousness and the ability of pupils to react to light, every 15 to 20 minutes or as ordered. Accurately and carefully record this information so that a picture of gradual change will become apparent.

A child's prognosis after coma depends on the initial cause of the coma. If the increased ICP can be relieved before any permanent brain damage results, the effects of the coma will be transient. Prognosis is always guarded, however, because coma reflects a potential health problem for a child.

Nursing Diagnoses and Related Interventions

Care of the child in coma is directed toward maintaining body function in an optimal state until the child reawakens.

Nursing Diagnosis: Risk for ineffective airway clearance related to brainstem pressure

Outcome Evaluation: Child's respiratory rate remains between 16 and 20 breaths/minute; there are no retractions or signs of obstruction.

Some children who are comatose require endotracheal intubation or tracheostomy to ensure an open airway. Some are placed on mechanical ventilation. Oxygen may be prescribed if arterial blood gases

Glasgow Coma Scale			A.M.		P.M.						A.M.					
Assessment	Reaction	Score	8	10	12	2	4	6	8	10	12	2	4	6	8
Eye Opening	Spontaneously	4	X						X	X	X	X	X		
Response	To speech	3		X				X							
	To pain	2			X	X	X

	Inappropriate speech	3			X										
	Incomprehensible sounds	2				X	X								
	No response	1													

FIGURE 52.5 Glasgow Coma Scale scoring for a child. A score of 3 to 8 denotes severe trauma; 9 to 12, moderate trauma; 13 to 15, slight trauma. Notice the gradual improvement from coma in this example.

BOX 52.3 ✻ Scoring for Glasgow Coma Scale

Eye Opening

4. Child opens eyes spontaneously when you approach.
3. Child opens eyes in response to speech (spoken or shouted).
2. Child opens eyes only in response to painful stimuli, such as pressure on a nail bed.
1. Child does not open eyes in response to painful stimuli.

Motor Response

6. Child can obey a simple command such as "hand me a toy" (infant smiles or attunes).
5. Child moves an extremity to locate a painful stimulus applied to the head or trunk and attempts to remove the source.
4. Child attempts to withdraw from the source of pain.
3. Child flexes arms at the elbows and wrists in response to painful stimuli to the nail beds (decorticate rigidity).
2. Child extends arms (straightens the elbows) in response to painful stimuli (cerebrate rigidity).
1. Child has no motor response to pain on any extremity.

Verbal Response

5. Child is oriented to time, place, and person (child >4 years old knows name, date, and where he or she is; infant appears to recognize parent).
4. Child is able to converse, although not oriented to time, place, or person (does not know who or where he or she is; infant says words but does not appear to differentiate parents from others).
3. Child speaks only in words or phrases that make little or no sense ("I want frazzle no"; infant's vocabulary is less than it is normally).
2. Child responds with incomprehensible sounds, such as groans.
1. Child does not respond verbally at all.

Modified from Teasdale, G., & Bennett, B. (1974). Assessment of coma and impaired consciousness: A practical scale. *Lancet, 2*(7872), 81–84.

reveal poor oxygenation of body cells (oxygen tension [Po_2] lower than 80 mm Hg). Endotracheal tubes are replaced with a tracheostomy after 3 to 7 days to prevent necrosis of the pharynx from pressure of the endotracheal tube.

Nursing Diagnosis: Risk for impaired skin integrity related to lack of mobility

Outcome Evaluation: Child exhibits no areas of broken or irritated skin.

Bathe children who are comatose daily to stimulate skin circulation. Include the hair as part of the bath about every 3 days. Change their position at least every 2 hours to prevent pressure ulcer formation and development of hydrostatic pneumonia from pooled secretions. When turning, assess skin for reddened points. Keep linen dry and free from wrinkles. Perform thorough passive range-of-motion exercises to maintain muscle tone and prevent contractures. Use of a sheepskin, an egg-carton foam, or an alternating pressure or water mattress also can be important in decreasing pressure to the skin.

Nursing Diagnosis: Risk for imbalanced nutrition, less than body requirements, related to inability to take in oral food or fluid

Outcome Evaluation: Child's skin turgor is normal; weight remains within acceptable percentile; hourly urine output remains greater than 1 mL/kg.

Children who are unconscious cannot be fed orally or they might aspirate. Therefore, nutrition is maintained by nasogastric (NG) or gastrostomy tube feedings, IV fluid administration, or total parenteral nutrition. IV fluid is only a short-term answer, because adequate protein and fat cannot be supplied solely by this route. NG or gastrostomy feedings can supply total nutrient needs. Always aspirate NG or gastrostomy tubes for stomach contents before giving a feeding to check tube placement and assess gastric residual amounts. Return any amount of stomach residue aspirated, because if this is discarded each time, a child will lose a large amount of stomach acid, possibly leading to alkalosis. Check whether the amount of the feeding should be reduced by the amount of fluid remaining in the stomach before feeding the full amount of prescribed formula.

Give mouth care at least twice daily with clear water and a padded tongue blade. Coat lips with petrolatum to prevent drying and cracking. If a child's eyes tend to be dry, close them to prevent corneal ulceration. Artificial tears (methylcellulose) may be prescribed to keep eyes from drying until the child regains consciousness.

Choking Games

Adolescents, seeking an inexpensive way to experience a "rush" or euphoria, induce a partial or complete loss of consciousness in themselves by intentionally depriving their brain of oxygen for a short period of time by strangulation or hanging or reducing the oxygen able to reach their nose by some technique such as pulling a plastic bag over their head. Extreme hyperventilation to induce hypocapnia is yet another technique.

The practice may be seen as a rite of passage or initiation into a gang or club. The practice is also known as erotic asphyxiation as it also induces a sexual response. Unfortunately, the game results in injury and death. At least 82 adolescents between the age of 6 and 19 have died in the United States as a result of the game. Of these 86.6% were male; the mean age was 13.3. The majority of

the deaths occurred while the adolescent was alone; over 90% of the parents of the child were unaware of the game (CDC, 2008a).

Injuries such as concussion, bone fractures, and tongue biting may occur from falling. Teach parents that the game exists and to be aware of signs that their child might be interested or participating in the game. Common signs are discussion of the game, bloodshot eyes, ligature marks on the neck, severe headaches, disorientation, and the presence of choke collars, ropes, scarves, or belts tied to bedroom furniture.

ABDOMINAL TRAUMA

When children are brought to a health care facility after suffering a multiple-injury trauma, several medical specialists may be required: a neurosurgeon for consultation about a head injury; an orthopedic physician for consultation about a fractured extremity; and a thoracic surgeon to intubate or investigate lung trauma. A nurse may serve the important function of being the person who is best able to observe a total child and recognize the subtle signs of abdominal trauma.

Assessment

Abdominal trauma results from an object striking the abdomen, such as a baseball bat or a seat belt drawn tight in a motor vehicle crash (Humphries, 2008). Assess vital signs frequently until they are stable. Hypotension (less than 80 mm Hg systolic pressure in an older child; less than 60 mm Hg in an infant) usually suggests hemorrhage, which may be hidden abdominal bleeding. In addition, children may have increasing pallor and rapid respirations. If internal bleeding is present, blood pressure will show little improvement when IV fluid is administered.

If abdominal trauma is suspected, an NG tube is passed and stomach contents are aspirated to be checked visually for blood and to test for occult blood. Attach the tube to low intermittent suction if the presence of blood is established. An indwelling urinary (Foley) catheter is also inserted to evaluate urine for blood and urine output. Evidence of blood in the urine or decreased output may indicate accompanying kidney or bladder trauma. If the urine contains blood, an emergency IV pyelogram or ultrasound may be ordered. Be aware that having NG tubes or catheters passed is always frightening for a child (unsure of their anatomy, children have no clear idea where the tubes are going). After an accident, when they are already frightened, they and their parents need a great deal of support to accept these procedures (Box 52.4).

An abdominal radiograph or ultrasound may be ordered to rule out a fractured pelvis, a condition that could contribute to blood loss. Air under the diaphragm on the radiograph suggests gastric or intestinal rupture with escape of air from these organs into the peritoneal cavity. Free fluid in the abdomen, shown on the radiograph when the child is turned on the side, suggests leakage of bowel fluid or splenic rupture and pooling of blood. Parents often find it difficult to appreciate the seriousness of abdominal trauma, because the signs are not as dramatic or obvious as those of fractured extremities or lacerations. Some parents may not bring their child to an emergency department immediately after abdominal trauma, because they are unaware that serious injury can result to this part of the body. Without frightening them, explain that an injury need not be obvious at first glance to be serious and need care. They may ask why a radiograph is necessary. When their child is asked to turn on the radiograph table so that an abdominal fluid level can be revealed, they may perceive this as unnecessary manipulation of an injured child.

BOX 52.4 ✻ Focus on Communication

Jason, a 5-year-old boy, is brought to the emergency room after an automobile accident. He is being assessed for multiple trauma.

Less Effective Communication

Mr. Varton: Why are you looking at his belly? He didn't hurt that.

Nurse: We need to assess his entire body just to make sure that there aren't any problems. He's had major trauma. You need to sign a consent form so he can have a central intravenous line and indwelling urinary catheter inserted and a CT scan to rule out any problems.

Mr. Varton: I don't want to put him through any more. What if something else goes wrong?

Nurse: If you don't consent to these tests and treatments, we cannot take care of your child.

Mr. Varton: OK. Do what you have to. But I'm still not sure.

Nurse: Good. Sign this consent for me.

More Effective Communication

Mr. Varton: Why are you looking at his belly? He didn't hurt that.

Nurse: We need to assess his entire body just to make sure that there aren't any problems. He's had major trauma. You need to sign a consent form so he can have a central intravenous line and indwelling urinary catheter inserted and a CT scan to rule out any problems.

Mr. Varton: I don't want to put him through any more. What if something else goes wrong?

Nurse: I know it's difficult for you to see your child in such pain. Are you worried about anything specific?

Mr. Varton: Is he going to die?

Nurse: The things we're doing are aimed to prevent that very thing. Let me explain a little more about what we're doing and why these things are necessary. I want you to feel comfortable signing the consent form.

In the first scenario, the nurse focuses on obtaining the parent's consent but fails to recognize the fear and apprehension in the parent. In the second scenario, the nurse recognizes and attends to the fears of the parent. By doing so, she helps to establish a sense of support and trust in addition to obtaining consent for procedures.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Pain related to abdominal injury

Outcome Evaluation: Child states that level of pain is tolerable; child does not grimace when body parts are touched.

Routinely, analgesics are not administered to most children after abdominal trauma unless their pain is severe, to avoid masking the pain, as the location of the pain can help identify which organs may be injured. If parents did not recognize that the child was injured, guilt and fear on their part may compound the problem. Goal setting is usually concerned with the immediate diagnostic procedures or anticipated surgery. Interventions differ according to the specific injury present.

Splenic Rupture

In children, the spleen is the most frequently injured organ in abdominal trauma, because it is usually palpable under the lower left ribs (Huether & McCance, 2007). It is frequently injured by inappropriately applied seat belts in automobiles and by handlebar injuries in bicycle accidents. It is increasingly caused by snowboard injuries (Box 52.5). Children with splenic injury have tenderness in the left upper quadrant, especially on deep inspiration, when the diaphragm moves down and touches the spleen. They may hold their left shoulder elevated, so that the diaphragm is raised on the left side, to keep this from happening. Occasionally, a child notices radiated left shoulder pain while lying in a supine position (Kehr's sign). A radiograph will show little about the spleen itself but may reveal a broken rib over the spleen, suggesting the extent of the trauma to that area.

An IV line is begun immediately for fluid replacement, and an IV pyelogram or MRI will be done to rule out damage to the left kidney, which, because of its location just behind the spleen, may also have suffered trauma. A complete blood count is done to estimate the extent of the blood loss. Blood is typed and cross-matched, so that blood for replacement can be readied if necessary. The child will be admitted to an observation unit if the blood loss from rupture appears to be mild. If bleeding is severe, immediate surgery, such as a partial or total splenectomy, may be necessary to halt bleeding and save the child's life.

After a splenectomy, children are very susceptible to infection, particularly pneumococcal infections. Therefore, a large percentage of children are managed expectantly to see if the bleeding will halt without spleen removal (Dobremez et al., 2007). Children who have their spleen removed are offered the pneumococcal vaccine to protect them against pneumococcal infections.

BOX 52.5 ✻ Focus on Evidence-Based Practice

Do snowboards cause as many injuries as skis in children?

Snowboarding is a relatively new sport. To compare the risk of unintentional injury as a result of skiing to the risk of injury by snowboarding, researchers analyzed the history of children seen in a pediatric trauma center over a seven-year period. During the study period, there were 57 snowboarders and 22 skiers seen for care. The site of the injuries differed as all skiing injuries occurred at recreational facilities whereas 12% of snowboard injuries occurred at home, another residence, or a public park. Forty-one (72%) of snowboarders and 16 (73%) of skiers required surgery for their injuries; 32 (56% of snowboarders and 9 (41%) of skiers sustained fractures; and 14 (25%) of snowboarders and 6 (27%) of skiers sustained abdominal injuries. Serious splenic injuries were more common in snowboarders (14% vs 4%) but the difference was not statistically significant.

Based on the above study, would it be important to ask if a child was skiing or snowboarding when brought into the hospital by the ski patrol?

Source: Hayes, J. R., & Groner, J. I. (2008). The increasing incidence of snowboard-related trauma. *Journal of Pediatric Surgery, 43*(5), 928–930.

Liver Rupture

Livers are also more prone to rupture in children than in adults, because the liver, like the spleen, is not completely sheltered by the rib cage in children (Tataria et al., 2007). Children with liver rupture or laceration usually have severe abdominal pain that is most marked on inspiration, when the diaphragm descends and touches the liver. They show symptoms of blood loss, including tachycardia, hypotension, anxiety, and pallor. The hematocrit will be low or falling. Such children need to be prepared for immediate surgery, because the liver is a highly vascular organ, and blood loss from it is acute and possibly life-threatening.

Occasionally, a communication between an artery and the bile duct occurs at the time of trauma. In this situation, symptoms are not immediate, but gastrointestinal (GI) bleeding, such as hematemesis or melena, may occur in a few days. The child may have colicky upper abdominal pain that is relieved by emesis. Liver studies, such as a liver arteriogram, are necessary to reveal the extent of the problem.

After either liver or spleen surgery, children need careful observation for return of bowel function, assessment for the possibility that peritonitis may develop, and careful reintroduction of oral nutrition.

DENTAL TRAUMA

Injuries to teeth occur most often from falls in which a child strikes the upper front incisors or from blows to the face by objects such as baseball bats or hockey sticks. Such accidents are always potentially serious, because they can lead to aspiration of the injured teeth or malalignment of future teeth. If permanent teeth that have been knocked out recently can be washed with saline in the emergency department and replaced, there is

a good chance that they will reimplant successfully. If a tooth is knocked out, parents should rinse the tooth in water, drop it in a salt solution or milk, and bring it to the emergency department with them (Andersson, 2007).

Some dentists advocate immersing the tooth in an antiseptic and then in an antibiotic solution before replacing it. If a tooth is replaced, it usually is wired into place to hold it in good alignment. The child receives a course of oral antibiotics, such as penicillin, to prevent infection. Only soft food must be eaten until the tooth has firmly adhered (approximately 2 weeks).

If a blow to a child's teeth was extensive, a radiograph may be taken to rule out a mandibular or maxillary fracture. If a portion of a tooth cannot be located, the possibility of aspiration must be considered and confirmed or ruled out by a chest radiography. In young children, often a tooth is not knocked out but is pushed back up into the gum. These teeth gradually regrow, and, although they may darken in color, they usually are healthy. If the affected tooth is a deciduous tooth, the permanent tooth is rarely injured even though it is already formed in the gum. At the appropriate time, the permanent tooth will erupt normally.

NEAR DROWNING

Drowning is death caused by suffocation from submersion in liquid. Inhaled water fills the lungs and therefore blocks the exchange of oxygen in the alveoli. More than 3500 children die from drowning annually, making it the second most common cause of death by unintentional injury among children. The term **near drowning** is used to describe the child with a submersion injury who requires emergency treatment and who survives the first 24 hours after injury (Lee, Mao, & Thompson, 2007).

Most infant drownings occur in bathtubs; 1- to 4-year-old children most frequently drown in artificial pools; older children most frequently drown in bodies of fresh water. The majority of drowning accidents that take place outside the home occur in the summer months, when more children are swimming and boating. Particularly at risk are male adolescents, because they may take dares to swim farther than their ability allows or may swim under the influence of alcohol, which impairs their decision-making ability and their physical coordination.

Pathophysiology of Drowning

When children's heads are submerged and they first inhale water, they cough violently from the irritation of the water in their nose and throat. If they cannot get their head out of water at this point, water will enter the larynx. This causes the larynx to spasm, preventing any further water but also air from entering the trachea, so asphyxia results. If a child is ventilated at this point, treatment usually is very effective because there is little water in the lungs. The condition more closely simulates asphyxia that occurs with croup or when a foreign body, such as a nut, lodges in the trachea and stops air flow.

If treatment is not given at this point, the larynx relaxes from the asphyxia and water enters the lungs. Oxygen can no longer be exchanged, because the alveoli fill with water. Hypoxia deepens, and cardiac arrest occurs.

Additional changes that occur when water enters the lungs depend on whether the water is fresh or salt. Salt water is hypertonic, causing fluid to osmose from the bloodstream and enter the alveoli, increasing the amount of fluid in the lung tissue and increasing hypoxia. Tachycardia and decreased blood pressure from hypovolemia result. Blood viscosity increases as shown by an increased hematocrit level.

Fresh water is hypotonic, so fluid in the lungs shifts into the bloodstream because of osmotic pressure. This can lead to hemolysis of red blood cells, a dilution of plasma, and possibly hypervolemia with tachycardia and increased blood pressure. If the release of potassium from destroyed red blood cells is great enough with fresh-water drowning, cardiac arrhythmias may occur. In both instances, loss of surfactant from lung alveoli, caused by introduction of water (adult respiratory distress syndrome), can lead to alveolar collapse on expiration (Bowers & Anderson, 2008).

Parents should advocate for neighborhood pools to be fenced and advise against hyperventilating before swimming. When children blow off carbon dioxide with hyperventilation this way, and then swim underwater for an extended period of time, carbon dioxide levels will rise, but not adequately enough to cause them to experience distress. Oxygen levels decrease causing drowsiness and listlessness (children drown without struggling or realizing their danger).

Very young children display a mammalian diving reflex when they plunge under cold water that helps them survive drowning. Immediately after plunging into cold water, a lifesaving bradycardia and shunting of blood away from the periphery of the body to the brain and heart occur. This reflex is triggered when water is 70° F (21° C) or less and the face is submerged first. This explains why very young children can survive better than older children after being submerged in water that is very cold.

Emergency Management

When a child is pulled from the water after near drowning, mouth-to-mouth resuscitation should be started at once. If cardiac arrest has occurred from hypoxia, simultaneous measures to initiate cardiac action must be taken. The technique of cardiopulmonary resuscitation for infants and children is discussed in Chapter 41.

Assuming that cardiopulmonary resuscitation is effective, the child needs follow-up care at a health care facility, because the child is certain to be acidotic from accumulated carbon dioxide and hypoxia (resulting from lack of oxygen because of the water in the alveoli) and is at risk for respiratory infection from contaminants in the water.

Follow-up care aims to increase the child's oxygen and carbon dioxide exchange capacity, using the lung areas that are not filled with water. Typically, a child is intubated with a cuffed intratracheal tube; mechanical ventilation with positive end-expiratory pressure may be necessary to force air into the alveoli. Because water has been swallowed, vomiting usually occurs as the child is revived. The cuff of the intratracheal tube prevents vomitus from being aspirated. The child is given 100% oxygen so that as much space as possible in the available lung alveoli can be used. An NG tube is inserted to decompress the stomach, prevent vomiting, and free up breathing space. Usually, albuterol is administered by aerosol to prevent bronchospasm and, again, to allow the child to make maximum use of the oxygen administered. If the child aspirated salt water, plasma may be administered to replace protein being lost into the lungs and prevent hypovolemia.

If the child's body temperature is very low, gradual warming (not using a warming blanket) is advised so that the metabolic requirement does not rise sharply before alveolar space is ready to accommodate this need. Extracorporeal membrane oxygenation may be used.

Unfortunately, neurologic damage occurs in as many as 21% of near-drowning incidents. If the child is awake or only lethargic at the scene of the accident and immediately afterward in the hospital, the prognosis is greatly improved over that of the child who is comatose.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for infection related to foreign substance in respiratory tract

Outcome Evaluation: Child's temperature remains within normal parameters orally; rales are absent on lung auscultation; respiratory rate is within age-acceptable parameters.

Following near drowning, a child may be prescribed prophylactic antibiotic therapy to prevent pneumonia and additional airway interference. Assess vital signs and auscultate lung sounds for adventitious sounds, such as rales or fine rhonchi. Turning the child every 2 hours if on bedrest and encouraging deep breathing and incentive spirometry every hour help to aerate the lungs fully and prevent the accumulation of fluid, which promotes infection.

Nursing Diagnosis: Fear related to near-drowning experience

Outcome Evaluation: Child discusses fears; child states that she understands that, although frightening, the experience is over, and she is now safe.

Children may be admitted to an observation unit for monitoring of blood gases until water from the alveoli is absorbed and they once again can ventilate effectively on their own. Such children may wake at night from a nightmare that they are drowning. They need their parents to reassure them that they are now safe and definitely out of the water. Near drowning is a thoroughly frightening experience. Encourage children to verbalize this fright. They may need support from parents before they try swimming again after such a frightening experience.

POISONING

Poisoning occurs most commonly in children between the ages of 2 and 3 years. It occurs in all socioeconomic groups. Common agents include soaps, cosmetics, detergents or cleaners, and plants. Poisoning can occur from over-the-counter drugs, such as vitamins, iron compounds, aspirin, or acetaminophen, or from prescription drugs, such as antidepressants. Unlike other unintentional injuries, poisoning is entirely preventable. Parents need education about the high risk for poisoning and strategies for maintaining a home environment that is safe for children of all ages. Be aware that when poisoning occurs in an older child, it may not be poisoning but a suicide attempt.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for injury related to maturational age of child and presence of poisons

Outcome Evaluation: Parents identify poisonous and toxic items in the home and describe how they are stored safely; parents state local poison control center number; parents describe measures to seek help immediately if poisoning occurs.

Emergency Management of Poisoning at Home

If poisoning occurs, parents should telephone their local poison control center to ask for advice. Information parents need to provide includes:

- Child's name, telephone number, address, weight, and age and what the child swallowed
- How long ago the poisoning occurred
- The route of poisoning (oral, inhaled, sprayed on skin)
- How much of the poison the child took (the bottle should say how many pills or liquid it originally held).
- If the poison was in pill form, whether there are pills scattered under a chair or if they are all missing and presumed swallowed
- What was swallowed; if the name of a medicine is not known, what it was prescribed for and a description of it (color, size, shape of pills)
- The child's present condition (sleepy? hyperactive? comatose?)

If one child has swallowed a poison, parents should investigate whether other children have also poisoned themselves as a preschooler often shares "candy" with a younger sibling.

Emergency Management of Poisoning at the Health Care Facility

In the emergency department, the best method to deactivate a swallowed poison is the administration of activated charcoal, either orally or by way of an NG tube.

Activated charcoal is supplied as a fine black powder that is mixed with water for administration. A sweet syrup may be added to the mixture to make it more palatable. Caution parents that, as the charcoal is excreted through the bowel over the next 3 days, stools will appear black (Box 52.6).

Always follow emergency measures to neutralize a poison with an education program for the family to prevent poisoning from happening again. Specific measures for each age group are discussed in previous chapters, along with problems and concerns of that age group.

Acetaminophen Poisoning

Acetaminophen (Tylenol) is the drug most frequently involved in childhood poisoning today, because parents use acetaminophen to treat childhood fevers. Told that acetaminophen is safer than aspirin, parents may not be as careful

BOX 52.6 ✻ Focus on Pharmacology

Activated Charcoal

Classification: Activated charcoal is an antidote for poisoning.

Action: Absorbs toxic substances that have been swallowed to prevent them from being absorbed by the stomach (Karch, 2009).

Pregnancy Risk Category: C

Dosage: Provided as a powder that must be mixed with water and administered orally or by way of nasogastric (NG) tube.

Possible Adverse Effects: Vomiting, diarrhea, black stools

Nursing Implications

- Administer orally to conscious victims only.
- Give the drug as soon as possible after poisoning.
- Store the drug in a closed container, because it absorbs gases from the air and is inactivated.
- Know that the solution feels gritty and tastes disagreeable, so young children have difficulty swallowing the drug. May have to be administered by NG tube.
- Caution child or parent that stools will be black for several days after administration.

about putting this drug away as they were with aspirin. If their child swallows acetaminophen, they may delay bringing the child for help, thinking it is a harmless drug. Acetaminophen in large doses, however, is not an innocent drug; it can cause extreme liver destruction (Morgan & Borys, 2008).

Immediately after ingestion, the child will experience anorexia, nausea, and vomiting. Soon, serum aspartate transaminase (AST [SGOT]) and serum alanine transaminase (ALT [SGPT]), liver enzymes, become elevated. The liver may feel tender as liver toxicity occurs.

Parents should call their local poison control center. In the emergency department, activated charcoal or acetylcysteine, the specific antidote for acetaminophen poisoning, will be administered. Acetylcysteine prevents hepatotoxicity by binding with the breakdown product of acetaminophen so that it will not bind to liver cells. Unfortunately, acetylcysteine has an offensive odor and taste. Administer it in a carbonated beverage to help the child swallow it. For small children, it is administered directly into an NG tube to avoid this difficulty. If the child is admitted to an observation unit, continue to observe for jaundice and tenderness over the liver; assess ALT and AST levels as ordered.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Situational low self-esteem related to child's poisoning

Outcome Evaluation: Parents state guidelines for continued assessment of child at home; parents state ways they can improve "childproofing."

After the child is stabilized, take some time to talk with the parents about how they feel about this event. Remember that poisoning tends to happen in homes where there is stress. If stress was already present, how has this poisoning added to it?

Before the child is discharged from a health care facility, be certain the parents are comfortable with any further assessment measures they will need to continue at home, such as temperature taking and urging a high fluid intake. Talk with the parents about the necessity for childproofing their home.

✔ Checkpoint Question 52.1

You see Jason's sister in the emergency department after acetaminophen poisoning. Which of the following would be an appropriate action to take?

a. Advise the parents that their child must never receive acetaminophen again.
b. Counsel the parents about not taking medications in front of children.
c. Question an order to give activated charcoal to neutralize the drug.
d. Sympathize with parents, but reassure them this poisoning is not serious.

Caustic Poisoning

Ingestion of a strong alkali, such as lye, which is often contained in toilet bowl cleaners or hair care products, may cause burns and tissue necrosis in the mouth, esophagus, and stomach. It is important that the parents do not try to make a child vomit after ingestion of these substances, because they can cause additional burning as they are vomited (ATSDR, 2008).

Assessment

After a caustic ingestion, the child has immediate pain in the mouth and throat and drools saliva because of oral edema and an inability to swallow. The mouth turns white immediately from the burn. Later, the mouth turns brown as edema and ulceration occur. There may be such marked edema of the lips and mouth that it is difficult to examine them. The child may immediately vomit blood, mucus, and necrotic tissue. The loss of blood from the denuded, burned surface may lead to systemic signs of tachycardia, tachypnea, pallor, and hypotension.

A chest radiograph may be ordered to determine whether pulmonary involvement has occurred from any aspirated poison or whether an esophageal perforation has allowed poison to seep into the mediastinum. An esophagoscopy under conscious sedation may be done to assess the esophagus, although this test may be omitted because of the possibility that an esophagoscope might perforate the burned esophagus. After 2 weeks, a barium swallow or esophagoscopy may be performed to reveal the final extent of the esophageal burns.

Therapeutic Management

When parents whose child has ingested a caustic substance call a poison control center to ask for advice on how to proceed, they will be advised to immediately take the child to a health care facility for treatment. There is a high possibility

that pharyngeal edema will be severe enough to obstruct the child's airway by even 20 minutes after the burn.

To detect respiratory interference, assess vital signs closely, especially the respiratory rate. In infants, increasing restlessness is an important accompanying sign of oxygen want. In the emergency department, intubation may be necessary to provide a patent airway. Assess the child also for the degree of pain involved. A strong analgesic, such as morphine, may need to be ordered and administered to achieve pain relief.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for ineffective airway clearance related to burns of esophagus and mouth

Outcome Evaluation: Child's respiration rate remains within 16 to 20 breaths/minute.

Starting therapy immediately after a caustic burn with a steroid such as dexamethasone (Decadron) and continuing it for about 4 weeks helps to reduce the chance of permanent esophageal scarring. In addition, children may be prescribed a prophylactic antibiotic to reduce the possibility of infection and additional inflammation in the denuded mouth and esophageal area.

Children who respond well to steroid therapy usually recover with no important sequelae. Children who do not receive steroid therapy for some reason may be left with scarring of the esophagus, resulting in complete obstruction. To correct complete obstruction, a gastrostomy for feeding and repeated surgical procedures are necessary. Sometimes transplantation of intestinal tissue or a synthetic graft is required to replace stenosed esophageal tissue.

Nursing Diagnosis: Risk for imbalanced nutrition, less than body requirements, related to esophageal stricture from burn scarring

Outcome Evaluation: Child's diet meets recommended daily allowance requirements for age.

Oral intake commonly will be a problem for the first week following a caustic injury because of soreness in the child's mouth. Liquid food is introduced first. Liquid passing through the burned and scarring esophagus tends to maintain esophageal patency, so it is therapeutic for the burn as well as nutritious for the child. Observe children carefully the first time they attempt to drink something for coughing, choking, or cyanosis, signs that are indicative of esophageal stenosis or perforation. IV fluid may be needed as a supplement for such children. If a child is totally unable to swallow, gastrostomy feedings or total parenteral nutrition will be necessary.

Hydrocarbon Ingestion

Hydrocarbons are substances contained in products such as kerosene and furniture polish. Because these substances are volatile, fumes rise from them, and their major effect is respiratory, not gastric, irritation (see Chapter 40).

Iron Poisoning

Iron is frequently swallowed by small children because it is an ingredient in vitamin preparations, particularly pregnancy vitamins. When it is ingested, it is corrosive to the gastric mucosa and leads to signs and symptoms of gastric irritation (Aldridge, 2007). The immediate effects include nausea and vomiting, diarrhea, and abdominal pain. After 6 hours, these symptoms fade, and the child's condition appears to improve. By this time, however, hemorrhagic necrosis of the lining of the GI tract has occurred. By 12 hours, melena (blood in stool) and hematemesis (blood in emesis) are present. Lethargy and coma, cyanosis, and vasomotor collapse may occur. Coagulation defects may occur, and hepatic injury also can result. Shock resulting from an increase in peripheral vascular resistance and decreased cardiac output can occur. Long-term effects can include gastric scarring from fibrotic tissue formation.

Assessment

It is difficult to estimate the amount of iron a child has swallowed, because parents can only guess at the number of pills in the bottle. In addition, the amount of elemental iron in compounds varies. The child's serum iron level should be measured to establish a baseline.

Therapeutic Management

Parents should contact their poison control center immediately after the ingestion. In the emergency department, stomach lavage will be done to remove any pills not yet absorbed. A cathartic may be given to help the child pass enteric-coated iron pills. Activated charcoal is not given, because it is not effective at neutralizing iron. A soothing compound such as Maalox or Mylanta (aluminum hydroxide and magnesium hydroxide) may be given to help decrease gastric irritation and pain.

A child who has ingested a potentially toxic dose will be given a chelating agent, such as IV or intramuscular (IM) deferoxamine. Chelating agents combine with metals and allow them to be excreted from the body. Caution parents that deferoxamine causes urine to turn orange as iron is excreted.

An exchange transfusion is another way that excess iron can be removed from the body. An upper GI x-ray series and liver studies may be ordered 1 week after the ingestion to screen for long-term effects. The hope is that the iron load was removed from the stomach in time so that not all of it was absorbed.

Assist with emergency measures, such as gastric lavage, and administer chelating agents as ordered. Parents may be asked to test any stool passed for the next 3 days for occult blood, to assess for stomach irritation and subsequent GI bleeding. Be certain that parents understand how to do this accurately.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Deficient parental knowledge related to the danger of iron as a poison

Outcome Evaluation: Parents state ways they have safeguarded their child from future iron exposure.

Iron poisoning occurs frequently because parents do not think of iron pills or vitamins containing iron as real medicine. Additionally, because many children's vitamins are manufactured in the shapes of familiar television or cartoon characters, children often think of vitamins as candy.

When you instruct parents to use an iron supplement for themselves or their children, stress that overdoses can be fatal to small children. Teach them to think of iron as they would any other medicine and keep it out of the reach of small children.

Lead Poisoning

When lead enters the body, it interferes with red blood cell function by blocking the incorporation of iron into the protoporphyrin compound that makes up the heme portion of hemoglobin in red blood cells (Morgan & Borys, 2008). This leads to a hypochromic, microcytic anemia. Kidney destruction may occur in addition, causing excess excretion of amino acids, glucose, and phosphates in the urine. The most serious effect, however, is lead encephalitis: inflammation of brain cells because of the toxic lead content. Lead poisoning **(plumbism),** like all forms of poisoning in children, tends to occur most often in the toddler or preschool child. (See Chapter 30 for measures to prevent lead poisoning.)

Assessment

Lead poisoning is said to be present when the child has two successive blood lead levels greater than 10 μg/dL. A classification of levels of lead poisoning is shown in Table 52.3. The usual sources of ingested lead are paint chips or paint dust, home-glazed pottery, or fumes from burning or swallowed batteries (Olson, 2009). Paint tastes sweet, and a child will repeatedly pick chips up off the floor or off the walls. If a crib rail is painted with lead paint, a child will ingest it as the child teethes on the rail. Chewing on windowsills is also common. In fishing communities, swallowing lead sinkers can be a common source. Restoring an older home saturates the air with lead dust. In such homes, lead plumbing also may contaminate the drinking water.

Many children with fairly high blood lead levels are asymptomatic. Others show insidious symptoms of anorexia and abdominal pain caused by the presence of lead in the stomach. Children with encephalopathy usually have beginning symptoms of lethargy, impulsiveness, and learning difficulties. As the child's blood level of lead increases, severe encephalopathy with seizures and permanent neurologic damage will result.

The most widely used method of screening for lead levels is the blood lead determination (serum ferritin). Unfortunately, this test requires the use of atomic absorption spectrophotometry, which is a costly procedure. The free erythrocyte protoporphyrin test is a simple screening procedure that involves only a fingerstick. Because protoporphyrin is blocked from entering heme by the lead, it will be elevated in a child with lead poisoning.

Basophilic stippling (an odd striation of basophils) may be apparent on a blood smear. A radiograph of the abdomen may reveal paint chips in the intestinal tract (Fig. 52.6A). "Lead lines" (areas of increased density) may be present near the epiphyseal line of long bones (see Fig. 52.6B). The thickness of the line shows the length of time lead ingestion has been occurring (Kosnett, 2007).

Damage to the kidney nephrons from the presence of lead leads to proteinuria, ketonuria, and glycosuria. Urine analysis reveals this. The CSF may have an increased protein level.

Therapeutic Management

A child with a blood lead level between 10 and 14 μg/dL needs to be rescreened to confirm the level. If the lead level is 15 μg/dL or higher, a child needs active interventions to prevent further lead exposure. These interventions may include removal of the child from the environment containing the lead source or removal of the source of lead from the child's environment. Removal of the lead source can be difficult. If the family lives in a rented apartment, the landlord may be legally obligated to remove the lead. Simple repainting or wallpapering does not remove a source of peeling paint adequately. After some months, the new paint will begin to peel because of the defective paint underneath. The walls must therefore be covered by paneling or Masonite.

TABLE 52.3 ✻ Classification of Lead Poisoning Risk

Class	Lead Blood Level Concentration (μg/dL)	Recommended Action
Class I (low risk)	< 9	Retest at 24 months for children age 6–35 months who are considered low risk; retest every 6 months for ages 6–35 months who are considered high risk
Class IIa (rescreen)	10–14	Retest yearly; continue retesting yearly for children >36 months until age 6 years
Class IIb (moderate risk)	15–19	Retest every 3–4 months for children age 6–35 months
Class III (high risk)	20–44	Retest every 3–4 months; begin home abatement program
Class IV (urgent risk)	45–69	Initiate chelating therapy and environmental remediation
Class V (urgent risk)	> 70	Immediately treat with a chelating agent

Centers for Disease Control and Prevention. (2008). *Preventing lead poisoning in young children.* Washington, DC: U.S. Department of Health and Human Services, Public Health Service.

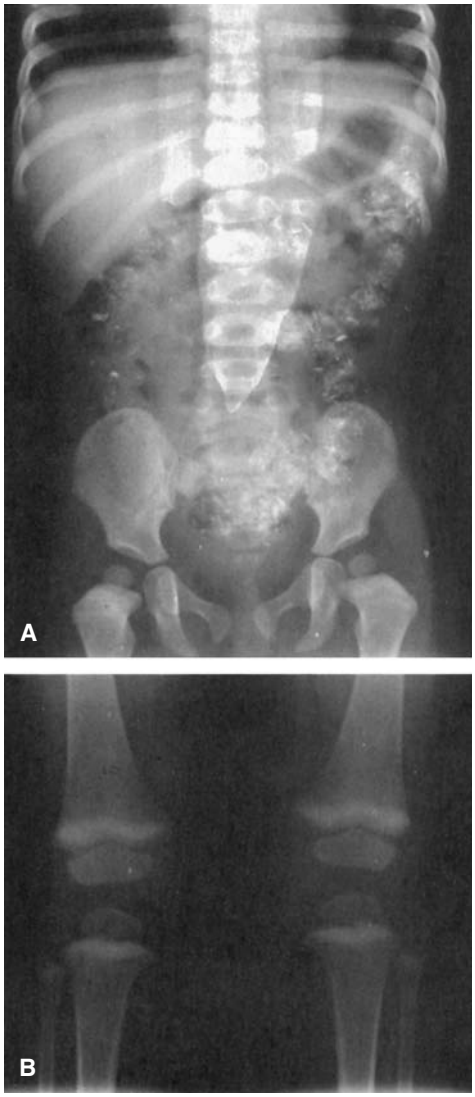

FIGURE 52.6 (**A**) Ingested paint chips (white crescents) in the intestinal tract. (**B**) A radiograph of the long bones of a child with chronic lead ingestion showing the characteristic "lead line" or white marking at the epiphyseal line. (Radiographs courtesy of Dr. Jerald P. Kuhn, Children's Hospital, Buffalo, NY.)

All children with lead levels greater than 20 μg/100 mL may be prescribed an oral chelating agent such as succimer (Box 52.7). Children with blood lead levels of greater than 45 μg/100 mL may be admitted to the hospital for chelation therapy with agents such as dimercaprol (BAL) or edetate calcium disodium (CaEDTA) (Karch, 2009).

Chelating agents remove the lead from soft tissue and bone (although not from red blood cells), allowing it to be eliminated in the urine. Injections of EDTA, which must be given IM into a large muscle mass, are painful and may be combined with 0.5 mL of procaine. EDTA also removes calcium from the body; therefore, serum calcium must be measured periodically to determine whether it is at a safe level. Measure intake and output to ensure that kidney function is adequate to handle the lead being excreted. BUN, serum creatinine, and protein in urine may also be assessed to ensure that kidney function is adequate. If kidney function is not adequate, EDTA may lead to nephrotoxicity or kidney damage.

BOX 52.7 ✻ Focus on Pharmacology

Succimer (Chemet)

Classification: Succimer is a chelating agent.
Action: Forms water-soluble chelates with lead, leading to increased urinary excretion of lead (Karch, 2009)
Pregnancy Risk Category: C
Dosage: Orally, starting with 10 mg/kg or 350 mg/m^2 every 8 hours orally for 5 days, then reducing dosage to 10 mg/kg or 350 mg/m^2 every 12 hours for 2 weeks. The drug is taken for a total of 19 days.
Possible Adverse Effects: Nausea; vomiting; loss of appetite; back, stomach, flank, head, or rib pain; chills; flulike symptoms

Nursing Implications

- Obtain serum lead levels before beginning therapy and again at the close of therapy.
- Instruct parents and child about the need to take the full 19-day course for optimal effectiveness.
- If the child has difficulty swallowing capsules, encourage parents to open capsules and mix capsule contents with a small amount of soft food or administer capsule contents on a spoon followed by a fruit drink.
- Urge the child to drink increased amount of fluid to provide enough urine for removing the chelated lead from the body.
- Ensure that a lead abatement program is instituted concurrently to reduce the amount of lead to which the child is exposed.

BAL has the advantage of removing lead from red blood cells, but, because of severe toxicity, it is used only for children who have severe forms of lead intoxication. Penicillamine (Cuprimine) is yet another drug used for lead poisoning. It is given orally after BAL or EDTA. Weekly complete blood cell counts and renal and liver function tests accompany the administration of penicillamine. It may be given for as long as 3 to 6 months.

Nursing Diagnoses and Related Interventions ✻

Care planning can be difficult when a child is diagnosed with lead poisoning because parents are upset at learning their child has been exposed to lead. They may experience a loss of self-esteem and a sense of powerlessness when realizing that their financial circumstances or lifestyle has hurt their child.

Nursing Diagnosis: Deficient knowledge related to the dangers of lead ingestion

Outcome Evaluation: Parents state ways they have safeguarded their child against further lead ingestion; parents identify measures to reduce lead in the environment.

Parental education about the risk of lead poisoning is crucial. Teach parents to keep toddlers away from windowsills and other common sources of lead paint. Placing the television or an overstuffed chair against the windowsill may be effective as a temporary measure. As a rule, children's cribs should be placed about 3 feet away from walls in older homes to reduce the risk of children's picking at loose wallpaper when they first wake in the morning or before they fall asleep at night (plaster, which contains lead, clings to the wallpaper). All children with elevated lead levels need careful follow-up care to determine the seriousness of their condition and to ensure that they are kept from a lead source. Because children who recover from symptomatic lead poisoning have a high incidence of permanent neurologic damage, all children with elevated blood lead levels need appropriate follow-up care to evaluate development and intelligence (CDC, 2008b).

Pesticide Poisoning

Pesticide poisoning can occur by accidental ingestion or through skin or respiratory tract contact when children play in an area that has recently been sprayed. Long-term exposure may result from exposure to a parent's clothing if the parent comes home covered with pesticide spray. Although pesticide poisoning was once thought to be only a rural problem, the increase in the use of lawn sprays by commercial lawn care companies now makes this a suburban problem as well (Olson, 2009).

Many pesticides have an organophosphate base that causes acetylcholine to accumulate at neuromuscular junctions; this accumulation leads to muscle paralysis. Within a few minutes to 2 hours after exposure, children develop nausea and vomiting, diarrhea, excessive salivation, weakness of respiratory muscles, confusion, depressed reflexes, and possibly seizures.

In the emergency department, activated charcoal may be administered if the pesticide was swallowed. If clothing is contaminated, remove it and wash the child's skin and hair. To prevent coming in contact with the pesticide yourself, wear gloves while bathing the child.

Intravenous atropine and a cholinesterase reactivator, pralidoxime (Protopam Chloride) are effective antidotes to reverse symptoms. If parents apply a pesticide to children to help avoid mosquito bites to reduce exposure to West Nile virus infection or tick bites to reduce exposure to Lyme disease, diethyltoluamide (DEET)-based pesticides appear to be safe if used sparingly, not applied to a child's face, and washed off when the child returns indoors (AAP, 2008).

Plant Poisoning

Plant poisoning (ingestion of a growing plant) occurs because parents commonly do not think of plants as being poisonous (Froberg, Ibrahim, & Furbee, 2007). Common plants to which children may be exposed and the effects of ingestion are shown in Box 52.8. Parents should phone their poison control center for specific emergency steps.

Poisoning by Drugs of Abuse

Adolescents and even grade-school children are brought to health care facilities by parents or friends because of a drug overdose or a "bad trip" caused by an unusual reaction or the effect of an unfortunate combination of drugs. Typical drugs involved include codeine and antidepressant drugs. Frequently, the drugs taken were prescription drugs removed from the family medicine cabinet (Schiesser, 2007).

Children are often extremely disoriented after this form of ingestion. They may be having hallucinations. Obtaining a history may be difficult because children may have no idea what they took except that it was a red or a yellow capsule. They may know but may be reluctant to name a drug if it was obtained illegally.

Assessment

Although a child may not appear to hear well or may not seem coherent, try to elicit a history. Avoid shouting or aggravating, because children who are having a paranoid reaction will be unable to cope rationally with this approach. If friends accompany an ill child, point out that your role is not that of a law enforcer. Your role is to help the child, and you cannot do that effectively unless the drug is identified. Approaching a child's friends in this way is more likely to result in their naming the drug. If a child is brought in by parents who have no idea what drug could possibly have been taken, ask them to have someone at home check the child's bedroom for drugs or what could be missing from the medicine cabinet (provided the child became ill while at home).

Expect to obtain blood specimens for electrolyte levels and a toxicology screen. If the child is vomiting, save any vomitus for analysis. Try to determine whether the ingestion was an accident (perhaps the child was unaware that two drugs would react this way or took a wrong dose) or whether the child was actually attempting suicide. All poisonings or drug ingestions in children older than 7 years of age should be considered potential suicides until established otherwise. If the ingestion was

BOX 52.8 ✻ Focus on Family Teaching

Identifying Poisonous Plants

Q. Jason's father says to you, "We never realized plants could be poisonous to our children. Which ones should we be aware of?"

A. Several common plants can lead to poisoning in children. Here are some and the symptoms they produce:

English ivy: Nausea, vomiting, excess salivation, diarrhea, abdominal pain
Holly (berries): Vomiting, diarrhea, abdominal pain
Hydrangea: Nausea, vomiting, muscular weakness, seizures, dyspnea
Lily of the valley: Vomiting, abdominal pain, diarrhea, cardiac disturbances
Mistletoe: Vomiting, diarrhea, bradycardia
Morning glory (seeds): Nausea, diarrhea, hallucinations
Philodendron: Swelling of the tongue, lips, irritation of mouth
Poinsettia: Nausea, vomiting
Rhododendron: Nausea, vomiting, abdominal pain, seizures, limb paralysis
Rhubarb (leaves): Irritant action on gastrointestinal tract

an accident, the child will need counseling to avoid drug use or about which drugs do not mix. If the incident was an attempted suicide, the child will need observation and counseling toward more effective coping mechanisms in self-care.

Therapeutic Management

Children need supportive measures for their specific symptoms, including oxygen administration, electrolyte replacement (particularly if there is accompanying nausea and vomiting), and perhaps IV fluid administration in an attempt to dilute the drug.

Children who have swallowed a drug of abuse need immediate treatment followed by investigation into the events leading to the poisoning. This potentially lethal ingestion may act as a turning point in the child's life, possibly alerting the child and family to a drug problem and the need for help. Factors such as reduction of fear and anxiety, increased coping mechanisms, knowledge of the effects of drug use, and availability of referral sources for a drug problem are important areas to address. (See Chapter 33 for more information related to adolescents and drug use.)

✔ Checkpoint Question 52.2

Suppose Jason's older brother had lead poisoning. What is the most common source of lead poisoning in young children?

a. Smelling lead fumes from cooking utensils.
b. Chewing on batteries that fall out of toys.
c. Drinking lead-contaminated drinking water.
d. Chewing on chips of lead-based outdoor paint.

FOREIGN BODY OBSTRUCTION

Foreign bodies can become lodged in children's esophagus, ear canals, or noses, causing stasis of secretions and infection. Direct obstruction or laceration of the mucous membrane may also result, leading to serious consequences.

Whether a foreign substance is inhaled or embedded elsewhere, nursing interventions should focus first on comforting the child and aiding in removal of the substance, and then on teaching the child and parents ways to avoid such occurrences in the future.

Foreign Bodies in the Ear

Any child with a history of draining exudate from the ear canal needs an otoscopic examination to establish the reason for the drainage. In toddlers and preschoolers, the drainage often is the result of a foreign body in the ear canal. The object might be a small piece of a toy, a piece of paper, a small battery, or food, such as a peanut (Singh et al., 2007).

Removal of a foreign body from the ear is difficult because children are afraid that the instrument used will hurt them, so they have difficulty lying still for the procedure. If there is reason to think that the tympanic membrane is intact, irrigating the object from the ear canal with a syringe and normal saline may be possible. This should not be done if the object is a substance that will swell when wet, such as a peanut. If it is possible that the tympanic membrane is ruptured, the ear canal must not be irrigated or fluid will be forced into the middle ear, possibly introducing infection (otitis media).

Often, it is better to wait for an otolaryngologist to care for the child, because trauma to the ear canal during an attempt to remove a foreign body will increase the edema and make removal even more difficult.

Foreign Bodies in the Nose

Foreign objects stuffed into the nose eventually cause inflammation and purulent discharge from the nares. The odor accompanying such impaction is often the first sign noticed by a parent. Objects pushed into the nose usually can be removed with forceps. A local antibiotic might be necessary after removal if ulceration resulted from the local irritation.

Foreign Bodies in the Esophagus or Stomach

Children tend not to chew food well or to swallow portions that are too big to pass safely through the esophagus. Pieces of candy, such as Lifesavers, are common objects caught in the esophagus in young children; coins may be swallowed by adolescents playing drinking games. Orthodontic appliances may become dislodged and swallowed. Intense pain at the site where the object is lodged will result. If it is an object that will dissolve, such as a Lifesaver or a piece of digestible meat, offer the child fluid to drink to help flush the object into the stomach. Even after the object dissolves or passes into the stomach, the child will feel transient pain at the original site of the obstruction.

Magnets, particularly those in watches or hearing aids, are also frequently swallowed by young children. These need to be removed by endoscopy as soon as possible as they can lead to bowel perforation or volvulus (Schierling et al., (2008). Objects, such as a part of a toy or a chicken bone, that will not dissolve and should not be passed, are also removed by endoscopy (Weissberg & Refaely, 2007).

Small coins, such as pennies and dimes, usually pass by themselves without difficulty. Parents (or children themselves if adolescents) should observe stools over the next several days to determine that the coin does pass through the GI tract (about 48 hours after ingestion). Without frightening them, caution parents to observe for signs of bowel perforation or obstruction, such as vomiting or abdominal pain, until the object has passed. If there is any doubt, a radiograph taken 3 to 7 days after ingestion will establish whether the object has been evacuated from the body.

Subcutaneous Objects

Children receive many wood splinters in the hands and feet. These usually are removed easily by a probing needle and tweezers after cleaning with an antiseptic solution. If the penetrating object is metal, such as a sewing needle or nail, its presence can be detected by radiography. If the object is one that would have been in contact with soil, such as a rusty nail, the child will need tetanus prophylaxis after extraction of the object if tetanus immunization is not current.

What if... You received a call from your neighbor stating that her 2-year-old son has swallowed a penny? What interventions would you expect to be necessary? What signs and symptoms would suggest GI obstruction?

BITES

Children receive bites from snakes and animals such as dogs or raccoons; they occasionally receive bites from other children. The source of a bite needs to be documented as human bites can also result from sexual abuse.

Mammalian Bites

Dog bites account for approximately 90% of all bites inflicted on humans, and children and adolescents are involved in one third to one half of reported incidents. The dog is usually one owned by the child's family. Cat bites, wild animal bites, and human bites also constitute a threat, although they are less common in children. All of these bites can cause abrasions, puncture wounds, lacerations, and crushing injuries related to the size of the animal and the location of the bite (Jacobs, Guglielmo, & Chin-Hong, 2009). The biggest concerns associated with animal bites are the possibility of long-term scarring and disfigurement and the possibility of infection, especially rabies, from the presence of microorganisms in the animal's mouth. This latter subject is discussed in Chapter 43.

Snakebite

In the United States, snakebites tend to occur during the warm months of the year, from April to October. Most fatal snakebites (envenomations) in the United States are copperhead or rattlesnake bites. Copperheads are found in eastern and southern states, and rattlesnakes in almost every state. A few bites occur from cottonmouth moccasins or coral snakes (both found in southeastern states). The effect of the bite of a rattlesnake, copperhead, or cottonmouth moccasin (all pit vipers) is a failure of the blood coagulation system (Clark, 2007). Coral snakes are known for the small coral, yellow, and black rings encircling their body. Fortunately, they are shy and seldom bite. However, the venom injected through the bite of these snakes leads to neuromuscular paralysis.

Assessment

Reaction to a pit viper bite is almost immediate. A white wheal forms at the site, showing the puncture marks, accompanied by excruciating pain at the site. Purplish erythema and edema begin to extend rapidly from the site.

By the time a child is seen at a health care facility, sanguineous fluid may be oozing from the bite. Systemic symptoms, such as dizziness, vomiting, perspiration, and weakness, may be present. Because snake venom interferes with blood coagulation, the child may have hematemesis or bleeding from the nose, intestines, or bladder because of subcutaneous or internal hemorrhage. The pupils may be dilated, showing the potent effect on cerebral centers. If the envenomation is not treated, seizures, coma, and death may result.

Emergency Management at the Scene

At the scene of a snakebite, apply a cold compress to the bite, in the hope of slowing the spread of the venom and to reduce edema formation. Urge the child to lie quietly, to slow circulation. Keep the bitten extremity dependent, again to slow venous circulation. Commercial snakebite kits have rubber suction cups in them for suctioning out venom. If these are available, they should be used at the site where the bite occurred. Excising the bite with a knife and sucking out the venom orally (often shown in old western movies) is of questionable value and contradicts rules of standard infection precautions. If the person administering the treatment has open mouth lesions, such as carious teeth, the procedure could be dangerous to that person (venom is not dangerous when swallowed, only when absorbed through open lesions). Excising the bite also may lead to secondary infection and, if done too vigorously, may injure tendon or muscle. No time should be wasted before the child is transported to a health care facility for treatment.

Emergency Management at the Health Facility

In the emergency facility, ask the child or a person who was with the child to describe the snake. In areas where snakebites are frequent, keep available photographs of the venomous snakes commonly found. Even a preschooler may be able to identify the snake by pointing to a photograph. Specific antivenin is then administered. Because rattlesnakes, copperheads, and cottonmouth moccasins are all one type of snake (pit vipers), one form of antivenin acts against all of these bites. Specific antivenin is prepared for coral snake or cobra bites and is kept at most zoos. If the child receives antivenin promptly after a bite, the prognosis for full recovery is good. Tetanus prophylaxis is instituted if the child's immunization status is unknown or if it has been more than 10 years since a tetanus immunization was given.

Antivenin may contain a horse-serum base. Therefore, before the serum is injected IM or IV, a skin test may need to be performed to prevent a possible anaphylactic reaction to the horse serum. If the serum is given IM, do not inject it into an edematous body part, because medication absorption will be poor. Giving antivenin in the limb opposite the bitten limb is just as effective as administering it into the bitten limb.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Fear related to seriousness of child's condition

Outcome Evaluation: Parents and child state that they are able to cope with the degree of fear present.

Children with snakebites are extremely frightened. Their parents who have seen old western movies showing the agony of snakebite also are thoroughly frightened. Children need a great deal of support from health care personnel, because their parents may be too frightened to offer adequate support.

As a final care measure, teach children safety rules for avoiding snakebites:

- Look for snakes before stepping into underbrush.
- Do not lift up rocks without looking at what could be under them.
- Listen for the telltale sound of a rattlesnake.
- Be aware that snakes sun on warm rocks.
- Know the markings of poisonous snakes.

THERMAL INJURIES

Thermal injuries include those caused by either cold (frostbite) or by excessive heat (burns).

Frostbite

Frostbite is tissue injury caused by freezing cold (Stallard, 2008). Cold exposure leads to peripheral vasoconstriction, cutting off the oxygen supply to surrounding cells. In children, the body parts involved usually are the nose, fingers, or toes. Cells at the site can be so injured that they die.

Assessment

The affected body part appears white or erythematous; edema is present and it feels numb. Degrees of frostbite are summarized in Table 52.4. Explore the cause of frostbite by careful history taking. It occurs most frequently in children who have been skiing, snowmobiling, or snowboarding for long periods. If parents failed to provide adequate clothing because they underestimated the degree of cold outside, the possibility of neglect or child abuse must be ruled out as a cause. Frostbite also can occur from sucking on popsicles and from inhalant abuse.

Therapeutic Management

Always warm frostbitten areas gradually. Sudden warming increases the metabolic rate of cells; without adequate blood flow to the area because of still-present vasoconstriction, additional damage can occur. Administration of a vasodilator and use of hyperbaric oxygen may help reduce the effect on body cells.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Pain related to frostbite damage to cells

Outcome Evaluation: Child states that pain is controlled at a tolerable level.

As soon as warming begins, the frostbitten area becomes extremely painful because the cells that are injured register their anoxic state. Children need an analgesic for pain, such as IV morphine. Morphine administered epidurally can be used for pain relief in lower body areas.

During the next few days after severe frostbite, necrosis of destroyed tissue occurs, and the affected tissue sloughs away. Apply dressings as necessary to avoid secondary bacterial contamination of a necrotic injury site. Assess body temperature conscientiously to detect early symptoms of infection at the site.

TABLE 52.4 Degrees of Frostbite

Degree	Description
First	Mild freezing of epidermis; appears erythematous with edema
Second	Partial- or full-thickness injury; appears erythematous with blisters and pain occurring after rewarming
Third	Full-thickness injury (epidermis, dermis, and subcutaneous tissue); appears white
Fourth	Complete necrosis with gangrene and possible ultimate loss of body part

Burns

Burns are injuries to body tissue caused by excessive heat (heat greater than 104° F [40° C]). Such injuries commonly occur in children of all ages after infancy. They are the second greatest cause of unintentional injury in children 1 to 4 years of age and the third greatest cause in children age 5 to 14 years. Toddlers are often burned by pulling pans of scalding water or grease off the stove and onto themselves or from bath water that is too hot (Leahy et al., 2007). They can bite into electrical cords. Older children are more apt to suffer burns from flames when they move too close to a campfire, heater, or fireplace; touch a hot curling iron; or play with matches or lighted candles. Eye burns can occur from splashed chemicals in science classes (Pavan-Langston & Hamrah, 2008). Some burns (particularly scalding) can be caused by child abuse (Hicks & Stolfi, 2007). Burn injuries tend to be more serious in children than in adults, because the same size burn covers a larger surface of a child's body. As many as 50% of burns could be prevented with improved parent and child education.

Assessment

When children are brought to a health care facility with a burn injury, the first questions must be, "Where is the burn and what is its extent and depth?" Burns are classified according to the criteria of the American Burn Association as major, moderate, or minor (Huether & McCance, 2007). These classifications are shown in Table 52.5. Along with the

TABLE 52.5 Classification of Burns

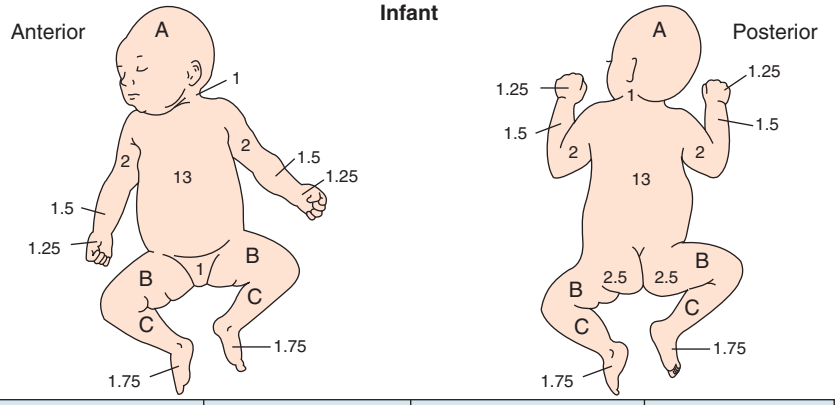
Classification	Description
Minor	First-degree burn or second-degree burn <10% of body surface or third-degree burn <2% of body surface; no area of the face, feet, hands, or genitalia burned
Moderate	Second-degree burn between 10% to 20% or on the face, hands, feet, or genitalia or third-degree burn <10% of body surface or if smoke inhalation has occurred
Severe	Second-degree burn >20% of body surface or third-degree burn >10% of body surface

size and depth, be certain to assess and document the location of the burn. Face and throat burns are particularly hazardous because there may be accompanying but unseen burns in the respiratory tract. Resulting edema could lead to respiratory tract obstruction. Hand burns are also hazardous because, if the fingers and thumb are not positioned properly during healing, adhesions will inhibit full range of motion in the future. Burns of the feet and genitalia carry a high risk for secondary infection. Genital burns are also hazardous because edema of the urinary meatus may prevent a child from voiding.

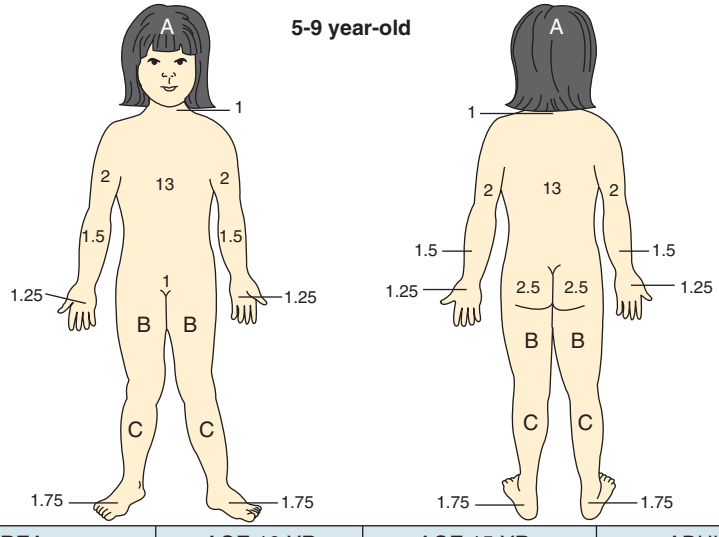
With adults, the "rule of nines" is a quick method of estimating the extent of a burn. For example, each upper extremity represents 9% of the total body surface; each lower extremity represents two 9s, or 18%, and the head and neck represent 9%. Because the body proportions of children are different from those of adults, this rule does not always apply and is misleading in the very young child. Data for determining the extent of burns in children are shown in Figure 52.7. Computer analysis is now available to rapidly assess the extent of burns.

Depth of Burn. When estimating the depth of a burn, use the appearance of the burn and the sensitivity of the area to pain as criteria. Descriptions of tissue at various burn depths are shown in Table 52.6 and are illustrated in Figure 52.8. *Partial-thickness* burns include first- and second-degree burns. A first-degree burn involves only the superficial epidermis. The area appears erythematous. It is painful to touch and blanches on pressure (Fig. 52.9A). Scalds and sunburn are examples of first-degree burns. Such burns heal by simple regeneration and take only 1 to 10 days to heal.

A second-degree burn involves the entire epidermis. Sweat glands and hair follicles are left intact. The area appears very



AREA	BIRTH	AGE 1 YR	AGE 5 YR
A = 1/2 of head	9 1/2	8 1/2	6 1/2
B = 1/2 of one thigh	2 3/4	3 1/4	4
C = 1/2 of one leg	2 1/2	2 1/2	2 3/4



AREA	AGE 10 YR	AGE 15 YR	ADULT
A = 1/2 of head	5 1/2	4 1/2	3 1/2
B = 1/2 of one thigh	4 1/2	4 1/2	4 3/4
C = 1/2 of one leg	3	3 1/4	3 1/2

TABLE 52.6 ✻ Characteristics of Burns

Severity	Depth of Tissue Involved	Appearance	Example
First degree (partial thickness)	Epidermis	Erythematous, dry, painful	Sunburn
Second degree (partial thickness)	Epidermis Portion of dermis	Blistered, erythematous to white	Scalds
Third degree (full thickness)	Entire skin, including nerves and blood vessels in skin	Leathery; black or white; not sensitive to pain (nerve endings destroyed)	Flame

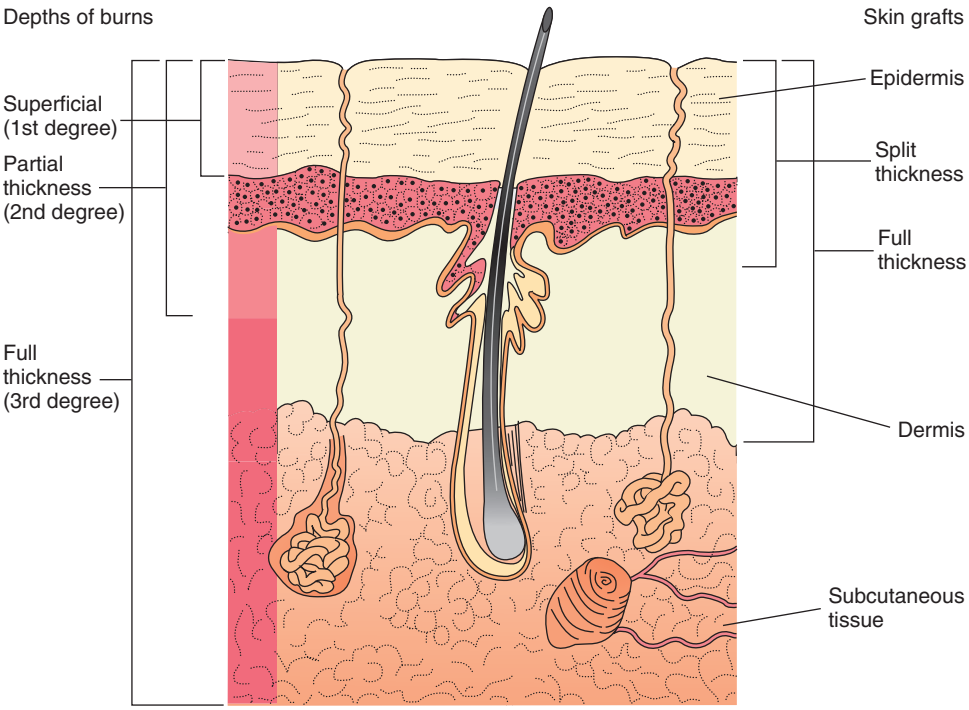

FIGURE 52.8 Depths of burns.

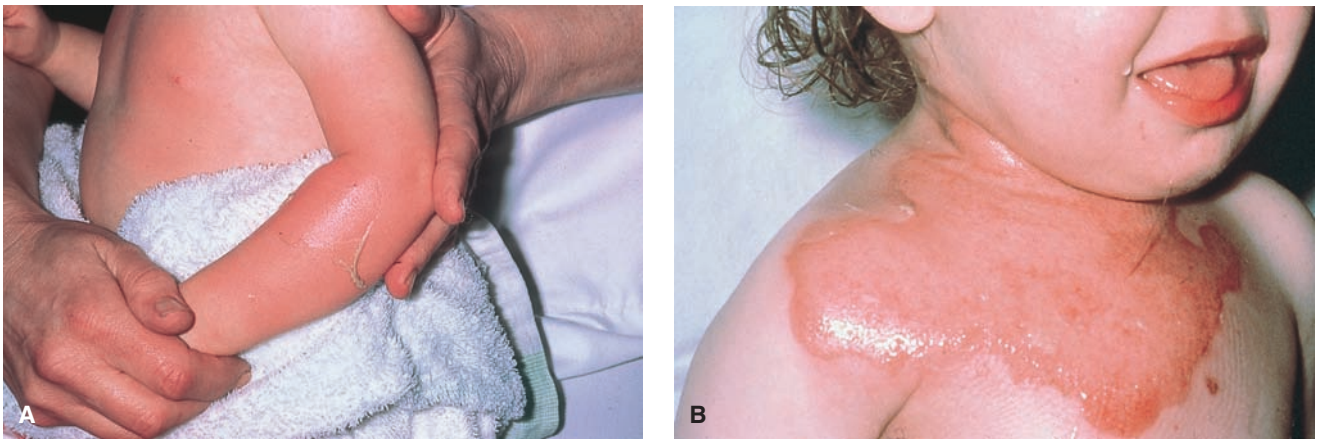

FIGURE 52.9 Partial-thickness burns. (**A**) An infant with a first-degree burn on the arm and chest caused by scalding with hot water. (**B**) A toddler with a second-degree burn caused by scalding. The area appears severely reddened and moist with some blistering. (**A,** © Dr. P. Marazzi/SPL/Science Source/Photo Researchers. **B,** © NMSB/Custom Medical Stock Photograph.)

FIGURE 52.10 Full-thickness (third-degree) burn of the foot. Both layers of skin are involved with this type of burn. (© Dr. Michael English/Custom Medical Stock Photograph.)

erythematous, blistered, and moist from exudate. It is extremely painful. Scalds can cause second-degree burns (see Fig. 52.9B). Such burns heal by regeneration of tissue but take 2 to 6 weeks to heal.

A third-degree burn is a full-thickness burn involving both skin layers, epidermis and dermis. It may also involve adipose tissue, fascia, muscle, and bone. The burn area appears either white or black (Fig. 52.10). Flames are a common cause of third-degree burns. Because the nerves, sweat glands, and hair follicles have been burned, third-degree burns are not painful. Such burns cannot heal by regeneration because the underlying layers of skin have been destroyed. Skin grafting is usually necessary, and healing takes months. Scar tissue will cover the final healed site. Many burns are compound, involving first-, second-, and third-degree burns. There may be a central white area that is insensitive to pain (third degree), surrounded by an area of erythematous blisters (second degree), surrounded by another area that is erythematous only (first degree).

Undress children with burns completely so the entire body can be inspected. A first-degree burn is painful, whereas a third-degree burn is not. Therefore, a child may be crying from a superficial burn that is obvious on the arm, although the condition needing the most immediate attention is a third-degree burn on the chest, which is covered by a jacket.

Be certain to ask what caused the burn, because different materials cause different degrees of burn. Hot water, for example, causes scalding, a generally lesser degree of burn than one caused by flaming clothing. Ask where the fire happened. Fires in closed spaces are apt to cause more respiratory involvement than fires in open areas.

Ask whether the child has any secondary health problem. In their anxiety over the present burn, parents may forget to report important facts, such as the child has diabetes or is allergic to a common drug. After a fire, parents may pick up a burned child and bring the child to a health care facility, leaving other children unprotected at home. Ask about other children and where they are. Parents may have burned hands from putting out the fire on the child's clothes and need equal care, but in their anxiety about the child's condition, they do not mention this. Ask who put out the fire. Were any other family members or animals hurt? Does anyone else need care?

Emergency Management of Burns

All burns need immediate care because of the pain involved (Rieman, Gordon, & Marvin, 2007).

Minor Burns. Although minor burns (typically first-degree partial-thickness burns) are the simplest type of burn, they involve pain and death of skin cells, so they must be treated seriously. Immediately apply ice to cool the skin and prevent further burning. Application of an analgesic–antibiotic ointment and a gauze bandage to prevent infection is usually the only additional treatment required. The child should have a follow-up visit in 2 days to have the area inspected for a secondary infection and to have the dressing changed. Caution parents to keep the dressing dry (no swimming or getting the area wet while bathing for 1 week). A first-degree burn heals in about that time.

Moderate Burns. Moderate or second-degree burns may have blisters. Do not rupture them, because doing so invites infection. The burn will be covered with a topical antibiotic such as silver sulfadiazine and a bulky dressing to prevent damage to the denuded skin. The child usually is asked to return in 24 hours to assess that pain control is adequate and there are no signs and symptoms of infection. Broken blisters may be débrided (cut away) to remove possible necrotic tissue as the burn heals.

Severe Burns. The child with a severe burn is critically injured and needs swift, sure care, including fluid therapy, systemic antibiotic therapy, pain management, and physical therapy, to survive the injury without a disability caused by scarring, infection, or contracture.

Electrical Burns of the Mouth. If a child puts the prongs of a plugged-in extension cord into the mouth or chews on an electric cord, the mouth will be burned severely (Kidd et al., 2007). Electrical current from the plug is conducted for a distance through the skin and underlying tissue, so a tissue area much larger than where the prongs or cord actually touched is involved, leaving an angry-looking ulcer. If blood vessels were burned, active bleeding will be present. The immediate treatment for electrical burns of the mouth is to unplug the electric cord and control bleeding. Pressure applied to the site with gauze is usually effective. Most children are admitted to a hospital for at least 24 hours in an observation unit because edema in the mouth can lead to airway obstruction.

Supply adequate pain relief as long as necessary. Clean the wound about four times a day with an antiseptic solution, such as half-strength hydrogen peroxide, or as otherwise ordered to reduce the possibility of infection (a real danger in this area, because bacteria are always present in the mouth).

Eating will be a problem for the child because the mouth is so sore. The child may be able to drink fluids from a cup best. Bland fluids, such as artificial fruit drinks or flat ginger ale, are best.

Electrical burns of the mouth turn black as local tissue necrosis begins. They heal with white, fibrous scar tissue, possibly causing a deformity of the lip and cheeks with healing. This can be minimized by the use of a mouth appliance, which helps maintain lip contour. Some children have difficulty with speech sounds because of resulting lip scarring. They need follow-up care by a plastic surgeon to restore their

lip contour. Obviously, you need to review with parents the importance of not leaving "live" electrical cords where young children can reach them.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Pain related to trauma to body cells

Outcome Evaluation: Child states that pain is at a tolerable level.

Morphine sulfate is commonly the agent of choice. It can be administered IM, but, because circulation is impaired in children with shock, IV or epidural administration is most effective. Use of patient-controlled analgesia before performing any burn care such as débridement (the removal of necrotic tissue from a burned area) is also effective. Be sure to assess after administration that pain relief was adequate.

In addition to the pain from the burn, children may be required to remain in awkward positions to keep joints overextended for most of every day. Doing so helps to prevent formation of contractures from scar tissue (Fig. 52.11). If the anterior throat is burned, for example, the head will be hyperextended to keep scar tissue that forms on the anterior neck from pulling the chin down against the chest in a contracture. It is difficult for children to watch television in this position or even to view activities on the unit so they need to be encouraged to maintain this position. If they have burns at extremity joints, they may have splints applied over burn dressings to maintain the joints in extension. Again, this makes activities very difficult and adds to their stress if they do not have adequate pain relief.

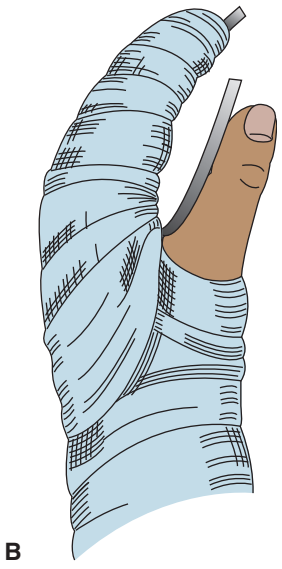

FIGURE 52.11 (**A**) An adolescent's hand scarred from third-degree burns. Note the proper extension and alignment of the hand and fingers, which were maintained by the use of splints (**B**) during healing. (**A,** © Dr. P. Marazzi/SPL/Science Source/Photo Researchers.)

Children who experience smoke inhalation may be unconscious from brain anoxia immediately after a burn. Most children, however, are awake and very aware of the pain and treatments involved. Therefore, a priority need is immediate pain relief. After the first week following a major burn, some children develop symptoms of delirium, seizures, and coma that result from toxic breakdown of damaged cells, sensory deprivation, isolation, and lack of sleep. Nursing care aimed at reducing unnecessary stimuli and providing adequate pain relief helps to prevent these late symptoms from occurring.

Nursing Diagnosis: Deficient fluid volume related to fluid shifts from severe burn

Outcome Evaluation: Skin turgor remains good; hourly urine output is greater than 1 mL/kg, with specific gravity between 1.003 and 1.030; vital signs are within acceptable parameters.

Immediately after a severe burn, the child's circulatory system becomes hypovolemic, because of a loss of plasma, which oozes from blood vessels into the burn site and then sequesters in edematous tissue surrounding the site. This outpouring of plasma is caused by an increased permeability of capillaries (or damage to capillaries). It is most marked during the first 6 hours after a burn. It continues to some extent for the first 24 hours.

A primary response of the myocardium to the shock of burn injury and hypovolemia can lead to a marked reduction in cardiac output and decreased blood pressure. Therefore, even with relatively minor burns, monitor vital signs closely to allow early detection of this event. A child may be severely anemic because of injury to red blood cells caused by heat and loss of blood at the wound site. The large amount of sodium lost with the edematous burn fluid and the release of potassium from damaged cells can lead to an immediate hyponatremia and hyperkalemia (Table 52.7).

Lactated Ringer's solution is the commercially available solution most compatible with extracellular fluid. Usually, it is one of the first fluids begun for fluid replacement, although normal saline may be used. A child may also need plasma replacement and additional fluid, such as 5% dextrose in water. Do not administer potassium immediately after a burn until kidney function is evaluated, to be certain that extra potassium can be eliminated. IV fluid is usually administered by the most convenient venous access, so that morphine sulfate can be administered to relieve pain. A more stable fluid line may then be inserted.

TABLE 52.7 ✻ Fluid Shifts After Burn Injury

Fluid Shifts in First 24 Hours	Remobilization of Fluid After 48 Hours
Burn	Edematous tissue surrounding burn area
↓	↓
Increased capillary permeability	Intravascular compartment
↓	↓
Hypoproteinemia Hyponatremia Hyperkalemia Hypovolemia	Hypervolemia Hypernatremia Hypokalemia

The amount of fluid necessary is calculated carefully, based on predicted insensible fluid loss and loss because of the burn. The Parkland formula is commonly used to calculate the amount of fluid needed for the first 24 hours: 4 mL/kg body weight for each 1% of body surface area burned.

This fluid is administered rapidly for the first 8 hours (half of the 24-hour load), then more slowly for the next 16 hours (the second half). It is important that administration be continued beyond the time of increased capillary permeability (at least the first 24 hours). The administration site, therefore, must be protected to prevent infiltration. A central venous pressure or pulmonary artery catheter may be inserted to determine hemodynamic and fluid volume status and evaluate that the child is receiving adequate fluid.

About 48 hours after the burn, as inflammation decreases, the extracellular fluid at the burn site begins to be reabsorbed into the bloodstream. Edema begins to subside; the child has diuresis and loses weight. The heart rate increases because of temporary hypervolemia. The hematocrit level is low because red blood cells are diluted. The child needs frequent evaluation of electrolyte levels to determine fluid balance during this period. Potassium supplements may be necessary to maintain normal heart function, because, although potassium was released into the serum from destroyed cells, it is rapidly excreted by the kidneys. If the child needs continued electrolyte replacement at this time, carefully monitor the rate of flow so the blood volume does not exceed the child's tolerance. If many red blood cells were destroyed at the burn site, the child may need packed red blood cells to maintain an adequate hemoglobin level.

Nursing Diagnosis: Risk for ineffective tissue perfusion related to cardiovascular adjustments after burn injury

Outcome Evaluation: Child's vital signs stay within normal limits; hourly urine output remains greater than 1 mL/kg.

Take height, weight, and vital signs on admission, and continue to take vital signs every 15 minutes until they are stable. Once vital signs are stabilized, record pulse, blood pressure, and central venous pressure hourly until the child passes the immediate danger of shock (at least 24 hours). Another important period occurs at 48 hours after the injury, when fluid is returning to the bloodstream. Remember that gradual but persistent changes in blood pressure may be as informative as sudden changes.

A complete blood cell count, blood typing and cross-matching, electrolyte and BUN determinations, and blood gas studies to ascertain blood levels of oxygen and carbon dioxide are important to obtain.

Nursing Diagnosis: Risk for ineffective breathing patterns related to respiratory edema from burn injury

Outcome Evaluation: Child's respiratory rate remains within 16 to 20 breaths/minute; lung auscultation reveals no rales.

If a child inhaled smoke from a fire, the injury from the smoke inhalation can be more serious than the skin surface burns. Smoke coming from a fire is at the temperature of the fire. Inhaling smoke, therefore, is the same as exposing the upper respiratory tract to open flame. In addition, toxic substances and soot given off by the fire cause even more irritation to the respiratory tract. If carbon monoxide is inhaled with the smoke, it enters red blood cells in place of oxygen, shutting off the oxygen supply to body cells. If this is extensive, it can lead to loss of consciousness because of cerebral anoxia. If the trachea is burned, edema fluid will pass into the injured bronchioles and trachea, causing pulmonary edema or obstruction limiting air inflow. This can lead to dyspnea and stridor. About 1 week after the smoke inhalation, the child is at risk for the development of pneumonia because of denuded tracheal and bronchial tract areas. The fact that inhalation of smoke or flame from a fire can be more serious than the skin burns the child suffers may be difficult for parents to understand. They are relieved if they learn that the child has suffered only smoke inhalation. They may need an explanation of the physiologic consequences that can result from pulmonary injury.

To help rule out smoke inhalation, obtain a history to assess whether the fire occurred in a closed space, such as a garage. Assess for burns of the face, neck, or chest, which would indicate that the fire was near the nose and respiratory tract. Assess the quality of the child's voice (it will be hoarse if the throat is irritated from smoke). Carefully monitor the respiratory rate of all burned children, because respiratory rate increases with respiratory obstruction. A child also may become restless and thrash about because of lack of oxygen. Measurement of blood gases will demonstrate the degree of hypoxia present from carbon monoxide intoxication. Administration of 100% oxygen is the best therapy for displacing carbon monoxide and providing adequate oxygenation to body cells. The child may need endotracheal intubation or a tracheostomy with assisted ventilation to ensure adequate oxygenation. Intubation is best, because tracheostomies can lead to infection, and this child is at a much higher risk for pneumonia than the average child.

Symptoms of smoke inhalation may not occur immediately but only 8 to 24 hours after the burn. A chest radiograph taken at this time will reveal collecting edematous fluid and decreased aeration. Continue to assess the child's temperature every 4 hours for the first week after the injury, to assess that lung infection is not developing. Bronchodilators and antibiotics may be prescribed. High-frequency ventilation may be helpful to keep alveoli functioning. Some children need extracorporeal membrane oxygenation (ECMO) support because smoke inhalation has compromised their lung function to such a great extent.

Nursing Diagnosis: Risk for impaired urinary elimination related to burn injury

Outcome Evaluation: Child's urine output is greater than 1 mL/kg of body weight per hour.

Because the child's blood volume decreases immediately after a burn, renal function is threatened by kidney ischemia just when it is needed to rid the body of breakdown products from burned cells. If the child is burned over more than 10% of body surface, urinary output may decrease immediately. Blood volume must be maintained by IV fluid administration to establish good urinary output once more. Urine output should be 1 mL/kg of body weight per hour. The specific gravity of urine also should be monitored to determine whether the kidneys can concentrate urine to conserve body fluid (failing kidneys lose this ability rapidly). In the days after the burn, because products of necrotic tissue and toxic substances must be evacuated by the kidneys and antidiuretic hormone and aldosterone levels are increased in response to low blood pressure, kidney function may fail again. If free hemoglobin from destroyed red blood cells plugs kidney tubules (acute tubular necrosis), urine color will be red to black because of the hemoglobin present.

An indwelling urinary (Foley) catheter should be inserted in the emergency department, and an immediate urine specimen should be obtained for analysis. A diuretic, such as mannitol, may be administered to flush hemoglobin from the kidneys. If this is effective, the urine returns to its usual straw color. Throughout the child's hospital stay, observing urinary output is a major nursing responsibility.

Nursing Diagnosis: Risk for imbalanced nutrition, less than body requirements, related to burn injury

Outcome Evaluation: Child's weight remains within normal age-appropriate growth percentiles; skin turgor remains normal; urine specific gravity remains between 1.003 and 1.030.

After burns, the metabolic rate increases in children as the body begins to pool its resources to adjust to the insult. If children do not receive enough calories in IV fluid, their body will begin to break down protein. This is particularly dangerous because a child needs protein for burn healing. Additionally, breakdown of protein can lead to acidosis.

After a severe burn, some children are nauseated from the systemic shock. An NG tube may be inserted and attached to low, intermittent suction as prophylactic therapy to prevent aspiration of vomitus. The tube must remain in place until bowel sounds are detected. This usually occurs within 24 hours but may take as long as 72 hours in severely burned children. Fluid suctioned from an NG tube may be blood-tinged (coffee-ground fluid) because of bleeding caused by stomach vessel congestion. Closely observe this drainage for a change to fresh bleeding, which can be caused by a stress ulcer (Curling's ulcer). This type of ulcer can be prevented by administering a histamine-2 receptor antagonist, such as cimetidine (Tagamet) or a proton pump inhibitor such as omeprazole (Prilosec) in an attempt to reduce gastric acidity and ulcer formation.

If a bleeding ulcer occurs, gastric lavage with iced saline may be necessary. Blood for transfusion should be readily available, because the blood loss from a GI ulcer can be rapid and severe.

If a child has burns over more than 30% of the body surface, paralytic ileus may occur. Symptoms of intestinal obstruction, such as vomiting, abdominal distention, and colicky pain, will appear within hours of the burn.

Children with severe burns usually are allowed nothing by mouth for 24 hours because of the danger of vomiting or paralytic ileus. After this, most children are able to eat, so oral feedings are begun as soon as possible. To supply adequate calories for increased metabolic needs and spare protein for repair of cells, the diet is high in calories and protein (25 kcal/kg body weight plus 40 kcal for each percent of burn surface per 24 hours). Children may also need supplemental vitamins (particularly B and C) and iron supplements (Moelleken, 2009). High-protein drinks may be necessary between meals to ensure an adequate protein intake (Faries & Battan, 2008).

Because adequate nutrition is important, it may be necessary to supplement the child's diet with IV or parenteral nutrition solutions or NG tube feeding. As additional methods of stimulating interest in eating, encourage school-age children to help add intake and output columns, help the dietitian add a calorie-count list, or keep track of their own daily weight (taken at the same time each day in the same clothing). It may be helpful to make contracts with older children for a good nutritional intake.

Nursing Diagnosis: Risk for injury related to effects of burn, denuded skin surfaces, and lowered resistance to infection with burn injury

Outcome Evaluation: Child's temperature remains at 98.6° F (37° C); skin areas surrounding burned areas show no signs of erythema or warmth.

There appears to be some defect in the ability of neutrophils to phagocytize bacteria after burn injury. The formation of immunoglobulin G antibodies also apparently fails. For these reasons, a child has reduced protection against infection. *Staphylococcus aureus* and group A β-hemolytic streptococci are the gram-positive organisms, and *Pseudomonas aeruginosa* is the gram-negative organism, that commonly invade burn tissue. Children are usually prescribed parenteral penicillin to prevent group A β-hemolytic

streptococcal infection and tetanus toxoid to prevent tetanus. In addition to bacteria, fungi also may invade burns. *Candida* species are the most frequently seen (Madoff, 2008).

Nose, throat, and wound cultures may be done immediately and then daily to detect offending organisms. Bacteria and fungi can penetrate the burn eschar readily, so this tissue offers little protection from infection. Fortunately, granulation tissue, which forms under the eschar 3 to 4 weeks after the burn, is resistant to microbial invasion.

Systemic antibiotics are not very effective in controlling burn-wound infection, probably because the burned and constricted capillaries around the burn site cannot carry the antibiotic to the area. For this reason, any equipment used with the child must be sterile, to avoid introducing infection. Children are placed on a sterile sheet on the examining table. Personnel caring for the severely burned child should wear caps, masks, gowns, and gloves, even for emergency care.

Although their burns may be covered by gauze dressings, children usually are cared for in private rooms to help reduce the possibility of infection. Helping children maintain their self-esteem and keeping them from withdrawing from social contacts can be difficult when infection control precautions are required.

Therapy for Burns

Second- and third-degree burns may receive open treatment, leaving the burned area exposed to the air, or a closed treatment, in which the burned area is covered with an antibacterial cream and many layers of gauze. These two methods are compared in Table 52.8. A synthetic skin covering (Biobrane), artificial skin (Integra), or amniotic membrane from placentas can be used to help decrease infection and protect granulation tissue. As a rule, burn dressings are applied loosely for the first 24 hours to prevent interference with circulation as edema forms. Be certain not to allow two burned body surfaces, such as the sides of fingers or the back of the ears and the scalp, to touch, because, as healing takes place, a webbing will form between these surfaces. Do not use adhesive tape to anchor dressings to the skin; it is painful to remove and can leave excoriated areas, which provide additional entry for infection. Netting is useful to hold dressings in place, because it expands easily and needs no additional tape.

Topical Therapy. Silver sulfadiazine (Silvadene) is the drug of choice for burn therapy to limit infection at the burn site for children. It is applied as a paste to the burn, and the area is then covered with a few layers of mesh gauze. Silver sulfadiazine is an effective agent against both gram-negative and gram-positive organisms and even against secondary infectious agents, such as *Candida*. It is soothing when applied and tends to keep the burn eschar soft, making débridement easier. It does not penetrate the eschar well, which is its one drawback.

Antiseptic solutions, such as povidone-iodine (Betadine), may also be used to inhibit bacterial and fungal growth. Unfortunately, iodine stings as it is applied and stains skin and clothing brown. Dressings must be kept continually wet to keep them from clinging to and disrupting the healing tissue.

If *Pseudomonas* is detected in cultures, nitrofurazone (Furacin) cream may be applied. If a topical cream is not effective against invading organisms in the deeper tissue under the eschar, daily injections of specific antibiotics into the deeper layers of the burned area may be necessary.

If a burned area, such as the female genitalia, cannot be readily dressed, the area can be left exposed. The danger of this method is the potential invasion of pathogens.

Escharotomy. An eschar is the tough, leathery scab that forms over moderately or severely burned areas. Fluid accumulates rapidly under eschars, putting pressure on underlying blood vessels and nerves. If an extremity or the trunk has been burned so that both anterior and posterior surfaces have eschar formation, a tight band may form around the extremity or trunk, cutting off circulation to distal body portions. Distal parts feel cool to the touch and appear pale. The child notices tingling or numbness. Pulses are difficult to palpate, and capillary refill is slow (longer than 5 seconds). To alleviate this problem, an **escharotomy** (cut into the eschar) is performed (Moelleken, 2009). Some bleeding will occur after escharotomy. Packing the wound and applying pressure usually relieves this.

Débridement. **Débridement** is the removal of necrotic tissue from a burned area. Débridement reduces the possibility of infection, because it reduces the amount of dead tissue

TABLE 52.8 ✻ Comparing Open and Closed Burn Therapy

Method	Description	Advantages	Disadvantages
Open	Burn is exposed to air; used for superficial burns or body parts that are prone to infection, such as perineum	Allows frequent inspection of site; allows child to follow healing process	Requires strict isolation to prevent infection; area may scrape and bleed easily and impede healing
Closed	Burn is covered with non-adherent gauze; used for moderate and severe burns	Provides better protection from injury; is easier to turn and position child; allows child more freedom to play	Requires dressing changes that are painful; possibility of infection may increase because of dark, moist environment

present on which microorganisms could thrive. Children usually have 20 minutes of hydrotherapy before débridement to soften and loosen eschar, which then can be gently removed with forceps and scissors. Débridement is painful, and some bleeding occurs with it. Premedicate the child with a prescribed analgesic, and help the child use a distraction technique during the procedure to reduce the level of pain. Transcutaneous electrical nerve stimulation (TENS) therapy or patient-controlled analgesia may also be helpful. Praise any degree of cooperation. Plan an enjoyable activity afterward to aid in pain relief and also to help re-establish some sense of control over the situation.

Children need to have a "helping" person with them, to hold their hand, to stroke their head, and to offer some verbal comfort during débridement: "It's all right to cry; we know that hurts. We don't like to do this, but it's one of the things that makes burns heal" (Fig. 52.12). Nursing personnel need a great deal of talk time to voice their feelings about assisting with or doing débridement procedures. Be careful when serving as the "helping" person that you do not project yourself as the healer and comforter and a fellow nurse as the hurter or "bad guy." It helps if people alternate this chore so that, on alternate days, each serves as the protector or the comforter.

If eschar tissue is débrided in this manner day after day, granulation tissue forms underneath. When a full bed of granulation tissue is present (about 2 weeks after the injury), the area is ready for skin grafting. In some burn centers, this waiting period is avoided by immediate surgical excision of eschar and placement of skin grafts. Another trend in débridement is the use of collagenase (Santyl), an enzyme that dissolves devitalized tissue.

Grafting. **Homografting** (also called **allografting)** is the placement of skin (sterilized and frozen) from cadavers or a donor on the cleaned burn site. These grafts do not grow but provide a protective covering for the area. In small children, **heterografts** (also called *xenografts*) from other sources, such as porcine (pig) skin, may be used. **Autografting** is a process in which a layer of skin of both epidermis and a part of the dermis (called a *split-thickness graft*) is removed from a distal, unburned portion of the child's body and placed at the prepared burn site, where it will grow and replace the burned skin (Robinson, 2008). Cultured epithelium is derived from a full-thickness skin biopsy. This can be grown into a coherent sheet and supply an unlimited source for autografts. Larger areas may require mesh grafts (a strip of partial-thickness skin that is slit at intervals so that it can be stretched to cover a larger area; Fig. 52.13). The advantage of grafting is that it reduces fluid and electrolyte loss, pain, and the chance of infection.

After the grafting procedure, the area is covered by a bulky dressing. So that the growth of the newly adhering cells will not be disrupted, this should not be removed or changed. The donor site on the child's body (often the anterior thigh or buttocks) is also covered by a gauze dressing. Both donor and graft dressings should be observed for fluid drainage and odor. Observe the child to determine whether there is pain at either site, which might indicate infection. Monitor the child's temperature every 4 hours. A rise in systemic temperature may be the first indication that there is infection at the graft or donor site. Autograft sites can be reused every 7 to 10 days, so any one site can provide a great deal of skin for grafting.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Social isolation related to infection control precautions necessary to control spread of microorganisms

Outcome Evaluation: Child states that he understands the reason for infection control precautions; child accepts it as a necessary part of therapy.

Infection control measures involved in the care of children with major burns consist of more than just placing the child in a private room. Aseptic technique and appropriate barriers are necessary to reduce the risk of exposing the child to infection. In some agencies, all the people who come into the room must wear gowns, masks, caps, and sterile gloves. The child is doubly isolated—by distance and by never being touched directly.

It is easy for children with burns (who were told measures such as not to play with matches or go too close to the fireplace) to interpret confinement in a room as punishment. Make every effort to make the child's environment as warm and comforting as possible, despite infection control procedures. Place children's beds so they can see as much unit activity as possible. Decorate walls in front of them with cards they receive or with a changing gallery of pictures drawn by staff members of things in which the child appears interested.

Provide time for children to discuss their feelings about being kept in a room by themselves. A question such as, "It's hard to understand a lot of things about a hospital; do you understand why your bed is in this special room?" gives children a chance to express their feelings.

Show parents how to put on gowns, gloves, and masks (depending on agency policy), so they can participate in the child's care as much as possible. Parents often do not ask to do these things spontaneously when their children are severely burned. They are in a state of grief, so they do not react in a normal manner. They may believe the bulky dressings will make it impossible for them to hold the child. Actually, the closed bulky dressings on the burned area make it *possible* for the child to be held. If it is not possible for the child to be held, help the parents to see that stroking their child's face or touching a hand (even with gloves in place) gives the child a feeling of still being loved.

Nursing Diagnosis: Interrupted family processes related to the effects of severe burns in family member

Outcome Evaluation: Family members state that they are able to cope effectively with the degree of stress to which they are subjected; family demonstrates positive coping mechanisms.

Children with severe burns always have a difficult hospitalization because of the pain, restrictions, and (at some point) awareness of the disfigurement that accompanies major burns.

Some parents grieve so deeply over the child's condition or are so concerned with other upsetting factors in their lives (many burns happen because of situational crises in the family) that their interaction with the child seems to falter or proves very difficult for them. They may avoid visiting because the sound of the child's crying when they leave is more than they can endure. At the same time, they may have lost their home and possessions to fire. They may need help in establishing priorities. It may be important that they wait at home one morning for an insurance inspector to make an estimate on damage to their house or furniture caused by the fire. Other tasks, such as shopping or house cleaning, could possibly be done by relatives or neighbors, leaving them time to visit their child.

Nursing Diagnosis: Deficient diversional activity related to restricted mobility after severe burn

Outcome Evaluation: Child expresses interest in obtaining school homework; child communicates with friends and relatives by way of telephone, letters, or e-mail.

Remember that, even if a child's chest, abdomen, and hands are burned, he does not stop thinking so children who are burned need stimulation in their environment. A television set is good for passing time but should not be the child's main communication with the outside world. Listening to favorite tapes, having stories read to them, talking about what is going on at home or what they normally do at school, and doing schoolwork are also important.

It is important to make toys and play materials available. Make certain to visit the child just to talk to him or come to play a game at times other than procedure or treatment times. The child may be hospitalized for a long time. He needs to view the nursing staff as friends and caregivers. Frequent visits convey that he is not alone and that others are aware of important needs.

Nursing Diagnosis: Disturbed body image related to changes in physical appearance with burn injury

Outcome Evaluation: Child expresses fears about physical appearance; demonstrates desire to resume age-appropriate activities.

Children with burns are often forced to become extremely dependent on the nursing staff because of the position in which they must lie and because the bulky dressings that cover their arms or hands prevent them from feeding themselves. They respond to this forced dependence at first with gratitude. They are hurt, and someone is taking care of them. After a period, however, their response may become less healthy. The young school-age child or preschooler may revert to bedwetting or baby talk. Older children respond by becoming openly aggressive to counteract their feelings of helplessness. They attempt to re-establish independence in the ways that they can, often by refusing to eat or to lie in a position that is best for them. Make certain to allow independent decision-making whenever possible. Children must take their 10 o'clock medicine, for example, but they can choose the fluid they want to swallow after it. They must be fed meals because of the bulky dressings over their hands, but they can decide which food they will eat first. They must have their dressings changed, but they can choose the story you will read them afterward.

Be careful not to give choices when there really are none to give. Inappropriate questions include, "Can I change your dressing now?" "Do you want dinner now?" "Will you swallow this pill?"

Immediately after a severe burn, children (if they are old enough to understand), parents, and probably the hospital staff are most concerned with whether the child will live. After body systems have stabilized and it seems appropriate to reassure the parents that their child will live, thoughts turn to the child's cosmetic appearance. At first, it is easy for children and parents to ignore this problem, because the burned areas are covered by dressings. Even when the dressings are removed for débridement or whirlpool therapy, it is easy for children to assume that the appearance of the burned area is only temporary and that the area will eventually heal and have a good appearance. They have probably never seen anyone with a scar from a second- or third-degree burn and have no reason to worry about it (Fig. 52.14).

When children see others on the unit with burn scars, they begin to realize what healing will look like. Depending on the extent and the site of the burn, parents and children have varying degrees of difficulty accepting this reality. It can cause them to lose confidence in health care personnel.

Parents and children need time to talk about their feelings. A girl may be extremely concerned if her chest is burned because she is worried that breast tissue will not develop, a very real concern, depending on the extent of the burn (Foley et al., 2008). Her parents may be most concerned because they can see that, although a blouse can cover her chest, her right hand will not have full function. Do not assume that your biggest concern is the same as the child's or the parents' biggest concern. A father who dreamed that his son would be a great track star may be most concerned about a leg scar; the child may be most concerned about a facial burn.

Children watch you as you care for them to see if you find them unattractive. As dressings are removed, children may expose parts of their body seemingly inappropriately, to see if you are shocked or revolted by them. It is easy to think that you will not react this way, but, for everyone, the first sight of a severe burn is a shock and it is difficult not to react accordingly. Imagining how children feel, realizing that this mutilated skin is their skin, helps health care providers maintain a professional attitude.

Returning to school can be difficult for children who have been hospitalized or have been receiving home care for a long time. Their old friends have new friends, so they may feel cut out of school activities. They look different if they have burn scars. The appearance of scar formation can be improved by the application of pressure dressings that the child wears 24 hours a day. If the child has facial burns, facing friends with a compression bandage in place or returning for laser therapy to reduce burn scarring may be difficult. They need a great deal of support from health care personnel to be able to endure this. Some children need referral for formal counseling. Some parents need formal counseling also, to help them accept their child's changed appearance.

FIGURE 52.14 Extensive scarring on the chest of a 9-year-old boy with third-degree burns. The child and his family will need much support to help them deal with his appearance. (© Dr. P. Marazzi/SPL/Science Source/Photo Researchers.)

✔ Checkpoint Question 52.3

If Jason spilled scalding hot water on his hand, which of the following would be the best emergency action?

a. Apply an ice compress to his hand.
b. Pour vegetable oil over his hand.
c. Cover his hand with a gauze dressing.
d. Apply hand lotion to keep the area moist.

Key Points for Review

- Children need total body assessment after an unintentional injury, because they may be unable to describe other injuries besides the primary one they have suffered.
- Be aware that some trauma in children occurs as a result of child abuse. Screen for this by history and physical examination.
- Use aseptic technique when caring for trauma victims, so that the child does not develop an additional unnecessary infection.
- Head injuries are always potentially serious in children. Skull fractures, subdural hematomas, epidural hematomas, concussions, and contusions can occur. Coma (unconsciousness from which a child cannot be roused) may be present after severe head trauma.

- Abdominal trauma resulting in rupture of the spleen or liver may occur in connection with multiple trauma.
- Near drowning can occur in salt or fresh water. The physiologic basis for complications after drowning differs depending on the type of water.
- Common substances children swallow that result in poisoning include acetaminophen (Tylenol), caustic substances, and hydrocarbons. Teach parents to keep the number of the local poison control center next to their telephone and always to call first before administering an antidote for poisoning.
- Lead poisoning most frequently occurs from the ingestion of paint chips in older housing units. Preventing this is a major nursing responsibility.
- Burns are classified as mild, moderate, and severe and can be divided into three types—first, second, and third degree—depending on the depth of the burn. Burns produce systemic body reactions and require long-term nursing care.

CRITICAL THINKING EXERCISES

1. Jason, a 5-year-old boy, is seen in the emergency department after an automobile accident. He is crying and upset, although the only visible signs of trauma are a reddened and edematous area on the middle of his forehead. Vital signs reveal the following: temperature, 99.4° F (37.5° C); respirations, 18 breaths per minute; pulse, 62 beats per minute; and blood pressure, 110/62 mm Hg. His left pupil is more dilated than his right; it reacts sluggishly to light. His Glasgow Coma Scale score is 10. His mother tells you, "I'm sure he's not injured badly. He was wearing his seat belt." You are the triage nurse. Would you rate Jason as a child to be seen immediately, or could he be given second priority?
2. Jason's twin sister was seen in the emergency department for acetaminophen poisoning last month. Her father tells you they normally lock all medicine away carefully. His wife left acetaminophen on the counter because she had a bad headache. Would you want to discuss the necessity of poisoning prevention with these parents, or should they have learned from this experience that their actions were not safe?
3. A 10-year-old girl has third-degree burns on her legs from lighting a fire to burn leaves. She will probably have a lengthy hospitalization and may need skin grafts to improve healing. What precautions does this child need to prevent infection until healing is complete? What areas of care would you plan to address during the hospitalization?
4. Examine the National Health Goals related to trauma and children. Most government-sponsored funds for nursing research are allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to Jason's family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to unintentional injuries in children. Confirm your answers are correct by reading the rationales.

Chapter 53

Nursing Care of a Family When a Child Has a Malignancy

KEY TERMS

- biopsy
- chemotherapeutic agent
- Ewing's sarcoma
- leukemia
- lymphoma
- metastasis
- neoplasm
- nephroblastoma
- neuroblastoma
- oncogenic virus
- osteogenic sarcoma
- rhabdomyosarcoma
- sarcoma
- tumor staging

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe normal cellular growth and theories that explain how cells alter to become malignant in children.
2. Identify National Health Goals related to the care of the child with a malignancy that nurses can help the nation achieve.
3. Use critical thinking to propose ways that nursing care for a child with a malignancy can be more family centered.
4. Assess a child with a common malignant process, such as a rhabdomyosarcoma, neuroblastoma, nephroblastoma, or leukemia.
5. Formulate nursing diagnoses related to a child with a malignancy.
6. Establish expected outcomes for a child with a malignancy.
7. Plan nursing care specific to a child with a malignancy.
8. Implement nursing care for a child receiving cancer therapy such as explaining why chemotherapy destroys malignant cells.
9. Evaluate expected outcomes for achievement and effectiveness of care.
10. Identify areas related to care of children with malignancies that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of abnormal cell growth in children with the nursing process to achieve quality maternal and child health nursing care.

Geri is a 6-year-old boy you meet at a health maintenance organization clinic. He is there for a well-child checkup. His mother tells you that Geri wakes up every morning with a headache and then vomits. Immediately after that, he is fine. The problem began just after he started a new school in the fall, so she is certain it is related to this. His teacher has suggested that Geri needs an eye examination because he cocks his head to see the chalkboard. You notice that he has lost weight. "What do I do for school phobia?" his mother asks you.

Previous chapters described the growth and development of well children and disorders associated with specific body systems. This chapter adds information about the dramatic changes, both physical and psychosocial, that occur when children develop a malignancy, a phenomenon that can present in any body system. Such information forms a base for care and health teaching.

Is Geri's mother describing school phobia? What additional questions would you want to ask her to help discover whether this is something more serious?

The terms *malignant* and *cancerous* describe cells that are growing and proliferating in a disorderly, chaotic fashion. In adults, cancer usually occurs in the form of a solid tumor. In children, the most frequent type of cancer is that of immature white blood cell overgrowth, or leukemia (Rugo, 2009).

Many parents assume that a diagnosis of cancer means that their child's life will be very limited. Because of the tremendous advances in cancer research and treatment over the past 20 years, however, the prognosis for children and the chances for a cure improve daily. Ninety-five percent of children with leukemia can expect to be cured, for example. To help parents and children adjust to this illness, however, nursing support is necessary from the time of diagnosis throughout the long-term therapy required. National Health Goals related to malignancies and children are shown in Box 53.1.

Nursing Process Overview

For Care of a Child With a Malignancy

Assessment

The symptoms of malignancy in children are often insidious and difficult to define. Headaches or pain at a particular body site can often be explained away by other factors, such as sports injuries or fatigue. Weight loss, however, is a common symptom of cancer and is never normal in healthy children. Therefore, at every health care visit, plot and analyze a child's height and weight to document evidence of this important finding. Be sure to refer children with swelling or pain of major joints to their primary health care provider for further assessment so that bone tumors will not go undetected.

Nursing Diagnosis

Selected nursing diagnoses established for the child with a malignancy address specific symptoms caused by the malignancy itself, side effects of therapy, or coping abilities of the child and family. Examples are:

- Pain related to neoplastic process in bone
- Imbalanced nutrition, less than body requirements, related to stomatitis from radiation therapy
- Risk for infection related to immunosuppressive effects of chemotherapy
- Disturbed body image related to loss of hair after radiation treatment
- Compromised family coping, related to long-term chemotherapy program

Outcome Identification and Planning

When a neoplasm (abnormal growth that does not respond to normal growth-control mechanisms) is first diagnosed in their child, parents may be able to deal only with short-term outcomes and plans. They may concentrate on learning about the effect or toxic properties of a particular chemotherapeutic drug given their child, or they may ask how long the child's surgical incision will be. Dealing with such specifics helps them to control their anxiety because it prevents them from dealing with the overall picture or prognosis—that their child has a potentially fatal illness.

The family of a child with cancer needs support beginning with the diagnosis. When planning, sit down with the parents and discuss the treatment protocol. Explain measures they will need to take to make their child more comfortable during therapy such as not forcing food if their child is nauseated, playing games or reading stories while an intravenous [IV] chemotherapy agent is administered.

Parents are usually eager for results of diagnostic tests. They may need support while waiting until all the findings have been assembled for an accurate assessment of staging and prognosis. Establishing a primary relationship with both the child and the parents is important so that, no matter how many hospitalizations are necessary, they know a support person is waiting to help them through this long-term illness. Long-term therapy can be expensive, so consider the family's financial capabilities, helping them make any necessary financial arrangements for care. The siblings of a child with cancer should be included in planning care, not only because the illness is serious but also because the treatment may last for an extended period, further stressing the family (Nolbris, Enskar, & Hellstrom, 2007).

Parents hear of many questionable cancer cures from newspapers or friends during the course of their child's illness. Help them to voice their hopes and concerns for these cures as they hear them but urge them to discuss these with their primary care provider. Open discussion helps parents keep such cures in perspective without putting any more emphasis on them than they warrant. If these questionable cures cannot be discussed with health care personnel, they

BOX 53.1 * Focus on National Health Goals

Several National Health Goals concern cancer prevention and children:

- Reduce the overall cancer death rate from a baseline of 200.8 per 100,000 to 158.6 per 100,000 of the population.
- Increase the proportion of adolescents in grades 9 through 12 who follow protective measures that may reduce the risk of skin cancer.
- Reduce the rate of melanoma cancer deaths, from a baseline of 2.6 per 100,000 to a target level of 2.3 per 100,000 of the population (http://www.nih.gov).

Nurses can help the nation achieve these goals by careful history taking at health assessments to reveal the symptoms of cancer, which are often subtle in children, and by active teaching of self-screening measures, such as testicular examination and preventive measures such as avoiding excessive sun exposure.

Areas that could benefit from additional nursing research are effective ways to teach young clients about the dangers of tanning booths and excessive sun exposure; reasons adolescents give for avoiding self-examination; and reasons parents give for delaying health care consultation after discovering an abnormal growth, unexplainable bruising, or weight loss.

appear to grow in importance, and parents may turn to them in preference to established therapy.

Parents can be expected to experience grief if they learn their child's prognosis is poor and move slowly through stages of denial, anger, bargaining, depression, and acceptance. During planning, be certain to take into account their current stage of grief (see Chapter 56).

Organizations that may be helpful in supplying information to parents are American Cancer Society (http://www.cancer.org), National Cancer Institute (http://www.cancer.gov), Children's Oncology Group (http://www.childrensoncologygroup.org), Candlelighters Childhood Cancer Foundation (http://www.candlelighters.org), and The Leukemia and Lymphoma Society (http://www.leukemia-lymphoma.org).

Implementation

Nursing interventions for a child with cancer include supporting the child and parents from the time of diagnosis through procedures such as surgery, radiation therapy, chemotherapy, and continued health supervision. This is a stressful and long-term process, because chemotherapy may be continued for 2 to 3 years after diagnosis. Increasingly, cancer treatment is offered on an ambulatory basis to keep hospitalization to a minimum, so many interventions include teaching the parents how to give care or monitor for recurring signs while at home.

Keep in mind that the stress of long-term treatment may put the child and family at risk for developmental or family coping problems. You can be a positive force in encouraging healthy adaptation to the demands of the child's illness and in reassessing the situation periodically during therapy to be certain the child is receiving appropriate stimulation for developmental growth. Providing comfort and alleviating pain are often primary concerns in oncology nursing. Measures for pain relief are discussed in Chapter 39.

Outcome Evaluation

Because cancer therapy includes long-term care, children need to be evaluated periodically to be certain that outcomes are being met and are still current. Some examples indicating outcome achievement are:

- Child keeps all appointments for chemotherapy treatments.
- Child maintains passing grades in school despite interruptions for therapy.
- Parents state that they can keep anxiety at an acceptable level between clinic appointments.

Children with cancer need the same well-child maintenance care that all children do, with one exception. While they are undergoing chemotherapy, which causes a decreased immune response, they should not receive live-virus vaccines.

Returning for health care follow-up visits causes anxiety. The child seems well, but parents may be apprehensive while the health care practitioner palpates the child's abdomen or blood specimens are obtained. Some parents may find the strain of returning for follow-up visits too great and miss appointments (not to know seems better than to be told bad news). Such parents need help in understanding that initial remissions can be maintained, and second remissions can be achieved, so maintenance therapy must be continued. Because a child with a tumor such as retinoblastoma and children who receive chemotherapy or radiation are more prone than others to develop a second cancer later in life, follow-up is an essential detection measure (Oberfield, 2007). The development of cardiovascular conditions in cancer survivors is also a risk (Shankar et al., 2008).

Most children with cancer, even if no cure is possible, will be cared for at home rather than being hospitalized. Their parents may need extensive preparation for home care (see Chapter 4). Help them to maintain close contact with health care personnel to prevent feeling abandoned. If the child dies, the parents may feel a need to return to their primary caregiver for support. This provides an opportunity to evaluate their adjustment to the child's death and offer support if needed. Being with a child who dies at home appears to make death a more understandable phenomenon for siblings and, in many instances, can be advocated. Care in a separate hospice setting is another option for the child in whom a remission cannot be achieved (see Chapter 56).

HEALTH PROMOTION AND RISK MANAGEMENT

Because childhood cancers do not seem to arise from environmental contaminants as much as adult cancers do, methods to reduce the risk are not as well defined. Urging parents to reduce children's exposure to secondary cigarette smoke and urging adolescents not to begin smoking (including the use of bidis or flavored tobacco products) can help reduce the incidence of lung cancer when they reach adulthood. Applying sunscreen and reducing the overall time of sun exposure for children can help reduce the development of skin cancer in later life. Children who receive chemotherapy or radiation for one cancer have a higher incidence of developing another cancer later in life. Therefore, urging these children to continue health appointments so that any additional tumor development can be discovered is another important preventive measure. Reminding parents to obtain the vaccine against human papillomavirus (HPV), which leads to cervical cancer, is an important preventive measure for adolescent girls.

Parents of a child with cancer may seek health maintenance care or evaluation for their other children more often than other parents would. This is because they are worried that what seems just a minor symptom is actually a sign of cancer in that child, also. They may need greater amounts of reassurance that their other children are well.

NEOPLASIA

All body tissue undergoes whatever type of growth is necessary to develop into that specific type of tissue. Normally, the body is able to maintain the proliferation necessary to replace old cells that die plus producing new cells for physical growth needs. Cancerous, or malignant, tissue, however, is unable to maintain this balance and begins to proliferate in disorderly, chaotic ways.

People in various cultures have differing beliefs regarding what causes cancer, ranging from evil spirits or evil past lives to totally environmental or psychological causes. Talking with the parents and the child, if old enough, about what they think is the cause of cancer can add understanding to parents' actions; it can make explanations of therapy more meaningful to parents, because explanations can be geared to fit within their beliefs.

The word **neoplasm** means "new growth"; it usually refers to a new *abnormal* growth that does not respond to normal growth-control mechanisms. Whether this process is one that produces a solid tumor or one that involves blood-forming elements, growth begins insidiously. The process may have been ongoing for some time before the parents or child realize that it is present. Even after they are aware that a change exists, some time may pass before they realize that it is serious enough to require health care, particularly if it is not well defined.

Although cancer in children is rare, it is the leading cause of death from disease among children younger than 15 years of age. Approximately 8000 new cases of cancer occur in children in the United States each year, and approximately 1700 deaths occur annually from this cause. Fortunately, the overall survival rate for children with cancer today has improved dramatically (National Cancer Institute, 2008). Knowing the processes involved in cell growth—both normal and abnormal—is essential to help parents understand what is happening to their child and why specific treatment measures are necessary at various stages of cell growth.

Cell Growth

The normal cell cycle consists of two main divisions: an interphase (resting) phase and a mitosis (dividing) phase. The interphase has four separate stages: G0, G1, S, and G2. Activity during these periods is summarized in Table 53.1. The time span of a cell's life cycle varies based on the type of tissue involved. A bone cell cycle is short—about 10 hours; a nerve cell cycle is long—the lifetime of the person. The rate of the cycle is slowed or increased by outside stimuli, such as hypoxia, genetic and immunologic factors, and physical and chemical agents. Normally, both resting and active cells are always present.

Body cells apparently have the ability to recognize their own type, possibly by recognizing surface enzymes or glucose particles on cell membranes. Normally, cells of like type do not migrate away from each other because they recognize and adhere to each other to form a solid mass. In neoplastic cells, the ability to keep together appears to be defective (they are autonomous). This may be related to decreased calcium in the cell membrane or to an increased negative charge that repels other cells rather than bonding them together.

Normally, like cells appear to be able to recognize when they are being crowded for the space they must occupy, and they apparently communicate with one another to halt growth when they touch or become crowded. Neoplastic cells do not respond to this communication or cannot receive it, so, despite how crowded they are, they continue to grow. By the time a tumor mass is detected by palpation, it is probably about 30 times the size of its original aberrant cell. In many instances, it may be necessary to kill as many as a billion cells to destroy the entire mass (Huether & McCance, 2007).

TABLE 53.1 ✻ Phases of the Cell Cycle

Phase	Activity
G	Gap, or the phase between mitosis and synthesis.
G0	Cell at rest. Cells remain in this state until some stimulant, such as death of surrounding cells, triggers the cell to enter an active phase; it is difficult to destroy cells in this resting state.
G1	Period until DNA stabilization is complete; it remains difficult to destroy cells in this phase.
S (synthesis)	Period (6–8 hours) during which DNA and chromosomes are duplicated or a cell readies itself for division into two daughter cells.
G2	Cell doubling in size as preparation for dividing into two daughter cells; if protein synthesis can be stopped at this point so that the cell cannot reach a "critical mass," mitosis (cell division) cannot take place.
M (mitosis)	Period of cell division into two like daughter cells.

Neoplastic Growth

Neoplasms can be either *benign* (growth is limited) or *malignant* (cancerous). Even when a tumor is benign, however, it may not be completely harmless. It can cause damage by pressing on adjacent tissue. For example, brain tumors in children are often benign, but they can cause extensive respiratory depression from increased pressure on the respiratory center.

Causes of Neoplastic Growth

The exact origin of neoplastic growth is unknown, and any growth may actually involve more than one cause. As more and more research is accomplished on the nature of genes, specific markers in tumors that fail to suppress, or stimulate, cancer-causing genes are being identified (Partap & Fisher, 2007). In adults, tumors may grow because normal cell growth has been altered by environmental irritation, such as chronic exposure to chemical irritants or cigarette smoke. Tumors of the skin, bladder, lung, and intestines involve organs exposed to such outside influences and irritation. In children, tumors most frequently occur in organs unexposed to the environment such as leukemia of the bloodstream, nephroblastoma of the kidney, brain tumors, or neuroblastoma in the abdomen. Because many tumors occur in children younger than 5 years of age, exposure to environmental carcinogens is limited, so this cause of tumors is probably not a great influence in childhood cancer. Exposure to harmful substances in utero may be a cause (Rugo, 2009). Two substances that lead to lung cancer and to which children may be exposed are secondary smoke and asbestos. Asbestos is a particular problem if a child's school or home is insulated

with this material or a parent works in asbestos removal and brings home particles on clothing.

A child who has survived one cancer appears to be at higher than normal risk for the development of a second cancer such as bone cancer (Kalra et al., 2007). Radiation exposure used to treat the first malignancy may be responsible for this. In addition, there may be a predisposition to cancer in some families (Kurt et al., 2008).

Another common theory of why neoplasms grow is the cell mutation theory. This suggests that carcinogenic agents and hereditary susceptibility combine to alter the nature of cells, leading to abnormal growth. A first stage of initiation may mark the cells for abnormal growth. A second stage of promotion actually begins the abnormal growth. Carcinogenic agents can be living (viral), physical (radiation), or chemical. Radiation during intrauterine life is a documented cause of leukemia. Radiation of the thyroid in infancy can cause thyroid cancer later in life. Use of androgenic steroids may lead to hepatocellular cancer.

This theory explains why the growth of neoplastic cells is irreversible (the cells cannot return to a normal state because they are intrinsically changed) and why neoplasms occur in some people but not in others (both an intrinsic and an extrinsic factor, or an inherited tendency and an environmental insult, must be present). It is difficult to document this process because it stipulates that two separate steps are necessary for a cell to become cancerous. If there is a lengthy time span between these steps, the cause-and-effect relationship is difficult to trace (Huether & McCance, 2007).

Yet another theory is that oncogenic (cancer-causing) viruses are responsible for tumor growth. According to the viral theory, **oncogenic viruses** have the ability to change the structure of DNA or RNA in cells. C-type RNA viruses may be implicated in leukemia. Epstein-Barr virus, a DNA virus, may be associated with Burkitt's lymphoma. This theory is supported by the fact that an immunodeficient state increases the risk for development of a neoplastic growth. When both viral surveillance and removal of abnormal cells are lost, virus invasion and abnormal cell growth is free to begin. Still another theory is that tumor suppressor cells exist in some individuals and not in others. Retinoblastoma is an example of a cancer that may occur when such cells are not present.

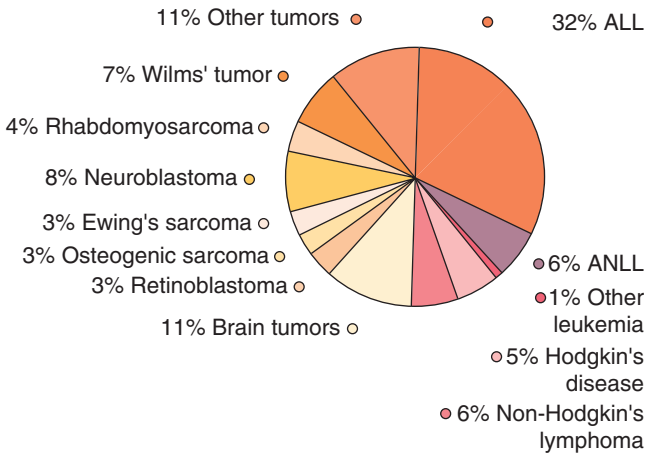

FIGURE 53.1 Approximate incidence of common childhood cancers.

ASSESSING CHILDREN WITH CANCER

The incidence of various types of childhood cancers is shown in Figure 53.1. Because these cancers involve different body systems, signs and symptoms can vary greatly (Box 53.2).

History

Many cancers in children have been developing for some time before a child is brought for care because the symptoms (bruising, nosebleeds, headache, pain in a knee, constipation) are not perceived as important by the parents. Thorough history taking at health care visits can help reveal these symptoms, so that a child can be further evaluated and a cancer discovered early in its growth. As malignant tumors grow, they tend to cause systemic effects in the child. Cachexia (loss of weight, anorexia) occurs if the tumor is growing so rapidly that it takes nutrients from normal cells. Excessive hormone production (overproduction of antidiuretic, thyroid, or adrenocorticotropic hormone) may occur because of tumor growth in a specific body area that leads to systemic symptoms. Although the warning signs of cancer listed by the American Cancer

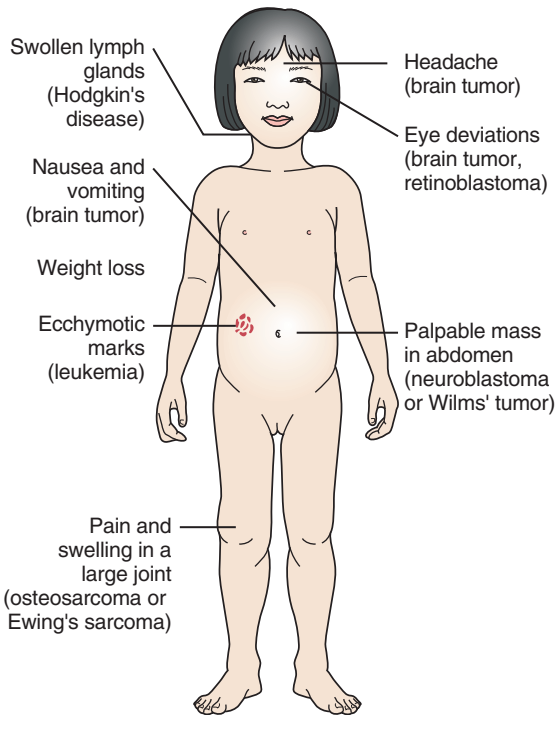
Box 53.2 Assessment

Assessing a Child for Signs of Cancer

History

Chief concern: Weight loss, loss of appetite, easy bruising, swelling in a body part, headache, eye deviations.
Past medical history: Family member with a history of cancer.

Physical examination



BOX 53.3 ✻ Warning Symptoms and Signs of Malignancy

General Symptoms

1. Unexplained weight loss
2. Fever
3. Fatigue
4. Pain
5. Skin changes (itching, darkening, reddening, hairiness)

General Signs

1. A change in bowel or bladder habits
2. A nonhealing sore
3. Unusual bleeding or discharge
4. A thickening or lump in the breast or other body part
5. Indigestion or difficulty swallowing
6. An obvious change in a wart or mole
7. A nagging cough or persistent hoarseness

The American Cancer Society. (2008). *Seven signs of cancer.* Atlanta: Author.

Society (Box 53.3) apply primarily to cancers in adults, they should also be kept in mind as general guidelines when assessing children.

Physical and Laboratory Examination

Any suspicion of a malignancy requires a thorough physical examination. Assessing height and weight of children is an important component. To confirm a diagnosis, several diagnostic procedures may be used, including radiography, ultrasound, magnetic resonance imaging (MRI), blood analysis, and biopsy.

Biopsy

A **biopsy** is the surgical removal of tissue cells for laboratory analysis. Most children with a possible diagnosis of cancer will have a biopsy performed to confirm their initial diagnosis (Minigh, 2007). Although biopsies are classified as minor surgery and usually are done on an ambulatory basis, do not treat them lightly. They carry a definite surgical risk if conscious sedation or general anesthesia is used. Moreover, they are an anxiety-producing procedure for the parents and the child. Up to this point, parents can convince themselves that their child has something innocent. A biopsy clouds this hope, because the word "biopsy" implies that cancer is at least a possibility. For this reason, parents and children need thorough preparation for the biopsy procedure and the care the child will need after the procedure. Anxious parents do not "hear" well and may need to have postoperative instructions repeated. Bone marrow aspiration is a frequent type of biopsy used with children. Although this can be done with only local anesthesia, it is equally frightening (see Chapter 44).

Staging

Tumor staging is a procedure by which a malignant tumor's extent and progress are documented. Knowing the stage of a tumor helps the health care team design an effective treatment program, establish an accurate prognosis, and evaluate the progress or regression of the disease. In general, stage I refers to a tumor that can be completely removed surgically. Stage II refers to a tumor that cannot be completely removed surgically. Stages III and IV designate tumors that have extended beyond the original site or have spread systemically **(metastasis)**. There are various staging systems, but one of the most common is known as the TNM system; it describes the tumor's size (T), its presence in the lymph nodes (N), and its metastasis (M) or spread to other organs, if any. A TNM system is most applicable to carcinomas (tumors of the epithelial tissue). Because most childhood tumors are sarcomas (tumors derived from connective tissue), the system is not as useful for childhood cancers as it is for adult cancers.

OVERVIEW OF CANCER TREATMENT MEASURES USED WITH CHILDREN

Therapy for a child with cancer focuses on devising ways to kill the growth of the abnormal cells while protecting normal surrounding cells. This is done by a combination of surgery, radiation, chemotherapy, bone marrow transplantation, immunotherapy (biologic response modifiers), and general health measures.

Radiation Therapy

Radiation therapy changes the DNA component of a cell nucleus to a point at which the cell cannot replicate DNA material and thereby inhibits further cell division and growth. Radiation is not effective on cells that have a low oxygen content (a proportion of cells in every tumor mass), nor is it effective at the time of cell division (mitosis). Therefore, radiation schedules are designed so that therapy occurs over a period of 1 to 6 weeks. In this way, cells that are not in a susceptible stage on one day will be in a susceptible stage on another. Tumors that require such a massive dose of radiation that normal tissue through which the radiation must pass to penetrate the tumor would also be destroyed in the process are said to be radioresistant.

Immediate Side Effects

Radiation has both systemic and localized effects. Radiation sickness (anorexia, nausea, vomiting) is the most frequently encountered systemic effect. This occurs if the gastrointestinal (GI) tract is irradiated. It also can occur to a lesser degree as a result of the release of toxic substances from destroyed tumor cells. A child may need to receive an antiemetic before each procedure to counter nausea and vomiting. Extreme fatigue is also common. Skin reactions, such as erythema and tenderness, are typical local effects.

Long-Term Side Effects

The long-term side effects of radiation are becoming more apparent as increasing numbers of children who have undergone intense radiation therapy survive. Because radiation

damages all cells in its path to some extent, any body tissue can be affected by radiation therapy.

Effects on Bone. Asymmetric growth of bones, easy fracturing, scoliosis, kyphosis, or spinal shortening can occur. Bones are most vulnerable during times of rapid growth, such as during the first year of life or during a prepubertal growth spurt. Scoliosis and kyphosis can be avoided if an entire vertebra is irradiated rather than only one side or the other; this means that a larger area of bone may be irradiated than formerly, so that both sides of the vertebra are in the radiation path.

Effects on Hormones. Radiation to the head and neck can result in long-term thyroid, hypothalamic, and pituitary gland dysfunction. This may result in growth hormone deficiency or hypothalamic-pituitary stimulation to the thyroid gland. Children's growth and thyroid function should be evaluated every 6 months for the next 3 years to detect these changes. Both hypothyroidism and hypopituitary growth failure can be treated with hormone replacement in coming years. Radiation to ovaries or testes can result in infertility. In girls, normal estrogen production may lag or fail, preventing the development of secondary sexual changes. In boys, testosterone production rarely fails. However, pretreatment sperm banking may be advocated for a boy past puberty before he undergoes radiation to the testes.

Effects on the Nervous System. Long-term effects of radiation to the nervous system are demyelination and necrosis of the white matter of the brain. This can result in symptoms of lethargy, sleepiness, and seizures. Effects on the gray matter can result in learning disabilities. There may be abnormal electroencephalograph tracings; a child may have low-intensity headaches, cataracts, salivary gland damage, and a chronic change in or loss of taste.

Effects on the Organs of the Chest and Abdomen. Radiation to the lungs may result in a chronic pneumonitis and pulmonary fibrosis or thickening. Heart effects may include pericardial thickening and reduced heart expandability. Radiation to the GI system can result in chronic malabsorption from changes in intestinal villi. Hepatic fibrosis can result in reduced liver function. Radiation to the kidney and bladder can result in nephritis and chronic cystitis.

The possibility of these long-term effects of radiation should be explained to parents when radiation is initially discussed, as a part of obtaining informed consent. At the early stage of diagnosis, however, parents rarely are concerned with these long-term effects. Their thoughts are understandably filled with such short-term outcomes as the achievement of a remission or destruction of the tumor.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Parental and child anxiety related to radiation procedure

Outcome Evaluation: Parents state that they understand necessity of therapy and can help support child during therapy.

Before Treatment. The points where radiation therapy will be directed are marked on the child's skin, usually in indelible ink. As a rule, no cream or lotion should be applied to radiation areas until the treatment series is complete. If a cream contains any metal, it could distort or interfere with the entrance of radiation. If the head will be irradiated, a dental consultation may be suggested. This is because radiation therapy can slow healing if a tooth extraction is necessary.

During Treatment. Most children have previously had x-ray films taken by the time that radiation therapy is begun, so they are not frightened by the procedure. However, because the procedure requires them to lie still for a period of time, possibly on an uncomfortable table in a room away from personnel or their parents, they may experience extreme fear. Reassure the parents and the child that during the treatment, just as there is no sensation from x-ray exposure, the child will experience no sensation from radiation exposure. Infants are usually prescribed a sedative or conscious sedation before therapy to ensure that they lie still during the procedure. To make this approach effective, keep the child fairly active early in the day and introduce calming activities after the sedative is administered. The child will be sleepy and may fall asleep during irradiation. An older child may want to plan an activity to think about during irradiation, such as selecting 10 people to take on a camping trip (and why), or choosing 10 places to visit next year—mental activities that require no movement.

After Treatment. If the head area is involved in therapy, alopecia (hair loss) will result. Moreover, radiation to the head may reduce salivary gland function, leading to a constantly dry mouth. Tooth growth may be halted because of root atrophy. Radiation to bone marrow may depress the production of white blood cells (WBCs) and platelets. Children undergoing radiation therapy need their leukocyte and platelet counts monitored periodically for changes. Teaching points for parents to maintain skin integrity are summarized in Box 53.4.

Chemotherapy

A **chemotherapeutic agent** is one that is capable of destroying malignant cells. In most instances, several chemotherapeutic agents are used to cause multiple damage to cells and thereby increase the chance that cells will no longer be able to reproduce. Like radiation, chemotherapy is scheduled over a period of time so that all cells can eventually be destroyed or cells that are not susceptible on one day because they are undergoing mitosis will be susceptible on the next day.

Types of Chemotherapeutic Agents

Several categories of chemotherapeutic agents are available. Typically, all agents that need mixing are prepared under a specialized hood in the pharmacy to prevent airborne drug residue. When administering such agents, wear gloves and wash your hands well afterward to prevent skin exposure and absorption of the drug.

Alkylating Agents. Alkylating agents interfere with DNA synthesis. They are cell-cycle specific or are most effective

BOX 53.4 * Focus on Family Teaching

Caring for the Child Receiving Radiation Therapy

Q. Geri's mother asks you, "What sorts of things do we need to do when Geri begins receiving radiation therapy?"

A. In addition to preventing infection, you need to take some special actions to meet your child's needs. Here are some tips designed to promote radiation's therapeutic benefits and minimize its adverse effects:

Skin Care

- Expose irradiated area to air but not to direct heat or sunlight.
- Avoid lengthy soaks in bath water or swimming pools.
- If the head is irradiated, use mild shampoo on hair and rinse gently with water. Air dry or pat excess moisture gently. Avoid rough towels and hair dryers.
- Supply a soft toothbrush to protect gums and oral mucous membranes. Keep the mouth moist by offering frequent sips of water—particularly if radiation decreases salivary gland secretions.
- Encourage clothing that fits loosely over irradiated areas.
- Because some skin preparations are drying and some interfere with radiation, do not apply creams or lotions unless prescribed.

Nutrition

- To promote retention of nutrients, administer antiemetics as prescribed.
- Encourage high-calorie meals when child is least likely to be nauseated. Praise the child's efforts to eat. Strive for peaceful and pleasant meal and snack times.
- Provide foods identified by child as special favorites. Serve easy-to-swallow foods at tolerable temperatures.

Hydration

- Reduce amounts of fresh fruit and veggies rich in cellulose, and eliminate apple juice from the child's diet, because these may contribute to diarrhea and subsequent fluid loss.
- If diarrhea occurs, administer antidiarrheal medication as prescribed.

Activity

- Provide adequate rest periods. Schedule activities to avoid waking the child frequently at night.
- Structure the child's activities to be stimulating but not physically tiring.
- Recommend mild activity that does not stress bones that may be weakened by radiation and, therefore, easily fractured.

Instruction and Distraction

- Prepare the child for the effects of radiation therapy, particularly hair loss. Some comfort measures may include wearing a wig or special cap; introducing play things, such as dolls without hair; and stressing that people like people for themselves, not for their appearance.
- Schedule a tour of the radiation department. As possible, let the child play-act and become familiar with the equipment. Provide ample time to answer questions.
- Encourage active games before the procedure and quiet games afterward.
- Help the child devise "mind games" to play during the procedure such as listing 10 friends to take camping, 10 activities to do, or 10 favorite games to play.

against cells in the G1 and S phases of growth. Alkylating agents commonly used with children are cyclophosphamide (Cytoxan) and chlorambucil (Leukeran).

Antimetabolites. Antimetabolites are drugs that so closely resemble natural products that a cell readily incorporates them into its structure. Because they are not the natural product, however, the cell cannot function or replicate with them in its structure and will die. They act only in the S (synthesis) phase of the cell cycle. Methotrexate (Folex PFS), a folic acid antagonist, is an example.

Plant Alkaloids. Plant alkaloids interfere with cell mitosis (M phase). Two commonly used plant alkaloids are vincristine (Oncovin) and vinblastine (Velban).

Antibiotics. Several antibiotics are effective in destroying malignant cells by impairing DNA synthesis. These are not cell-cycle specific, which means that they can be effective at any cell phase (resting or dividing). Dactinomycin (Cosmegen) and doxorubicin (Adriamycin) are examples.

Nitrosoureas. Nitrosoureas disrupt protein synthesis, thereby interfering with DNA synthesis. Because these drugs cross the blood–brain barrier, they are effective as chemotherapy agents in brain tumor therapy. A common example is carmustine (BCNU).

Enzymes. Body cells need a ready supply of L-asparagine (an essential amino acid) to grow. L-Asparaginase (El-spar), a chemotherapeutic agent, is an enzyme that converts

L-asparagine into L-aspartic acid, thereby making L-asparagine unavailable for cell growth.

Steroids. A corticosteroid, most frequently prednisone, binds to DNA to inhibit mitosis and probably RNA synthesis in cells. When it is added to therapy, the formation of new cells is prevented.

Immunotherapy. Immunotherapy is the stimulation of the body's immune system to attempt destruction of foreign or malignant cells. The administration of bacille Calmette-Guérin vaccine (the vaccine for tuberculosis) is an example of this type of therapy. The tuberculin antigen stimulates the immune system to identify and destroy an antigen, with the hope that the system will "recognize" foreign tumor cells and act against them as well. Interferon is an antiviral agent that prevents growth of viruses; stimulation of interferon or interferon therapy may be used to encourage the immune system to identify and halt malignant cell growth.

Immune therapy of these types is limited, however, if the immune system has been so altered by the malignant process that it cannot respond when stimulated. It is also possible that the immune response to malignant cells is so different from the response to invading microorganisms that specific types of immunotherapy are necessary to stimulate it. Neuroblastoma is an example of a childhood cancer that appears to respond to antibody-based therapy (Maloney et al., 2007).

Chemotherapy Protocols

Chemotherapy is scheduled for children at set times and days and by various predetermined routes. At first, children may remain in the hospital for a few days of treatment; later, they may report on a specific day for therapy, or parents may administer the designated therapy at home. Parents must learn about the child's treatment protocol so that they know which drug the child will be receiving each day and on which day each drug must be administered. Knowing the protocol and the specific drug therapy helps parents begin to prepare the child for it, such as increasing fiber in the child's diet for a few days before the beginning of a constipation-causing drug like vincristine. An example of such a protocol is shown in Table 53.2. Chemotherapy for acute lymphocytic leukemia (ALL), the most common cancer in children, is given first in a remission phase, next in a sanctuary or prophylactic phase, then in a delayed intensification phase, and finally in a maintenance phase for up to 3 years (Eapen et al., 2008).

While children are receiving chemotherapy, parents should not give them aspirin. In addition to increasing the child's susceptibility to Reye's syndrome, aspirin may interfere with blood coagulation, a problem that is already present because of lowered thrombocyte levels. Instead, they should use acetaminophen (Tylenol) or ibuprofen (Motrin) to relieve a headache or to reduce fever. A parent who wants to give a child vitamins should be certain that the vitamin preparation will not interfere with a chemotherapeutic agent. For example, administration of a vitamin that contains folic acid could interfere with the effectiveness of methotrexate, a folic acid antagonist.

Live-virus vaccines should not be given. The child's immune mechanism is so deficient that these vaccines could cause widespread viral disease. The child is particularly susceptible to infections and should be kept away from people with known infections. Zoster immune globulin will be needed if the child has not been immunized against varicella and is exposed to chickenpox during chemotherapy.

Side Effects and Toxic Reactions

All chemotherapeutic agents have side effects and toxic effects. Table 53.3 lists commonly used chemotherapeutic agents, their specific side effects, and their potential toxic effects. Malnutrition, nausea and vomiting, hair loss, stomatitis, constipation, diarrhea, cushingoid effects, and susceptibility to infection are side effects common to almost all of these agents. Nursing diagnoses and related interventions associated with these side effects are described in the following paragraphs.

If an IV infusion of a chemotherapeutic agent that is a vesicant infiltrates into the subcutaneous tissue, there is apt to be extensive tissue sloughing and damage. Monitor IV infusions of chemotherapeutic vesicants carefully to prevent extravasation. Discontinue the infusion if it occurs. Then, apply an ice pack to the site, to cause vasoconstriction and prevent further spread of the toxic solution. Hyaluronidase is an example of a drug that may be injected into the site to speed absorption. After this, application of warm compresses hastens absorption and clearance of the solution from subcutaneous tissue.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Imbalanced nutrition, less than body requirements, related to nausea, vomiting, or anorexia resulting from chemotherapy

Outcome Evaluation: Child is able to eat frequent, small meals; calorie intake is adequate for age and size.

TABLE 53.2 Sample Protocol for Treating Acute Lymphocytic Leukemia

TABLE 53.3 ✻ Commonly Used Chemotherapeutic Agents

Drug	Classification	Side Effects and Toxic Effects	Special Considerations
Asparaginase (Elspar)	Enzyme; deprives leukemic cells of asparagine, leading to cell death	Anorexia, weight loss, nausea, vomiting, hepatotoxicity, central nervous system toxicity, anaphylactic reaction	Staying with child for first hour of infusion is important; take vital signs q15 min for first hour to detect anaphylactic reaction.
Carmustine (BCNU; BiCNU)	Nitrosourea compound; crosses blood–brain barrier	Nausea, vomiting, bone marrow depression (after 3–4 wk), hepatotoxicity	Child may notice burning sensation along vein during administration because of alcohol diluent.
Chlorambucil (Leukeran)	Nitrogen mustard derivative	Bone marrow depression	Monitoring of white blood cell count is necessary.
Cisplatin (Platinol)	Alkylating agent; reacts with and injures cell nucleus	Bone marrow depression, nephrotoxicity (renal dysfunction), nausea, vomiting, loss of taste, tinnitus, high-frequency hearing loss	Infusion bottle must be covered with aluminum foil to keep out light, or decomposition will result.
Cyclophosphamide (Cytoxan)	Alkylating agent (nitrogen mustard derivative)	Bone marrow depression, anorexia, nausea, vomiting, stomatitis, alopecia, cystitis, (hemorrhagic) hepatotoxicity	Fluid intake is encouraged; maintain IV line to limit bladder irritation; test urine for blood and specific gravity.
Cytosine arabinoside (Ara-C)	Antimetabolite (pyrimidine analog)	Nausea, vomiting, bone marrow depression, stomatitis, alopecia, photosensitivity	Child may need to wear sunglasses in bright light.
Dacarbazine (DTIC)	Alkylating agent	Bone marrow depression	Extravasation causes severe tissue damage.
Dactinomycin (Cosmegan)	Antibiotic; inhibits DNA synthesis	Nausea, vomiting, bone marrow depression, stomatitis	Tissue inflammation occurs if it extravasates into tissue.
Daunorubicin (DaunoXome)	Antibiotic; vesicant	Alopecia, bone marrow depression	Extravasation causes severe tissue damage.
Etoposide (Toposar)	Mitotic inhibitor; inhibits DNA synthesis	Fatigue, alopecia, nausea and vomiting	Slow IV administration is necessary to avoid irritation.
Doxorubicin (Adriamycin)	Antibiotic; inhibits DNA synthesis; vesicant	Nausea, vomiting, bone marrow depression, alopecia, stomatitis, possible heart toxicity	Urine may turn red; take pulse for full minute to detect arrhythmia; tissue necrosis occurs if extravasated.
Ifosfamide (Ifex)	Alkylating agent; interferes with DNA synthesis	Leukopenia, alopecia, hemorrhagic cystitis	Maintaining hydration is important to prevent cystitis.

Lomustine (CCNU; CeeNu)	Alkylating agent (nitrosourea compound)	Nausea, vomiting in 6 hr, bone marrow depression (after 3–4 wk)	Administration on an empty stomach enhances absorption.
Mercaptopurine (Purinethol)	Antimetabolite (purine analog)	Bone marrow depression, nausea, vomiting, stomatitis, hepatotoxicity	Allopurinol delays the degradation of mercaptopurine and thus increases toxicity; question order if both are to be administered.
Methotrexate (MTX)	Antimetabolite	Stomatitis, bone marrow depression, nausea, vomiting, alopecia, hepatotoxicity, nephrotoxicity at high dosage	Decreased effect occurs if administered with salicylates; often followed by leucovorin to decrease toxicity to normal cells.
Prednisone	Corticosteroid; suppresses lymphocyte production	Weight gain, cushingoid facies, depressed systemic response to infection	Child needs support to accept changed appearance.
Procarbazine (Matulane)	Antineoplastic; interferes with DNA and RNA synthesis	Nausea, vomiting, bone marrow depression	Drug may cause blurriness of vision; avoid foods with high tyramine content.
Thioguanine	Antimetabolite	Bone marrow suppression	Monitoring of hepatic function tests is necessary.
Vincristine (Oncovin)	Plant alkaloid; vesicant	Constipation, alopecia, joint and muscle pain, muscle weakness	Paresthesia of fingers and toes, foot-drop may occur; may need stool softener; tissue necrosis occurs if infiltrated.
Additional Agents			
Allopurinol (Allopurinol, Lopurin, Zyloprim)	Antigout agent	Nausea, vomiting	Prevents uric acid formation from destroyed cells.
Bacillus Calmette-Guérin (BCG) vaccine*	Vaccine	Local inflammation	Stimulates immune system.
Leucovorin (Wellcovorin)	Folic acid derivative		Neutralizes the toxicity of methotrexate.
Interferon	Antiviral agent	Fever	Blocks virus replication.
Filgrastim (Neupogen)	Granulocyte colony-stimulating factor	Nausea, vomiting	Leukocyte count increases.
Epoetin alfa (Procrit)	Recombinant human erythropoietin	Hypertension; headache	Red blood cell count increases.

*Otherwise used to vaccinate against tuberculosis.

It is easy for a child with cancer to become malnourished. The fast-growing malignant cells take more than their share of nutrients from normal cells. Nausea and vomiting resulting from chemotherapy make it difficult to maintain an adequate oral intake. If stomatitis occurs as a result of chemotherapy, eating becomes difficult because of mouth pain (Maloney et al., 2007). Stomach and intestinal ulcers can interfere with absorption. Changes in fatty acid metabolism may alter the responsiveness of body cells to insulin metabolism. Unable to use glucose effectively, cells cannot function at an optimum level. This may account for the sense of fatigue that children with cancer frequently report (Whitsett et al., 2008). Anorexia may occur from a factor produced by the tumor that acts directly on the center for hunger in the hypothalamus, reducing appetite and altering taste perception. Cyclophosphamide, a commonly used chemotherapeutic agent, is associated with taste changes. Many children report that foods taste bitter; they do not describe foods as sweet until they are very sweet. Because of these taste changes, foods the child used to enjoy are no longer enjoyable. Unwilling to try new foods, the child decreases oral intake.

To counteract these taste changes, you may need to suggest different foods or methods of food preparation or include a dietitian as a major health team member. Chicken, for example, often tastes less bitter than beef or pork. Sprinkling brown sugar on cereal gives a different sweet taste than plain sugar. Many children believe that sugar is bad for them and therefore are reluctant to use a lot of it to make foods taste good. Reassure them that eating is the most important thing to think about now. Carefully cleaning the teeth after eating will preserve teeth even if a great deal of sugar is eaten. Do not recommend honey as a sweetener. Botulism organisms can grow in honey, placing the immunosuppressed child at risk for infection.

Parents need to take specific actions to make mealtime a pleasant time. Urge them to allow the child to make choices whenever possible. Consultation with a nutritionist can help improve food selection (Fig. 53.2).

A small meal that can be finished is more satisfying than a large meal half finished. Urge parents to make snack foods nutritious (perhaps a malted milkshake rather than a cola beverage). Also suggest planning larger meals to be eaten early in the day, before chemotherapy begins, when the child is less likely to be nauseated.

Nursing Diagnosis: Risk for deficient fluid volume related to nausea and vomiting resulting from chemotherapy

Outcome Evaluation: Skin turgor remains good; mucous membranes are moist; vomiting does not occur more than once a day.

Nausea and vomiting are common side effects of chemotherapy because the cells lining the stomach are fast-growing and therefore are among the first cells to incorporate the drug. Nausea and vomiting can often be prevented by administering an antiemetic, such as hydroxyzine (Atarax) or ondansetron (Zofran), before chemotherapy and at 4- to 8-hour intervals during the course of therapy. These drugs effectively prevent nausea and vomiting in children but do not necessarily relieve it once it is present. Begin these medications prophylactically or before chemotherapy begins therefore for best results (Box 53.5).

Do not encourage children who are nauseated to eat. Encourage them to take clear fluids, however, because this helps prevent uric acid buildup in the

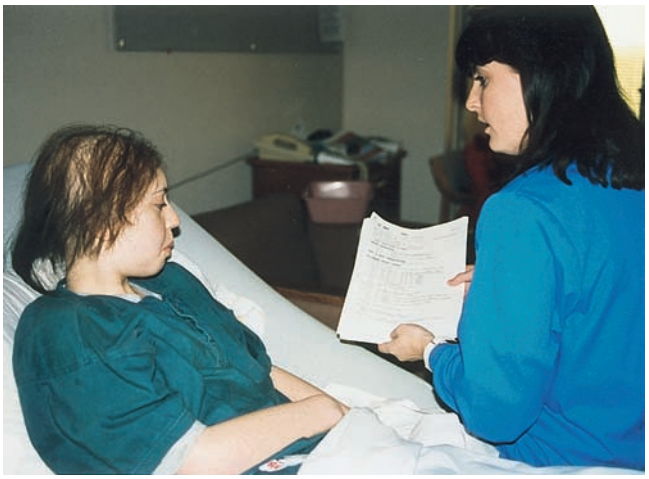

FIGURE 53.2 Children receiving radiation or chemotherapy often have reduced appetites. Here a nurse discusses nutrition and food choices with a 15-year-old with leukemia. (© Caroline Brown, RNC, MS, DEd.)

BOX 53.5 ✻ Focus on Pharmacology

Ondansetron hydrochloride (Zofran)

Classification: Ondansetron is an antiemetic agent.

Action: Blocks central and peripheral serotonin receptor sites to prevent chemotherapy-induced nausea and vomiting in adults and children older than 3 years of age (Karch, 2009).

Dosage: 4 mg orally three times daily, first dose administered 30 min before beginning chemotherapy, with subsequent doses at 4 and 8 hours after chemotherapy continued every 8 hours for 1 to 2 days after chemotherapy treatment; or three doses of 0.15 mg/kg IV, first dose started 20 minutes before chemotherapy and given over 15 minutes, with subsequent doses at 4 and 8 hours.

Possible adverse effects: Dizziness, headache, pruritus, myalgia, pain at injection site

Nursing Implications

- Be aware of timing of chemotherapeutic treatment to ensure that first dose is given 20 to 30 min before beginning chemotherapy.
- Instruct parents to continue oral form for 1 to 2 days after completion of chemotherapy to maximize effects.
- Advise parents to administer the oral drug every 8 hours around the clock for maximum results.

kidneys from the malignant cells being destroyed. If children are vomiting or cannot take even clear fluid, IV hydration therapy will be necessary. With a drug such as cyclophosphamide, which is known to cause cystitis if fluid intake is reduced, an IV line for adequate fluid intake is prescribed.

Nursing Diagnosis: Risk for disturbed body image related to changes in physical appearance caused by chemotherapy

Outcome Evaluation: Child discusses feelings about appearance changes with nurse and parents; child states that, although she does not like them, they do not alter her in any other way.

Because chemotherapy causes changes in body appearance, both children and their parents can benefit from frank discussion of symptoms and their feelings about these changes (Mitchell, 2007). This can help to maintain self-esteem (Box 53.6).

Alopecia. Alopecia, or hair loss, is a side effect that occurs with almost all chemotherapeutic drugs, because hair cells are fast-growing and easily killed as they incorporate the drug. Even when forewarned that such a consequence is likely, most children and parents are surprised at the suddenness of the hair loss (entire curls may fall out at one time, and a child can become totally bald in 2 to 3 days). Even so, hair loss is often a greater problem for the parents than the child. Coping mechanisms may be enhanced by wearing a wig or a scarf, playing and identifying with a doll without hair, and being reminded that those who love the child love the whole person, not just the packaging (Fig. 53.3).

FIGURE 53.3 A child with alopecia. It helps the child to know that hair loss does not prevent meaningful interactions with people. (© SIU Biomedical Communications/Custom Medical Stock Photo.)

Cushingoid Appearance. Children receiving long-term corticosteroid (prednisone) therapy develop a typical "moon face," red cheeks, and a stocky build. Like the loss of body hair, a cushingoid appearance can be devastating to children, the final insult in light of all the other things happening to them. Provide support and reassurance that this appearance is only temporary and will fade after they are no longer on therapy.

Nursing Diagnosis: Impaired oral mucous membrane related to effects of chemotherapy

Outcome Evaluation: Child states that mouth discomfort is at tolerable level; no signs of ulceration are present.

Stomatitis, or ulcers of the gum line and mucous membranes of the mouth, often occurs with administration of antimetabolic drugs. The child may need a soft or light diet because chewing is painful. Brushing the teeth with a soft swab rather than a brush, or having the child just rinse the mouth with half-strength hydrogen peroxide and water, is helpful. Viscous lidocaine (Xylocaine) may be prescribed to be swabbed on individual lesions for comfort. Lidocaine can cause paralysis of the gag reflex if it is swallowed, so it must be swabbed on individual lesions, *not* used for rinsing out the mouth as it is in adults. (Children younger than 8 years of age are most likely to rinse and swallow.) General measures to reduce stomatitis are summarized in Box 53.7.

Because mucous membrane ulcers can occur throughout the GI tract, avoid taking rectal temperatures for children on antimetabolic therapy, to prevent aggravation or perforation of rectal ulcers.

Nursing Diagnosis: Risk for constipation related to effects of chemotherapeutic agents

Outcome Evaluation: Child maintains usual pattern of bowel elimination; child reports (and parent confirms) no existence of hard stools.

Some chemotherapeutic agents, particularly vincristine, cause constipation. Anticipate the need for a stool softener, such as docusate sodium (Colace), to

BOX 53.6 ✻ Focus on Evidence-Based Practice

How do children with cancer rate their quality of life? To discover this answer, researchers asked 37 children who had been diagnosed with cancer to complete a Pediatric Quality of Life Inventory questionnaire. Their mothers were asked to complete the quality of life inventory plus a Hierarchical Personality Inventory. For a control group, 54 healthy children and their mothers filled in the same questionnaires. The results of the study showed, not surprisingly, that the children with cancer rated their quality of life as lower than their healthy counterparts. Personality measures showed substantial variance, suggesting that personality affects children's quality of life beyond the effects that occur from experiencing a negative life event such as cancer and its treatment.

Based on the above, would you guarantee a school-age girl about to have chemotherapy, that after her therapy, her life will be just as it was before?

BOX 53.7 ✻ Focus on Family Teaching

Tips for Relieving the Discomfort of Stomatitis

Q. Geri's father tells you, "Our son has developed ulcers in his mouth from the chemotherapy. What can we do to help him feel more comfortable?"

A. Continuing oral care despite discomfort is important to minimize the number of germs in the mouth and ideally prevent infection. Here are some tips for relieving the discomfort:

- Use a soft toothbrush to minimize discomfort.
- Make oral hygiene fun. Make up a game about mouth care that the whole family can play.
- Serve soft foods like mashed potatoes and pudding, rather than hard ones, such as toast crusts or crunchy cereal, to avoid further abrasions to tender gum lines.
- Encourage your child to rinse his mouth with lukewarm water three times a day (half-strength hydrogen peroxide may be prescribed), both for comfort and to encourage healing.
- Provide nonacidic foods, such as gelatin instead of orange juice, which can sting if sores are present.
- Encourage your child to drink as much fluid as possible, because proper hydration helps to keep lips from cracking.
- Keep lips well lubricated with petroleum jelly or a commercial product. This care also prevents cracking.

prevent hard stools from exacerbating rectal ulcers. Record the frequency of bowel movements so that constipation is recognized early in its course. Additional measures for dealing with constipation include increasing the intake of fluids and increasing dietary roughage.

Nursing Diagnosis: Risk for diarrhea related to effects of chemotherapeutic agents

Outcome Evaluation: Child maintains usual pattern of bowel elimination; child reports (and parent confirms) no existence of watery stools.

Diarrhea may occur from effects of chemotherapeutic agents on the absorptive surfaces of the intestine. Keep careful records of the number and consistency of bowel movements in children receiving chemotherapy to detect this. If diarrhea is present, IV fluid will usually be prescribed to supplement fluid loss; an antidiarrheal agent may be prescribed for older children. Be certain to change infants' diapers frequently to prevent excoriation of the skin from the acid stool content. Diarrhea is frightening for children because of the loss of control they experience. Offer support and comfort for this annoying side effect of their primary therapy.

Nursing Diagnosis: Risk for deficient diversional activity related to neuropathy resulting from chemotherapy

Outcome Evaluation: Child identifies activities in which he can participate that do not require fine motor skills while neuropathy is present.

Almost all children receiving chemotherapy experience fatigue and are unable to participate in their usual activities. If they develop neutropenia (reduced number of white blood cells), they may require temporary seclusion from other children to prevent exposure to and subsequent development of infection. Help children who are restricted in these ways to find an activity they enjoy, such as drawing, coloring, or playing handheld video games, so they can remain active.

Vincristine therapy results in specific neurologic symptoms, such as weakness, tingling, and numbing of the extremities and sometimes an inability to walk. Children may be unable to hold a pen or pencil or maneuver small parts of toys because their fingers are so affected. These symptoms subside after the medication is discontinued. Think of games they can accomplish until the numbness in the hands fades. Children on bedrest may develop foot drop with vincristine. In some children, physical therapy may be needed along with special braces or boots to prevent foot drop.

Nursing Diagnosis: Risk for infection related to therapy-induced depression of immune system

Outcome Evaluation: Child's temperature remains lower than 98.6° F (37.0° C); no areas of erythema or other signs or symptoms of infection are present.

Children with cancer are very susceptible to infection, not only because their immune system is depressed by chemotherapy but also because they develop a degree of malnutrition that decreases the effectiveness of macrophage and phagocytosis functions, and possibly the production of interferon, which is important for destroying viral invaders. A malignant process in the body decreases the body's overall ability to recognize foreign invaders and respond with the usual efficient rejection process. Frequent insertion of IV devices, the development of dry and cracking mucous membranes, and ulcer formation throughout the GI tract provide ready sites for the entrance of microorganisms.

When infection occurs, it may be difficult to recognize because common findings such as local erythema, swelling, systemic fever, and swollen lymph glands may not be present or may be reduced in relation to the degree of infection present.

Although not well studied in children, administration of colony-stimulating factors such as filgrastim (Neupogen) can help the body quickly begin replacing damaged WBCs (Karch, 2009). Even with the use of this agent, bacterial infections are common. Gram-negative bacteria such as *Escherichia coli, Pseudomonas aeruginosa,* and *Klebsiella pneumoniae,* and gram-positive bacteria such as *Staphylococcus aureus* and streptococci, are common organisms responsible for causing infections. Viral infections such as varicella (chickenpox), varicella zoster (shingles), herpes simplex, viral hepatitis, and cytomegalovirus also are common invaders.

When children are treated with immunosuppressive drugs, protozoal infections, such as *Pneumocystis carinii* pneumonia (normally a very rare pneumonia),

BOX 53.8 ✻ Focus on Family Teaching

Preventing Infection in the Child With Neutropenia

Q. Geri's mother asks you, "What special things should I do to help prevent my child from developing an infection until his white blood cell count returns to normal?"

A. Here are some suggestions to help prevent infections:

- Arrange for your child to sleep in a single bed and room, if possible, to avoid close contact with other family members who may be developing upper respiratory tract infections.
- Limit the child's exposure to large crowds, such as those at movie theaters.
- Screen and prohibit visitors who have signs of infection such as runny nose, oral herpes, or rashes; who have been exposed to a communicable disease, such as chickenpox; or who have recently been vaccinated.
- Wash your hands frequently before child care and after handling potentially contaminated items such as tissues, diapers, or other containers of body secretions or fluids.
- Urge the child to wash hands well after using a bathroom and before eating.
- Keep child's immediate surroundings free of plants, flowers, and goldfish, all of which could harbor mold spores.
- Be sure the child has a daily bath or shower. Clean mouth with soft toothbrush to reduce opportunity for bacteria, always present in the mouth, to invade.
- Inspect mouth daily for breaks in the tissue, bleeding, or white patches that suggest oral thrush (*Monilia*) infection. Apply a moisturizing and protective barrier, such as KY Jelly, to the lips to help prevent them from cracking.
- Take pulse and respiratory rate and temperature daily. Avoid taking rectal temperatures, to protect against injuring rectal tissue.
- Inspect all skin surfaces daily for scratches that could become entrances for infection. Include IV or IM injection sites, venous access device insertion sites, and the diaper area.
- Administer stool softeners, if prescribed, to promote soft stools and bowel movements and avoid rectal tears.
- Provide high-calorie, high-protein foods and food supplements to help rebuild white blood cells. Do not serve the child fresh fruits and vegetables, because they have more potential to harbor infectious organisms than cooked foods.
- Assess for respiratory tract infection by listening for cough and throat clearing; inspect throat for redness and nasal passage for discharge. Keep child active and moving through playing a game, such as "Simon Says," that encourages deep breathing.
- Assess for possible genitourinary tract infections. Note the color, clarity, frequency, and concentration of urine. If necessary, obtain a urine specimen using a clean-catch method for testing. Promote increased fluid intake to keep urine flowing. Advise girls to wipe from front to back after voiding or defecating, to avoid bringing organisms forward to the urethra. If a girl is menstruating, sanitary napkins do not have the potential to harbor as many germs as tampons do; urge her to change pads frequently (every 4 hr).
- Question the administration of any vaccine made with a live virus until the child's white blood cell count returns to normal.

may occur. To compound the problem, treating bacterial infections with antibiotics can cause overgrowth of fungal infections such as candidiasis or aspergillosis.

If infection is discovered in a child with cancer, the causative agent is identified by culture. Specific antibiotics are then prescribed. Box 53.8 identifies interventions to reduce the possibility of infection occurring in a child with neutropenia.

What if... Geri's mother tells you that she does not want her child to have an antiemetic drug before chemotherapy, because she sees the nausea and vomiting as proof that the chemotherapy is working? Would you give the drug?

Bone Marrow Transplantation

Transplantation of bone marrow that was previously harvested from a child with cancer or transplantation of marrow from a well person to a child with cancer has become a frequently used treatment for children. This can allow higher doses of chemotherapy and radiation to be used because, in the event of severe bone marrow depression, the child can have healthy marrow restored. Immune cells in the transplanted marrow may actually help to kill remaining cancer cells in the child's circulation.

If the child's own marrow is used, the procedure is called an *autologous* transfusion. Bone marrow may be donated by someone who is histocompatible (immune compatible) with the child; this is an *allogeneic* transplant. A *syngeneic* transplant is one between twins.

Before transplantation, the child receives a chemotherapy agent, such as cyclophosphamide, and total-body irradiation to kill as many marrow cells as possible, suppress the child's immune response to the transplanted tissue, and create space in the bone marrow to allow the newly transplanted cells a place to grow.

Bone marrow is aspirated from the child and treated to reduce the number of abnormal cells present (called purging), or

stem cells are removed from the circulating blood of a designated donor or donated placenta. Parents of newborns today are able to freeze and bank cord blood to use as stem cells in the future. After recovery from a stem cell bank or donor, bone marrow or stem cells are processed and transfused into the child intravenously. The new stem cells or marrow begins to function after about 3 weeks. Until this time, a child is at extreme risk for infection. Everyone coming in contact with the child must wash their hands well, and specific infection control precautions must be maintained. Transfusion of blood products may be necessary to maintain functional blood components until the transplanted marrow begins to function.

Not all medical centers perform bone marrow transplantation, so a family may have to travel a distance for the therapy. Complications of bone marrow transplantation are discussed in Chapter 44, because this technique also is used for children with blood dyscrasias. Previously used only with children with leukemia, it is now being used in children with other cancers, such as neuroblastoma and Hodgkin's disease (Soejima et al., 2007).

Pain Assessment

Because growing tumors displace cells, causing anoxia to those cells, pain is a common symptom experienced by children with cancer. Methods to assess pain and interventions to help children deal with pain are discussed in Chapter 39.

THE LEUKEMIAS

Leukemia is the distorted and uncontrolled proliferation of WBCs (leukocytes) and is the most frequently occurring type of cancer in children.

Acute Lymphocytic (Lymphoblastic) Leukemia

Acute lymphocytic leukemia (ALL) accounts for 75% of leukemias (Rugo, 2009) and involves lymphoblasts or immature lymphocytes. With the rapid proliferation of immature lymphocytes, the production of red blood cells (RBCs) and platelets falls, and invasion of body organs by the rapidly increasing WBC elements begins. Because the abnormally proliferating cells are so immature, they may be identifiable only at the immature "blast cell" or "stem cell" stage.

The highest incidence of ALL is in children between 2 and 6 years of age. The prognosis in children younger than 1 year or older than 10 years at the time of first occurrence is not as good as in those between 2 and 10 years of age. The prognosis in children who have a WBC count higher than 50,000/mm^3 or who have more than 10% L2 cells (see classification of cells, described later) in bone marrow at the time of diagnosis is not as good as in those with a lower WBC count and fewer L2 cells at first diagnosis. The incidence of ALL is slightly higher in boys than in girls, and the disease is seen more often in white children than in children of other races (Maloney et al., 2007).

Although it can be shown that leukemia in mice and cats is of viral origin, the cause of leukemia in children is unknown. Radiation, exposure to chemicals, or genetic factors may have some influence on the occurrence. Children with Down syndrome or Fanconi syndrome are more likely to develop leukemia than are other children. If a twin has leukemia, the other twin (as opposed to a nontwin sibling) is more likely to develop it as well. Bone irradiation may be implicated, so children should be submitted to as few radiographs as possible, including while in utero. An association between magnetic fields or power lines and leukemia is disputed (Feychting et al., 2007).

Assessment

With ALL, bone marrow overproduces lymphocytes and therefore is unable to continue normal production of other blood components. The first symptoms of ALL in children usually are pallor, low-grade fever, and lethargy (symptoms of anemia caused by decreased RBC production). A child may have petechiae and bleeding from oral mucous membranes and may bruise easily because of a low thrombocyte count. As the spleen and liver begin to enlarge from infiltration of abnormal cells, abdominal pain, vomiting, and anorexia occur. As abnormal lymphocytes invade the bone periosteum, the child experiences bone and joint pain. Central nervous system (CNS) invasion leads to symptoms such as headache or unsteady gait.

Physical assessment reveals painless, generalized swelling of lymph nodes, especially of the submaxillary or cervical nodes. Laboratory studies reveal a variable leukocyte count. In most children, the leukocyte count is markedly elevated. In others, the count is normal or even slightly decreased but is composed almost entirely of immature blast cells. The platelet count and hematocrit are low, but the RBCs that are present are normocytic and normochromic (of normal size and color).

A bone marrow aspiration is done to identify the type of WBC involved or to document the type of leukemia. If there are more than 25% blast cells present, a leukemia diagnosis is established. In children, bone marrow is aspirated at the iliac crest rather than the sternum, both because this is less frightening and because it yields more marrow. Radiographs of the long bones may reveal lesions caused by the invasion of abnormal cells. A lumbar puncture may show evidence of blast cells in the cerebrospinal fluid (CSF).

✔ Checkpoint Question 53.1

Parents are often unaware that their child is developing leukemia. What are the first signs commonly seen in a child with acute lymphocytic leukemia (ALL)?

a. Nodules and pink rash.
b. Headaches and sleepiness.
c. Fatigue and bruising.
d. Joint pain and coughing.

Therapeutic Management

Up to 95% of children will have a first remission. If a child experiences a relapse, the chances of long-term survival are reduced to approximately 70%. Although remission can be reinduced, the length of each subsequent remission tends to be shorter and less effective.

Disease Classification and Prognosis. Leukemia is classified to define subgroups of cells and to predict the usual response to treatment. Blasts with B-lymphocyte cell characteristics can be recognized by the presence of immunoglobulin and antigen–antibody receptors on their surfaces. B-lymphocyte cell types account for 85% of instances of ALL. A specific

antigen found on cell surfaces has been named CALLA, and cells are labeled as CALLA positive or CALLA negative. The other 15% to 20% of children have T-lymphocyte cell involvement. T lymphocytes are also categorized as CALLA positive or negative.

Cure as Goal. The goal of therapy for leukemia is complete cure, based on the use of chemotherapeutic agents. A chemotherapy program is aimed at, first, achieving a complete remission or absence of leukemia cells (induction phase); second, preventing leukemia cells from invading or growing in the CNS (sanctuary or consolidation phase); third, administering delayed intensive therapy; and fourth, maintaining the original remission (maintenance phase).

Chemotherapy in children is often administered by means of a central venous catheter or port, because administration of drugs into a major vessel helps prevent irritation to the vessel walls. These access devices have the secondary advantage of being able to be clamped or "trapped" so that the child can be ambulatory between treatments.

Drugs frequently used to initiate a remission include vincristine, prednisone, L-asparaginase, doxorubicin, and methotrexate. These are given over a period of about 1 month. Because so many cells are destroyed by chemotherapy, a high level of uric acid is excreted during treatment. This can lead to plugging of kidney glomeruli and loss of kidney function. To prevent this, a drug such as allopurinol is often administered with chemotherapy, to reduce the formation of uric acid. Keeping a child well hydrated also helps maintain safe uric acid excretion.

Because many chemotherapy drugs do not cross the blood–brain barrier in effective concentrations, leukemic cells in the CNS continue to flourish even with remission chemotherapy. A combination of intrathecal administration (injection of drugs into the CSF by lumbar puncture) of a drug such as methotrexate and oral administration of 6-mercaptopurine is next instituted to eradicate this source of leukemic cells. This is called a *consolidation* or *sanctuary phase,* because no "sanctuary" is given to malignant cells. Cranial radiation, once used extensively for this purpose, is less used today than previously because, over the long term, minimal learning disorders may result from this.

The third phase of therapy intensifies the assault against leukemic cells using chemotherapeutic agents such as vincristine, prednisone, L-asparaginase, doxorubicin, cyclophosphamide, cytosine arabinoside (ARA-C), or 6-thioguanine.

Maintenance and Monitoring. Maintenance chemotherapy aims to eliminate completely any remaining leukemic cells, so that the child's immune system can complete the eradication. Standard maintenance therapy includes a combination of daily 6-mercaptopurine, weekly methotrexate, and sporadic vincristine and prednisone, and intrathecal methotrexate. This is continued for 2 to 3 years. A drug such as leucovorin is usually given after systemic methotrexate, to neutralize its action and protect normal cells from the effect of the drug. During the maintenance phase, the child's blood values must be monitored at least monthly. If there is serious bone marrow depression, medication levels may be reduced or a transfusion may be necessary.

If a bone marrow study during the maintenance phase shows that leukemic cells are again evident, a new induction phase will be initiated, followed by a new sanctuary, intensification, and maintenance phase. Children who are free of disease for 4 years are considered cured, and their maintenance therapy can then be stopped. Bone marrow transplantation or immunotherapy may be used with children who do not respond well to standard therapy. Newer drugs are constantly being investigated to use for relapse therapy. Help parents evaluate the use of nonapproved drugs and the safety of using them with chemotherapeutic agents during this time (Box 53.9).

BOX 53.9 * Focus on Communication

Geri, a 6-year-old boy, was diagnosed with a brain tumor 3 months ago. His mother brings him into the emergency room because of a severe nosebleed. While you are putting pressure on his nose, you notice that one eye seems to have poor alignment.

Less Effective Communication

Nurse: Is Geri still having chemotherapy, Mrs. Miller?
Mrs. Miller: No. He's in remission.
Nurse: Is he taking anything that would lower his platelet count or clotting factors?
Mrs. Miller: All he takes is asparagus powder we get from Mexico.
Nurse: From Mexico?
Mrs. Miller: It's a new treatment that's not legal here.
Nurse: Has he been back to clinic here for a checkup or follow-up?
Mrs. Miller: No. Asparagus powder is a kind of chemotherapy.
Nurse: Well, let's focus right now on getting this bleeding stopped.

More Effective Communication

Nurse: Is Geri still having chemotherapy, Mrs. Miller?
Mrs. Miller: No. He's in remission.
Nurse: Is he taking anything that would lower his platelet count or clotting factors?
Mrs. Miller: All he takes is asparagus powder we get from Mexico.
Nurse: From Mexico?
Mrs. Miller: It's a new treatment that's not legal here.
Nurse: Are you worried that he still has so many new black and blue marks?
Mrs. Miller: No, asparagus powder is a kind of chemotherapy.
Nurse: Well, let's get this nosebleed stopped. Then we can take a minute to talk about what chemotherapy means.

Of all known diseases, no other disease has as many false "cures" as cancer. When talking with parents, see if they are using any of these unproven methods. Some of them do no harm, so parents can continue to give them along with proven therapies. Others actually interfere with the action of a chemotherapy drug and are contraindicated. In the above scenario, the parent has chosen an unproven regimen. Ignoring the possibility that this choice may be an unhelpful one and denying a potential recurrence of cancer or other problem is not therapeutic and could be detrimental in the long term.

Complications

Throughout therapy, the health care team and family need to be alert for complications of therapy. Among these problems are CNS, renal, and reproductive system disorders.

Central Nervous System Involvement. If CNS involvement occurs, it can become severe and intense. Blindness, hydrocephalus, and recurrent seizures are possible. The meninges and the sixth and seventh cranial nerves are the structures most often affected. With meningeal involvement, the child develops nuchal rigidity, headache, irritability, and perhaps vomiting and papilledema. A lumbar puncture reveals the presence of blast cells in the CSF. If these are discovered, the child will be treated with intrathecal injections of methotrexate. Always check that a child is not prescribed oral or IV methotrexate at the same time, because some of the dose of intrathecal methotrexate is absorbed systemically and could lead to a toxic reaction. Inserting silicon tubing into a cerebral ventricle and threading it under the scalp (an Ommaya reservoir) provides easy access to the CSF for sampling or injection without the need for repeated lumbar punctures (Fig. 53.4).

Renal Involvement. Kidney involvement, resulting from invasion of leukemia cells, is a second serious complication. The kidneys may enlarge, and their function will be impaired. If uric acid levels rise as a result of the breakdown of leukemic cells during chemotherapy, plugging of renal tubules with uric acid crystals and kidney failure may result. Renal involvement may limit the use of chemotherapeutic agents, because they cannot be excreted effectively because of the kidney damage.

Testicular Invasion. In boys, leukemic cells tend to invade the testes. Unless this problem is specifically addressed, these cells will not be destroyed by chemotherapy. As a result, once chemotherapy is halted, the leukemic cells may grow and proliferate again. In most boys, therefore, the testes will be irradiated to destroy this sanctuary site for cells. This treatment leads to sterilization. If a boy is past puberty and is forming sperm, sperm banking might be suggested before chemotherapy and radiation to preserve sperm for reproduction later in life.

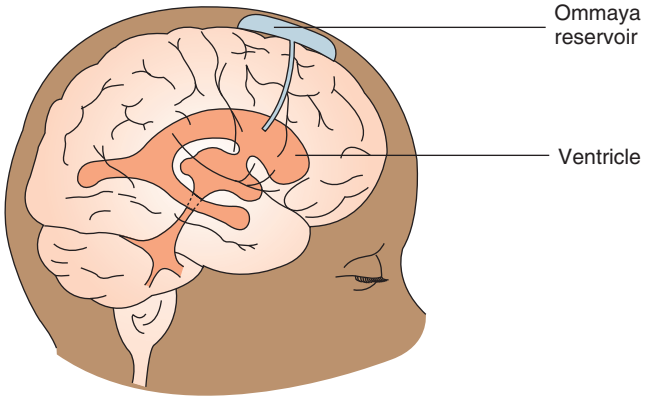

FIGURE 53.4 An Ommaya reservoir. Medication injected into the reservoir flows down to the ventricle and enters the cerebrospinal fluid.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for infection related to nonfunctioning WBCs and immunosuppressive effects of therapy

Outcome Evaluation: Child's temperature remains lower than 98.6° F (37.0° C); no areas of erythema or drainage are present on skin.

Because the number of functioning WBCs is reduced and the drugs used for treatment are immunosuppressive, children with leukemia are at an extremely high risk for infection during chemotherapy. Most deaths in children result from infections, such as septicemia, pneumonia, or meningitis. *Pseudomonas* is commonly an invading organism.

While children are receiving care at home, parents must learn to observe them carefully and to promptly report any indication of infection, such as low-grade fever or behavior that does not seem typical of the child. The sooner the symptoms are reported, the sooner anti-infective therapy can begin.

Children may be prescribed prophylactic antibiotics to reduce the possibility of infection. Parents may be advised to limit visitors, especially anyone with an infection, until the child's functioning WBC improves.

To increase the functioning leukocyte count, leukocytes may be transfused. Symptoms of fever and chills from leukocyte transfusion tend to be more common than with RBC transfusion. This is not a true transfusion reaction and usually is not a reason to stop the transfusion.

Nursing Diagnosis: Risk for deficient fluid volume related to increased chance of hemorrhage from poor platelet production

Outcome Evaluation: No evidence of hemorrhage is present (no epistaxis, hematuria, hematemesis); pulse rate and blood pressure remain normal for age group.

Because the platelet count is low because of poor platelet production and the effect of chemotherapy, children with leukemia also are extremely prone to massive hemorrhage. Epistaxis (nosebleed) is the most common kind of bleeding; GI, renal, or CNS bleeding also may occur.

Digital pressure is usually effective to stop epistaxis. The application of Gelfoam soaked in topical thrombin may be necessary. In some children, postnasal packing is necessary. Children may need a transfusion to replace the lost blood volume. Platelet-rich plasma or a concentrated preparation of platelets is prescribed to improve the platelet count. Because the life span of transfused platelets is short (1 to 3 days), frequent platelet transfusion may be necessary. After an intramuscular (IM) injection or the removal of an IV needle, always apply firm pressure to the injection site to prevent bleeding.

Because children with leukemia have blood samples drawn frequently, receive transfusions, and have

IV chemotherapeutic drugs administered, they need the opportunity for therapeutic play with needles and syringes or IV tubing so they can work through some feelings about these intrusive, hurtful procedures (Kettwich et al., 2007). Advocate for intermittent infusion devices such as heparin locks or multilumen central venous catheters that minimize the need for repeated venipunctures.

Nursing Diagnosis: Pain related to invasion of leukocytes

Outcome Evaluation: Child states that pain is tolerable (if infant, not crying).

Children with acute leukemia experience pain because of the vast number of WBCs that invade the periosteum of the bones. Assess pain using a standard scale for accuracy. Handle legs and arms gently to minimize pain. Use of an alternating mattress or sheepskin underneath body joints helps to reduce skin irritation caused by always resting in the same position. Give analgesia as needed.

Nursing Diagnosis: Ineffective health maintenance related to long-term therapy for leukemia

Outcome Evaluation: Parents and child state importance of regular health maintenance visits; child continues chemotherapy regimen at home and keeps all ambulatory appointments.

During the maintenance phase of therapy, children can participate in usual activities and should attend regular school. Encourage parents to continue to report promptly any sign of infection, so antibiotic therapy can be started early. Because chickenpox can be fatal to a child who is immunosuppressed, have parents ask the child's school to notify them if any other child in the school develops chickenpox, so appropriate immune protection can be given. If the child has not received immunization against varicella (chickenpox) before this, varicella immune globulin will need to be administered.

Evaluation of children at follow-up visits should include not only the state of their blood but also whether they are making forward-thinking plans or thinking of themselves as well children again.

Parents may continue to need a great deal of support during the maintenance phase of therapy. They live from day to day, hoping that the remission will not end, and because leukemia is a curable disease today, they need a great deal of support if a relapse does occur. If death occurs, the reality of what has happened may be extremely difficult for the parents to accept. They may return to the hospital for visits weeks or months after the child's death in an effort to accept reality and work through their grief.

Acute Myeloid Leukemia

Acute myeloid leukemia (AML) involves the overproliferation of granulocytes (neutrophils, basophils, and eosinophils). It is most often seen in adults so accounts for only about 20% of all childhood leukemias. The frequency of the disorder increases in late adolescence as children reach adulthood.

With AML, granulocytes grow so rapidly that they often are forced out into the bloodstream while still in the blast stage. As with ALL, the overproliferation of granulocytes limits the production of RBCs and platelets.

Assessment

Children with AML have the same symptoms as those with ALL. Because they do not have mature granulocytes, they are susceptible to infection and may have noticed many recent upper respiratory tract infections before the time of diagnosis.

Therapeutic Management

The diagnosis is established by bone marrow aspiration and biopsy. Cells are typed (M1 to M6) to establish prognosis. After diagnosis, chemotherapy to effect remission begins. Cytarabine and and anthracycline (daunorubicin) are two drugs commonly used for therapy. It may take 1 to 2 months to reach a full remission (Wetzler, Byrd, & Bloomfield, 2008).

During the maintenance phase, additional chemotherapeutic agents in common use are cyclophosphamide and 6-thioguanine. Maintenance therapy is continued for 6 to 9 months.

Remission is more difficult to achieve in children with AML than in those with ALL, and if one is achieved, it may be brief. Bone marrow transplantation may be attempted after the initial remission to ensure new growth of normal granulocytes.

THE LYMPHOMAS

Lymphomas are malignancies of the lymph or reticuloendothelial system; they account for about 15% of all malignancies and are categorized as Hodgkin's or non-Hodgkin's lymphomas. Although Hodgkin's disease is better known, non-Hodgkin's lymphomas are more common worldwide in children (about 60% versus 40%). They both occur more frequently in males than in females (Linker, 2009).

Hodgkin's Disease

With Hodgkin's disease, lymphocytes proliferate in the lymph glands, and special *Reed-Sternberg cells* (large, multinucleated cells that are probably nonfunctioning monocyte-macrophage cells) are found. Although these lymphocytes are capable of DNA synthesis and mitotic division, they are abnormal because they lack both B- and T-lymphocyte surface markers and cannot produce immunoglobulins (Linker, 2009).

As with all neoplastic diseases, the etiology of Hodgkin's disease is unknown, but both genetic and environmental factors probably play a part. It is rarely seen in children younger than 7 years of age. The incidence increases greatly during adolescence and young adulthood. Metastasis is through lymphatic channels. Late in the disease, spread to lung, liver, and bone marrow occurs.

Assessment

Symptoms of Hodgkin's disease usually begin with only one painless, enlarged, rubbery-feeling lymph node, usually a cervical node. Other nodes then become involved, along with the liver, spleen, bone marrow, and, eventually, the CNS.

The child usually has accompanying symptoms of anorexia, malaise, night sweats, and loss of weight. Fever may be present. The sedimentation rate is elevated; anemia is usually present as a result of reduced RBC survival.

Hodgkin's disease is confirmed by biopsy of the lymph nodes. Further studies (bone marrow analysis, liver function tests, chest and abdominal computed tomography [CT] scans, lymphangiography, and abdominal biopsy) are done to classify the clinical stage of the disorder. Chest radiograph reveals enlarged mediastinal nodes; the abdominal CT reveals enlarged lymph nodes of the abdomen.

A lymphangiogram, performed by injecting dye into the hand or foot, allows visualization of the lymphatic system. A catheter is inserted into a lymph vessel, and radiopaque dye is added, as in angiography. Lymphatic channels can then be visualized on x-ray films. The lymph system does not eradicate opaque dye readily; in some children, lymph chains will still be outlined on x-ray films for up to 1 year. The original dye injected into the skin to visualize the lymph vessels stains the skin a bluish green at the point of injection. This dye will remain as a skin stain for about 1 year. Nodes opacified by lymphangiogram dye can be used as markers of disease progress on plain, flat-plate x-ray films for 6 to 12 months.

Therapeutic Management

Four subcategories of Hodgkin's disease can be documented: lymphocyte predominant, nodular sclerosing, mixed cellularity, and lymphocyte depletion. The most frequently occurring types in children are nodular sclerosing and lymphocyte predominant. The disease is staged according to regional involvement (Table 53.4). Such staging may be determined by a CT scan followed by multiple lymph node and bone marrow biopsies.

Treatment depends on the clinical stage of the disease at the time of diagnosis. Although Hodgkin's disease once was treated mainly with radiation therapy, children today in all stages but stage 1 receive chemotherapy. Common agents include combination chemotherapy using doxorubicin (Adriamycin), bleomycin, vincristine, and dacarbazine (an ABVD regimen). Other drugs used may include cyclophosphamide and cytarabine. Current therapy results in a 90% 5-year survival rate for children with stage I or stage II disease, and 60% to 90% for more advanced disease. If a relapse occurs, additional chemotherapy, radiation, or bone marrow transplantation will be scheduled.

Children need conscientious follow-up for symptoms of Hodgkin's disease relapse during adult life. A relapse is often retreatable, using a chemotherapy course different from that used initially.

TABLE 53.4 ✻ Stages of Hodgkin's Disease

Stage	Extent of Disease
I	Disease affects single lymph node or single extralymphatic organ or site.
II	Disease affects two or more lymph node regions on the same side of the diaphragm, or there is localized involvement of an extralymphatic organ or site.
III	Disease affects lymph node regions on both sides of the diaphragm, or there is localized involvement of an extralymphatic organ or site.
IV	There is diffuse or disseminated involvement of extralymphatic organs with or without associated lymph node involvement.

Nursing Diagnoses and Related Interventions ✻

The nursing diagnoses most often used with Hodgkin's disease address the child's impaired immune defenses and risk for infection, fear and feelings about the diagnosis, or changed body image (particularly in an adolescent). Both the parents and the child need opportunities to express their feelings about the seriousness of this disease.

Nursing Diagnosis: Risk for powerlessness related to constant possibility of disease recurrence

Outcome Evaluation: Child states that he feels healthy during remission, participates in school and extracurricular activities, and voices confidence in health care team to treat symptoms if they recur.

The course of treatment for Hodgkin's disease is long. Some adolescents, in whom the disease is most prevalent, live from day to day wondering whether symptoms will recur. Encourage adolescents to attend regular school during periods of remission, so that they can lead as normal a life as possible. Keep them informed about the disease and their progress. Some adolescents want to know exactly what stage they are in; others prefer not to be told, so they can continue to believe that a cure will be possible. Both adolescents and their parents need continued support from health care personnel during the long course of therapy.

Non-Hodgkin's Lymphoma

Non-Hodgkin's lymphomas are malignant disorders of the lymphocytes. They involve stem cells and lymphocytes in varying degrees of differentiation. In the pediatric population, diffuse lymphoblastic, undifferentiated, and large-cell lymphomas are commonly seen. Unlike Hodgkin's disease, spread is through the bloodstream rather than directly by lymph flow. The course of the disease is therefore unpredictable. Metastatic spread to the CNS tends to occur early in the disease. The most common age at occurrence is 5 to 15 years.

The cause of non-Hodgkin's lymphomas may be an oncogenic virus, because they occur with increased frequency in children with agammaglobulinemia or acquired immunodeficiency syndrome (AIDS) and in those who are receiving long-term immunosuppressive therapy, such as would be given after organ transplantation. Such immunosuppressed states may reduce the body's ability to recognize and destroy oncogenic viruses or malignant cells.

Assessment

Non-Hodgkin's lymphomas of the lymphoblastic type involve the lymph glands of the neck and chest most commonly, although axillary, abdominal, or inguinal nodes may be the first involved. If mediastinal lymph glands are swollen, the child may first notice a cough or chest "tightness." If mediastinal nodes press on the veins returning blood from the head, edema of the face may result. Diffuse, undifferentiated types manifest most commonly with an abdominal mass. Children notice abdominal pain; they may have diarrhea or constipation, and a mass may be palpable on examination.

To establish the diagnosis, biopsy of the affected lymph nodes and bone marrow is performed. It is often difficult to distinguish between undifferentiated lymphoma cells and ALL. This can be established by bone marrow analysis (if a bone marrow biopsy shows more than 25% blasts, the diagnosis is acute leukemia). Areas of metastases are identified by chest radiography; lymphangiography; gallium, liver-spleen, and CT scans; and bone marrow aspiration.

Therapeutic Management

Non-Hodgkin's lymphomas are treated with systemic chemotherapy, similar to that used for ALL. The initial phase of therapy is an induction phase (a time during which the child is put into remission, or no tumor can be detected by clinical means); this is followed by a maintenance phase up to 2 years long. Common drugs used are cyclophosphamide, vincristine, methotrexate, and prednisone (COMP therapy) and a multiple-agent program that includes cytosine arabinoside, cyclophosphamide, daunorubicin, vincristine, prednisone, L-asparaginase, thioguanine, and methotrexate. Intrathecal chemotherapy may be included because of the tendency for non-Hodgkin's lymphoma to metastasize to the CNS. Because the breakdown of cells is so rapid with chemotherapy, assess for hyperkalemia and hyperphosphatemia. Anticipate that allopurinol will be added to the therapy to prevent uric acid accumulation in the kidney. A granulocyte colony-stimulating factor may be given to prevent neutropenia.

Autologous bone marrow transfusion (using bone marrow removed at diagnosis, before the disease has spread to the marrow, and then replaced after blood components have been destroyed by chemotherapy) allows more aggressive chemotherapy to be used than formerly. Between 80% and 90% of children with non-Hodgkin's lymphoma with minimal symptoms achieve remission.

Burkitt's Lymphoma

Burkitt's lymphoma (a non-Hodgkin's lymphoma) is a specifically named but rare form of cancer in the United States; it is much more commonly seen in Africa. When this lymphoma does occur, however, it tends to affect children. Children 2 to 14 years of age have the highest incidence, with a peak at 7 years.

An association between Burkitt's lymphoma and Epstein-Barr virus, which causes infectious mononucleosis, exists. That is not to say that the virus causes the lymphoma, only that the virus is present at the same time as Burkitt's lymphoma (Koo & Shandera, 2009). It is also associated with HIV-positive individuals. The first indication of disease is an enlarged lymph node of the neck or abdomen. It is usually painless unless it blocks some body system.

A Burkitt's lymphoma is a rapidly growing tumor; the cell mass may double in size in 24 hours so early diagnosis and treatment is important. Surgery is used to remove the primary tumor. This is followed by chemotherapy; cyclophosphamide, methotrexate, doxorubicin, vincristine, and prednisone are commonly used agents. To prevent CNS involvement, intrathecal methotrexate may be given (Longo, 2008).

Because Burkitt's lymphomas are such rapidly growing tumors, they respond dramatically to chemotherapy (the cells are almost always in a susceptible state). As with other lymphomas, tissue breakdown may be so voluminous that the uric acid level of the urine may cause renal tubule plugging unless the child is kept well hydrated and a drug such as allopurinol is administered concurrently.

NEOPLASMS OF THE BRAIN

Brain tumor is the second most common form of cancer in children and the most common solid tumor form. Tumors tend to occur between 1 and 10 years of age, with 5 years being the peak age of incidence. In children, brain tumors tend to occur at the midline in the brainstem or cerebellum, located beneath the tentorial membrane; in contrast, they usually are lateral and above the tentorial membrane in adults. This feature makes them particularly difficult to remove in children without damage to normal brain tissue (Partap & Fisher, 2007).

Types of Brain Tumors

Common sites for brain tumors in children are shown in Figure 53.5. The most common brain tumors are cerebellar astrocytomas, medulloblastomas, and brainstem tumors.

Astrocytomas are slow-growing, cystic tumors that arise from the glial or support tissue of neural cells. They account for about one fourth of all brain tumors in children. The peak age of incidence is 5 to 8 years.

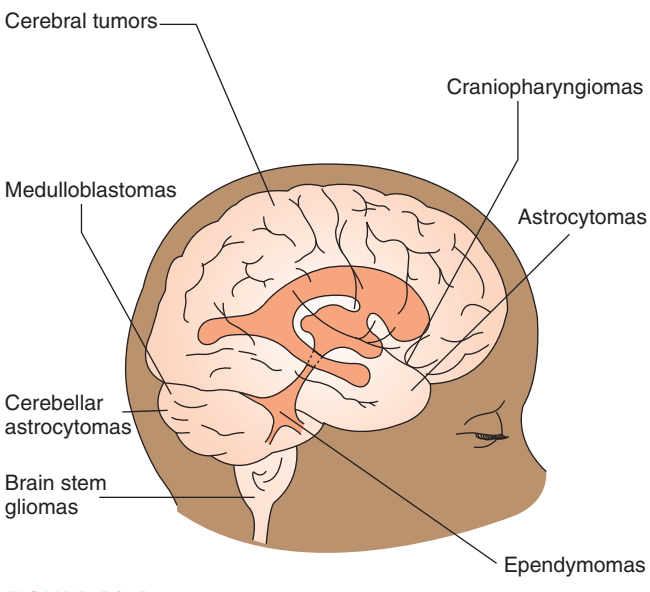

FIGURE 53.5 Common sites for brain tumors in children.

Medulloblastomas are fast-growing tumors found most commonly in the cerebellum. The peak age of incidence is 5 to 10 years. Usually found at the midline, they cause fourth-ventricle compression and disturbances in the flow of CSF.

Brainstem tumors arise from the support tissue of the neural cells. They often cause paralysis of the fifth, sixth, seventh, ninth, and tenth cranial nerves. They may produce symptoms of ataxia, nystagmus, and changes in respiratory and pulse findings because of pressure on these centers.

Assessment

Children with brain tumor develop symptoms of increased intracranial pressure: headache, vision changes, vomiting, an enlarging head circumference, or papilledema. Lethargy, projectile vomiting, and coma are late signs.

The headache associated with brain tumor usually occurs on arising in the morning. It may be intermittent throughout the day because of pressure changes related to position and the ability of the cranium to expand to some degree and temporarily relieve the associated pressure. It becomes intense on straining, such as occurs with coughing or bowel movements. A parent may report these symptoms as an increasingly irritable young child who is constipated because of reluctance to strain to pass stool. With some tumors, the pain is occipital. This is an important finding, because this is an unusual location for a headache from any other cause.

Vomiting, like headache, most commonly occurs on arising. Unlike the child who vomits because of GI distress, the child with a brain tumor is not usually nauseated and will eat immediately afterward. The vomiting pattern occurs morning after morning. It eventually become projectile after a long time, but projectile vomiting is not an initial symptom. Vomiting early in the morning may be discounted by parents as school phobia (reluctance to attend school), because the child is able to eat again immediately and seems to recover about half an hour after getting out of bed (at the same time the school bus leaves).

Diplopia because of sixth cranial nerve involvement or strabismus because of suppression of vision in one eye is usually noticed. Children with strabismus may tilt their head to the side or partially close one eye when viewing objects to compensate for the suppression and strabismus. A child may develop a torticollis (wry neck) or ptosis (lag of the eyelid). Papilledema (swelling of the optic nerve) may be evident on funduscopic examination.

Apart from these generalized symptoms of increased intracranial pressure, a growing tumor produces specific localized signs, such as nystagmus (constant horizontal movement of the eye), cranial nerve paralysis, or visual field defects. Tumors of the cerebellum cause a definite head tilt because of vision suppression. As tumor growth continues, symptoms of ataxia, personality change (emotional lability, irritability), and seizures may occur.

Four to 6 months may pass from the time of initial symptoms until symptoms become localized enough to arouse suspicion of a brain tumor. When this suspicion arises, a child needs a thorough neurologic examination; skull films, a bone scan, ultrasound or MRI, cerebral angiography, or a CT scan will be performed as needed. Myelography may be done to identify tumors that could have spread into the spinal column. Lumbar puncture must be done cautiously, because the release of CSF can cause the brainstem (under pressure from the tumor) to herniate into the spinal cord, interfering with respiratory and cardiac function.

Therapeutic Management

Therapy for brain tumors includes a combination of surgery, radiation, and chemotherapy, depending on the location and extent of the tumor. Because they are located so deeply, most tumors cannot be completely removed in children; this makes radiation and chemotherapy increasingly important. Radiation therapy may be intense because, if tumor tissue is not rapidly proliferating, cells are not easily destroyed. Chemotherapy is limited because many chemotherapeutic agents do not cross the blood–brain barrier. Lomustine (CCNU) and vincristine are two drugs that do cross the barrier and so are used. Administration of a drug directly into the ventricular system via a reservoir (Ommaya) may increase drug effectiveness. Research is revealing special gene activating factors found in children's brain tumors that will serve as a basis for future therapy.

The diagnosis of brain tumor at any age is always a serious one and a stress for parents (Aminoff, 2009). Closely observe a child who is admitted to the hospital for a possible diagnosis of brain tumor, to detect signs of increased intracranial pressure or new localizing signs as they occur. Record pulse rate, blood pressure, and respiratory rate with extreme accuracy, so that subtle changes become apparent. Note and document episodes of irritability, drowsiness, speech difficulty, and eye involvement. Statements such as, "Child says he sees two forks when I show him one" or "Child is unable to see objects held in her left field of vision" are much more meaningful to a neurosurgeon than "Child has difficulty seeing." Completely describe any seizure activity observed, particularly the beginning movements of the seizure, because these may help to localize the point of maximum brain pressure. Side rails should be in place for protection in case a seizure occurs while the child is in bed.

Preoperative Care

Before brain surgery, a child may receive a stool softener to prevent straining with bowel movements. Usually no preoperative enema is given, because expelling an enema increases intracranial pressure.

Dexamethasone (Decadron) may be prescribed to reduce edema by shifting fluid from extracellular to intravascular spaces. An anticonvulsant such as phenytoin (Dilantin) will be prescribed if the child is experiencing seizures or if surgery is apt to induce seizures. Before surgery, a portion of the child's head is shaved. Prepare the child for this in a positive way by emphasizing that hair grows back very rapidly (Fig. 53.6).

If the child will be cared for in an intensive care unit (ICU) for the first few days after surgery, a preoperative visit to meet the ICU staff should be made.

Postoperative Care

If laser surgery techniques were used for surgery, the postoperative course is simplified and shortened. Position the child as the surgeon prescribes. The position depends on the location of the tumor and the extent of surgery, but in general a child is positioned on the side opposite the incision. Keep the bed flat or only slightly elevated. Do not lower the head of the bed, because this would increase intracranial pressure

FIGURE 53.6 A nurse uses a doll to help prepare a child for shaving her head for brain surgery. (© Caroline Brown, RNC, MS, DEd.)

from accumulation of increased blood in the area. Note carefully how much movement of the child's neck is allowed. If surgery was in the low occipital area, the surgeon may want the child to be moved as though the head and neck were a single body part. A neck brace or cast can be applied to stabilize the head and neck and prevent movement.

You can expect the child to be comatose or extremely lethargic for several days after surgery because of brain irritation and edema. In addition, a child may require mechanical ventilation because of pressure on the respiratory center. Unless they are being ventilated, comatose children need to be positioned on their side so that oral secretions drain from the mouth, to prevent aspiration. Many children have such extreme facial edema that they cannot close their eyelids completely or their nasal breathing space is impaired. Cool compresses over the eyes may help to reduce edema. Saline eye drops or eye dressings (with the eyes carefully closed under the dressings) may be prescribed to keep the cornea from drying and ulcerating. Carefully assess the pulse and respiratory rates, pupillary size and ability to react to light, muscle strength (ask children to squeeze your hands), and level of consciousness (ask their name or give a simple instruction to follow).

Obtain vital signs frequently (about every 15 minutes) until these are stable and there is no apparent increase in intracranial pressure. A child's temperature may be either elevated or decreased immediately postoperatively because of the effect of the edema on the hypothalamus. Measures to reduce hyperthermia (sponging, antipyretics given by gavage or rectal administration because of lethargy or coma, or a hypothermia blanket) may be necessary to reduce the temperature to less than 101° F (38.4° C).

Regulate the rate of IV fluid infusions carefully because an increase in the infusion rate will increase intracranial pressure. Children may receive solutions of mannitol or hypertonic dextrose to aid in evacuating the cerebral hemispheres of edematous fluid. As the child regains consciousness, small amounts of oral fluid may be begun. Make certain, when introducing fluid, that the child is free of nausea from the anesthetic, because vomiting increases intracranial pressure.

Observe head dressings carefully for serosanguineous drainage. A wet dressing is no longer a sterile dressing, because pathologic organisms can filter through its folds to reach the meninges and cause meningitis. Place a sterile towel under a wet dressing or reinforce the dressing with sterile compresses. Report signs of drainage, and estimate the extent of the seepage so that you can tell later whether seepage has increased.

Children regaining consciousness after brain surgery usually are confused regarding time and place; they may have difficulty performing simple tasks that they could do easily before. As the cerebral edema subsides and children begin to regain consciousness, they may need to be restrained to stop them from touching their head dressing or IV line. Use as few restraints as possible because fighting restraints is yet another way to cause intracranial pressure to increase. Help the child gradually regain independence in self-care (see Focus on Nursing Care Planning Box 53.10).

BOX 53.10 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Child Receiving Chemotherapy

Geri, 6 years old, has had surgery to remove a brain tumor. He is now on ambulatory care receiving additional chemotherapy postoperatively. His father states, "He's nauseated all the time. He says he's never going back to school because he looks so funny. This cure is worse than the disease."

Family Assessment ✻ Child lives with parents and two older sisters (ages 10 and 12 yr) in four-bedroom first-floor flat. Father is manager of a local computer store. Mother used to work as a manicurist. Is stay-at-home-mom since Geri was diagnosed with cancer. Father rates finances as, "Okay. If nothing unexpected happens."

Client Assessment ✻ Sad and pale-appearing school-age child with bald head and recent surgical scar. Weight decreased 5 lb in last 2 weeks. Skin turgor sluggish. Oral mucous membranes red and irritated. Two ulcers noted on inner aspect of left cheek at gum line. Child states, "I look like an old man."

Nursing Diagnosis ✻ Disturbed body image related to hair loss and nausea secondary to the effects of chemotherapy

Outcome Criteria ✻ Child states effect of hair loss and nausea on appearance and feelings; verbalizes measures to cope with hair loss and nausea; reports continued participation in age-appropriate activities.

(continued)

BOX 53.10 ✻ Focus on Nursing Care Planning (continued)

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Assess whether child is capable of self-care in light of changes that have occurred with chemotherapy.	Encourage child to perform as many self-care activities as he did before becoming ill.	Maintaining self-care activities is a way of maintaining self esteem and competence.	Child states that although he doesn't feel well, he will try to do self-care.
		Consultations		
Nurse	Assess whether parents would like an oncology nurse to discuss nutritional side effects of chemotherapy with them.	Contact oncology nurse if desired to review problems with nutrition during chemotherapy.	An expert can help parents to determine more effective strategies to combat and accept the nausea and appearance caused by chemotherapy.	An oncology nurse speaks with the parents if indicated.
		Procedures/Medications		
Nurse	Assess oral mucous membrane to detect and document oral lesions.	Instruct child and parent in oral care. Advise using a soft toothbrush or swabs to cleanse teeth.	Good oral care is essential to prevent further ulceration.	Child is able to maintain nutrition despite oral lesions.
Physician/ Nurse	Assess whether topical anesthetic solution would help to decrease pain from mouth ulcers.	Teach parent to apply topical anesthetic to the ulcers as appropriate.	Topical anesthetics may decrease the discomfort of the ulcers and improve nutrition.	Child states he would like to try topical therapy to see if it can reduce ulcer pain.
		Nutrition		
Nurse	Assess whether child has had any relief from prescribed antiemetics.	Administer prescribed antiemetic approximately 30 min before initiating chemotherapy.	Antiemetics administered before chemotherapy help to prevent nausea and vomiting.	Child agrees to administration of antiemetic before chemotherapy to help reduce nausea.
Nurse/ nutritionist	Assess child's intake by a 24-hr recall history.	Encourage parent to offer food early in the day before chemotherapy. Suggest frequent, high-calorie snacks, such as high-energy snack bars.	Eating before chemotherapy enhances nutrition because the child is less likely to be nauseated at this time.	Parent states she will try to have child eat highly nutritious snacks during times he is not nauseated, to optimize nutrition intake.
		Patient/Family Education		
Nurse	Assess parents' and child's understanding of the action of chemotherapy.	Teach parents about the type of medications child is receiving and their usual actions and side effects.	Understanding that side effects are expected, not unique, can help parents and child accept the appearance changes that occur.	Parents/child state they understand what changes to expect and they understand these are temporary.

		Psychosocial/Spiritual/Emotional Needs		
Nurse	Assess the child's understanding of hair loss and its cause.	Review the structure and function of the hair and explain why hair loss develops.	Understanding that this appearance change, although dramatic, is not permanent can help the child to accept it.	Child states he understands his hair will grow back.
Nurse	Assess whether child can devise any measures that would make him feel better about his changed appearance.	Brainstorm with child and parents about measures such as wearing a scarf or cap or modeling an action figure.	Fostering a positive outlook can help child accept changed appearance as a mark signifying he is managing a stressful time of life very well.	Child states he will try to view hair loss as a positive feature, not a detrimental one.
		Discharge Planning		
Nurse	Assess whether parents or child have any further questions before discharge about nutrition or appearance.	Urge parent to contact clinic if child develops further ulcerations or experiences continued weight loss or an increase in nausea and vomiting.	Continued nausea and vomiting, weight loss, or development of more ulcers requires further evaluation and follow-up to minimize the risk of additional problems for the child.	Parents and child state they feel confident in managing nutrition adequately during remainder of chemotherapy.
Nurse	Assess whether parents are aware of continuous pattern of chemotherapy and need to return for further therapy.	Review the chemotherapy protocol with parents and child so they know the dates of therapy.	When chemotherapy is administered on an ambulatory basis it can better keep a family intact.	Parents/child state they understand the importance of return appointments and will keep them.

After a child is discharged from the hospital, encourage parents to allow their child as near-normal activity as possible. Some children may need a football helmet to protect their head if a section of skull was removed or is not yet firmly closed. When the bulky head dressing is removed, the child may become aware of baldness for the first time. Some children need support to return to school because they are aware that other children will treat them differently now, having heard from their parents that they are dying or "had to have their head fixed." Urge parents to make the school administration aware of what has happened to the child; the school nurse should be encouraged to take an active role in helping the child readjust to school after a long absence.

Late effects may occur in children who survive a malignant brain tumor. Long-term neurologic and pituitary dysfunction (especially lack of growth hormone) and learning challenges are not unusual in survivors of pediatric brain tumor, especially if they received high doses of cranial radiation at a very young age.

✔ Checkpoint Question 53.2

Geri is going to have surgery for a brain tumor. Why may children be prescribed a stool softener before this type of surgery?

a. Constipation stimulates the release of hypopituitary hormones.
b. Straining with bowel movements increases intracranial pressure.
c. Constipation can lead to anal fissures and a source of infection.
d. Children in Trendelenburg positions cannot evacuate bowels well.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Fear related to diagnosis of brain tumor

Outcome Evaluation: Parents and child continue to maintain function as a family, visit in hospital, and plan appropriately for discharge and continued care.

Parents of children with brain tumors usually are not prepared for the severity of their child's diagnosis. They bring the child to a health care facility because of insidious symptoms—vomiting, headache, strabismus. They may think that the child has a mild GI upset or needs eyeglasses. They are shocked to learn that such benign symptoms are signs of a condition that may be fatal. This can cause such distress at the time of the initial diagnosis that they cannot think of questions to ask. In the hours or days after the diagnosis,

they often have a great need to talk to people who are familiar with the care of children with brain tumors and to ask questions of the neurosurgeon.

Most parents want to hear a definite statement about prognosis—for example, "All of the tumor can be removed; your child will be as good as new" or "Your child's chances are 1 in 4 of surviving surgery (or of having permanent effects)." Because the type of tumor, its exact location, and its extent are not fully known until surgery, these predictions cannot be made with more than an informed guess. Reassure parents that it is normal in these instances for a surgeon not to give more definitive information. Otherwise, they may interpret a surgeon's unwillingness to give them definite figures as incompetence or lack of interest. Help assure parents that earlier diagnosis would not have made a difference in the outcome. This makes it possible for them to live with themselves afterward and not be overwhelmed by the guilt, thinking that they could have prevented a bad outcome by recognizing symptoms earlier. Symptoms of brain tumor *are* insidious when they first begin, and the average parent cannot be expected to recognize them as important.

Help parents also to understand that, because of the importance of brain tissue, brain surgery is never minor surgery. Be sure that they understand how their child will appear after surgery: Their child will have a large, bulky head dressing; be drowsy or unresponsive; and have possible facial edema. Still, even parents who are well prepared are likely to be shocked at the actual sight of their child. Before you take them to the child's room after surgery, review with them once more that the child has a bulky dressing and is unconscious.

Some parents may not "hear" the full extent of their child's diagnosis before surgery. They cannot believe that the surgeon will not be able to remove the entire tumor and cure their child. After surgery, when they are told that the entire tumor could not be removed, a very genuine grief reaction occurs. As a result, they may be unable to sit and hold the child's hand, read to the child, or talk, because their minds have already jumped ahead to the time when the child might die. The child may have difficulty relating to them because they are no longer acting like the parents the child knew before surgery (more like two strangers). Parents need a great deal of support from the time a child is first seen until the surgery, through discharge and readmissions, to the last hospital admission, when the child finally dies.

Children as young as 5 years old are aware that the head and the brain are important parts of the body. They are also very aware of the feeling tone they detect in the words of parents and health care personnel. Because they undergo several diagnostic studies, followed by surgery and prolonged therapy, provide children with opportunities to express their feelings about intrusive procedures through play with puppets or hospital equipment. Remember that, when a patient becomes unconscious, hearing is often the last sense lost. Although children do not appear to respond after surgery, they may be able to hear everything that is said.

BONE TUMORS

Tumors derived from connective tissue, such as bone and cartilage, muscle, blood vessels, or lymphoid tissue, are called **sarcomas.** They are the second most frequently occurring neoplasms in adolescents (only lymphomas occur more frequently). Bone tumors may arise during adolescence because rapid bone growth is occurring at this time. Because girls have a puberty growth spurt earlier than boys, bone tumors tend to occur slightly earlier in girls than in boys (13 compared with 14 or 15 years of age). The two most frequently occurring types are osteogenic sarcoma and Ewing's sarcoma (Fig. 53.7).

Osteogenic Sarcoma

An **osteogenic sarcoma** is a malignant tumor of long bone involving rapidly growing bone tissue (mesenchymal-matrix forming cells). It tends to occur more commonly in boys than in girls. The most common sites of occurrence are the distal femur (40% to 50%), the proximal tibia (20%), and the proximal humerus (10% to 15%). Osteogenic sarcoma can occur in children who have had radiation for other malignancies as a later life effect (Kalra et al., 2007). Children with retinoblastoma have a higher incidence than normal of osteosarcoma, so a hereditary influence may be present.

Although bones do not have a lymphatic system, metastasis occurs early because of the extensive vascular system in bones (Patel & Benjamin, 2008). Metastasis to the lungs is the most common site; as many as 25% of adolescents have lung metastasis already by the time of initial diagnosis. When this is present, the adolescent usually has a chronic cough, dyspnea, chest pain, and leg pain (if the tumor originates in the leg). Other common sites of metastasis are brain and other bone tissue.

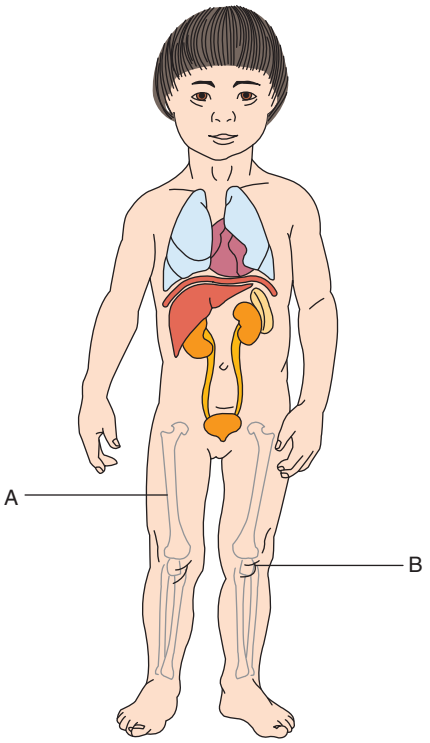

FIGURE 53.7 (**A**) The diaphysis (midshaft) is one of the most frequent sites of Ewing's sarcoma. (**B**) The epiphysis of a bone is a common site of osteogenic sarcoma.

Assessment

Children with osteogenic sarcoma often are taller than average, indicating rapid bone growth. They notice pain and swelling at the tumor site. Often, they report a history of recent trauma to the site such as they fell playing basketball and bumped their knee and attribute pain in the knee to this injury for some time. All adolescents with extremity pain and swelling, particularly near the knee, require evaluation because of the possibility that a malignant process may be the cause. It is important that both adolescents and their parents understand that trauma did not cause the process; it merely called attention to the leg or arm where a malignant process was at work. This prevents adolescents from thinking that they caused the tumor.

The area may be inflamed and feel warm, because tumors are highly vascular and therefore call increased blood into the area. As the tumor invades and weakens bone tissue, a pathologic fracture of the bone can occur.

Bone cells produce alkaline phosphatase, and rapidly growing bone cells raise the serum level of this enzyme markedly, so serum analysis for alkaline phosphatase will be obtained. For final diagnosis, a biopsy is done of the area under suspicion. To determine metastasis, a complete blood cell count, urinalysis, chest radiograph, chest CT scan, and bone scans will be done. Caution children not to bear weight on an affected appendage while waiting for tests or surgery. The bone may be so weakened by the growing tumor that weight bearing could result in a fracture at the tumor site.

Therapeutic Management

An adolescent may have chemotherapy to shrink the tumor before surgery. Parents may be very concerned with this delay. They need an explanation that, with bone tumor, this is an accepted and helpful intervention before surgery. Common treatment drugs include methotrexate, cisplatin, doxorubicin, and ifosfamide.

If the tumor is in the leg and is small at the time of diagnosis, and if the child has reached adult height, the single bone involved may be surgically removed and replaced with an internally placed bone or metal prosthesis. This will preserve the child's leg. If the tumor is extensive at the time of diagnosis, the leg may be amputated at the joint above the tumor (this usually involves a total hip amputation). If the cancer has spread to the lung, metastasis tumors can usually be removed by thoracotomy.

Only a few years ago, a diagnosis of osteogenic sarcoma was ominous; few children survived into adulthood. Today, 70% of adolescents in whom the diagnosis is made early and who are treated rigorously can be cured (Muscolo et al., 2008).

Nursing Diagnoses and Related Interventions

Diagnosis of malignant bone tumor is a shock to both parents and children. The symptoms begin so insidiously that the diagnosis seems unreal. Parents can be reassured that any delay in seeking treatment would not have had a marked effect on the chances for a cure. Neither the adolescent nor the parents could have been expected to seek medical attention any earlier. This is important preparation, because guilt-ridden parents cannot function effectively to help a child through this extensive illness.

Be certain that outcomes established are realistic. It is not realistic, for example, for an adolescent to accept with understanding leg surgery that could compromise an athletic career. The highest achievable outcome might be that the adolescent realizes surgery is necessary to save her life.

Nursing Diagnosis: Risk for injury related to surgery and bone prosthesis

Outcome Evaluation: Extremity distal to surgical incision remains warm to touch; capillary filling is less than 5 seconds; adolescent reports no tingling or numbness in distal extremity.

The major danger associated with surgery for excising osteosarcoma and placement of a bone prosthesis (limb salvage surgery) is that the swelling that occurs during surgery or immediately afterward can disrupt neurologic or circulatory function to the lower leg. Always position and handle the leg carefully to prevent further disruption. Assess frequently for signs that the neurologic and circulatory systems are intact distal to the surgery (toes are warm and pink; capillary filling is less than 5 seconds; adolescent reports no numbness or tingling).

Adolescents who had pain in the leg before surgery may continue to feel this pain even after the involved bone segment has been removed. This is known as *phantom pain*, and it occurs because nerve tracts continue to report pain for a time after the pain has been relieved. Although you might think that phantom limb pain could be simply explained away, this is not true. The pain is very real. An adolescent may need an analgesic to control it.

Ewing's Sarcoma

Ewing's sarcoma is a malignant tumor occurring most often in the bone marrow of the diaphyseal area (midshaft) of long bones. It spreads longitudinally through the bone (see Fig. 53.7). Ewing's sarcoma occurs primarily in young adolescents and older school-age children; it is slightly more common in boys than in girls. It almost never occurs in African Americans. Metastasis is usually present at the time of diagnosis; the lungs and bones are the most common sites. Without therapy, CNS and lymph node sites become involved (Patel & Benjamin, 2008).

Assessment

Most children have had pain at the site of the tumor for some time before seeing a physician. At first, the pain is intermittent, and the child attributes it to an injury (perhaps a friend punched his leg; he bumped it against a footstool). Finally, the pain becomes constant and so severe that the child cannot sleep at night. Because of this delay, multiple areas of involvement are often found at the time of diagnosis.

Radiographs reveal an unusual "onion-skin" reaction (overlapping fine lines disclosed on the x-ray film) surrounding the invading tumor cells. A bone scan, bone marrow aspiration

and biopsy, CT scan of the lungs, and IV pyelogram or kidney MRI will probably be done to determine whether metastasis to the lung, bone, kidney, or lymph nodes has occurred. A biopsy of the tumor site will be done for a definite diagnosis. During tests, urge the child to avoid bearing weight on the affected extremity, because this could cause a pathologic fracture at the site.

Therapeutic Management

With Ewing's sarcoma, therapy consists of a combination of surgery to remove the primary tumor, radiation, and chemotherapy. Drugs often used are vincristine, dactinomycin, cyclophosphamide, doxorubicin, etoposide, and ifosfamide. Irradiation of the entire involved bone may be scheduled.

About 50% of children survive for at least 5 years; older children have a better survival rate than younger children. Caution adolescents to continue to be careful about stress on a leg that has received extensive radiation (no football, no weight lifting with pressure on that leg) because it may not be as strong as normal afterward.

What if... A parent tells you his son developed an osteosarcoma from falling while playing basketball? Is that a possible cause of bone cancer?

OTHER CHILDHOOD NEOPLASMS

Neuroblastoma

Neuroblastomas are tumors that arise from the cells of the sympathetic nervous system; cells are highly undifferentiated and invasive, occurring most frequently in the abdomen near the adrenal gland or spinal ganglia. They are the most common abdominal tumor in childhood (Maloney et al., 2007). Neuroblastoma occurs primarily in infants and preschool children; it is slightly more common in boys than in girls. These tumors may occur so early in life that they are detected by fetal ultrasound or at birth. There may be an association between the development of neuroblastomas and fetal alcohol syndrome or cigarette or marijuana smoking by parents. Common sites of metastasis include the bone marrow, liver, and subcutaneous tissue.

Assessment

The growing tumor is most often discovered on abdominal palpation as an abdominal mass. The general symptoms of weight loss and anorexia may be present. Pressure on the adrenal gland from the tumor may cause excessive sweating, flushed face, and hypertension. Abdominal pain and constipation may be present. Compression on the spinal nerves or invasion into the intervertebral foramina may cause loss of motor function in lower extremities.

If the primary lesion is in the upper chest, children will report dyspnea; swallowing may be difficult, and neck and facial edema may occur from compression on the vena cava. If liver metastasis is present, children may have jaundice. If metastasis to the skin has occurred, blue or purplish nodules (prominent raised areas) on arms or legs may be seen.

The extent of the tumor and any metastases present are identified by an IV pyelogram (a mass growing on the adrenal gland just above the kidney will demonstrate kidney compression); an arteriogram (neuroblastomas are vascular tumors and incorporate veins and arteries into their structure as they grow); ultrasound, CT or MRI scan of the chest, abdomen, and pelvis; a gallium bone scan; or bone marrow aspiration and biopsy. If an adrenal tumor is present, it will stimulate production of adrenal gland hormones or catecholamines. To detect these substances, a urine sample will be tested for the presence of catecholamines or vanillylmandelic acid and homovanillic acid (the breakdown products of catecholamines). Children who have a high level of serum ferritin have a poorer prognosis than do those with a low level.

A biopsy of the tumor site will be planned so the tumor can be definitely identified and staged (Table 53.5).

Therapeutic Management

If the tumor is localized (stage I), therapy will consist of surgical removal of the primary tumor. If the tumor is stage II to IV, surgery will be followed by chemotherapy using agents such as doxorubicin, cyclophosphamide, etoposide, vincristine, ifosfamide, cisplatin, and carboplatin. A "second look" surgical procedure may be scheduled within several months to determine the effectiveness of therapy and to attempt the possible removal of further tumor. If aggressive chemotherapy is not effective, bone marrow transplantation to restore functioning bone marrow may be scheduled. Administration of *cis*-retinoic acid, a growth-inhibiting agent, improves eradication of residual disease. Immunotherapy is another possibility to eliminate residual disease after chemotherapy.

Stage IV disease is a unique form because it has a high rate of spontaneous regression. This occurs because the tumor either spontaneously degenerates or undergoes differentiation to normal tissue.

Overall, children with neuroblastoma have a 5-year survival rate of 70% to 90%. Although most children have a positive initial response to therapy, recurrence is common within the first year. The prognosis is better in children diagnosed before 1 year of age.

Rhabdomyosarcoma

A **rhabdomyosarcoma** is a tumor of striated muscle (White, Levy, & Alam, 2008). It arises from the embryonic mes-

TABLE 53.5 ✻ Staging Neuroblastoma

Stage	Extent of Disease
I	Tumor is well encapsulated and completely removed by surgery.
II	Tumor cannot be completely removed by surgery or disease extends to lymph nodes.
III	Tumor extends beyond the midline; regional lymph nodes may be involved bilaterally.
IV	Distant metastases; bone, eyes, or liver involved.
IVs	Metastasis is present in child <1 year old.

enchyme tissue that forms muscle, connective, and vascular tissue. The peak age of incidence of these tumors is 2 to 6 years, with a second peak occurring during puberty. Common sites of occurrence include the eye orbit, paranasal sinuses, uterus, prostate, bladder, retroperitoneum, arms, and legs. CNS invasion occurs from direct tumor extension. This results in cranial nerve palsy, nuchal rigidity, bradycardia, or bradypnea (because of brainstem compromise). Distant metastasis most commonly occurs in lungs, bone, or bone marrow.

Assessment

The symptoms relate to the site of the tumor (Table 53.6). A biopsy specimen of the tumor is taken and examined for tissue identification. Metastasis is ruled out by bone scan, chest radiography, CT scanning, MRI, and bone marrow aspiration.

Therapeutic Management

The primary treatment is surgical removal of the tumor, followed by chemotherapy with agents such as vincristine, dactinomycin, cyclophosphamide, doxorubicin, etoposide, and ifosfamide. The child receives chemotherapy every 3 or 4 weeks for 18 to 24 months. If CNS extension has occurred, intrathecal chemotherapy may be included in the regimen.

A child's prognosis depends on the size of the tumor and whether metastasis was present at the time of initial diagnosis. If the entire tumor was removed and no lymph node metastasis has occurred, the chances are as high as 80% that the tumor will not recur. If some of the tumor had to be left because of its size or location, the chance of recurrence rises to about 50%. If metastasis to the lungs or bone was present at the time of the initial diagnosis, the prognosis drops still further; about 20% of children in this situation have long-term survival. Among children who do survive, long-term complications such as cardiomyopathy and infertility may occur from the side effects of chemotherapy.

TABLE 53.6 ✻ Common Sites and Associated Symptoms of Rhabdomyosarcoma

Site of Tumor	Symptoms
Orbit	Proptosis (extruding eye); visible and palpable conjunctival or eyelid mass
Neck	Hoarseness, dysphagia; visible and palpable mass in neck
Nasopharynx	Airway obstruction, epistaxis, dysphagia, visible mass in nasal or nasopharyngeal passages
Paranasal sinuses	Swelling, pain, nasal discharge, epistaxis
Middle ear	Pain, chronic otitis media, hearing loss, facial nerve palsy, mass protruding into external ear canal
Bladder and prostate	Dysuria, urinary retention, hematuria, constipation, palpable lower abdominal mass
Vagina	Mass protruding from uterus or cervix into vagina, abnormal vaginal bleeding
Trunk, extremities	Visible and palpable soft-tissue mass
Testicles	Visible and palpable soft-tissue mass

Nephroblastoma (Wilms' Tumor)

Nephroblastoma (Wilms' tumor) is a malignant tumor that rises from the metanephric mesoderm cells of the upper pole of the kidney (McLean & Castellino, 2008). It accounts for 20% of solid tumors in childhood; there is no increased incidence based on sex or race. It occurs in association with congenital anomalies such as aniridia (lack of color in the iris), cryptorchidism, hypospadias, pseudohermaphroditism, cystic kidneys, hemangioma, and talipes disorders. Some children with the disorder have a deletion on chromosome 11. Without therapy, metastatic spread by the bloodstream is most often to the lungs, regional lymph nodes, liver, bone, and, eventually, brain.

Assessment

A nephroblastoma is usually discovered early in life (6 months to 5 years; peak at 3 to 4 years), although it apparently arises from an embryonic structure present in the child before birth. Nephroblastomas distort the kidney anteriorly so that the tumor is felt as a firm, nontender abdominal mass. Parents sometimes are aware that their infant has a mass in the abdomen but bring the infant to their health care provider thinking that it is hard stool from chronic constipation. Fathers may discover the tumor when they toss a baby in the air, catch the infant by the abdomen, and feel the abdominal mass. Parents often report that the mass seemed to appear overnight. This actually can happen, because tumors can hemorrhage into themselves, doubling their size in a matter of hours. Because of this, nephroblastoma may manifest with hematuria and a low-grade fever. The child may be anemic from lack of erythropoietin formation by the diseased kidney. Although hypertension may also occur because of excessive renin production, blood pressure is not taken routinely in children of this age, so the tumor is rarely discovered by this method.

A CT scan or ultrasound reveals the primary tumor and any points of metastasis. Kidney function studies, such as glomerular filtration rate or blood urea nitrogen, will be done to assess function of the kidneys before surgery. Little time, however, can be allotted for preoperative testing, because these tumors metastasize rapidly as a result of the large blood supply to the kidneys and adrenal glands.

It is important that the child's abdomen not be palpated any more than is necessary for diagnosis, because handling appears to aid metastasis. Place a sign reading "No Abdominal Palpation" over the child's crib to prevent this.

Therapeutic Management

Nephroblastomas are staged according to the criteria of the National Wilms' Tumor Study Group (Table 53.7) to predict therapy and prognosis. The tumor will be removed by nephrectomy (excision of the affected kidney). This is usually followed immediately by radiation therapy (omitted in stage I tumors) and by chemotherapy with dactinomycin, doxorubicin, or vincristine. The chemotherapy may be given at

TABLE 53.7 ✻ Staging Nephroblastoma (Wilms' Tumor)

Stage	Description
I	Tumor confined to the kidney and completely removed surgically
II	Tumor extending beyond the kidney but completely removed surgically
III	Regional spread of disease beyond the kidney with residual abdominal disease postoperatively
IV	Metastases to lung, liver, bone, distant lymph nodes, or other distant sites
V	Bilateral disease

varying intervals for as long as 15 months. A second surgical procedure may be scheduled after 2 or 3 months to remove any remaining tumor.

If tumor involvement is bilateral, the operative decisions obviously become more complex. If the tumors are small, both kidneys can be removed, leaving functioning kidney cells intact. Or only the kidney with the larger tumor may be removed. Tumor sites are then treated with both radiation and chemotherapy.

Complications can occur from nephroblastoma therapy. Both small bowel obstruction from fibrotic scarring and hepatic damage from radiation to the lesion can occur. Nephritis in the kidney also is a possibility. In girls, radiation-related damage to the ovaries may result in sterility. Radiation to the lungs may result in interstitial pneumonia; spine radiation can result in scoliosis.

Therapy for nephroblastoma is so effective that about 90% of children who had no metastatic spread at diagnosis survive for at least 5 years.

Retinoblastoma

Retinoblastoma is a malignant tumor of the retina of the eye (Sands & Drack, 2007). A rare tumor, it accounts for only 1% to 3% of childhood malignancies. In about 10% of children, these tumors develop because of an inherited autosomal dominant pattern that causes an alteration of chromosome 13. Parents who have one child with retinoblastoma have about a 4% chance of having a second child with a similar tumor. If two or more children have the tumor, the parents are probably carriers, and it can be predicted that up to 50% of their children will be affected. Because of the dominant pattern of inheritance, a person who survives retinoblastoma has a 90% chance of having a child with a similar tumor. Parents who may be carriers, or a parent who has survived the disease, need genetic counseling so that they are aware of the risk to their children. Because the 5-year survival rate for children with retinoblastoma is good (at least 90%), this will become a very important counseling role in the future.

Retinoblastoma occurs most often, however, as spontaneous development, not the inherited type. Children with the inherited type tend to develop bilateral disease; those with the spontaneous type may or may not have the tumor in both eyes.

Assessment

Retinoblastoma occurs early in life, from about 6 weeks of age through the preschool period. It occurs equally in boys and girls, and there is no preference for either the right or the left eye. One tumor or many individual tumors may be present. Tumors are located on the retina or in the vitreous fluid or extend backward into the choroid, the optic nerve, and the subarachnoid space.

On examination, the child's pupil appears white (the red reflex is absent) or is described as a typical "cat's eye." The child develops strabismus as the eye becomes nonfunctional. This tumor metastasizes readily along the course of the optic nerve to the subarachnoid space and brain; it quickly involves the second eye. Metastasis to distant body sites, such as bone marrow and liver, occurs because of the rich blood supply to the brain.

Children with a family history should be examined at least three times yearly until they reach 5 years of age. If a tumor is suspected, an examination under general anesthesia or conscious sedation is scheduled, because children this age cannot cooperate well with eye examinations. CT scanning and ultrasound may be ordered to detect intraocular calcification or the presence of tumor. The possibility of distant metastasis is evaluated by lumbar puncture, liver and skeletal survey, MRI, or bone marrow biopsy.

Therapeutic Management

Retinoblastomas are serious tumors involving the retina of the eye; allowed to grow, they cause blindness. If the tumor is very small at the time of diagnosis, it may be treated with cryosurgery (freezing the tumor to destroy local cells). This will preserve partial vision in the eye. Photocoagulation using laser surgery to destroy the blood vessels supplying the tumor may be used. Localized radioactive applicators or plaques sutured to the sclera over the tumor may be used. Such plaques remain in place for 4 to 7 days. The child may also receive radiation treatment and chemotherapy (nitrogen mustard, vincristine, and cyclophosphamide are commonly used) if the tumor has metastasized.

If the tumor is large when first discovered, enucleation of the eye may be necessary. After enucleation, the child has a large pressure dressing applied to the empty socket. Observe for bleeding on the dressing and assess vital signs frequently. To keep young children from tugging at the dressing and removing it, they may need to be restrained if a parent cannot be with them constantly. After about 48 hours, the pressure dressing is removed (usually by the surgeon), and a small eye patch is applied. Irrigation of the empty socket with normal saline solution or application of an antibiotic ointment may be prescribed with future dressing changes.

An eye prosthesis is fitted about 3 weeks after surgery. Prostheses in children do not need to be removed and cleaned daily, and, in children this young, leaving the prosthesis in place prevents the child from playing with it (an interesting, colorful, round ball).

As discussed earlier, the long-term survival rate for children with retinoblastoma is as high as 90%. Evaluation of the child after retinoblastoma must include not only whether

metastasis can be detected but whether the child is adjusting to the loss of sight in one or both eyes. Children who do not have binocular vision this early in life usually do not have difficulty adjusting. They notice it most at school age when they are unable to compete in sports that require three-dimensional sight, such as baseball. They may be restricted from obtaining a driver's license. If radiation was used for therapy, cataracts may develop several years later. The high incidence of osteogenic and soft-tissue sarcomas that occurs following retinoblastoma therapy may not be related to therapy as much as to a tendency for tumor growth.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Decisional conflict related to approval of eye removal to save child's life

Outcome Evaluation: Parents and child state that they can accept removal of eye to save child's life.

With the diagnosis of retinoblastoma, parents may be asked to make a most difficult decision. To save their child's life, they must agree to the removal of an eye. Even after this procedure, the second eye may become involved or distant metastasis may occur. Parents need support in the decision they make. If there is metastasis at a later date, they may feel guilty that they agreed to enucleation, thinking they have put the child through the surgery for nothing. They may feel guilty that they did not notice that the child's eye was abnormal before metastasis occurred. They may have noticed that the eye was abnormal but thought nothing more than that the child needed glasses and so delayed seeking health care. Be certain that parents understand fully what enucleation surgery will entail (loss of the eye). Provide time for discussion to help them work through this very emotional time in their life.

Skin Cancer

One in five people develop skin cancer in their lifetime (Berger, 2009). Three types are involved: basal cell carcinoma (a surface epithelial growth that manifests as a small ulcer that does not heal), squamous cell carcinoma (a tumor of the epidermis that manifests as a white scaly lesion), and malignant melanoma (a tumor originating in melanocytes or nevi) that manifests as a mole that changes in appearance. All three types of skin cancer are increasing in incidence and, although the symptoms usually do not appear until adulthood, the chief cause (excessive sun exposure) begins in childhood (Huether & McCance, 2007).

Malignant Melanoma

Melanomas can be differentiated from benign moles by an A-B-C-D assessment: asymmetry, border irregularity, color (variable or dark pigmentation), and diameter (over 6 mm). Melanomas are treated with surgery, radiation, and adjuvant interferon-α2b to improve overall survival. Nurses can play a major role in helping to reduce the incidence of skin cancer by teaching parents and adolescents ways to identify these malignancies and better protect against excessive sun exposure by measures such as:

- Apply a sunscreen or wear protective clothing if a child will be out in the sun for longer than 20 minutes.
- Avoid indoor tanning beds or ultraviolet light. If used, maintain the same precautions as with sunlight.
- Avoid sunburn, because there is a direct association between two or more episodes of sunburn in adolescence and the development of malignant melanoma in young adulthood.

✔ Checkpoint Question 53.3

What is an important intervention to take for a child with nephroblastoma (Wilms' tumor)?

a. Post a sign over the crib: "No Abdominal Palpation."
b. Alert the mother that her child will be infertile after surgery.
c. Be certain the child eats no red vegetables before surgery.
d. Record a head circumference in the nursing care plan.

Key Points for Review

- After a diagnosis of malignancy, parents and children need help to change their thinking from an older concept of cancer as being an always painful, fatal disease to a newer concept of cancer as a condition for which there is therapy and hope.
- Because the therapy for cancer involves so many health care visits and so much parental concern, the siblings of children with cancer may begin to feel left out of family activities. Remind parents to incorporate the entire family into activities whenever possible, to help them grow as a family during the course of therapy.
- Radiation is an important treatment modality in cancer therapy. Immediate side effects include anorexia, nausea, vomiting, and hair loss if radiation is to the head. Long-term effects may include growth restriction or learning disabilities.
- A chemotherapeutic agent is one that is capable of destroying malignant cells. Common side effects are the same as those for radiation therapy. Help children to use time during chemotherapy treatments in constructive ways, such as playing a game, to keep them mentally stimulated yet quiet.
- Be aware of the need to use gloves, and mix preparations under a hood when preparing a chemotherapy drug, to protect yourself from adverse effects of the medication.
- Leukemia is the distorted and uncontrolled proliferation of WBCs and is the most frequently occurring type of cancer in children. About 90% to 95% of children with an initially good prognosis now have long-term survival.
- Hodgkin's disease and non-Hodgkin's lymphomas are malignancies of the lymphatic system. Hodgkin's disease occurs most often in adolescents; the initial symptom is often one painless, enlarged lymph node. Therapy is radiation and chemotherapy.

- Brain tumors are the most common solid tumors occurring in childhood. Beginning symptoms are usually those of increased intracranial pressure. Therapy may include a combination of surgery followed by radiation and chemotherapy.
- Bone tumors occur in two main forms: osteogenic sarcoma and Ewing's sarcoma. These tumors tend to be fast growing because of the ready blood supply to bone. Therapy consists of surgery followed by radiation and chemotherapy.
- Neuroblastomas are tumors that arise from the cells of the sympathetic nervous system. They are the most common abdominal tumor in childhood. Therapy is surgery and chemotherapy.
- Rhabdomyosarcomas are tumors of striated muscle. The peak age of incidence is 2 to 6 years. Therapy is surgery and chemotherapy.
- Nephroblastoma (Wilms' tumor) is a malignancy that arises from the metanephric mesoderm cells of the kidney. It is usually discovered early in life. Therapy is surgery followed by radiation and chemotherapy.
- Retinoblastoma is a malignant tumor of the retina of the eye. It may be inherited as an autosomal dominant pattern. Therapy involves surgery, radiation, chemotherapy, and possibly enucleation if the tumor is large.
- Skin cancer is a type of malignancy that begins in childhood. Cautioning children about sensible sun exposure can be an important health promotion role for nurses.

CRITICAL THINKING EXERCISES

1. Geri is the 6-year-old boy you met at the beginning of the chapter. His mother told you that he wakes up every morning with a headache and then vomits. She says this pattern began just after school started, so she is certain it is related to school. His teacher has suggested that Geri have an eye examination. What are some additional questions you would want to ask to determine whether you should pursue this problem further?
2. A 2-year-old child is going to be receiving chemotherapy after surgery for a neuroblastoma. How would you prepare the child for chemotherapy? What activities would you propose to keep the child occupied while an IV solution is infusing?
3. An adolescent has been diagnosed as having Hodgkin's disease. How would you explain this disease to him? He is active in a school sports program and works part-time in a supermarket. How will you answer if he asks you whether he should stop these activities?
4. Examine the National Health Goals related to neoplasms and children. Most government-sponsored funds for nursing research are allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to Geri's family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to children with malignancies. Confirm your answers are correct by reading the rationales.

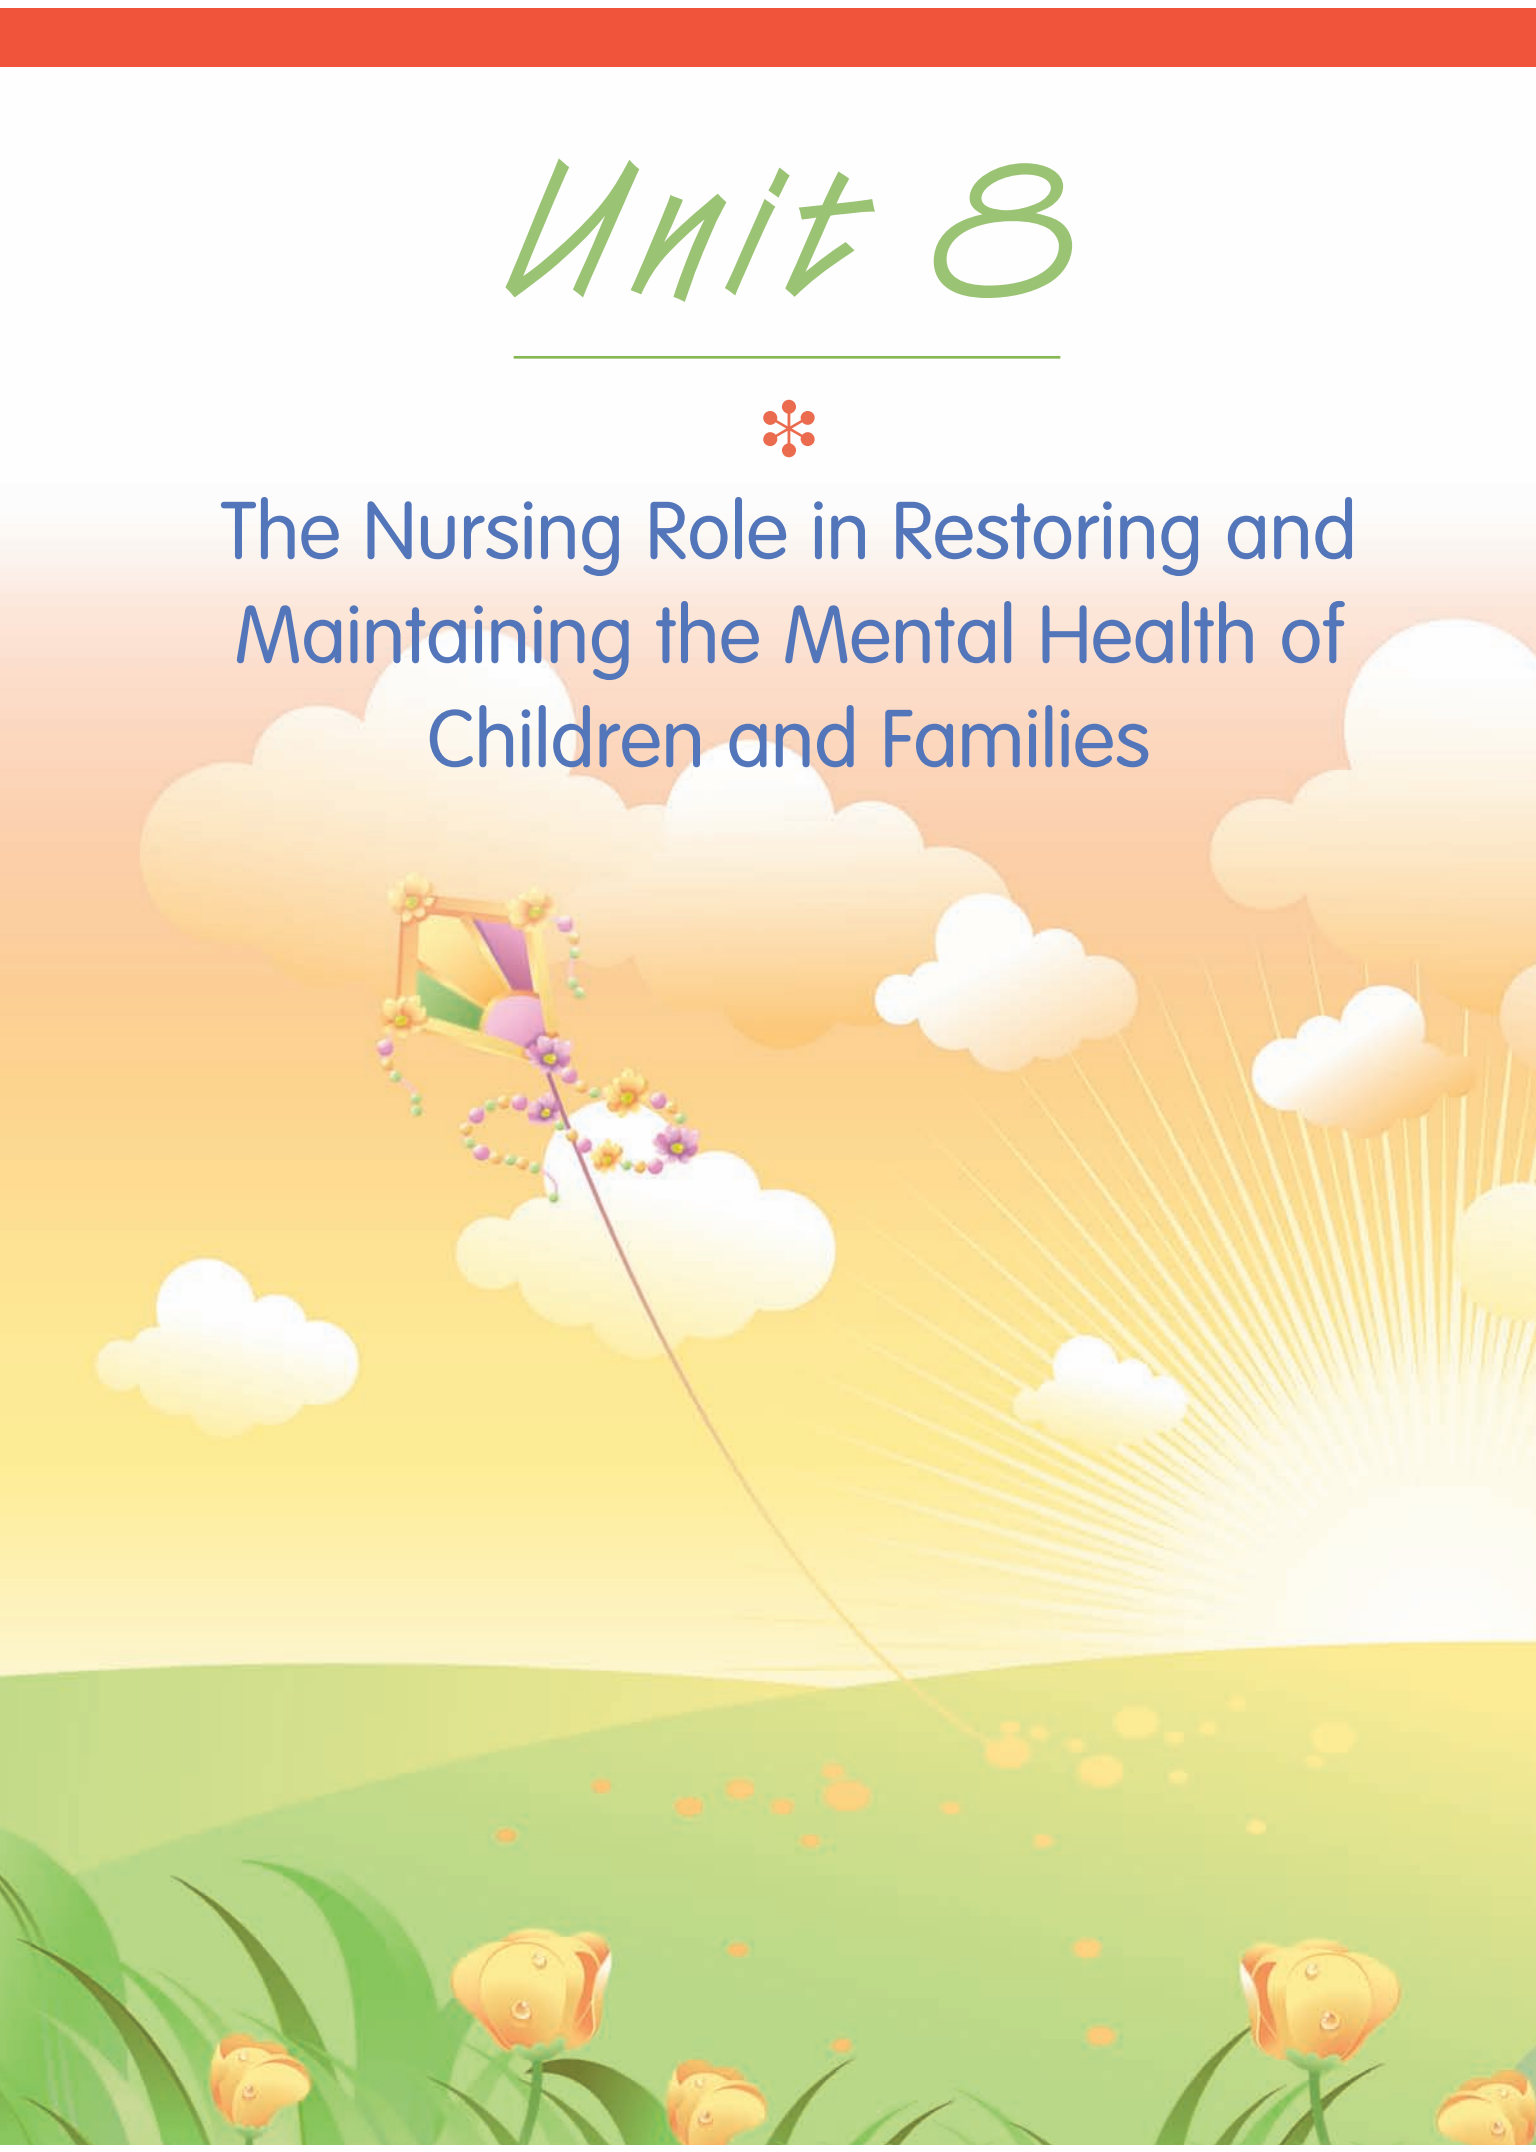
Unit 8

The Nursing Role in Restoring and Maintaining the Mental Health of Children and Families



This page intentionally left blank.

Chapter 54

Nursing Care of a Family When a Child Has a Cognitive or Mental Health Disorder

KEY TERMS

- anhedonia
- binge eating
- catatonia
- choreiform movements
- complex vocal tics
- coprolalia
- dyslexia
- echolalia
- flat affect
- graphesthesia
- hyperactivity
- labile mood
- motor tics
- palilalia
- purging
- stereognosis
- vocal tics

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe common cognitive and mental health disorders that occur in children.
2. Identify National Health Goals related to cognitive or mental health disorders nurses can be instrumental in helping the nation achieve.
3. Analyze ways that care of a child with a cognitive or mental health disorder can be more family centered.
4. Assess a child for a cognitive or mental health disorder.
5. Formulate nursing diagnoses related to the cognitive or mental health disorders of childhood.
6. Establish expected outcomes for a child with a cognitive or mental health disorder.
7. Plan nursing care for a child with a cognitive or mental health disorder.
8. Implement nursing care for a child with a cognitive or mental health disorder, such as helping a parent reduce environmental stimuli.
9. Evaluate expected outcomes for achievement and effectiveness of care.
10. Identify areas related to cognitive or mental health that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of childhood cognitive and mental health disorders and nursing process to achieve quality maternal and child health nursing care.

You are working as a school nurse and meet Todd, a second grader who was diagnosed with attention-deficit/hyperactivity disorder (ADHD) approximately 6 months ago. You observe Todd coloring, running to the window, running to the door and opening and closing the door, and then throwing pamphlets out of an information rack. His mother tells you she is "at her wits' end" because Todd's attention span is so short and his behavior so disruptive. His father tells you he's proud that his son is "all boy."

Previous chapters described the growth and development of well children and the care of children with physiologic disorders. This chapter adds information about the dramatic changes that occur when children demonstrate a cognitive or mental health disorder. Such information builds a base for care and health teaching.

How can you help Todd's family? What additional education do they need?

Children who are mentally healthy successfully master the tasks of each developmental phase of childhood, develop the ability to trust adults, and grow up to possess a positive self-concept and sense of contentment within their own limits. In addition, there is a good emotional relationship between the parents and the child and a sense of safety and security in the home environment. Promoting healthy family functioning during health care visits, providing anticipatory guidance for parents about developmental milestones and needs, and listening carefully to both children and parents are important in fostering both the physical and mental health of children.

Mental health implies that a child is able to use adaptive coping mechanisms appropriately to meet the normal stressors of life. Often, these stressors provide growth-producing challenges or help a child achieve the tasks of each developmental phase, such as establishing a sense of trust or independence. This is one of the reasons why providing age-appropriate stimulation is an essential nursing responsibility. Some stressors in life, however, go beyond what is considered "the norm." Acute illness and hospitalization and a natural disaster such as a flood are examples of increased stress. Chronic illness may provide an even greater stress, as the acute phase fades into recognition of long-term disability or an ultimately fatal prognosis. Nurses must be able to recognize the effects of illness and hospitalization on children and their families and to provide interventions to prevent maladaptive coping mechanisms. Being aware of the potential emotional responses a child might have to a particular illness and the implications for family functioning is essential to this ability (Eisendrath & Lichtmacher, 2009).

Children can develop the same mental health disorders that affect the adult population, such as depression or schizophrenia. In addition, several disorders such as pervasive developmental disorders (autistic disorders) begin in childhood. Some problems, such as separation anxiety, may consist of behavior that is considered normal at one stage of development (infancy) but pathologic at another (adolescence). Current research attributes some of these disorders to genetic vulnerability and others to disruption in family life, temperament, or inadequate parent–child bonding and attachment difficulties. Children with mental illness, whatever the cause, must be evaluated and treated by specialists in the mental health field as early in their disease process as possible. The child health nurse is often the first to become aware of such problems and can be instrumental, through appropriate referrals, in helping a child and family adjust to the disorder.

Cognitive and mental health disorders addressed by National Health Goals are shown in Box 54.1.

BOX 54.1 ✻ Focus on National Health Goals

Cognitive and mental health disorders in children produce major costs to the nation, as well as to individual families, because these disorders have the potential to reduce the earning power and contributions of future citizens. Several National Health Goals directly address this issue:

- Increase the proportion of children with mental health problems who receive effective treatment from a baseline of 59% to 66%.
- Reduce the proportion of adolescents who engage in disordered eating behaviors in an attempt to control their weight from a baseline of 19% to 16%.
- Increase the proportion of juvenile residential facilities that screen admissions for mental health problems from a baseline of 50% to 55%.
- Reduce the proportion of children and adolescents with disabilities who are reported to be sad, unhappy, or depressed, from a baseline of 31% to a target level of 17% (http://www.nih.gov).

Nurses can help the nation achieve these goals by educating parents to seek prenatal care, so that low birth weight and the threat of physical challenges can be reduced; educating about ways to reduce stress in families; and identifying children in school and health care agency settings who demonstrate a high level of stress or other symptoms of mental illness.

Additional nursing research questions for this area could include: What are the questions on a health history that would best reveal mental stress? Can nurses successfully identify adolescents who are at high risk for eating disorders? What support measures are most helpful to families of a child with mental illness or cognitive challenge?

Nursing Process Overview

For Care of a Child With a Cognitive Challenge or Mental Illness

Assessment

Both personality and mental growth potential in a child are influenced by several factors, including genetic makeup, cultural background, family environment, and community resources. All of these need to be taken into account when assessing a child's cognitive or mental health. Assess children for emotional as well as physical problems at regular health maintenance visits. If an emotional problem has been identified or is suspected, obtain a detailed history of the presenting problem, the presumed reason for its appearance, relevant past history, the child's school and social history, the child's developmental history, the family history, and the current pattern of family functioning.

Nursing Diagnosis

Nursing diagnoses established for ill children often address mental health or the response of children and their families to their condition or treatment. Examples of these diagnoses are:

- Anxiety related to surgical experience
- Fear related to potential loss of independence secondary to traumatic injury
- Situational low self-esteem related to disfiguring scars after accident
- Powerlessness related to loss of independence and control in hospital environment
- Hopelessness related to prolonged caretaking responsibilities for chronically ill child

- Compromised family coping related to overwhelming number of stressors placed on family at one time

Additional nursing diagnoses are appropriate if a problem of cognitive or mental health is present:

- Risk for self-directed violence related to impulsivity
- Impaired social interaction related to short attention span and distractibility
- Interrupted family processes related to inability of child to follow instructions
- Disturbed thought processes related to the effects of schizophrenia
- Impaired verbal communication related to depression and withdrawn behavior
- Ineffective health maintenance related to inattention to food or hygiene needs
- Situational low self-esteem related to lack of successful coping strategies

Outcome Identification and Planning

Although the diagnosis of a mental health disorder or referral to a child guidance or psychiatric clinic does not carry the stigma it once did, many parents still believe that such a referral is a mark of inadequacy or a sign of failure for themselves as parents. Help parents to see that this type of referral is no different from one to a cardiologist or orthopedist for a purely physical reason.

Parents can be reminded that everyone recognizes the many pressures and stresses on children today that cannot be controlled or guarded against completely. Many parents find it reassuring to be told that their contact with a child guidance clinic, psychologist, or psychiatrist will be kept confidential. They also feel reassured by knowing that the health care personnel making the referral will continue to offer episodic or health maintenance care—that they are not being "transferred out" but asked to seek additional help only in this one area.

Organizations that might be helpful for referral include Anorexia Nervosa and Related Eating Disorders, Inc. (http://www.anred.com), Autism Society of America (http://www.autism-society.org), Tourette Syndrome Association, Inc. (http://www.tsa-usa.org), National Association for Down Syndrome (http://www.nads.org), and National Mental Health Association (http://www.nmha.org).

Implementation

Often what parents and children need most when a cognitive or mental health disorder is identified is an empathic but uninvolved person to listen to their story objectively and to provide support for them as they try to resolve and manage the situation to a satisfactory conclusion. Recognizing when you are the person best able to serve this function requires professional judgment. Serving in this capacity can not only be a help to families but be personally satisfying as well.

Outcome Evaluation

Children who have a cognitive or mental health disorder need ongoing evaluation by health care personnel at routine visits, because these disorders are long term. In addition, it is important to determine whether any circumstances that might have led to a temporary problem have truly been corrected or only superficially changed. If the circumstances surrounding the child remain the same, the child's problem may return or be manifested later in another way.

Examples suggesting achievement of expected outcomes are:

- Child does not injure himself during the coming month.
- Parents state they are able to cope with child's disruptive behavior since prescription of antipsychotic drug.
- Child ingests a minimum of 500 calories daily with no binge eating.
- Parents state that they accept that their child is cognitively challenged.

HEALTH PROMOTION AND RISK MANAGEMENT

Nurses play a key role in assessing and promoting the mental and cognitive health of children and their families. A working knowledge of the typical growth and development of a child provides the basis for assessment (Box 54.2). This knowledge also helps develop appropriate educational strategies for parents so that they can better cope with child care. Like adults, children and adolescents cannot be completely shielded from stress; when stress does enter their lives, they cope with this differently than adults. Nurses can help parents better understand how children respond to and cope with stress, which also aids in early identification should a problem arise. Acting as educator, facilitator, and advocate, nurses can assist children

BOX 54.2 ✻ Focus on Evidence-Based Practice

Why do adolescents think they are not as mentally healthy as their parents think they are?

To determine if this is true, researchers examined data on 1157 adolescents aged 12 to 15 years from the National Health and Nutrition Examination Survey. Results of the analysis showed that parents and youth differed in their judgments regarding the child's health, even when these differences were not supported by other health indicators such as days of school missed because of illness or injury or documented days of poor mental or physical health. Adolescents from a lower socioeconomic status reported worse self-rated health than higher-income youth, and their parents rated them this way, also. Poor youth who had gone for a mental health visit in the last year reported better health than others, but their parents saw these mental health visits as an indication of poor health.

Based on this study, would you want to ask a 16-year-old boy or ask his father about whether the boy was feeling depressed?

Source: Johnson, S. B., & Wang, C. (2008). Why do adolescents say they are less healthy than their parents think they are? The importance of mental health varies by social class in a nationally representative sample. *Pediatrics, 121*(2), e307–e313.

TABLE 54.1 ✻ Guidelines for the Mental Health Interview of a Child

Observational Data	Examples of Possible Findings
General appearance	Height, weight, grooming and hygiene, nutrition, physical health, distinguishing features (deformities, tics), maturity level
Motor behaviors	Fine and gross balance, bizarre motor activity
Speech and language	Receptive, expressive; content, tone, and articulation
Affect	Range of emotion, predominant emotion (depressed, angry, anxious, happy, irritable, labile), emotional reactions to process and/or content of interview (appropriate, inappropriate)
Thought process	Estimated intellectual level via language and knowledge base (organization and thought content), orientation (to person, place, time), perceptual distortions (hallucinations, illusions, tangentiality, obsessions, delusions), attention span, learning disabilities
Ability to relate to evaluator	Eye contact, attitude toward interviewer (negative, positive, shy, suspicious, withdrawn, friendly, self-centered)
Behaviors displayed during interview	Impulsivity, aggression, inhibition, distractibility, low frustration tolerance, ability to have fun, sense of humor, creativity
Interview Data	
Interpersonal relationships	Attitudes toward and perceptions of family, siblings, peers, transitional objects (inanimate objects used to allay anxiety), pets; social skills with peers, best friend; relationships with family, siblings, and peers; conflicts; behavior problems; adjustment to changes in routine or new situations
Self-concept and image	Self-appraisal (does child like self?), comparison of self with others (siblings, peers), what does child like most about self? What would the child like to change about self? Sense of pride in accomplishments, sex role, and gender identity
Conscience	Understands right and wrong, is able to express common judgments or values.

and families to identify their needs and implement measures to meet them. Table 54.1 lists some helpful observational and interview data for assessing these areas.

Cognitive and mental health disorders have always been perplexing to people, so the history of acceptance for children with such disorders is poor. In ancient civilizations, physicians bored holes in children's heads to let out what they perceived to be evil spirits; modern television programs or movies still show distorted perceptions of behaviors associated with people who are cognitively challenged or have a mental illness. Such misperceptions make it difficult for parents or siblings to accept these diagnoses. Taking time to talk with them about modern management of these disorders and the ways that children who are mentally ill or cognitively challenged can be integrated into a family can be a major intervention in helping families adjust to and grow with these disorders.

Various factors have been associated with an increased risk for mental health disorders in children, including:

- Trauma or neglect
- Difficult temperament
- Attachment problems
- Experience of major losses
- Negative sibling relationships
- Medical problems and illnesses
- Exposure to high-risk activities, such as drug abuse
- Poverty and homelessness
- Parental substance abuse

A thorough assessment of the child and family can provide clues to the existence of such possible risk factors and suggest strategies to reduce their impact. If a child develops a cognitive or mental health disorder, nurses can act as advocates to obtain referrals to support services and early intervention programs, helping to minimize the overall effects of the disorder on the child and family.

CLASSIFICATION OF MENTAL HEALTH DISORDERS

For many years, psychopathology in children was not classified according to a standard system; as a result, conditions were not clearly defined or described. Today, after several revisions, the *Diagnostic and Statistical Manual of Mental Disorders—Text Revised, Fourth Edition (DSM-IV-TR*; 2000), published by the American Psychiatric Association (APA), provides a standardized classification system that can be used by all members of the mental health care team.

DEVELOPMENTAL DISORDERS

Developmental disorders, although not related by etiology, typically share a common feature in that there is a delay in one or more areas of development. These areas include attention, cognition, language, affect, and social and moral behavior. Because these behaviors are interrelated, a delay in one area may interfere with development in another area. Developmental disorders include cognitive challenge, pervasive developmental disorders, and specific developmental disorders such as learning disorders, motor skills disorders (developmental coordination disorders), and communication disorders.

Cognitive Challenge

The DSM-IV-TR defines cognitive challenge (mental retardation) on the basis of two criteria: significantly subaverage general intellectual functioning—an intelligence quotient (IQ) of 70 or lower with onset before 18 years of age—and concurrent deficits in adaptive functioning (APA, 2000). For infants, because available intelligence tests do not yield numerical values, a clinical judgment of significant subaverage intellectual function must be made.

Approximately 2% of children in the United States are cognitively challenged. This is not the result of a single cause but of conditions such as genetic abnormalities like fragile X syndrome and Down syndrome (trisomy 21) and metabolic disorders such as phenylketonuria. In addition, an interplay of several genes with environmental factors (polyfactorial causes) have been identified as a possible cause in some children (Box 54.3).

Children who are cognitively challenged are seen in health care settings for diagnosis, and they come to health settings throughout their lives for the same reasons as other children—for well-child care at ambulatory health maintenance visits; for treatment of lacerations or poisoning in emergency departments; or for treatment of illnesses such as pneumonia or appendicitis in in-service units. For these reasons, child health nurses need to be skilled in meeting the needs of cognitively challenged children.

Classification

It is unfair to categorize children only according to the results of intelligence tests, because children do not always perform well in testing situations. Commonly, cognitive challenge is classified as mild, moderate, severe, or profound according to IQ. The IQ level of 70 was chosen as the upper limit of cognitive challenge because most children with IQs below this level are so limited in their functioning that they require special services, protection, and schooling. IQ tests are considered to have an error of measurement of about 5 points. Therefore, many children with an IQ of 75 are included in special schooling programs. Assessing for physical illness in children who are cognitively challenged at any level is difficult because they cannot relate symptoms as well as other children (Goldson & Reynolds, 2008).

Mild Cognitive Challenge. About 85% of children who are cognitively challenged fall into this category (APA, 2000). In this group, a child's IQ is between 50 and 70. The category is equivalent to the category "educable" used by school systems. During early years, these children learn social and communication skills and are often not distinguishable from average children. They are able to learn academic skills up to about the sixth-grade level. As adults, they can usually achieve social and vocational skills adequate for minimum self-support. They can live independently but need guidance and assistance when faced with new situations or unusual stress.

Moderate Cognitive Challenge. Children in this category have an IQ between 35 and 49. About 10% of cognitively challenged children fall into this category (APA, 2000). During preschool years, these children learn to talk and communicate, but they have only poor awareness of social conventions. They can learn some vocational skills during adolescence or young adulthood and can learn to take care of themselves with moderate supervision. They are unlikely to progress beyond the second-grade level in academic subjects. As adults, they may be able to contribute to their own support by performing unskilled or semiskilled work under close supervision in a sheltered workshop setting. They may learn to travel alone to familiar places. They need supervision and guidance when in stressful settings.

Severe Cognitive Challenge. Children in this group have an IQ between 20 and 34. About 4% of cognitively challenged children fall into this category (APA, 2000). During the preschool period, these children develop only minimal speech and little or no communicative speech. They usually have accompanying poor motor development. During school years, they may learn to talk and can be trained in basic hygiene and dressing skills. As adults, they may be able to perform simple work tasks under close supervision, but as a group they do not profit from vocational training. They need constant supervision for safety.

Profound Cognitive Challenge. The IQ of children in this group is less than 20. Fewer than 1% of cognitively challenged children fall into this group (APA, 2000). During the preschool period, these children show only minimal capacity for sensorimotor functioning. They need a highly structured environment and a constant level of help and supervision. Some children respond to training in minimal self-care, such as toothbrushing, but only very limited self-care is possible.

Assessment

Assessment regarding whether a child is cognitively challenged is done by history taking and IQ testing. Early assessment is key and should be done as soon as parents become aware that their child is experiencing problems with development. This helps to prevent parents from developing unrealistic expectations of children or punishing children for doing things that they don't understand not to do. Assessment also allows parents to look at the things children can do and to see where they can be of most help.

Intelligence is routinely measured with standardized tests, such as the Stanford-Binet test. Adaptive behavioral

BOX 54.3 ❇ Common Causes of Cognitive Challenge

- Chromosomal abnormalities such as Down syndrome and fragile X syndrome
- Infection in utero, such as rubella or cytomegalic inclusion disease
- Anoxia at birth from such causes as umbilical cord compression
- Fetal alcohol syndrome
- Inherited metabolic disorders such as phenylketonuria
- Head trauma
- Lead poisoning
- Hypothyroidism
- Brain malformations such as anencephaly
- Very low birth weight
- Infections such as measles encephalitis

functioning, which may vary in different environments, is judged according to several methods, including standardized instruments for assessing social maturity and adaptive skills. A composite picture of life functioning is drawn from these multiple sources.

Parents may react to the diagnosis of cognitive challenge in the same way as parents who have been told that their child has a chronic or fatal illness—with a grief reaction. This may be manifested as disbelief, anger, or extreme sorrow. The grief may become chronic—always present, always waiting to strike a parent especially hard at times when the child would have reached milestones in life, such as the first day of school or high school graduation. Work with the family to develop plans that are realistic. A child cannot achieve more than an individual disability will allow, but you can help parents better accept the child's limited capabilities.

Therapeutic Management

To aid in planning, parents need a realistic prognosis for their child. This may be difficult to offer in early life, because infant intelligence tests are not accurate and more sophisticated tests are difficult to administer until the preschool years. Because prediction based on these early tests involves some subjective input, a child's potential may be overrated or underrated by them. Once parents have a realistic expectation based on the best judgment possible, however, they are ready, with guidance, to help their child achieve the child's full potential.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Health-seeking behaviors related to increasing knowledge of care needs of a cognitively challenged child

Outcome Evaluation: Parents identify their particular options; identify child's care needs; demonstrate measures to care for child.

Parents of children who are cognitively challenged have several important decisions to make concerning care of their child.

Institutional Care Versus Home Care. At one time, if a child was born with a disorder such as Down syndrome, parents were advised to place the child in an institution immediately. Today, very few institutions of this type are available. Parents are encouraged to keep children at home and to maintain a home and school environment for them that is as near normal as possible. This plan has definite advantages for children who are only mildly or moderately delayed. The give-and-take of a home environment improves a child's ability to relate to other people. Because a small group of people cares for them, stimulation and desire to achieve are increased.

Parents shoulder a great deal of responsibility to provide constant watchful care, especially for a child with problems affecting judgment. This responsibility increases as both the child and the parents grow older. The parents' freedom to go on vacation or to have an adult life apart from the child is restricted. They may spend so much time with the child that other children in the family feel left out, unloved, or burdensome.

If parents are unable to care for a child at home, a suitable foster home placement may be possible, offering the child the advantage of a family setting. Halfway houses or group homes (6 to 12 children living in a home with assigned counselors) can provide a care setting with a home atmosphere and community experiences.

Before giving advice to any family about where a child should be raised, consider the individual circumstances of the family. Every family has its own coping mechanisms, and individual parents may be at different stages of coping, especially during the first year after the birth of a child with a severe disability. Be certain to consider the feelings of each family member and how adequately they are coping.

Health Maintenance Needs. Children who are cognitively challenged need the same health maintenance supervision as other children. At health care visits, parents may need reinforcement and review of precautions against accidents. Remind them to treat children according to their intellectual age, not their chronologic age. All 2-year-old children would turn on the burners of the stove to see the flame if they could reach them. Most do not, however, because they cannot reach that high. The mother of a 6-year-old child who thinks like a 2-year-old must be exceedingly careful: her child can reach the same dangerous areas as any 6-year-old child can but may explore and touch them with a 2-year-old child's judgment.

Illness. It may be more difficult to detect illness in children who are cognitively challenged because they may not be able to describe the problem. For example, children experiencing pain may respond to it by generalized crying, as infants do. Parents must observe their child closely for symptoms such as tugging at an ear, refusing to swallow food, rapid breathing, or limping, because these symptoms will help to localize the discomfort. When they call health care personnel, parents may be apologetic about their lack of ability to judge their child. Help parents to become advocates for their child. They know their child better than anyone else. The parents may not know exactly what is wrong, but they do know that something is wrong. Reassure the parents that they have done the correct thing by calling to check out the problem.

When children with a cognitive challenge are seen in an emergency department or an ambulatory setting for care, they need simple explanations of what will happen. The average 6-year-old child sees you with a thermometer in your hand and thinks, "She's going to take my temperature." Your explanation that you are going to do that only confirms what the child has already guessed. A child who is cognitively challenged may be unable to make this association between the thermometer and what you are going to do. Your explanation, therefore, is the first introduction to the event. Make certain that it is adequate.

When children are admitted to the hospital, nursing care must meet the needs of a child's intellectual age,

not the chronologic one. For example, whether safety precautions such as side rails or possibly restraints will be necessary must be judged according to intellectual age. The explanations and preparations for procedures also must be geared to intellectual age.

When cognitively challenged children are discharged from a hospital, parents need careful explanations of signs and symptoms to look for to ensure continued good health in the child. Remember that such signs may be more difficult to elicit, depending on the degree of the child's cognitive challenge. Be sure parents have a telephone number they can call to seek further information or advice if they are unsure of their own observations in the period immediately after discharge.

Education. Most children who are cognitively challenged do well in preschool programs, possibly giving them a head start in learning to socialize with peers and to develop fine and gross motor coordination.

The school chosen for the child depends on the degree of intellectual delay and on the school settings available in the community. Children should be included in regular classes as much as possible–termed inclusion or main streaming (Fig. 54.1). These classes offer children a great deal of stimulation and help them reach their best potential. They also help them learn to work and socialize with people, something they will need to do for the rest of their lives. Advocating for school placement of a child in an inclusive program may be necessary. By federal law, children have the right to be educated in the least restrictive environment possible. Children who are cognitively challenged need an individualized education plan (IEP) developed based on the child's individual learning style and projected capabilities. In addition, they need safety instructions such as how to locate the correct bus for the trip home from school. If they walk to school, they need appropriate supervision to ensure safety when crossing streets.

FIGURE 54.1 A teenage boy with Down syndrome participates in a high school art class. (© Richard Hutchings/Science Source/Photograph Researchers.)

Nursing Diagnosis: Delayed growth and development related to cognitive impairment

Outcome Evaluation: Child performs self-care within limits of disorder; exhibits feelings of satisfaction with accomplishments.

Self-Care Activities. Children who are cognitively challenged need to learn the maximum amount of self-care possible. Doing so provides them with a sense of control and accomplishment. Carefully assess whether children need special aids to achieve such skills as brushing teeth, combing hair, taking a bath, and eating. Even after children learn how to perform these skills, they may need continued reminders to do them, because they are unaware of the reason for or importance of the skill. If you perform these skills for children, such as during a period of hospitalization, they can forget how to perform them and need to be retaught after they return home (Box 54.4).

Play. Children with intellectual delays enjoy play like any child. Guide parents to choose toys that are appropriate for their child's developmental, not chronologic, age. Toys that cover a wide age range, such as

BOX 54.4 ✻ Focus on Family Teaching

Teaching Guidelines for the Cognitively Challenged Child

Q. The mother of a child who is cognitively challenged says to you, "How can we make sure our son can learn as much as he is able?"

A. Here are some guidelines for teaching:

- Teach one step at a time. Short-term memory is often possible, whereas long-term memory is not. This means a child can learn only one step of a skill at a time (remembering three consecutive steps requires long-term memory).
- Introduce motivators for learning, such as generous praise. Learning may not be rewarding all by itself when intelligence is impaired.
- Reduce the number of extra stimuli present. Faced with too many stimuli, a child cannot focus attention on the task to learn (or realize that the task is more important than surrounding stimuli).
- Demonstrate the skill to be learned. Seeing a skill performed is generally better than just hearing it explained.
- Keep things simple. Cognitively challenged children may have difficulty with learning principles or abstractions. They may be able to learn to wash their hands, for example, but not why they should wash them (other than that it pleases you).
- Give praise accordingly. Remember that accomplishing even the most simple skill may be very difficult for your child. Learning to tie shoes may take the same effort as another child spends learning mathematics. Learning to cross streets safely may be equivalent to earning a high school diploma.

music boxes or CD players, are good choices. Because children who are cognitively challenged may be older and stronger than the age stated for a toy, toys that are developmentally correct still may not be appropriate because they break too easily to be safe.

Social Relationships. The ability to communicate may be delayed in children who are cognitively challenged, because the ability to develop language is often delayed. Speech therapy may be necessary to help them articulate correct sounds. Talking picture boards (boards with pictures on them, available commercially or made by parents), to which children can point if they want something can help speed communication.

Teaching early social behavior, such as saying "thank you" and "excuse me," shaking hands, and taking turns, is important to help children relate to other children and adults. Cognitively challenged children imitate this type of behavior the same as other children do. Providing good role models is an effective way of teaching social behavior.

Encourage parents to enroll children in preschool programs to help them learn to be comfortable with other children at the earliest time possible. Many programs enroll children as early as 1 year of age to begin education. For a school-age child, participating in organized groups such as Girl Scouts or Special Olympics is an important way to learn to interact with others and feel successful.

Preparation for Adulthood. As children who are cognitively challenged reach adolescence, they benefit from orientation to sexual responsibility, the same as all children. Girls can understand a simple explanation of menstruation and necessary menstrual hygiene. Both boys and girls need explanations of how pregnancy occurs and the measures they need to take to prevent this. Help them understand socially acceptable sexual activities.

If a girl is going to use a contraceptive and lives with a responsible adult, she can be given an oral contraceptive daily by that adult. Longer-acting contraceptives, such as Depo-Provera, which do not require daily administration, also are available. Sterilization is not recommended, because it is difficult for a cognitively challenged adolescent to understand fully the implications of the procedure, so their consent is not fully informed. If pregnancy should occur, an adolescent who is cognitively challenged can be counseled but not forced to have an abortion. If the adolescent decides to continue the pregnancy, assist her through the pregnancy and planning safe care for her child.

What if... A 15-year-old girl who is mildly cognitively challenged, comes to your school office. During your conversation, she asks you if she should have a baby. How would you respond?

Pervasive Developmental Disorders: Autistic Disorder

As a category, pervasive developmental disorders are characterized by impairment in social and communication skills and the display of stereotypical behaviors (APA, 2000). Autistic disorder is marked by severe deficits in language, perceptual, and motor development; defective reality testing; and an inability to function in social settings. There often is a lack of responsiveness to other people, gross impairment in communication skills, and bizarre responses to various aspects of the environment, all developing within the first 30 months of age. It is not as rare as once thought, occurring in 16-40/10,000 children (Hagman & Dech, 2008). Autism occurs more often in boys than in girls and may have a genetic cause (Volkmar, 2008). As many as 50% of children with the disorder are also cognitively challenged (APA, 2000). As many as 20% may have coexistent mental health diagnoses (Mouridsen et al., 2008). A former concern that immunization may precede or cause the disorder has now been ruled out as a cause (Clifton, 2007).

Assessment

Common symptoms of autistic disorder are summarized in Box 54.5. Because of the lack of responsiveness to people that is part of the syndrome, normal attachment behavior does not develop. Although autism often is not diagnosed until the child is 2 to 3 years of age, parents report that they were worried much earlier because their infant failed to cuddle, make eye contact, or exhibit facial responsiveness. Infants may not reach to be picked up. They are unable to play cooperatively or make friendships. Parents may first bring a child to a health care facility thinking that the child is deaf because of this inability to establish normal relationships.

The impairment in communication is shown in both verbal and nonverbal skills. Language may be totally absent. If a child does speak, grammatical structure may be impaired, such as the use of "you" when "I" is intended. There is inability to name objects (nominal aphasia) and abnormal speech melody, such as question-like rises at the end of statements. **Echolalia** (repetition of words or phrases spoken by others) and concrete interpretation also may be present.

Bizarre responses to the environment may include intense reactions to minor changes in the environment (perhaps screaming if a toy box is moved across the room) and attachment to odd objects such as always carrying a string or a shoe. Repetitive hand movements, rocking, and rhythmic body movements are

BOX 54.5 ✻ Common Symptoms in the Child With Autistic Disorder

- Failure to develop social relations
- Stereotyped behaviors such as hand gestures
- Extreme resistance to change in routine
- Abnormal responses to sensory stimuli
- Decreased sensitivity to pain
- Inappropriate or decreased emotional expressions
- Specific, limited intellectual problem solving abilities
- Stereotyped or repetitive use of language
- Impaired ability to initiate or sustain a conversation

often observed. Children are intensely preoccupied by objects that revolve, such as a fan, the swirling water in the toilet bowl, or a spinning top. Music often holds a special interest for them. Hitting, head banging, and biting also may be present.

Children with autistic disorder are said to have a **labile mood** (crying occurs suddenly and is followed immediately by giggling or laughing). They may react with overresponsiveness to sensory stimuli, such as light or sound, but then be unaware of a major event in the room, such as the sound of a fire alarm.

In contrast to these mannerisms, long-term memory and "savant" skills (exceptional skills such as virtuoso piano playing) may be excellent (Nicholas et al., 2008). Autistic children may be able to recall dates and spoken words from conversations that took place years before. This excellent memory previously led to the belief that most of these children have normal intelligence. Actually, the majority of children with autistic disorder have an IQ of less than 70 (APA, 2000). Intelligence testing is difficult, however, because children with autistic disorder do not respond well to test situations, and they score poorly on the verbal parts of these tests. Tasks requiring manipulative or visual skills or immediate memory may be performed at above-normal levels.

Therapeutic Management

Autistic disorder is a perplexing condition. Parents need a great deal of support so that they do not reject their child because the child seems to be rejecting them because of a lack of interaction. Behavior modification therapy may be effective in controlling some of the bizarre mannerisms that accompany autism, but, because the basic cause of the disorder is not known, therapy will not always succeed. Although various medications such as SSRIs (selective serotonin reuptake inhibitors) have been tried because of their potential to alleviate anxiety and reduce behavioral rigidity no medications specific for autism are as yet effective.

As children mature, they develop greater awareness of and attachment to parents and other familiar adults. A day care program can help to promote social awareness. Some children may eventually reach a point where they can become passively involved in loosely structured play groups. Some children may be able to lead independent lives, although social ineptness and awkwardness may remain, especially if accompanied by cognitive challenges.

✔ Checkpoint Question 54.1

Suppose Todd had symptoms of autism. Which of these symptoms is common in autism?

a. Lack of short-term memory.
b. Hallucinations of voices talking.
c. Constant whirling around in a circle.
d. Severe depression or feelings of sadness.

Specific Developmental Disorders

Specific developmental disorders are characterized by the more narrowed area of development involved with the delay. Typically, these include learning disorders, communication disorders, and motor skills disorders.

Learning disorders occur in approximately 5% of children in the United States. Although the degree may vary, these disorders involve a discrepancy between actual achievement and what is expected based on the child's age and intelligence. Learning disorders may involve **dyslexia** (reading reversal), mathematics, or writing. Children may develop accompanying low self-esteem and deficits in social skills because of the primary disorder (APA, 2000). Children need individualized educational plans to help them achieve at the highest level possible.

Communication disorders involve problems of speech (motor aspect) or language (formulation and comprehension of verbal communication). Examples include expressive disorders, phonologic disorders, and stuttering. Like learning disorders, these conditions can lead to a lack of self-esteem unless a child receives support and encouragement from parents, teachers, and health care providers. Speech therapy can effectively improve these disorders and allow children to achieve sufficiently to become successful adults.

ATTENTION-DEFICIT AND DISRUPTIVE BEHAVIOR DISORDERS

Attention-deficit disorder and the disruptive behavior disorders may begin with behavior problems that are not so different from what most families experience. For this reason, parents may be unaware of the need for intervention initially. By the time they do seek help, they may already be extremely distressed about the seeming unmanageability of their child.

These disorders need to be diagnosed as early as possible, before the child's behavior leads to a deteriorating level of self-esteem, compromised social skills, and complications in family functioning. The home environment may be the most important factor in determining whether a disorder turns into a more complicated psychopathologic process or can be channeled into purposeful, productive activity.

Attention-Deficit/Hyperactivity Disorder

Attention-deficit/hyperactivity disorder (ADHD) is a persistent pattern of inattention and/or hyperactivity-impulsiveness revealed before the age of 7 years (APA, 2000). It is estimated to occur in about 3% to 7% of school-age children in the United States. Boys are affected more frequently than girls. Although the cause is unknown, it occurs more frequently among some families than in the general population, indicating a possible genetic etiologic component. ADHD has also been associated with child neglect, lead poisoning, and drug exposure in utero (APA, 2000). Both drug and behavior modification treatment methods have been used with success, a fact that may support the theory of varying causes.

The disorder is characterized by three major behaviors: inattention, impulsiveness, and hyperactivity (Sykora, 2008). Inattention makes children unable to complete tasks effectively. They become easily distracted and often may not seem to listen. Impulsiveness causes them to act before they think and therefore to have difficulty with such tasks as awaiting turns at games. With hyperactivity, children may shift excessively from one activity to another, exhibiting excessive or exaggerated muscular activity, such as excessive climbing onto objects, constant fidgeting, or aimless or haphazard running.

Assessment

The disorder is diagnosable by 36 months of age, although parents may excuse the behavior as "active" or "always on

the go" until school age, when it is apparent that the child cannot sit still in school or concentrate on problem solving for long periods. When the disorder is first suspected, a thorough initial history to reveal the extent of the problem needs to be obtained. The history is important, because some children have enough control in a one-to-one situation that their extremes of behavior are not apparent in an ambulatory health care setting.

Review the pregnancy and birth history, the child's ability to meet developmental milestones, and a typical day for the child. The term **hyperactivity,** or excessive movement, is commonly carelessly used by parents to describe any active child. Have the parent give an exact description of what the child is unable to do, such as sitting still long enough to finish a full meal or running to the window 10 times in 15 minutes, to document that hyperactivity truly exists.

Assess for activity that is not only excessive but also disorganized. For example, in school, children with ADHD may run from the back of the room to the front of the room, to the window, to the teacher's desk, to their own desk throughout class. They perform repetitive activities such as pencil tapping, arm swinging, and finger tapping. At home, they may leave a project they are working on or a television program they are watching intently and run to the window or open the refrigerator door, unaware of why they are running. This is driven or compulsive behavior.

Variability is another important symptom. Everyone has days when they perform at their peak and days when their performance is less than optimum. Children with ADHD may have behavior so variable that they have good and bad *moments.* This type of variability causes them to lose track of systems and methods, not just answers, so school performance may falter. When asked to add, for example, a child might add 4 and 3 correctly, but then lose track of the system and add 2 and 3 as 23 or 32.

A high level of impulsiveness can cause children to make statements without thinking, to touch objects they have just been told not to touch, or to speak or act before they have time to think about what they want to say or do. When angered, they may shout, strike out, or bite before they can be offered an explanation. They may be unable to wait in line for a drink of water—their impulsiveness tells them that they must have their drink immediately.

Usually, children can filter out stimuli that are not important to them at that moment. Children with ADHD seem to have an "all-or-none" reaction to stimuli. They may block out all incoming stimuli and, as a result, do not hear their parents or a teacher calling them. They may be disciplined at school for something such as not answering a fire drill (unaware that a bell was ringing and that children around them were moving toward the exit). At other times, they may be unable to suppress any incoming stimuli. They mean to concentrate on a desk assignment in school, but, outside the window, they hear a bird singing; next to them, they smell a girl's perfume; they feel their watch on their wrist—so they cannot concentrate on the problem at hand. This may be reported by parents or teachers as an exceedingly short attention span.

Children with ADHD may also have difficulty with concepts such as *right* and *left*, *before* and *after*, *in front of*, *in back of*, and *yesterday* and *tomorrow*, because these concepts call for sequencing, the process of relating things to one another in time or space. If children cannot tell the difference between left and right, they can have difficulty forming common letters such as *b* and *d,* which vary only in the direction of the bottom loop. They can have difficulty with common tasks such as washing their hands, because they never know which way to turn a faucet. Turning door knobs and keys, tying shoe laces, and screwing on bottle caps are all complex tasks for a child who has difficulty with sequencing. They may show awkward motor movements and cannot work all muscles gracefully in proper sequence. These children may reach beyond an object, possibly spilling a glass of milk at the table at every meal.

Long after the average child is speaking in fluent sentences, children with ADHD may have difficulty using conjunctions or prepositions correctly (sequencing of words). They may have difficulty learning to read. To read words of more than one syllable, they must sound the first syllable, then retain that sound in their mind while they sound the second syllable. If they have difficulty retaining the first syllable long enough to connect it with the second, they cannot construct the word. Similarly, they can have difficulty with arithmetic, because they may be unable to retain the sum of two numbers long enough to add a third. Spelling may be equally difficult. Not only are they unable to sequence the letters in a word correctly, but they also cannot retain memory rules such as "i before e" to help them.

As a rule, children with ADHD do not have a deficit in intelligence, although they may seem to because of their impulsive behavior. They may be unaware that their behavior is upsetting to family, friends, and teachers and therefore are not anxious about their inability to conform to society's rules.

On physical assessment, these children often show many "soft" neurologic signs, such as inability to use a pencil or scissors well. A thorough neurologic examination often is difficult because their attention span is so short. On such an examination, they often have difficulty performing tests such as a finger-to-nose test or rapid hand movements such as touching one finger after another with the thumb. They tend to show "mirroring" with this movement (the second hand imitates what the first hand attempts to do). Cerebellar difficulty may be evidenced further by inability to perform a tandem walk or a heel-to-shin test. They may be able to identify one touch but not two simultaneous touches on their body. They may not show the normal responses of **graphesthesia** (ability to recognize a shape that has been traced on the skin) or **stereognosis** (ability to recognize an object by touch). When asked to stand with arms outstretched, **choreiform movements** (aimless movements) and rising of the fingers are often present. More definite neurologic signs, such as a unilateral Babinski reflex or strabismus, may also be present. Testing children through the use of games may be necessary so that their attention is maintained long enough to complete the assessment.

IQ testing is used to document intelligence. The Wechsler Intelligence Scale for Children (WISC), the test most often chosen, consists of two portions: a verbal scale and a performance scale. A child is given three final scores: verbal IQ, performance IQ, and combination or full-scale IQ. The child with perceptual and motor deficits tends to do poorly on the performance scale but average or better on the verbal scale. Children with language difficulty typically do poorly on the verbal scale but average or greater on the performance scale. Children with ADHD show a "scatter" pattern on both performance and verbal portions, doing well on some portions and poorly on others.

Children who have difficulty filtering out stimuli do poorly on group-administered intelligence tests because they are too distracted by those around them. For this reason, such children should take IQ tests individually. Neurologic examinations also should be performed in rooms that are free of distractions such as attractive toys.

Children with ADHD are often referred to a health care facility because they are having difficulty achieving in school. Parents may have been reassured on previous occasions that, although their child had difficulty settling down to tasks, this was because he was "all boy" or "every child is different." They may need time to accept that their child has a condition that interferes with learning. Active listening is essential. This is a difficult situation that may have persisted for a long time. The parents may be unaware themselves of the strain that has been produced until they start to describe it.

Therapeutic Management

A variety of treatment methods are used, often in combination, in the management of ADHD.

Environment. Construction of a stable learning environment is crucial for children with ADHD. This may include special instruction, free from the distractions of an entire class. Parents may have difficulty accepting the fact that their child needs special schooling (the intelligence test, after all, said their child was above average). They may need help in seeing that their child's condition interferes with intellectual functioning and that a special program must be constructed for the child to succeed.

Parents at home need to construct an environment that is as free of stimulating distractions as possible. Decorating with pastel colors rather than primary colors reduces environmental stimuli. Parents having difficulty at home with discipline and management often appreciate support and advice. Encourage them to be fair but firm and to set consistent limits. Although every child has the right to an opinion, many decisions that the average child enjoys making must be made for a child with ADHD. "Do you want to wear your red or your blue shirt today?" is less effective than "Here is your blue shirt to wear today."

Children who are easily distracted have difficulty completing chores or picking up their toys. They can be assigned age-appropriate chores with the understanding that a parent must give many reminders to them to get the job completed. Teach parents to give instructions slowly and to make certain that they have their child's attention before beginning instructions. Breaking down a chore into several steps may help (get the toy box is one step; pick up toys is a second). This helps to avoid confrontation that arises when children do not hear or do not process what is said to them.

All children like to participate in dinner conversation or discussions about their day. Children with ADHD often have difficulty telling a story or repeating a joke told to them (a sequencing problem). Suggest that parents help them by asking questions such as "Why?" "Where?" or "Who?" to reach the point of the story. Also encourage parents to be sure, when they correct behavior, that their anger is about something the child has deliberately done wrong, not about some incident that happened because of the child's inability to sequence, filter, or integrate concepts. Punishment should follow an offense quickly, because children with ADHD quickly forget what they did. As with all children, parents should make sure a child understands that the parent is angry at the behavior, not the child. Children with ADHD commonly develop poor self-esteem because, although they are intelligent, they cannot succeed. Help parents to build, not hinder, the development of self-esteem at every stage possible.

Medication. Several medications are helpful in reducing the excessive activity of children with ADHD and in lengthening the attention span or decreasing the distractibility so that they can function in normal classrooms. All of these medications have advantages and disadvantages.

Methylphenidate hydrochloride (Ritalin, Concerta [extended-release form]) is frequently prescribed for this disorder (Box 54.6). It works by stimulating dopamine receptors to

BOX 54.6 ✻ Focus on Pharmacology

Methylphenidate Hydrochloride (Ritalin, Concerta)

Classification: Methylphenidate is a central nervous system stimulant.

Action: Acts paradoxically in children with ADHD, possibly by stimulating dopamine receptors to calm rather than stimulate activity (Karch, 2009).

Pregnancy Risk Category: C

Dosage: Initially, 5 mg orally before breakfast and lunch, gradually increased in 5- to 10-mg increments weekly, not to exceed 60 mg/day. The extended-release form (Concerta) is administered once daily; dosage is determined by weight and symptoms.

Possible Adverse Effects: Nervousness, insomnia, anorexia, pulse rate changes, hypertension or hypotension, tachycardia, leukopenia, anemia, and growth suppression.

Nursing Implications

- Administer the drug exactly as prescribed, and instruct parents to do the same. Reinforce proper administration of once-daily extended-release form; instruct parents to have child swallow extended-release tablets whole and to refrain from chewing or crushing them.
- Instruct the parents to administer the drug before 6 PM to prevent interference with sleep.
- Advise the parents and child to avoid over-the-counter drugs, such as cold remedies and cough syrups that contain alcohol.
- Obtain baseline vital signs and monitor on follow-up visits for changes.
- Arrange for follow-up laboratory tests, including complete blood count for children on long-term therapy.
- Stress the need for adequate nutrition in light of possible anorexia. Monitor child's weight closely for changes.
- Assess child's growth on subsequent visits for possible growth suppression.
- Keep in mind that the safety of using methylphenidate for children younger than 6 years of age has not been established.

achieve a more regular nerve transmission. Insomnia and anorexia are side effects. The insomnia may be relieved by administering the drug early in the day. The extended-release form is advantageous in that it needs to be administered only once a day. Children receiving the drug for extended periods of time need careful height and weight assessment to evaluate that long-term anorexia is not causing weight loss. Caution parents that Ritalin gives a "high" to children who do *not* have ADHD, so their child must be careful that his medication is not stolen to be used by other children for its drug euphoria effect (Kuehn, 2007). Other medications that may be useful are atomoxetine, norepinephrine reuptake inhibitors, and tricyclic antidepressants (Goldson & Reynolds, 2008).

Family Support. Parents of a child with ADHD often need frequent health care visits while their child is growing up. A responsive, listening ear is crucial to their ability to handle the challenge of raising a child with these symptoms. Any parents can grow short-tempered and irritable at times with a child who does not seem to hear them or follow what they say. They may need reminders at intervals that their child does not act this way on purpose. Help them to understand that, because of a very complex and as yet ill-understood syndrome, the behavior is the best their child can achieve. Children with ADHD have an increased number of childhood accidents such as burns, so they need close parental supervision to avoid injury (See Focus on Nursing Care Planning Box 54.7).

BOX 54.7 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a School-age Child With Attention-Deficit/Hyperactivity Disorder (ADHD)

Todd, a second grader, is admitted to the 1-day surgery unit to have plaque removed from his teeth under conscious sedation. He was diagnosed with attention-deficit/hyperactivity disorder (ADHD) approximately 6 months ago; he has had symptoms since he was 6 months old. You observe Todd coloring; running to the window; running to the door, opening and closing the door; and then throwing pamphlets out of an information rack. His mother tells you she is "at her wits' end" because Todd's attention span is so short and his behavior so disruptive. His father tells you he's proud that his son is "all boy."

Family Assessment ✻ Child lives with two parents in two-bedroom condominium. Father works as a sail maker; mother works part-time in local fish market. Father rates finances as "Not good. My wife wants to work more, but we can't find anyone to watch Todd, he's such a handful."

Client Assessment ✻ A 7-year-old, slightly overweight male. Child observed holding toy dog tightly. Mother states, "He talks to the dog about what he wants to do." Some difficulty interacting and talking with others. He often repeats himself, asking "What's your name?" and "What do you like to do?" Mother feeds him mainly fast food meals because his attention span is so short. Toilet trained but sometimes has accidents as he "forgets" to go. Needs supervision dressing because he loses track of task at hand. Refuses to let mother brush teeth. Mother says, "He gets upset and cries easily if his routine changes." Attends special class in public school, as he was too disruptive in regular classroom.

Nursing Diagnosis ✻ Impaired social interaction related to short attention span and distractibility

Outcome Criteria ✻ Child states he understands purpose of dental procedure; cooperates to extent possible with IV therapy and bedrest after conscious sedation.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Assess what self-care activities child typically does for himself.	Allow child to change to hospital gown; supervise bathroom use.	Self-care can offer a sense of control unless it becomes frustrating.	Child cooperates to help with self-care to the extent a short attention span will allow.
		Consultations		
Nurse	Assess whether child care specialist is available for consultation.	Consult with child care specialist about what games, toys would be best for child with short attention span.	Games can become frustrating if they can't be completed in a short period.	Child care specialist visits with child and mother and suggests at least two activities for period before surgery.

		Procedures/Medications		
Nurse	Assess whether child has past experience with IV therapy.	Begin IV line in nondominant hand.	Use of nondominant hand allows child to complete small, frequent tasks.	Child states he understands purpose of IV line. Does not try to remove it.
Nurse	Assess whether child took his daily methylphenidate hydrochloride pill before admittance.	Check with physician and dental surgeon to determine whether child should receive medicine if it was not taken before procedure.	Methylphenidate hydrochloride can substantially reduce behavior symptoms of ADHD.	Mother reports whether morning medication was taken.
		Nutrition		
Nurse/ nutritionist	Assess what mother means by "fast food" meals.	Discuss a diet with child that doesn't involve so many fatty foods, if appropriate.	Child is overweight, a finding that can be caused by eating fat-heavy fast food meals.	Mother states she understands that even though child eats in a hurry, his meals can still be nutritious.
		Patient/Family Education		
Nurse	Assess what parent understands about good tooth care.	Talk to mother about techniques to make toothbrushing a game, not a chore.	Plaque will form again on teeth if they are not brushed after this procedure.	Mother suggests two different ways, such as Simon Says, that she could interest child in toothbrushing.
Nurse/ physician	Assess what parents understand about ADHD.	Educate parents that ADHD is a disorder, not normal boyish behavior.	As long as one parent continues to think of child's behavior as within normal limits, it will be difficult for them to be consistent in care.	Mother and father state they understand that their son's condition is one that needs therapy.
		Psychosocial/Spiritual/Emotional Needs		
Nurse	Assess what mother means by "at wits' end"; whether she feels she has adequate support to care for a child with extreme behaviors.	If appropriate, talk with mother about "respite" time to give her relief; perhaps contact a local school of nursing to find a trusted babysitter.	A child's activity level with ADHD can easily exhaust a parent if the parent cannot fit in some time for self.	Mother states whether she feels she needs additional outside support or whether her husband can provide this.
Nurse	Assess whether child can take favorite toy to operating room.	Respect that toy dog is favorite toy and important to child.	Children can find comfort and security in a favorite toy.	Toy is respected by unit and surgery personnel.
		Discharge Planning		
Nurse	Assess whether parents have any questions about care at home after dental procedure.	Discuss that child will be sleepy for remainder of day after conscious sedation.	Conscious sedation is necessary because of child's resistance to new procedures.	Mother repeats care needed for next 24 hrs to safeguard still sleepy child.

Although hyperactivity fades, some children with ADHD continue to experience problems with impulsivity and inattention into adulthood. They achieve best if they can find careers that allow them to cope with these behaviors.

Oppositional Defiant Disorders

Oppositional defiant disorders consist of hostile, negativistic, or defiant behaviors that result in disturbed functioning in academic and social domains and last for longer than 6 months. Children typically have difficulty controlling their temper; such anger is often directed at an authority figure (APA, 2000).

The disorder develops most frequently in late preschool or early school age. The cause may be a combination of temperament, inheritance, and adverse social factors. Therapy must be individually designed to meet the needs of the child and includes such techniques as family therapy and anger management.

Conduct Disorders

Conduct disorders are persistent antisocial acts that involve violations of personal rights or societal rules, such as disobedience, stealing, fighting, destruction of property, fire setting, and early sexual behavior (APA, 2000). Symptoms can be clustered as involving aggression toward people and animals, destruction of property, deceitfulness and theft, and serious violations of rules. Many teenage runaways may fall into this category. The incidence is about 5% of children (Scott, 2007).

Conduct disorders are seen more frequently in males than in females, particularly if property or violent crimes are involved; however, the prevalence of conduct disorders in girls is increasing, which may reduce the male predominance over time. Children seem to develop an increasing loss of self-regulation or an inability to know when to stop an action.

Several etiologic factors have been described for this disorder, including genetic predisposition, neurologic deficit correlates, and sociologic factors related to poverty and cultural disadvantage. In addition, the home environment is frequently characterized by rejection, frustration, and harsh and inconsistent discipline. Parents may have marital conflicts or substance abuse problems, or children may have had a series of inconsistent caretaking by stepparents or foster parents (APA, 2000).

Therapy for children with conduct disorders focuses on modifying the home environment and training the child in social and problem-solving skills. Social skills training teaches children to recognize how their behavior affects others. Problem-solving skills training teaches children to generate alternative solutions to situations, sharpen thinking about the consequences of choices, and evaluate responses. Parental education is also important but can be difficult until the parents realize that this is a family problem. Removing the child from the home to a structured day care environment may be necessary. Unfortunately, the child may interpret this as more rejection, further compounding the problem. Any new environment that is created should be consistent and loving, not institutional, to be effective.

Numerous medications such as carbamazepine (Tegretol), propranolol (Inderal), and lithium carbonate may reduce the aggressive behavior. Long-term therapy with an agent such as buspirone (BuSpar) may be effective in helping children control temper or explosive outbursts.

✔ *Checkpoint Question 54.2*

Children like Todd, with ADHD, have difficulty with concepts such as *before* and *after*. This difficulty reflects which underlying problem?

a. Not being able to sequence.
b. Not hearing equally in both ears.
c. Feeling chronically depressed.
d. Being too hyperactive to care.

ANXIETY DISORDERS OF CHILDHOOD OR ADOLESCENCE

Because anxiety is considered a normal part of certain phases of development (stranger anxiety in the 6- to 8-month-old child, separation anxiety in the toddler, fear of mutilation and fear of the dark in the preschooler, and performance anxiety or school avoidance in the school-age child or adolescent), genuine anxiety disorders in children may often be overlooked. If these disorders are left untreated, however, children may cope with fear by becoming overdependent on others for support or by turning away from the problem and withdrawing into themselves. This can leave a child socially immature and unable to achieve in school. The DSM-IV-TR identifies separation anxiety disorder and anxiety-based school refusal as anxiety disorders in children (APA, 2000). Separation anxiety is normal in infants so this type is discussed in Chapter 29. School refusal is discussed with other concerns of the school-age child in Chapter 32.

Separation Anxiety in the Older Child

Separation anxiety is considered a disorder when an older child shows excessive anxiety about separation or the possibility of separation from those to whom the child is attached. Children may worry when apart from parents that their parents will have an accident or become ill. This causes them to be so worried that they have difficulty falling asleep at night or insist on sleeping with their parents or just outside their parents' bedroom door. They experience acute distress, frequent nightmares about separation, and reluctance and refusal to separate. Repeated reports of physical symptoms during separations or when separation is anticipated are also possible. Such a degree of anxiety can be incapacitating to children; it may prevent them from visiting at friends' houses, enjoying a camp experience, or actively participating in school.

Separation anxiety tends to run in families and occurs slightly more frequently in girls than in boys. Unresolved internal conflicts, uncertainty about one's caregiver, and parent-induced anxious attachment are psychodynamic factors attributed to this disorder. Temperament may also be a contributing factor.

Treatment for separation anxiety includes individual counseling sessions combined with antidepressant medication. In addition, family therapy may be helpful to allow the family to gain greater insight into the dynamics of the problem and aid a child to gain more confidence in the ability to function independently. Remind parents that when children take antidepressant medication they need to be observed closely as this can lead to thoughts of suicide (Simon, 2008).

Posttraumatic Stress Disorder

Posttraumatic stress disorder is a condition that occurs in children who have survived an experience that is more traumatic than usual, such as child abuse, domestic violence, a natural disaster such as a hurricane, a harrowing accident such as a house fire, a home robbery, or a near-fatal illness. Children continue to have recurring recollections or dreams of the event or demonstrate intense psychological symptoms if a reminder of the initiating event occurs. They may feel guilt that they survived the event if a close family member or friend did not.

Absence of effective support people can contribute to symptoms. Therapy consists of counseling with psychological debriefing perhaps through play therapy to help a child rework the event and reduce the feeling of threat (Gaffney, 2008).

EATING DISORDERS

Eating disorders in young children consist of pica, rumination, and feeding disorders. In older children, eating disorders include anorexia nervosa and bulimia (APA, 2000).

Pica

Children who persistently eat nonfood substances such as dirt, clay, paint chips, crayons, yarn, or paper are said to have pica (Starn & Udall, 2008). *Pica* is the Latin word for magpie (a bird that is an indiscriminate eater). The primary danger lies in the possibility of accidental poisoning. Other complications include constipation, gastrointestinal malabsorption, fecal impaction, and intestinal obstruction. The disorder is seen predominantly between the ages of 2 and 6 years, although it may be present into adolescence. Often, it is not diagnosed until a child presents with a pica-induced complication, such as lead poisoning (see Chapter 52).

The incidence of pica increases in children who are cognitively challenged, possibly because of their inability to distinguish edible from inedible substances as early as other children. It is highly associated with and may be caused by iron deficiency anemia, and it occurs with a high incidence in pregnant teenage girls (who also may be iron deficient) (Mills, 2007). In these children, correcting the anemia also corrects the pica. An individualized therapy plan needs to be devised to meet the child's needs until the phenomenon fades. Keeping the child safe from ingesting inedible substances is a major responsibility until then.

Rumination Disorder of Infancy

The term *rumination* comes from the Latin word for "chewing the cud" (as cattle do). It is the act of regurgitating and then reswallowing previously ingested food. It is a rare disorder that usually affects infants between the ages of 3 and 12 months. It is seen most often in children who are cognitively challenged and appears to be a pleasurable act (Lyons et al., 2007). Both organic and environmental theories have been explored to explain the disorder. In some children, an accompanying gastroesophageal reflux disorder has been implicated. It has also been postulated that rumination is a form of self-stimulation by the infant, similar to actions such as head banging and body rocking. It may be related to an understimulating environment, but attempts to implicate the role of the primary caregiver in contributing to the disorder have failed (APA, 2000).

A parent may report that a child is constantly "spitting up" or vomiting or that the child's breath smells sour. Children can lose a great deal of fluid and electrolytes through this process if they do not reswallow the regurgitated fluid, so they may show signs of failure to thrive (failure to thrive as a distinct problem is discussed in Chapter 55). Distracting infants by holding, rocking, and talking to them tends to decrease rumination. Thickening formula or expressed breast milk with cereal occasionally is effective because this is more difficult to regurgitate. Attachment between the child and the parents may be at risk because of the anxiety the parents experience from their infant's constant regurgitation of food and lack of growth. Parents may need support, reassurance, and education to help them maintain or re-establish this bond.

Food Refusal or Aversion

Food refusal or aversion is, as the name implies, failure to eat adequately because of food dislikes (Scott & Downey, 2007). The persistent failure to eat adequately results in significant failure to gain weight or actual weight loss although no medical reason or lack of food is present. The disorder begins in infancy and is usually seen in children younger than 6 years of age. Meal time becomes a battlefield as parents insist on the child's eating and the child persistently refuses food or exhibits extremely faddish or bizarre food preferences. As many as 35% of children may demonstrate some degree of this disorder.

Therapy is a combination of counseling for the parents, to help them appreciate that food refusal used this way can be a potent controlling measure, and therapy for the child, to learn to recognize hunger as a stimulant to eating rather than using food refusal as a controlling or attention-getting mechanism.

Anorexia Nervosa

Anorexia nervosa is a disorder characterized by refusal to maintain a minimally normal body weight because of a disturbance in perception of the size or appearance of the body (Zandian et al., 2007). It includes three separate features: a self-induced starvation to a significant degree; a relentless drive for thinness, a morbid fear of fatness, or both; and medical signs and symptoms resulting from starvation.

Specific characteristics of a child with anorexia nervosa include:

- Body mass index (BMI) less than 17.5 or less than 85% of expected weight
- Intense fear of gaining weight or becoming fat even though underweight
- Severely distorted body image
- Refusal to acknowledge seriousness of weight loss
- Amenorrhea (in girls)

Anorexia nervosa occurs most often in girls (90%), usually at puberty or during adolescence between 13 and 20 years of age. It is more common among sisters and daughters of mothers who also had the disorder.

The disorder may be manifested as severe weight restriction controlled by limiting food intake, by excessive exercise, or by **binge eating** or **purging**—episodes of uncontrollable intake of large amounts of food over a specified period of

time (binge eating) followed by self-induced vomiting or the use of laxatives, enemas, or diuretics (purging) (Latner & Clyne, 2008).

Children who develop eating disorders probably have a genetic susceptibility to these illnesses. Stressors in the environment such as parental divorce, social pressure to lose weight, and personal psychological trauma such as attempted rape set into motion a chain reaction that, coupled with the genetic tendency, leads to the development of eating disorders. Children may have a poor self-image (they cannot live up to their own expectations). Excessive dieting gives them a sense of control over their own body.

Lack of nutrition becomes so extreme that it causes delayed psychosexual development. With a lean, almost starved appearance, girls do not appear as sexually developed or as old as their chronologic age. They may have significant symptoms of dehydration and acidosis because of starvation. They may develop severe osteoporosis from loss of calcium (Jayasinghe, Grover, & Zacharin, 2008).

Assessment

Because of an intense fear of becoming obese, children with anorexia come to perceive food as revolting and nauseating, and refuse to eat or else vomit food immediately after eating. They may use Ipecac to induce vomiting. Always ask if the child is using this or laxatives or diuretics or extensively exercising to further lose weight. The lack of food plus these measures leads eventually to excessive weight loss, acidosis, dependent edema, hypotension, hypothermia, bradycardia, and the formation of lanugo (fine, neonatal-like hair). Compulsive mannerisms such as handwashing may also develop. If the process is allowed to continue without therapy, it can lead to starvation and death. The use of Ipecac can be exceptionally damaging as it is cardiotoxic.

By the time most children are seen at health care facilities, they are already extremely underweight, pale, and lethargic. Amenorrhea is commonly present. Often, the child's parents have tried various methods of getting the child to eat, such as threatening, coaxing, and punishing; as a result, parent–child relationships may be strained. Parents may feel guilty for insisting their child lose weight if the girl was once overweight.

Therapeutic Management

Planning and outcome identification for a child with anorexia nervosa or binge eating need to be realistic. Remember that, although the condition began as a psychosocial problem, by the time a child is seen for care, physical starvation and its effects have become a second important component. A girl who grows nauseated just looking at food cannot quickly begin to ingest a large amount of it. For therapy, typically, oral foods are withheld to prevent vomiting and total parenteral nutrition is initiated to supply needed fat, protein, and calories. Children usually accept total parenteral nutrition well because they view it as medicine, not as food. Enteral feedings may also be accepted and used to restore weight.

In addition, establishing trust and effective communication are crucial measures to help the child resolve any interpersonal issues that are present (Box 54.8). Other therapeutic interventions include:

- Medications such as antidepressants
- Identification of emotional triggers
- Self-monitoring (awareness training)
- Education about normal nutritional needs

Gradual weight gain is recommended, because rapid gain of weight can cause a child to begin dieting to reduce this weight gain. Weighing once a week is better than every day, to reduce the focus on weight. Box 54.9 describes common strategies for assisting family and friends to help a child with anorexia.

Children who have had anorexia nervosa need continued follow-up after weight is regained, to be certain that they do not revert to their former dieting pattern (Fig. 54.2). Counseling may need to be continued for 2 to 3 years to be certain that self-image is maintained. With adequate counseling, most girls achieve full recovery with adulthood.

BOX 54.8 ✻ Focus on Communication

Brenda is a 15-year-old female who is diagnosed with anorexia nervosa. She is 5 ft 8 in tall and weighs 95 lb.

Less Effective Communication

Nurse: Let's talk about your weight, Brenda.
Brenda: I'm fat. Look at this belly of mine.
Nurse: You need to eat at least three good meals a day.
Brenda: I do. I eat a lot.
Nurse: You should have a healthy breakfast. After all, it is the most important meal of the day.
Brenda: I eat huge breakfasts. I'm just so active, I don't gain weight.

More Effective Communication

Nurse: Let's talk about your weight, Brenda.
Brenda: I'm fat. Look at this belly of mine.
Nurse: You feel fat?
Brenda: Yes, just look at me.
Nurse: Tell me what you eat for a typical breakfast.
Brenda: A lot. I pig out for breakfast.
Nurse: Pig out? What did you eat this morning?
Brenda: A quarter piece of toast.
Nurse: Anything else? Tell me more about what it is that you eat.

In the first scenario the nurse is intent on getting the client to eat. In the second scenario, the nurse is attempting to obtain more information about the client, her image of herself, and her diet.

Bulimia Nervosa

Bulimia refers to recurrent and episodic binge eating and purging, accompanied by an awareness that the eating pattern is abnormal but not being able to stop (APA, 2000). A period of depression or guilt usually follows the period of bingeing. Like anorexia nervosa, bulimia typically is seen in adolescence or early adult life and predominantly in girls. The disorder may last for months or years. Periods of normal eating may be interspersed with bingeing. Food consumed during a binge often has a high caloric content and a texture that facilitates rapid eating. It may be eaten secretly, such as late at night or in the privacy of a bedroom. After ingestion of this food, abdominal pain develops, and the teen will

BOX 54.9 ✻ What Family Members and Friends Can Do to Help Those With Eating Disorders

- Tell the person that you are concerned, that you care and would like to help. Suggest that the person seek professional help.
- If the person refuses to seek help, encourage reaching out to an adult such as a teacher, school nurse, or counselor.
- Do not discuss weight, the number of calories being consumed, or particular eating habits. Try to talk about things other than food, weight, counting calories, or exercise.
- Avoid making comments about the person's appearance. Concern about weight loss may be interpreted as a compliment; comments about weight gain may be interpreted as criticism.
- Offer support but keep in mind that, ultimately, the responsibility for accepting help and deciding to change belongs to the person.
- Read and educate yourself about these disorders.

White, J. H. (2007). Eating disorders. In M. A. Boyd (Ed.). *Psychiatric nursing: Contemporary practice* (4th ed.). Philadelphia: Lippincott Williams & Wilkins.

vomit to decrease the physical pain of abdominal distention and to improve self-concept.

Like those with anorexia nervosa, adolescents with bulimia may abuse purgatives, laxatives, and diuretics to aid in weight control (Sigel, 2008). The combination of frequent vomiting and use of these drugs can result in serious physical complications, notably electrolyte abnormalities, which can ultimately lead to changes as severe as cardiac arrest. Adolescents with bulimia may develop severe erosion of their teeth because of the constant exposure to acidic gastrointestinal juices from vomiting. Esophageal tears may also result (Baron, 2009).

FIGURE 54.2 This anorexic teen, who is in the later stages of treatment, continues to meet with the counselor to discuss her food choices, exercise program, and overall well-being. (© Barbara Proud.)

Like adolescents with anorexia nervosa, these teens exhibit great concern about their weight and overall body image and appearance. In contrast to children with anorexia, however, most of those with bulimia are only slightly underweight or are of average weight and therefore may be discounted as merely slim unless a thorough history is obtained. As with anorexia nervosa, counseling is aimed at increasing the child's self-esteem and sense of control (APA, 2000).

✔ Checkpoint Question 54.3

Which child is most apt to have anorexia nervosa?

a. Jake, a 7-year-old boy whose parents are divorced.
b. Mary, a 15-year-old girl who has a poor self-image.
c. Odom, a 14-year-old boy who plays varsity sports.
d. Jenny, a 13-year-old girl who is overweight.

TIC DISORDERS

Tic disorders are abnormalities of semi-involuntary movement that are thought to result from dysfunction in the basal ganglia. *Tics* are rapid, repetitive muscle movements, such as rapid eye blinking or facial twitching. They usually become more pronounced during periods of stress and diminish during sleep. **Motor tics** include eye blinking, neck jerking, and facial grimacing. Simple **vocal tics** include coughing, throat clearing, snorting, and barking. Complex motor tics include facial gestures, grooming behaviors, jumping, touching, and smelling objects.

Children are most prone to these disorders between the ages of 9 and 13 years. They occur more frequently in boys than in girls, and more frequently in children who demonstrate obsessive–compulsive behavior. Some instances tend to be familial, possibly because of dopamine receptor inhibition. Tic disorders are subclassified into Tourette's syndrome, chronic motor or vocal tic disorder, and transient tic disorder. They occur so frequently that as many as 15% of children experience some form of transient tic disorder (APA, 2000). Because transient tics are associated with high stress, treatment usually focuses on reducing areas of stress in the child's life. Pointing out the mannerism to the child is not usually helpful and may intensify the manifestation if it increases stress. Behavior modification may be successful in eliminating a particular tic. If the stress is not removed, however, the child may substitute another compulsive mechanism for the original tic.

Tourette's Syndrome

Tourette's syndrome is an inherited syndrome of motor and phonic vocal tics (Xia & Rao, 2008). It occurs three times more frequently in boys than in girls. Often, there is some other form of tic in other family members. **Complex vocal tics** include the repeated use of words or phrases out of context—specifically, **coprolalia** (use of socially unacceptable words, usually obscenities), **palilalia** (repeating one's own words), and echolalia (repeating others' words). Some children with this syndrome have nonspecific electroencephalographic abnormalities and soft neurologic signs. Typically, the age of onset is around 7 years, with motor tics usually occurring before vocal tics. Although most children can suppress their tics for short periods, the syndrome lasts a lifetime. Children with

Tourette's syndrome can develop low self-esteem because of their uncontrollable actions before the syndrome is fully diagnosed. Fortunately, this syndrome responds to administration of neuroleptic agents such as haloperidol (Haldol) or pimozide (Orap).

ELIMINATION DISORDERS

Elimination disorders include functional enuresis (involuntary loss of urine) and encopresis (involuntary loss of feces). Developmental enuresis is discussed in Chapter 31 with the development of the preschooler.

Encopresis

Loss of feces is *encopresis* if there is repeated passage of feces at least once a month in places not culturally appropriate for that purpose. It is considered primary if the child was never fully toilet trained and secondary if the problem began after effective training (Culbert & Banez, 2007). Encopresis is considered to exist only after medical causes such as lactase deficiency, thyroid disease, hypercalcemia, Hirschsprung's disease, and infectious diarrhea have been ruled out. It is more common in boys than in girls.

Isolated occurrences of encopresis may happen when a sibling is born (as part of an overall regression reaction) or when a child is visiting at a strange house or new school and is too shy to ask for the bathroom. It can occur in school because a teacher does not allow children to use a bathroom when they wish or because a school bathroom is owned by a school gang.

Encopresis is a distressing condition for children, because other children in school can detect the odor of a bowel movement on clothing. In a few instances, encopresis occurs because of extreme constipation. Hard bowel movements cause anal fissures. Because it hurts to move the bowels, children avoid bowel movements, leading to chronically distended rectums. They are then no longer able to sense when they need to defecate, so involuntary or overflow defecation occurs (Philichi, 2008).

Assessment

To document encopresis, take a careful history of the condition, including usual bowel evacuation habits, the number of bowel accidents, and the times at which they occur. Investigate any recent changes or stress factors in the child's environment. A physical examination that includes a rectal examination should be done to establish whether there is proper anal sphincter control.

Therapeutic Management

Therapy is based on the apparent cause. If children evacuate their bowels before they leave for school in the morning, they are less likely to experience encopresis and embarrassment in school. Arranging to have children attempt to evacuate their bowels about two times daily (in the morning and after dinner) may create "habit" periods for them. Allowing children adequate time to sit on the toilet or encouraging them to take the time to defecate may be helpful. The administration of 1 to 6 tablespoons of mineral oil daily for 2 or 3 months often softens stools so that bowel movements are not painful. Children receiving long-term mineral oil therapy usually are given water-soluble forms of vitamins A, D, and K, because these vitamins tend to be removed from the gastrointestinal tract with the mineral oil. Imipramine (Tofranil), a tricyclic antidepressant, may be helpful in reducing encopresis, just as it is effective for enuresis.

Emphasize to parents that children should not be punished for encopresis. Encourage them to pay as little attention as possible to bowel accidents and to give praise for days when encopresis does not occur.

Enuresis

Enuresis is defined as repeated involuntary or intentional urination during the day or at night after an age at which a child has attained or should have attained control over bladder function, when no organic cause for the problem can be found (APA, 2000). Although stress may be a factor in occurrences of enuresis, its primary cause is unknown. Most children outgrow the problem by adolescence. As with encopresis, the most serious result of enuresis is related to the child's feelings of failure with each occurrence and associated rejection by peers, parents, or other caregivers. All this contributes to a lowered sense of self-esteem. The problem and associated nursing diagnoses are described in more detail in Chapter 46.

OTHER PSYCHIATRIC DISORDERS AFFECTING CHILDREN

Childhood Depressive Episodes

Children and adolescents can both have depressive episodes similar to those experienced by adults (Kaplan & Love-Osborne, 2008). The incidence ranges from 1% to 3% before puberty and 3% to 6% among adolescents. Depression is becoming an increasing concern in our society, because the escalating suicide rate among children and adolescents that arises from depression has become a major societal problem. A child is considered to be depressed when symptoms such as loss of interest or pleasure, significant weight loss or gain, depressed mood, insomnia, psychomotor agitation, feelings of worthlessness or excessive or inappropriate guilt, diminished concentration, recurrent thoughts of death, and suicidal ideation exist for 2 weeks or longer (APA, 2000). Because these symptoms are easily missed, a history should be taken from the child as well as from the parents. Depression can be differentiated from "normal" sadness when children report they cannot remember the last time they felt happy or had a good time **(anhedonia)** (Fig. 54.3).

Children who are depressed need treatment to prevent their depression from worsening. Counseling to discuss problems is necessary. Many children require antidepressant therapy, such as a selective serotonin reuptake inhibitor, to relieve the symptoms. In addition to the pharmacologic approach, family or individual counseling may be necessary to help the child regain self-esteem and the family to understand the level of depression that has occurred. Few antidepressants are approved for children, and when adolescents have been prescribed these drugs, attempts at suicide have been noticed to rise dramatically—possibly because, at the point at which the child feels less depressed, increased ability to act makes a suicide attempt possible (Simon, 2008). Observe any child who is prescribed an antidepressant carefully to detect presuicidal behavior.

FIGURE 54.3 Symptoms of depression are easily missed in school-aged children unless history taking is thorough. (© Caroline Brown, RNC, MS, DEd.)

Adolescent suicide as a result of depression is discussed in Chapter 33 with concerns of the adolescent.

Childhood Schizophrenia

Schizophrenia is actually a group of disorders of thought processes characterized by the gradual disintegration of mental functioning; it occurs in about 2 of every 10,000 children (APA, 2000). It is a devastating mental illness that usually strikes in adolescence or young adulthood. Symptoms during childhood may be undifferentiated or ill defined.

Over the years, there has been a great deal of debate about the cause of schizophrenia. For a long time, it was hypothesized that schizophrenia resulted solely from an impaired parent–child relationship. Current research, however, indicates that there is as much a genetic as an environmental basis for this disorder. Magnetic resonance imaging has shown that cerebral involvement, such as enlarged ventricles, decreased blood to the frontal lobe, or cortical cell loss may be present (Gogtay, 2008). Neurochemical mediators may influence or prolong the disorder.

Children with schizophrenia experience hallucinations (hear or see people or objects that other people cannot). They display rambling or illogical speech patterns. They may not be responsive (have a **flat affect),** or they may withdraw so completely that they are stuporous **(catatonia)**. They may be extremely suspicious that others want to harm them (paranoia). Although schizophrenic manifestations may occur suddenly after a major stress in a child's life (such as rejection by a boyfriend or girlfriend), subtle signs of mental illness have usually been present for some time (Eisendrath & Lichtmacher, 2009).

The diagnosis of a psychotic disorder of this extent is a shock to parents. Fortunately, therapy with modern antipsychotic drugs such as clozapine is effective in reducing children's hallucinations and bizarre thought processes. Parents may need help to support a child during a long period of therapy. Many children who are diagnosed as having schizophrenia in childhood continue to have mental illness as adults. Continuing support and long-term follow-up become essential (Meltzer, 2008).

What if... During a routine health maintenance visit, you notice that an adolescent boy has lost 20 lb in the last 6 months? His mother states, "He's the perfect son, always getting straight As in school." How would you respond?

Key Points For Review

- Both cognitive and mental health disorders pose long-term care concerns for children and their families.
- For children who are cognitively challenged, a stigma still may be present in many communities, although less so than previously. Parents may have a more difficult time accepting this diagnosis in their child than they would a physical illness. Help parents to gain the insight that cognitive challenges occur in a proportion of infants in every population and that having a child with this problem merely reflects a chance occurrence.
- Mental health disorders often begin subtly in children and are often first manifested as behavior problems in school. Assess thoroughly any child who is referred for disruptive behavior in a school class for the possibility that the child has a serious mental health problem.
- Autistic disorder is a pervasive developmental disorder that has a syndrome of behaviors, including fascination with movement, impairment of communication skills, and insensitivity to pain.
- Attention-deficit and disruptive behavior disorders, such as oppositional defiant and conduct disorders, may occur in childhood. Children with ADHD may be treated with methylphenidate hydrochloride (Ritalin, Concerta) to reduce the hyperactivity and allow them to achieve better in school and interact successfully at home.
- Eating disorders seen in childhood include pica, rumination, anorexia nervosa, and bulimia. All of these disorders can lead to loss of weight and electrolyte imbalances if left unrecognized and untreated.
- Tic disorders such as Tourette's syndrome are abnormalities of semi-involuntary movement that are thought to result from dysfunction of the basal ganglia or distorted dopamine reception.
- Encopresis is the repeated passage of feces in places not culturally appropriate for that purpose. Therapy is both physiologic and psychological.
- Children who are depressed are at high risk for committing suicide. They need thorough assessment and close observation to be certain that this does not happen. The administration of antidepressants to children to relieve depression may actually increase suicide attempts.
- Schizophrenia may occur in childhood. This usually presents as disorganized behavior. Long-term therapy is necessary.

CRITICAL THINKING EXERCISES

1. Todd is the second grader diagnosed with ADHD whom you met at the beginning of the chapter. His mother feels "at her wits' end" because his attention span is so short and his behavior so disruptive. His father is proud of his behavior. What suggestions could you make to his parents to help them adjust better to a child with ADHD?
2. A 3-year-old child who is cognitively challenged is critically ill with pneumonia. It is difficult to believe that her mother did not recognize how ill the child was becoming and bring her in sooner for care. What reasons might explain a parent's reacting this way?
3. The parents of an adolescent tell you that he seems increasingly depressed, so much so that he sleeps almost all day on weekends. Does this adolescent need a referral, or is he simply demonstrating usual adolescent behavior? What questions would you want to ask to be able to tell?
4. Examine the National Health Goals related to cognitive or mental health disorders in children. Most government-sponsored funds for nursing research are allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to Todd's family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to cognitive or mental health disorders and children. Confirm your answers are correct by reading the rationales.

Chapter

55 Nursing Care of a Family in Crisis: Abuse and Violence in the Family

KEY TERMS

- abuse
- failure to thrive
- incest
- intimate partner abuse
- learned helplessness
- mandatory reporters
- molestation
- Munchausen syndrome by proxy
- pedophile
- permissive reporters
- rape trauma syndrome
- shaken baby syndrome
- silent rape syndrome

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Discuss the types of abuse seen in families and the theories explaining their occurrence.
2. Identify National Health Goals related to an abused family that nurses can help the nation achieve.
3. Analyze ways that nurses can help make care more family centered and so ideally help to prevent family abuse.
4. Assess a family that is physically or emotionally abused.
5. Formulate nursing diagnoses related to an abused family.
6. Develop expected outcomes for an abused family.
7. Plan nursing care for a family in which abuse has occurred.
8. Implement nursing care for an abused family such as ways to role model better parenting.
9. Evaluate expected outcomes for effectiveness and achievement of care.
10. Identify areas related to care of the abused family that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of family abuse with nursing process to achieve quality maternal and child health nursing care.

Hillary is a 3-year-old you see in an emergency department. Her mother tells you Hillary fell off a swing in the back yard. Hillary has a broken forearm, a broken rib, and multiple bruises on her chest and back. You notice in her chart that Hillary was seen in the same emergency room a month ago for a burn on the palm of her hand. When you mention to her mother that Hillary's injuries seem extreme for a simple fall, her mother says, "Hillary isn't very pretty. I guess she's also clumsy." Previous chapters described the normal growth and development of children and care of children with disorders of specific body systems. This chapter adds information about the effect on children when abuse occurs in a family. Such information can build a base for care and for preventing further abuse.

You suspect that Hillary is a victim of child abuse. What additional questions would you want to ask her mother to help determine whether this is so?

Child abuse occurs at an incidence of 2 per 100,000 children per year in the United States. It accounts for 1500 deaths per year (DHHS, 2009). Abuse is associated with stress and has been linked to inability of a family to handle external and internal stressors. Accordingly, abuse in a family is rarely an isolated event but rather an indication of how much the family needs care overall.

Abuse, defined as the "willful injury by one person of another" (Helfer & Kempe, 1987), takes many forms: child abuse, which can be physical or emotional and includes neglect and sexual abuse; intimate partner abuse; and maltreatment of the elderly. Maternity, child health, and family care nurses need to be especially observant for signs of possible abuse in a family and prepared to handle this highly emotional and complex problem objectively. The victim's safety is paramount, but ensuring this safety must be done with sensitivity to the importance of maintaining and improving overall family functioning.

Abuse has long-term consequences, because as many as 30% of children from abusive families become abusive parents themselves (Sirotnak & Krugman, 2008). It also may lead to a posttraumatic stress disorder with long-term effects (Ullman, 2007). National Health Goals related to child abuse are shown in Box 55.1.

BOX 55.1 ✻ Focus on National Health Goals

Abuse of children is a national health disgrace and so is rated as a national health concern. Several National Health Goals specifically address this issue:

- Reduce the rate of maltreatment of children younger than 18 years of age from a baseline of 12.6 per 1000 to a target level of 10.3 per 1000.
- Reduce the rate of child maltreatment fatalities from a baseline of 1.6 per 100,000 to a target level of 1.4 per 100,000.
- Reduce the rate of physical assault by current or former intimate partners from a baseline of 4.4 per 1000 to a target level of 3.3 per 1000.
- Reduce the annual rate of rape or attempted rape from a baseline of 0.8 per 1000 to a target level of 0.7 per 1000 (http://www.nih.gov).

Nurses can help the nation achieve these goals by educating parents about how to parent more effectively and by identifying children in school or health care agency settings who have been abused or neglected.

Additional nursing research would be helpful to answer the following questions: Can potentially abusing parents be identified on postpartum units and helped to avoid this behavior? What counseling is necessary for adolescents who have been abused to help them be successful parents? What are the most helpful nursing interventions to use with parents when a child who has been abused is admitted to the hospital?

Nursing Process Overview

For Care of a Family That Experiences Abuse

Assessment

Commonly, nurses are the first individuals to identify symptoms of possible abuse in a family, because they are often the first to see a child undressed at a health care visit and recognize significant bruising, and they are often the person in whom a pregnant woman or child confides to about the problem (Box 55.2). If abuse in any form is suspected, it is essential to get as full a picture as possible. If child abuse is suspected, talk with the parents first, without the child, and then interview the child to help to uncover any inconsistencies in the parents' explanations.

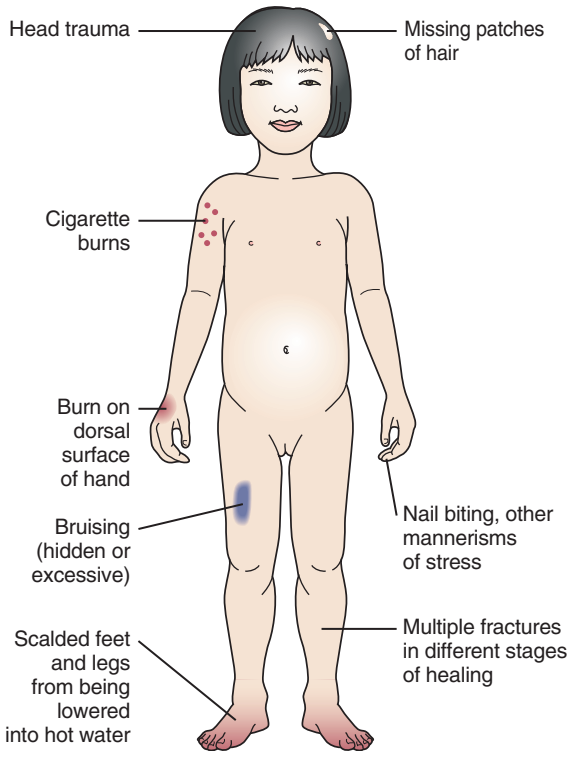
Nursing Diagnosis

Nursing diagnoses associated with abuse should address both the physical and the emotional results of abuse. Some examples are:

- Pain related to burn on hand
- Risk for injury related to previous abuse
- Risk for other-directed violence related to admitted poor self-control
- Impaired parenting related to high level of stress

Box 55.2 Assessment

Assessing a Child for Signs of Abuse



- Compromised family coping as manifested by child abuse related to alcohol use by father
- Disturbed self-esteem related to sexual abuse

Outcome Identification and Planning

Planning must center first on ensuring the safety of the abused family member and minimizing the effects of trauma. Second, it is concerned with reporting the discovery to authorities. Nurses are mandated by law to report child abuse; identifying and reporting this problem are important nursing actions. Long-term planning includes helping an abused family member find safe refuge and re-establishing self-esteem through a self-help or advocacy program. Teaching empowerment, or the ability to take charge of one's life, is particularly important for older children and women in abusive families. In addition, the abuser needs a program of therapy to help prevent future abuse.

The following organizations are helpful for referral: Parents Anonymous (http://www.parentsanonymous.org), Child Abuse Prevention Network (http://www.child-abuse.com), National Coalition Against Domestic Violence (http://www.ncadv.org), Victims of Child Abuse Laws (VOCAL) (http://www.menweb.org/throop/mitch/vocal2.html), and Women Organized Against Rape (WOAR) (http://www.WOAR.org).

Implementation

The most important intervention related to family abuse is prevention. Nurses can do much in all settings through serving as a role model or providing education to promote healthy patterns of childrearing and optimal ways of handling family stress. They can be particularly observant for families who seem to be at risk for abusive behavior, but also be alert to possible abuse in families that are not showing signs. Further education is an intervention that can help parents who may not recognize their children's needs or normal child behavior. Lecturing is not a useful intervention, but supportive education can be extremely valuable.

Outcome Evaluation

Expected outcomes should focus on specific measures of improved family interaction, such as:

- Parent holds baby in a caring manner and maintains good eye contact.
- Parent admits to losing control with children at home and voices desire to undergo counseling for problem.
- Parent states she has the Crisis Center telephone number by the telephone and will call for help if she feels under threat by partner.
- Adolescent states she can still think of herself with high self-esteem despite rape by stepbrother.
- Parent attends monthly meetings of Parents Anonymous.

HEALTH PROMOTION AND RISK MANAGEMENT

Prevention must be the goal of health care providers to reduce the incidence of child abuse (Box 55.3). Because many child abusers were abused themselves, stopping child abuse in any one generation helps prevent it in the next.

Identifying parents who are potential abusers is a necessary step in prevention. Some parents can be identified as potential abusers during pregnancy. Listen carefully to the way pregnant women or their partners talk about the child they are expecting. A parent who is overly concerned about the physical appearance or sex of the child ("This had better be a girl" or "He'd better not have his father's nose") may have difficulty accepting a child who does not meet these expectations. Listen for a parent who is concerned about "not letting children get the upper hand" or who says a child "had better be good." Such parents may be conveying worry about how they will act when a child is "bad."

A parent may also be identified as a potential child abuser during the early postpartum period. Be aware of parents who do not touch their infant within 24 hours and those who make disparaging remarks about the child's appearance, as this lack of contact could signal risk. Remember, though, that not all parents immediately bond or react warmly to their newborns. They may only tentatively touch or pick up their infant. Risk factors during pregnancy and the early postpartum period are summarized in Box 55.4.

Parents may also be identified as potential abusers during health maintenance visits for an infant. By the time a baby is brought to a health care agency for an initial health maintenance visit, a good parent–child interaction should have begun. Listen for parents who say the baby is "nothing but

BOX 55.3 ✻ Measures to Prevent Child Abuse

1. Advocate for high school courses on parenting and growth and development of children.
2. Help children learn problem-solving techniques so they are not overwhelmed by mounting problems as adults.
3. Foster high self-esteem in children so they are not dependent on others but are assertive (they will not become passive observers to abuse).
4. Help parents with responsible reproductive planning, so children are desired.
5. Help parents locate support people in their community, such as Parents of Retarded Citizens or church or social contacts.
6. Teach children to verbalize their problems and to seek help for problems so problems do not mount to overwhelming proportions.
7. Role model caring behaviors with children for parents.
8. Identify children who may be viewed as special in some way by parents such as those who were separated from the family at birth, were premature, or are physically challenged.
9. Identify parents who were abused as children, and offer specific help to them to break the chain of child abuse.
10. Suggest that potential abusers join Parents Anonymous, an effective support group.

BOX 55.4 ✻ Characteristics of Parents at High Risk to Cause Child Abuse or Neglect

1. Frequent changes of address in the year before child's birth
2. Past or present psychiatric treatment
3. Emotional problems
4. Lack of intellectual ability
5. Unrealistic expectations of the new baby
6. Changed decision about adoption
7. Abuse or neglect of a previous child
8. History of parental violence or neglect in childhood
9. Low self-esteem
10. Unable to earn independent income

BOX 55.5 ✻ Questions to Ask to Detect the Potential for Child Abuse in New Parents

1. Does the parent have fun with the baby?
2. Does the parent establish eye contact (direct *en face* position) with the baby?
3. How does the parent talk to the baby? Is everything expressed as a demand?
4. Are most of the verbalizations about the child negative?
5. Does the parent remain disappointed about the child's sex?
6. Was the child named immediately? Does the name have meaning for the family?
7. Are the parent's expectations for the child's development far beyond the child's capabilities?
8. Is the parent very bothered by the baby's crying?
9. Does the parent see the baby as too demanding during feedings? Does she or he ignore the baby's demands to be fed?
10. What is the parent's reaction to the task of changing diapers? Is the parent repulsed by the messiness?
11. When the baby cries, does the parent or can the parent comfort the child?
12. Are the parents receiving adequate support?
13. Is sibling rivalry a problem?
14. Is the husband jealous of the baby's claim on the mother's time and affection?
15. When a parent brings the child to the physician's office, does the parent become involved and take control over the baby's needs and what is going to happen (during the examination and while in the waiting room)? Or does the parent relinquish control to the physician or nurse such as undressing the child, holding or allowing the child to express fears?
16. Can attention be focused on the child in the parent's presence? Can the parent see something positive in that focus?
17. Does the parent report nonexistent symptoms in the baby? Describe the child in terms that you do not recognize at all? Call with strange stories, such as the child has stopped breathing, changed color, or is doing something "on purpose" to aggravate the parent?
18. Does the parent make emergency calls to health care providers for very small things?

trouble," "cries all the time," or "is bad." Ask new parents how it feels to be a new parent. "I'm enjoying it" is a different answer from "not what I expected" or "it's not much fun." Specific observations to make during postpartum and pediatric health care checkups are summarized in Box 55.5.

Helping parents to seek assistance from support people is another necessary step in prevention. Home visits and organizations for parents who abuse, such as Parents Anonymous, can be highly effective in encouraging parents to reach out for help in times of crisis. Interventions that appear promising include home visits, family counseling, and therapy.

Another nursing responsibility aimed at preventing child abuse is helping young parents learn about normal growth and development of children and how to be better parents (Fig. 55.1). Courses in high school that describe sound parenting and review normal growth and development and the responsibilities involved in parenting are additional measures in preventing child abuse (Kendrick et al., 2009). Classes conducted in high-risk prenatal settings might also have an impact.

CHILD ABUSE

Because parenting is not an easy task and good parenting is not an automatic or truly instinctive ability, children in every community are injured because of abuse. Abuse may be physical (the child is beaten or burned), or it may be neglect (the child is not fed, clothed, supervised properly, or offered medical care or educational opportunities). Abuse may also be psychological or emotional (a child is made to feel unintelligent or inadequate). In some instances, women who threatened the health of their fetus by drug abuse have been viewed by the courts as child abusers (Sun, Freese, & Fitzgerald, 2007).

Abuse not only places a child at immediate risk for harm but can also lead to long-term effects. For example, physically abused children are found to be more angry, noncompliant, and hyperactive than others; they may demonstrate poor self-control and low self-esteem. Children whose parents do not interact with them (emotional abuse) are apt to be more withdrawn and to have a flatter affect than others. Because the abusive family is a disrupted one, children often have undiagnosed medical problems, such as anemia, otitis media, lead poisoning, or sexually transmitted infections. Children who suffer sexual abuse can have long-term effects of depression, guilt, and difficulty enjoying sexual relations (Chartier, Walker, & Naimark, 2007).

In addition, when children reach adulthood and begin parenting, they tend to rear their children in basically the

FIGURE 55.1 Teaching that all children have unique characteristics helps to prevent child abuse. Here, new parents explore the already noticeable unique aspects of their newborn. (© Caroline Brown, RNC, MS, DEd.)

same way as they were reared. Parents who themselves received little love or were abused as children may never form a basic sense of trust, and this may cause them to have parenting difficulties themselves.

Theories of Child Abuse

The most commonly accepted theory regarding why child abuse occurs is that a special triad of circumstances develops (Helfer & Kempe, 1987):

- A parent has the potential to abuse a child (special parent).
- A child is seen as "different" in some way by the parent (special child).
- An event or circumstance brings about the abuse (special circumstance).

Some health practices or illnesses can be confused with child abuse so are important to remember in assessment. For example, coin-rolling, a type of massage to draw illness out of the body used by some Asian cultures, leaves bruises on the back similar to those that would appear on a child who has been struck repeatedly. The practice involves heating a coin and then vigorously rubbing it over the body, leaving red welts.

Most toddlers have some ecchymotic spots on their legs from bumping into tables or chairs during normal toddler walking. Some childhood diseases, such as leukemia or purpura, begin with easy bruising. Children with osteogenesis imperfecta have frequent broken bones as a natural consequence of their disease. Because of inadequate fact-finding in these instances, false reports do occur. This can lead to severe stress on a family that has been falsely accused and can interfere with the relationship between the parents of an ill child and the health care personnel who will then give care to the child. Being aware of a practice such as coin-rolling aids understanding of the meaning of illness to parents and helps prevent false reports of child abuse.

Special Parent: Parents Who Abuse

Parents who abuse seem, on the surface, little different from others. Only a small fraction of them (probably less than 10%) have a history of mental illness. Many of these parents, however, were abused as children. Such parents may have less self-control than other parents. They may be unfamiliar with the normal growth and development of children and so have unrealistic expectations of a child. These parents may be socially isolated, with no support people readily available, and so can become overwhelmed by childrearing. The isolation may be by distance (a parent separated from other people in a farmhouse miles from neighbors), or it may be the type that exists in communities or apartment houses where neighbors do not routinely speak to one another. Abuse is strongly associated with excessive parental use of alcohol, a substance that removes inhibitions and self-control (Davison, 2007).

Special Child: Children Who Are Abused

Abused children are viewed as somehow "different" by their parents. They may be more or less intelligent than other children in the family; they may have been unplanned. They may have a birth defect; they may have an attention span deficit. A category of children who are at high risk includes those who are born prematurely or who have an illness at birth, because they are kept from parents or separated from them by special nurseries or equipment for the first weeks of life, the time during which usual bonding occurs. Because the child is perceived as different, a good parent–child relationship never develops.

When a child is injured, parents who are unable to deal with stress may not show the usual degree of compassion for their child's pain or offer to comfort. They may appear more concerned with how the injury affects them than how it affects the child: "Don't cry. You'll make me look like a bad parent," not "It's okay to cry. I know that hurts."

To prevent abuse, a child may assume a role reversal with the parent or become the comforting, solacing person. These children recognize very early in life that when a parent is upset, they will be hurt. They learn to comfort the parent and reduce the parent's stress and anxiety, thereby avoiding the hurt. It is important to assess who is comforting whom when a childhood injury occurs.

Special Circumstance: Stress

A third factor in child abuse is stress, which may be a response to an event that would not necessarily be stressful for an average parent. It might be something as common as a blocked toilet, an illness in the family, a lost job, a landlord asking for the rent, or a rainstorm that cancels a picnic. Child abuse crosses all socioeconomic levels because stress occurs at all levels. Stress generally has a greater impact on individuals who do not have strong support people around them. Families whose internal support system is faulty or who have not formed outside support systems are apt to have a higher incidence of abuse.

Reporting Suspected Child Abuse

State laws typically identify two levels of responsibility for reporting child abuse: **mandatory reporters** and **permissive reporters.** Nurses are included in the mandatory category in most states; this means they *must* report suspected child abuse when they identify it. Failure to do so can result in a fine or possible loss of nursing licensure. The fact that the information was given in a confidential interview

does not free a nurse from this responsibility (Mathews & Kenny, 2008).

All health care institutions and agencies have protocols on how the reporting of child abuse should be handled. It is important to learn the protocol required by your particular agency, community, and state. After an official report of child abuse has been made to a child protection agency, a health care agency has the right, in most instances, to hold the child for 72 hours for protection, to give an appointed caseworker time to investigate whether abuse has occurred. After the 72 hours, a court proceeding will determine whether the child should be returned to the parents' care or kept in a safer location. Because child abuse is a crime, the health care record of the child can be subpoenaed and displayed in court. Be certain when charting information related to child abuse that you make specific and factual notes (observations, not interpretations), such as "Parent spoke loudly and slurred his words," rather than "Parent was intoxicated," or "Mother stated 'This child is nothing but trouble,'" not "I think this mother dislikes this child." Record conversations with parents using exact quotations, if possible. Photographs of physical abuse enhance the strength of the testimony of abuse, so these are usually taken.

A second provision in state laws is protection from having a lawsuit brought against a health care provider for reporting suspected abuse that is then proved false. In other words, it is better to err on the side of reporting suspected abuse rather than not reporting it, from both a child safety standpoint and from a legal perspective. When abuse is officially reported, parents should be told that child abuse is suspected, because open lines of communication with parents are important to protect the child and to arrange counseling for the parents.

Physical Abuse

Physical abuse is the action of a caregiver that causes injury to a child. It is commonly revealed by burns or by injuries to the head or hands (see Focus on Nursing Care Planning Box 55.6).

BOX 55.6 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Child Who Has Been Abused

Hillary is a 3-year-old you see in an emergency department. Her mother tells you Hillary fell off a swing in the back yard. She has a broken forearm, a broken rib, and multiple bruises on her chest and back. You notice in her chart that Hillary was seen in the same emergency room a month ago for a burn on the palm of her hand. When you mention to her mother that Hillary's injuries seem extreme for a simple fall, her mother says, "Hillary isn't very pretty. I guess she's also clumsy." You suspect Hillary may be a victim of child abuse.

Family Assessment ✻ Mother divorced. Boyfriend lives with mother and child in one-bedroom apartment. Mother works as a waitress in a local restaurant from approximately 4 PM to midnight four nights a week. Finances rated as "not good." When physician suggested the child may have been beaten and abused, she stated, "What can I do? I need my boyfriend to watch her while I work."

Client Assessment ✻ A 3-year-old girl dressed in wool coat and cap carried in by mother. Outside temperature 80° F. Mother's boyfriend present and protesting removal of the child's clothing for examination: "It's too cold in here for that." Odor of alcohol noted on boyfriend's breath. On examination, child's right forearm is misaligned and swollen; 3 × 4-inch bruise on right side of anterior ribs. Further examination reveals four ½-inch-diameter circular lesions on right arm; large 4-cm ecchymotic area on both buttocks and anterior left thigh. Sharp, pointed, triangular blistering and inflamed area noted on back of left hand. Mother states circular lesions are "mosquito bites"; mark on hand is a "birthmark." Child remained passive while being examined but drew back when mother's boyfriend approached.

Nursing Diagnosis ✻ Fear related to repeated episodes of abuse

Outcome Criteria ✻ Child expresses fears verbally and through play; interacts with caregivers appropriately; demonstrates positive age-appropriate coping behaviors.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Assess what self-care activities child is able to complete after right arm is casted.	Assist child as necessary with self-care.	Abused children may lack self-esteem; allowing them to do as much self-care as able can help improve self-esteem.	Child names tasks she thinks she can do herself; asks for appropriate help for others.

(continued)

BOX 55.6 ✻ Focus on Nursing Care Planning (continued)

		Consultations		
Physician	Assess physical and history findings to establish suspicion of abuse.	Contact hospital Child Abuse Team and alert them to suspicious findings.	Child health care providers have an obligation to report abuse to the proper authorities.	Physician files report with Child Abuse Team. Police and social service are contacted.
		Procedures/Medications		
Nurse/nurse practitioner	Assess whether child has ever had a full physical and anogenital examination before.	Perform or assist with a complete physical and anogenital examination. Reassure and sooth child as much as possible.	Physical examinations, especially an anogenital examination, are frightening and refresh memories of the abuse.	Child has physical and anogenital examination completed within acceptable stress limits.
Nurse	Assess whether child has ever had photographs of her whole body taken before.	Accompany child to photography to have her injuries photographed.	Photographs are necessary to document the extent and type of injuries.	Child cooperates with photographer; photographs are obtained.
		Nutrition		
Nurse	Assess whether child is able to manage fork and spoon with cast in place.	Offer help with eating as necessary.	Eating is a self-care activity that can increase self-esteem.	Child demonstrates ability to eat satisfactorily with cast in place.
		Patient/Family Education		
Nurse/physician	Assess whether parent understands the seriousness of the diagnosis of child abuse.	Explain the reporting procedures and actions that accompany a child abuse report.	Child abuse is not a simple problem, so the parent's cooperation is essential to a successful outcome.	Mother states she understands what are the next steps to be taken; will cooperate with procedures.
Nurse	Assess whether child understands need for hospitalization.	Explain all procedures and treatments in language the child can understand.	Explanations in the child's terms help to alleviate additional stress and anxiety associated with the experience.	Child states she understands she will be in hospital at least overnight.
		Psychosocial/Spiritual/Emotional Needs		
Nurse	Assess which nurse would be the best primary care provider for the child.	Provide a primary care provider; assure child she is now in safe hands.	Removing the child from the threatening environment and providing a primary caretaker can help reduce fear.	Child states she feels safe in the hospital; participates in therapeutic play.
		Discharge Planning		
Nurse	Assess whether parent would like a referral to Parents Anonymous.	Make a referral as appropriate for support people for mother. Refrain from blaming.	Not having adequate support people may be one reason mother relied on unsafe caregiver for her child.	Mother states she will attend at least one parents' group meeting.
Physician/nurse	Assess whether mother understands child will not be safe with boyfriend in the future.	If boyfriend is not incarcerated, urge mother to obtain a restraining order against him for future.	A parent may believe an abuser can easily correct behavior and can be allowed to return as child caregiver in the future.	Mother states she understands she has placed her trust in an unsafe care provider; will not allow boyfriend into her or child's life in the future.

Assessment

Always ask parents to account for any injury to a child's body. Remember, however, that most childhood injuries are the result of unintentional injuries caused by the child's inability to distinguish safe situations from dangerous ones, or by parents' overestimating their child's ability to do such things as lighting a fire to burn trash or using a saw in a wood project.

If a child has been physically abused, the injury is usually out of proportion to the history of the injury given by the parent (Fig. 55.2). The parent may report, for example, that the child was playing underneath the coffee table when he reared up quickly and hit his head, sustaining a large hematoma and temporary loss of consciousness, or that an infant "rolled off the couch" and now has two broken arms. In other instances, the parents may give conflicting stories (the mother says that the child fell, but the father says that the child broke his arm throwing a baseball), or they may give no reason for the injury ("He woke up from his nap and couldn't move his arm; I don't know what could have happened").

When questioned about the injury, abused children often repeat the parent's story; this loyalty to parents seems misplaced, but they may fear further beatings or simply believe that living with such parents is better than not having anyone. Ask about behavior problems in school, because the constant stress under which these children live frequently results in disruptive school behavior.

It is often difficult to remain objective when talking to the parents of an abused child. Emotional involvement is not constructive, however; it rarely helps the parents to change, and it may cause them to avoid seeking health care in the future, leaving the child totally unprotected.

Always assume that the parents have done the best they could under the circumstances in which they found themselves. The fact that they have brought the child for care means they are seeking help; this may be their way of saying, "Help me; I don't want this to happen again." Child abuse is rarely an isolated phenomenon. Often a parent is

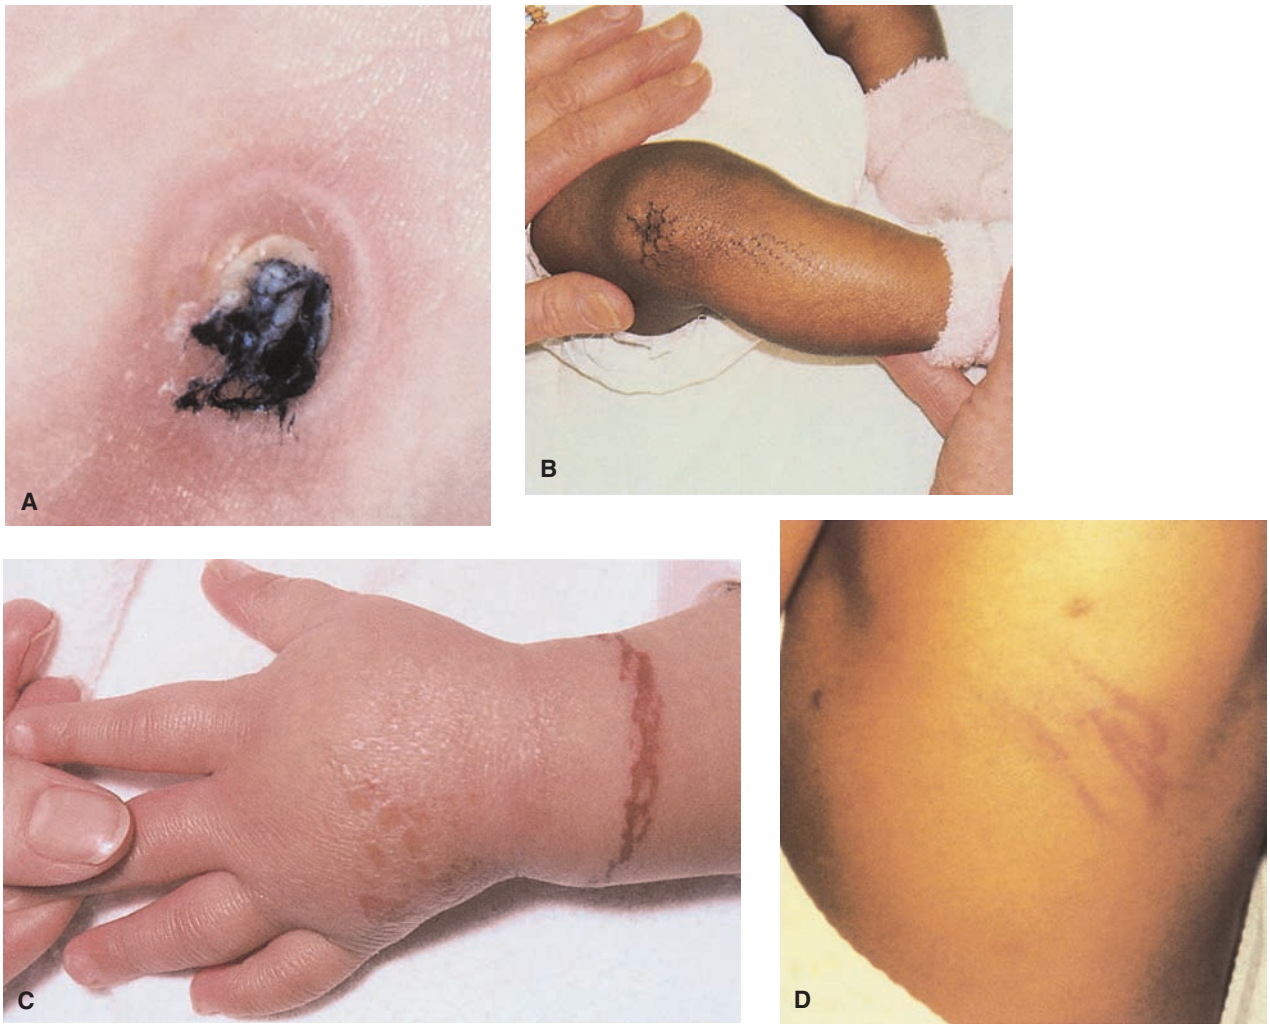


FIGURE 55.2 (**A**) Cigarette burn on child's foot. (**B**) Branding injury showing imprint of radiator cover. (**C**) Rope burn with edema and skin breakdown from being tied to crib rails. (**D**) Imprint marks from beating with a looped electrical cord. (From Zitelli, B. J., & Davis, H. W. [1997]. *Atlas of pediatric physical diagnosis* [3rd ed.]. St. Louis: Mosby–Year Book, Inc.)

also a victim and needs as much help and protection as the child.

Physical Examination. When children are examined at a well-child visit or because of illness, be certain that they are fully undressed (including removing all bandages and Band-Aids) so that the entire body can be observed. Plot height and weight on a standard growth chart. Delays in growth may suggest neglect.

Several injuries in children clearly signal child abuse. Most parents protect their children's hands carefully; children who are abused have a higher incidence of hand injury than others. Children who are beaten with electrical cords, belts, or clotheslines have peculiar circular and linear lesions (Fig. 55.2). Children who are beaten with a belt buckle have additional curved lacerations from the imprint of the buckle; few other weapons produce such contusions. Abrasions or ecchymotic areas on the wrists or ankles may be present if the child was tied to a bed or against a wall.

Burns or scalds are frequent injuries in abused children. The peak age at which children accidentally burn themselves is 2 years; that of burns related to abuse is closer to 3 years. When children burn their hand by accident, they usually burn the palm; burns from abuse are often on the dorsal surface. Scalding with hot water can occur from a child pulling a hot cup of coffee or a coffee maker off a table. It is often, though, a signal of child abuse (an adult deliberately scalded the child). A child who is placed in a tub of hot water buttocks first may have no burn in the center of the buttocks because they touched the tub; the result is a ring of burns causing a "doughnut-hole" effect. Young children do accidentally step into bathtubs containing water that is hot enough to burn. When this happens, however, the child usually falls forward and so also has burns on the hands and splash marks on the chest or face. If a child is lowered into scalding water as punishment, only the feet and the skin up to the knees are scalded.

Cigarette burns are another common finding on the bodies of physically abused children. A fresh cigarette burn causes a blister that resembles the scab of impetigo; differentiation at this stage is often difficult. Impetigo lesions, however, heal without scarring. Cigarette burns heal with a definite circular scar.

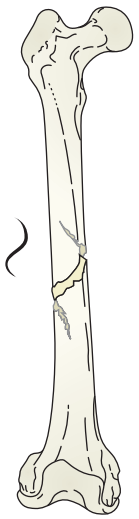

FIGURE 55.3 A spiral fracture around the bone is caused by a wrenching force and is frequently associated with child abuse.

FIGURE 55.4 Large bruises on a child's body. With this type of injury, carefully assessing the history of the traumatic event would be essential. (© Biophoto Associates/Photograph Researchers.)

Human bites or chunks of hair pulled off the scalp may be present. Head injury is common. Broken bones are another frequent finding. Children who are preschool age and younger usually do not fall far enough in normal accidents to break bones; a broken bone at this age suggests the child was thrown or struck so hard that the bone broke. Common findings include multiple fractures in different stages of healing, a single fracture with multiple bruises, rib or occipital fractures, and metaphyseal-epiphyseal injuries. Bones are not always broken if a child is shaken roughly, but the periosteum may be torn, so that a radiograph reveals a strange haziness along both sides of the bone shaft. Tibial torsion (twisting) is also often seen (Fig. 55.3).

Deliberate poisoning is yet another form of child abuse; this usually occurs in a child younger than 2.5 years. Bruises on a child who is too young to walk also are highly suspicious (Sirotnak & Krugman, 2008) (Fig. 55.4).

Listen to children while they are being examined. If they did not hear the parent's explanation of the accident, they may say something that is inconsistent with the parent's explanation. They may cry little in response to a painful procedure, such as an injection, because they are not used to receiving comfort for pain. They may draw back from an examiner more than the average child would because they are afraid of adults. These are very subjective observations, however, because children react in different ways to the fear produced by a recent injury or a health examination.

✔ Checkpoint Question 55.1

Which finding in Hillary's background is a typical finding of child abuse?

a. Hillary's mother describes her as "not pretty."
b. Hillary's birthday is in the fall of the year.
c. Hillary's mother works part-time for low pay.
d. Hillary's father smokes a pack of cigarettes a day.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for injury related to documented abuse by parent

Outcome Evaluation: Child has no further physical injuries identifiable as being inflicted by abusing parent.

Prevent Further Abuse. When child abuse is discovered, it would be ideal if the abuser's behavior could be changed and the family kept intact. In reality, once child abuse has been discovered, the child or the abuser must usually be removed from the home so that no more abuse occurs. Even so, it is impossible to reverse the damage that has been done to the child's sense of trust and self-esteem.

Provide Consistent Care and Support for the Abused Child. A major nursing role is supplying a consistent, caring adult presence for an abused child or furnishing a relationship that the child has never enjoyed.

Use a primary or case management type of nursing care assignment with abused children, to offer them consistency and the security of a one-to-one relationship. Many abused children are not used to playing for their own enjoyment but only to the point at which a parent wants to play a game; this means that they may watch you carefully for signs that you approve of their behavior. They may not be used to activities such as rocking or talking. Be careful when asking questions not to imply that any one answer is the correct one, or they will supply what they think you want to hear rather than the truth. (A question such as, "That feels better, doesn't it?" may be followed by an instant "yes" even though the child feels no improvement in symptoms.)

Evaluate and Promote Family Health. Nurses can help evaluate whether a child would be safe in the parents' care in the future. When parents who are suspected child abusers visit the health care facility, be certain they are given the same welcome and orientation to the facility and procedures as are other parents. When caring for a child, point out positive characteristics about the child, as well as growth and development markers that the child has reached and realistic expectations of the child's age, because lack of knowledge of normal growth and development may have contributed to the abuse.

For many parents, the response to a charge of child abuse is anger. For others, it is relief; now an unwanted child will be taken away from them. In some families, one of the parents is the abuser and the other is a victim as well as the child. The diagnosis of abuse may force the passive partner to make some important decisions about whether the partner wants to continue a marriage or relationship with the abusive partner. These are not easy decisions to make; if decision making of any kind were easy for this parent, the circumstances probably would never have reached the point at which child abuse occurred.

Praise abusing parents for the things they do well; take time to talk to them away from the child, so that your total attention is focused on them. Be certain they are referred for counseling.

Sometimes an abused child is removed temporarily from a home and then returned later, after the stress that led to the abuse has been removed. Such children need careful follow-up, because parents may revert to an abusive pattern if stress occurs again.

If a child was injured seriously enough to be hospitalized so has had to be removed permanently from the parents' care, the foster family should visit before discharge from the hospital to make the change less frightening for the child if at all possible. Children who are being removed from their parents in this way can feel an acute sense of loss and may grieve for the nonabusing parent or siblings very much. Abused children may also grieve for an abusing parent, especially if children are convinced that they were responsible for the abuse or that the parent was not to blame.

Outcome evaluation for abused children must include not only whether they are physically safe but also whether they are developing self-esteem, so that they can become adults who do not need role reversal with their children. It should include whether the abuser received counseling and changed behavior.

What if... Hillary keeps telling her mother that everything is all right and she knows her fall wasn't her mother's fault, even though the mother reported that she wasn't watching Hillary? Is this a typical sign of abuse?

Shaken Baby Syndrome

Shaken baby syndrome is caused by repetitive, violent shaking of a small infant by the arms or shoulders, which causes a whiplash injury to the neck, edema to the brainstem, and distinct retinal hemorrhages (Squier, 2008). This is a particularly insidious form of child abuse, because the damage inflicted on the infant is not readily apparent. Increased use of computed tomography (CT) scans and magnetic resonance imaging is helping to detect children with these internal symptoms. Parents have used covert camcorders ("Nanny cams") to reveal that a caregiver shook a baby this way.

Ritual Abuse

Ritual abuse is cult based or religiously, spiritually, or satanically motivated. It can involve physical, sexual, or psychological abuse with bizarre or ceremonial activities. With this type of abuse, multiple perpetrators may abuse multiple victims over an extended period (Sirotnak & Krugman, 2008).

Physical Neglect

Physical neglect is a more subtle form of abuse than physical abuse, but it can be just as damaging to a child's welfare. A neglected child may appear unwashed, thin, and malnourished or be dressed inappropriately, such as without mittens, a coat, or shoes in cold weather. In some families, no one has a warm coat to wear or receives enough food because there is no money for these things; that is different from the family in which parents do have these things, but the children or this particular child does not. This type of abuse may be overlooked because, if you never see the other members of the family, it is easy to believe that all are dressed poorly.

Failing to bring a child for immunizations and failing to seek early medical care for an infection are other signs of neglect (Box 55.7). Not requiring a child to attend school, deliberately keeping a child out of school without setting up

BOX 55.7 ✻ Focus on Evidence-Based Practice

Can underimmunization be used as a marker to suspect child abuse?

To see if there is an association between underimmunization and child abuse, researchers analyzed the records of 399 children, aged 3 to 48 months, who had been referred to a child advocacy center because of possible maltreatment. The results revealed that at 3 and 7 months of age, underimmunized children were four times more likely to have confirmed maltreatment than those children whose immunizations were up to date (32% of infants versus 17.6% at 3 months; 23.7% versus 8.6% at 7 months). By 19 months, the rates were no longer associated. There was no association to sexual abuse.

Based on the above, what questions would you want to ask a parent whose child at 6 months of age has not yet received any immunizations?

Source: Stockwell, M. S., et al. (2008). Is underimmunization associated with child maltreatment? *Ambulatory Pediatrics, 8*(3), 210–213.

a home school program, or allowing a child to go unsupervised after school may also be interpreted as neglect.

Neglect may be willful, or it may occur if parents simply do not realize the normal needs of a child. Such parents need guidance from health care personnel to understand their child's needs.

Psychological Abuse

Psychological abuse includes constant belittling or threatening, rejecting, isolating, or exploiting a child. Psychological neglect is the absence of positive parenting. Children who are psychologically abused are likely to have difficulty becoming emotionally confident adults. This type of abuse is the most difficult form of abuse to detect because it may occur only in the home, and its effects, although severe, may be subtle. However, it can be every bit as damaging to the child's ability to achieve as is physical abuse.

The parent who uses only negative terms to describe a child may be psychologically abusing the child. Be sure to include enough growth and development questions during a health assessment to reveal this, and observe the parent–child interaction to determine whether it is positive and healthy or negative and potentially unhealthy.

Munchausen Syndrome by Proxy

Munchausen syndrome by proxy refers to a parent who repeatedly brings a child to a health care facility and reports symptoms of illness when, in fact, the child is well (Beard, 2007). For example, a parent might report symptoms such as seizures, excessive sleepiness, or abdominal pain in a child. The reporting of these symptoms causes the child to undergo needless diagnostic procedures or therapeutic regimens. The parent may deliberately inflict injury on the child such as giving a laxative to induce diarrhea or slowly poisoning the child with a prescription drug. Two classic findings of the syndrome are usually present: first, the symptoms are not easily detected by physical examination, only by history; second, the symptoms are present only when the abuser is providing care and disappear when care is provided by another person. The parent usually has some degree of medical or child care knowledge; this knowledge may have been obtained through formal education, reading, or Internet browsing. The parent tends to stay with the child constantly, offering to give the majority of care. This can be very deceptive because wanting to stay and give care is also the hallmark of a very conscientious and caring parent. To diagnose this disorder, covert video surveillance may be necessary. Because this syndrome reveals distorted perceptions on the part of the parent, it is almost always necessary to remove the child from the home to protect the child, even if the parent receives counseling.

✔ Checkpoint Question 55.2

If Hillary had been abused as an infant, she might have experienced "shaken baby" syndrome. Which of the following is a usual finding with this syndrome?

a. A baby is fearful of strangers.
b. Retinal hemorrhages develop.
c. A baby develops Crohn's disease.
d. A major bone, such as a femur, is broken.

Failure to Thrive (Reactive Attachment Disorder)

Failure to thrive is a unique syndrome in which an infant falls below the 5th percentile for weight and height on a standard growth chart or is falling in percentiles on a growth chart. This condition can be divided into two categories: syndromes that can be explained because of organic causes, such as cardiac disease; and syndromes that occur because of a disturbance in the parent–child relationship, resulting in maternal role insufficiency (a nonorganic cause). Sometimes both physical and emotional factors play a role in failure to thrive (Stephens et al., 2008).

The nonorganic type can be considered a form of child neglect, although this represents a very complex interplay between parent and child. In many instances, the parent feels little emotional attachment to the child and may have a history of frequent moves and little family support. The parent may not be offering enough food (the parent may not be aware of the hunger cues the infant is offering, or the parent does not have enough concern for the child to offer food regularly). Some infants are offered sufficient food, but the emotional deprivation they sense makes them so lethargic that they do not eat enough. A child may contribute to the poor parenting interaction by being an irritable, fussy, colicky, or "difficult" child. In some instances, the child has minimal neurologic dysfunction resulting from a birth injury and so does not respond as a usual child. The mother may have interpreted this lethargic behavior as lack of response to her and so did not carry out her half of the interaction adequately. Failure to thrive begins with subtle signs that must be taken seriously, because it can lead to cognitive impairment in the child and even death if allowed to continue.

Assessment

Weigh all children at routine health assessments, and plot and compare their weight with standard growth curves so

that children who are failing to thrive can be identified. Because of a lack of parent–child interaction, accompanying motor and social developmental delays also may be present.

Take a detailed pregnancy history, because in many instances a breakdown in the development of parenting began in the prenatal period. A pregnancy that was unplanned or not accepted; a boyfriend or husband who left during the pregnancy; the death of a close friend or parent; an economic catastrophe, such as loss of a job; or a long-distance move during pregnancy are all situations that can cause inadequate parenting after the child is born.

On physical examination, these infants usually demonstrate typical characteristics:

- Lethargy with poor muscle tone, a loss of subcutaneous fat, or skin breakdown (Fig. 55.5)
- Lack of resistance to the examiner's manipulation, unlike the response of the average infant
- Rocking on all fours excessively, as if seeking stimulation, if emotionally deprived
- Possibly a greater reluctance to reach for toys or initiate human contact than is demonstrated by the average infant
- Staring hungrily at people who approach them as if they are starved for human contact. Some health care personnel have an uneasy feeling when caring for these infants because this eye contact is so intense.
- Little cuddling or conforming to being held by the second month of life
- Achievement of developmental milestones in the prone position such as lifting the head and chest and following an object with the eyes by the third or fourth month, but delays in other behaviors that should appear in later months such as sitting erect, pulling to a standing position, crawling, and walking because the child spends so much time alone

FIGURE 55.5 The child with failure to thrive experiences a loss of subcutaneous fat, muscle wasting, and skin breakdown. (From Zitelli, B. J., & Davis, H. W. [1997]. *Atlas of pediatric physical diagnosis* [3rd ed.]. St. Louis: Mosby–Year Book, Inc.)

- Markedly delayed or absent speech because of the lack of interaction
- Diminished or nonexistent crying

With advanced failure to thrive, the child's physical condition may be so extremely poor it nears acidosis from starvation. If an upper respiratory tract infection develops, the child's resistance to infection may be so low that it could result in death from pneumonia.

Therapeutic Management

With rare exceptions, children with failure to thrive need to be removed from the parents' care for evaluation and therapy. Severe failure to thrive in the early months must be treated rigorously, or it may lead to permanent neurologic damage or leave a child cognitively challenged because of protein deficits and interference with brain metabolism. If they are admitted to a hospital, studies other than routine admission blood work and urinalysis are usually delayed, to avoid submitting these understimulated children to needless pain.

Infants are placed on a diet appropriate for their ideal weight (the weight they would have been normally for their age). Rapid weight gain on this diet is diagnostic that their presenting illness was nonorganic failure to thrive.

Nursing Diagnoses and Related Interventions

A nursing diagnosis commonly used with children who fail to thrive is "Imbalanced nutrition, less than body requirements, related to lack of desire to eat or parental neglect regarding nutritional needs." In addition, "Impaired parenting related to disturbance in parent–child bonding" is often appropriate. Be certain that the plan of care designed for the family is realistic. Parents cannot be made to form a bond with their children instantly, particularly if lack of bonding has gone on for some time. On the other hand, one should never give up hope that this will happen. With the proper support and guidance over time, and when obstacles to bonding are removed, a healthy child–parent relationship could still develop.

Nursing Diagnosis: Imbalanced nutrition, less than body requirements, related to inadequate intake secondary to emotional deprivation

Outcome Evaluation: Child shows interest in bottle feedings; child is able to establish a regular eating pattern; child begins to gain weight.

Ensure Adequate Nutrition. Keep a careful record of intake and output so that the number of calories being consumed every day can be evaluated. Assess stools for pH and reducing substances (glucose) to be certain the child is absorbing nutrients. If a stool tests positive for glucose or has an acid pH (less than 7.0), it suggests that not even carbohydrates, the easiest food to absorb, are being processed.

Evaluate how well the infant sucks or is able to take food from a spoon and swallow. Record any symptoms,

such as pulling up the legs or crying after eating, that suggest gastrointestinal discomfort.

Nurture the Child. Because children with failure to thrive are suffering from emotional deprivation, they need effective "parenting" from the nurses who care for them. This does not mean that everyone who passes the crib should stop and play with the child for a few minutes; it means that a member of the nursing team should be chosen to be the child's "parent" during the hospital stay (a primary nursing or case management pattern of assignment). It is important that this person is able to spend time rocking the child, giving a leisurely bath, talking to the child, exposing the child to toys, and "parenting" the child rather than just giving routine care. Be certain that the person chosen for this role understands that interaction with the child must be active. Passive rocking without talking to the child or paying attention, for instance, may be no different than the parents' care.

Support and Encourage the Parents. Encourage the parents of children with failure to thrive to visit as much as possible while the child is hospitalized or in foster care; without encouragement, these parents may visit little or not at all. When they do visit, encourage them to feed the child if they want and to interact with the child as they choose. The parents cannot change their feelings about the child overnight. Telling them that they ought to pick up the baby more often or hold while feeding is ineffective and may only increase the parents' feelings of inadequacy. Giving some suggestions about how the baby tries to communicate with them might be more effective: "Do you know what I think he's trying to say when he stops sucking like that? I think he's saying he's ready to be burped." Pointing out the infant's ability to respond to the parent may be helpful: "Look how he turns his head at the sound of your voice. He recognizes you."

Occasionally, a parent is so distraught by such factors as the illness or death of an older child or relative that the parent simply becomes unaware of how much energy is being drained by these events. These parents quickly can become good parents to a deprived child as soon as they realize what has been happening. More often, however, the disturbance in a parent–child interaction began long before or is so great that a parenting bond cannot be established at this point. If the infant is discharged from the hospital to the parents' care, the parents will need effective follow-up in the months to come to see that they maintain parenting at an acceptable level. There is a very thin line between the child who fails to thrive and one who is abused. Some of these children need to be placed in foster homes for their own safety and to ensure that they receive adequate care.

Ensure Evaluation and Follow-up. Failure to thrive is easy to correct from a physiologic standpoint. When given proper food in a caring environment, the infant usually gains weight rapidly. Adequate follow-up to ensure that the child's emotional and physical needs continue to be met is a much larger issue, so big that the answer lies not in treatment but in prevention. Parents who may be at risk for poor parenting need to be identified during pregnancy, so they can receive counseling and close follow-up in the postnatal period. At health maintenance visits, secure careful, thoughtful pregnancy histories to elicit information about the psychosocial events that could lead to parenting breakdown. Some parents may need respite care for their children when they are overwhelmed by the task of parenting. They may need extended counseling to prevent parenting breakdown. Nurses can help in all phases of this care.

SEXUAL ABUSE

Sexual abuse is broadly defined as any sexual contact between a child and an adult (Nusbaum & Katsufrakis, 2008). Adolescents and older children may also be perpetrators. Sexual abuse involves the coercion of dependent, developmentally immature children or adolescents in sexual activities that they do not fully comprehend, to which they are unable to give informed consent, or that violate the social taboos of family roles. Adolescents have a higher rate of rape or sexual abuse than any other age group (8% to 10%) (Howard, Wang, & Yan, 2007). Remember that boys, as well as girls, can be sexually abused (Holmes, 2008). Abusers may contact children online through chat rooms making the monitoring of Web sites an important preventive measure for parents (Wolak et al., 2008).

Sexual abuse is physically and emotionally destructive; it leaves children unable to trust others, and may result in a sense of ambivalence toward intimacy and an overall sense of worthlessness. Children should be taught at an early age that their bodies are their own and to report anyone who tries to touch them in a way they do not like (Fig. 55.6). Children who have been sexually abused may have a sexual vocabulary beyond that expected by a child their age. They need a great

FIGURE 55.6 Teach children that their bodies are their own and that they have to give permission before anyone can touch them. (© Lesha Photography.)

deal of support to consent to an anogenital examination to document the abuse.

The physical exam often does not reveal signs of abuse, but is always important to perform.

Megan's Law is a federal law that requires law enforcement authorities to report when a sexual abuser moves into a neighborhood. Parents need to be aware of this law and insist that it be enforced. If they are aware that a former sexual abuser lives near them, they need to take appropriate precautions to protect their children's safety (Levenson, D'Amora, & Hern, 2007).

Types of Sexual Abuse

Sexual abuse involves a wide range of diagnoses from molestation to vaginal penetration.

Molestation

Molestation is a vague term that includes "indecent liberties" such as oral–genital contact, genital fondling and viewing, or masturbation.

A **pedophile** is an adult who seeks out children for sexual gratification (Cohen et al., 2007). In contrast to a rapist, whose crime is violent, the pedophile may be very gentle and limit the involvement to molestation. Such a person is usually a man who suffered sexual abuse as a child and repeatedly selects children who are of the same age at which his abuse occurred. The relationship may involve people with either homosexual or heterosexual orientations. Many pedophiles take photos or videotapes of their activities with children to use for sexual gratification at a later date.

Rehabilitation of pedophiles is difficult because they are fixated emotionally at a childhood level (seeing themselves as children, they do not perceive relationships with children as wrong). Listen carefully to children who report that someone enjoys photographing them; ask children to describe what they mean by someone "touching" or "feeling" them, to detect this type of abuse.

Incest

Incest is sexual activity between family members. It often involves an older man and a young girl, although it may involve an older woman and a younger boy, a brother and sister, or same-sex partners. It may involve foster, adopted, and stepchildren. Incest is a deviation from the norm and is so strongly viewed as such by most people that incest taboos are common to most cultures (Hebert et al., 2007). Incest results in a destructive relationship because it causes a great deal of guilt and loss of self-esteem in both the abusing and the abused person. The abuser is aware that this act is not culturally approved but still is unable to end the relationship; the victim recognizes this act as wrong but is unable to resist the advances. Other members of the family are likely to suspect that something is wrong; this leads to guilt and feelings of worthlessness on their part for not being able to protect the victim.

Pornography and Prostitution

Child pornography involves photographing or describing sexual acts by any medium involving children, or distributing such material in person or by mail or fax or over the Internet. Child prostitution involves arranging or participating in sexual acts with children. Both of these phenomena are demeaning to children and illegal. Child prostitution carries the additional risks of sexually transmitted infection and violence, the same as adult prostitution.

BOX 55.8 ✻ Focus on Family Teaching

Identifying Signs of Sexual Abuse

Q. A grandmother asks you, "What signs should I look for if I suspect my granddaughter is being sexually abused?"

A. Here are some general indications that a child is being sexually abused:

- Verbal reports of sexual activity with an adult
- An awareness of sex and sexual vocabulary beyond age expectations
- Participation in sexual expression with dolls
- Pregnancy in a girl younger than 15 years
- Perineal, vaginal, or anal inflammation
- Vaginal tears or anal fissures
- Presence of a sexually transmitted infection
- Symptoms of increased anxiety, such as sleep disturbance, development of tics, nail biting, or stuttering
- Change in school performance, school phobia, or truancy
- Fear of being left alone with a certain adult
- Vague abdominal pain or acting-out behavior

Assessment

Signs of sexual abuse are shown in Box 55.8. Symptoms of sexual abuse may be revealed by a health history such as a young girl worrying that she is pregnant; it may be revealed by a child's abnormal anxiety about a parent returning home from a hospital stay or anxiety about being left with a particular individual in the family (Box 55.9). Young children who are the victims of this type of relationship often have been threatened or bribed to keep it a secret; they have extremely low self-esteem and may think that they are so bad that they deserve to be treated this way.

Allowing young children to play with anatomically correct dolls is a common way of determining whether sexual abuse is occurring. For example, the average reaction of a preschooler or young school-age child who has not been abused is to undress the dolls, giggle for a moment or two about how they look, and then redress or put them aside. The child who is involved in an incestuous relationship is more apt to make the dolls perform a sexual act, such as placing the male doll's penis into the female doll's mouth. The use of such dolls is controversial because there is a concern that without a common protocol for their use, the child's actions could be overinterpreted. Asking the child to draw a picture of what happened may also be an effective way of revealing abuse.

Therapeutic Management

Sexual abuse, like physical abuse, must be reported. The perpetrator will then be interviewed by the police, because this is a criminal offense. It is important that this information be collected in such a way that the adult's rights are respected and the testimony is therefore admissible in court.

BOX 55.9 ✻ Focus on Communication

You notice during history taking that a 4-year-old girl uses several four-letter words to describe where she hurts.

Less Effective Communication

Nurse: Mrs. Holly, your daughter seems to know some words that are unusual for a 4-year-old.
Mrs. Holly: She gets that from watching cartoons on TV.
Nurse: Cartoon characters don't usually use the words she uses.
Mrs. Holly: We're proud she's advanced for her age.
Nurse: Okay. I just want you to know I think her vocabulary is advanced. Here is the medicine to apply to her bottom.

More Effective Communication

Nurse: Mrs. Holly, your daughter seems to know some words that are unusual for a 4-year-old.
Mrs. Holly: She gets that from watching cartoons on TV.
Nurse: Cartoon characters don't usually use the words she uses.
Mrs. Holly: We're proud she's advanced for her age.
Nurse: Using words with sexual connotations doesn't necessarily mean her vocabulary is advanced. It means she most likely keeps company with an adult who talks to her that way.
Mrs. Holly: That's probably her uncle. He babysits for us once a week.
Nurse: Does she mind staying with him?
Mrs. Holly: A free babysitter doesn't happen every day.
Nurse: Let's talk some more about her vocabulary, especially in light of her infection.

It is often very difficult for families to face the fact that a family member could be guilty of child sexual abuse. In these instances, it is necessary to pursue the subject, rather than let yourself be distracted, to help a parent examine what could be happening.

Both the adult and the child involved in a sexual abuse relationship need psychological counseling—the child to improve self-esteem and the adult to channel sexual expression to less destructive outlets. To improve the child's self-esteem, the adult in the relationship needs to admit that the fault is the adult's. Follow-up care is best done by one of the people who sees the child initially, so that the child does not have to recount the incident to strangers again and again. Treatment for sexually transmitted infections or protection against pregnancy should be provided if needed.

Parents may need as much counseling as the child, so that they can help the child work through feelings about this situation. In many instances, the offender is a family member, such as an uncle, stepfather, or older brother. Often the relationship has been occurring for some time before it is reported. The parents may feel guilty that they allowed the family member to have access to the child or did not listen to a child's protestations that being alone with this family member was uncomfortable for them. If incest involves a parent, it may be extremely difficult for the parents to continue to relate to each other effectively enough to help the child. Encourage parents to teach children simple rules to help them avoid sexual abuse (see Chapter 32, Box 32.5).

RAPE

Rape is sexual activity such as intercourse or penetration of a body orifice by a penis or other object under actual or threatened force. Statutory rape is sexual activity with a person under the age of consent (in most states, younger than 18 years) and is considered to have occurred regardless of the apparent willingness of the underage person. Sexual assault is used to refer to other forced sexual acts, such as oral–genital or anal–genital acts (Platt & Mallory, 2008).

Rape includes "date rape," a situation in which an individual forces a date or casual friend into having coitus despite a voiced unwillingness (Lu, Lu, & Halfin, 2007). The increasing misuse of flunitrazepam (Rohypnol), a drug easily dissolved in a drink, has led to an increase in the incidence of date rape (see Chapter 33). It may be very difficult for the victim of date rape to find a sympathetic ear if her companion insists he meant no harm; he simply didn't believe her. If the victim was given flunitrazepam, little or no memory of the event is present.

Both rape and sexual assault represent deviant behavior; they are crimes of violence, not acts of passion. They lack privacy and mutual consent, which are elements of "normal" sexual behavior, and so are degrading and dehumanizing, leaving the victim feeling completely helpless. Adolescent girls and boys should be informed about ways to prevent rape (including date rape) (see Chapter 33, Box 33.7).

Determining the actual incidence of rape is difficult; it seems to be more prevalent than formerly, but that may be because more people report it. Many adolescents want to avoid the secondary, but no less severe, trauma associated with reporting rape and therefore do not report it. This leaves them without the immediate treatment and follow-up care that are so important to a complete recovery.

Although victims can be of any age and either male or female, the average rape victim is an adolescent girl. Up to 75% of girls know their attacker. The rapist may be a relative or family friend, and rapists frequently commit the act in the neighborhood where they live. Based on arrest data, the average rapist is a young adult man with a background of aggressive behavior. His motivation usually relates to expressions of power or anger; sexual satisfaction does not appear to be a dominant motive. An excessive amount of alcohol intake often proceeds rape (Yazel & Herr, 2008). Rape tends to be a repetitive, planned activity rather than an isolated event.

Assessment

Many rape victims demonstrate immediate physical and emotional symptoms that can last for weeks. These symptoms constitute what has been termed **rape trauma syndrome,** a form of posttraumatic stress syndrome, and they usually occur in two stages: disorganization and reorganization. In the immediate *disorganization phase*, victims feel a combination of humiliation, shame and guilt, embarrassment, anger, and vengefulness. They feel that their lives have been completely disrupted by the crisis because they were

unable to protect themselves from the assault. They may tremble from fear or be in great pain from perineal lacerations. They are apt to start visibly at the sound of anyone approaching or touching them. They need gentle, sympathetic support people with them in the days after the event to allow them to feel safe. They may have nightmares of the attack occurring again. This immediate stage of disruption and disorganization usually lasts about 3 days.

The second stage of rape trauma syndrome, termed the *reorganization phase*, may last for months or years. Many rape victims report recurring nightmares, perhaps sexual dysfunction, and continuing inability to relate to men or to face new and surprising situations. They may continue to have a great deal of difficulty discussing the rape. Many rape victims, trying to escape from this personal offense, change their residence at great sacrifice to finances and lifestyle. If not offered constructive counsel, victims may still feel guilt or shame when thinking about the rape as long as 20 to 30 years later.

If victims do not report rape and therefore receive no counseling, symptoms indicative of **silent rape syndrome** can result. When the subject of rape is mentioned, people with silent rape syndrome may grow increasingly emotionally disturbed; it may be evident in their history that they altered their behavior toward men at a certain point in life and perhaps began to resist actions such as going outside by themselves or being alone in a house after that time. This condition can be devastating to their ability to maintain employment or remain independent. They need counseling as much as a person who reported a rape.

Emergency Care

Although most large city police forces have special officers assigned to investigate rape charges, victims can be confused and further traumatized by police officers who imply that they provoked the attack or could have at least done more to resist or prevent it. This increases the victim's feelings of shame and degradation. It may be especially harmful to adolescents, because people they have been taught to respect have no concept of the degree of fright they have experienced or the strength of their attacker. Health care providers usually are the second group of people victims see after an attack, so they need to be extremely cautious that they do not show this type of callous behavior.

Most health care agencies where many rape victims are seen have a rape trauma team with specially educated counselors to talk to victims immediately after a rape and to offer long-term counseling as needed. Nurses serve as important members of such teams and may provide primary care after a rape. Any nurse should be able to offer emergency support because it might be a long time before a specifically designated staff member arrives, and such services are not available in every community.

Because rape is a crime, the hospital chart of a rape victim is often displayed as part of a court procedure. For the victim to bring charges against the attacker, information concerning the victim's appearance and history needs to be detailed in the hospital chart. Be certain statements made in a chart are accurate and unbiased. When recording a history, quote the victim's exact words whenever possible. Describe the victim's physical appearance carefully, including the presence and location of injuries, such as bruises, lacerations, teeth marks, or abrasions, and the condition of clothing. Ask whether the victim bathed or washed before coming for care, because this can obscure evidence and obliterate the presence of sperm or DNA material. Ask whether the woman was menstruating or using a tampon. The force of penis penetration with rape can cause a tampon to tear through the posterior vaginal wall into the abdominal cavity, causing an extreme loss of blood internally. Photographs should be taken as necessary to document the extent of injuries. Any clothing that is ripped or stained should be considered as evidence of violent assault and secured according to hospital policy.

After this preliminary observation, a gynecologic or anal examination will be done to evaluate the physical condition of the victim and to document that rape occurred. This is done by recording the existence of any vaginal or perineal lacerations and aspirating sperm or semen for DNA analysis from the vagina or rectum. Acid phosphate, a component of prostatic fluid, is a substance that is not normally present in vaginal or rectal secretions but is present in semen. The presence of acid phosphate can be extremely important if the attacker is infertile or sterile, making DNA analysis difficult. Its presence may be the best evidence that rape occurred. Vaginal and anal cultures are taken for gonorrhea, and a Pap test is also performed. Blood is drawn for a pregnancy test and a VDRL test for syphilis. Prophylactic administration of antibiotics against gonorrhea and syphilis is given. If the woman is not menstruating, she may be given "morning after" therapy to avoid pregnancy. Victims may have a baseline blood sample drawn for human immunodeficiency virus (HIV) status.

Be certain during emergency care to provide privacy. Many people may want to ask the victim questions, including police officers or detectives, the victim's family, a rape trauma team, and the examining physician or nurse practitioner. Describing the experience is good, but lack of privacy during a perineal examination demonstrates little concern for the victim's self-esteem. Many female victims are uncomfortable with a male physician examining them after rape, because they are temporarily fearful of men. Having a female nurse remain with the victim during this time may be helpful. A male nurse can be equally supportive, because it is not the male–female contrast that a victim is seeking so much as a contrast between aggression and caring. Table 55.1 summarizes common tests and procedures for emergency care of rape victims.

Legal Considerations

Nurses working in emergency departments may be asked to testify in court about the victim's appearance after the assault, although the documentation in the chart is usually all that is necessary. Many victims, especially adolescents, do not press charges against their assailants because they were too frightened or unable at the time to observe the assailant's appearance and therefore cannot identify him later. They may fear that if they name him in court, he will return and kill them. Whether victims follow through with a legal action or not is their choice, but the incidence of rape might be reduced if rapists were aware that they are not apt to escape without a penalty for their crime. Taking the rapist to court may be an opportunity and appropriate time for victims to "fight back" and therefore not be as helpless as they were during the attack.

TABLE 55.1 ✻ Common Specimen Procedures After Rape*

Procedure	Purpose
Oral washing	Client rinses mouth with 5 mL sterile water, which is then collected in test tube. Analyzed for blood group antigens, or sperm or DNA of attacker.
Fingernail scraping	Scraping under all of client's fingernails is done, and scrapings are placed in envelope. Analyzed for blood, skin, DNA, and clothing fibers of attacker.
Blood VDRL, HIV, and HbsAg	Blood is drawn for antibody titer for syphilis, HIV, and hepatitis B.
Blood typing	Blood is drawn for typing to differentiate it from attacker's type.
Pregnancy test	Either blood or urine specimen is collected; complete vaginal examination before woman voids.
Hair samples	Both scalp and pubic hairs of client (about 10) are removed for comparison with attacker's and placed in envelope.
Vaginal smear for sperm and DNA	Vagina is swabbed with dry applicator and smeared onto slide. Allow to dry. Sperm and DNA analysis performed.
Gonococcus smear	Cervix, vagina, rectum are cultured (also throat is cultured if oral coitus was attempted).
Vaginal washing	5 mL of sterile saline is placed in vagina and aspirated. Analyzed to detect sperm, DNA, and acid phosphate.
Skin washings	Any dried stain of blood or semen on skin or clothing is touched with a moistened cotton swab, which is then dropped into test tube. Analyzed for attacker's blood, semen, or DNA.
Clothing	Any clothing stained or torn is placed into a paper bag. Evidence of violent attack.

* Label all specimens carefully, indicating where they were obtained, to aid medical therapy and provide legal evidence.

✔ Checkpoint Question 55.3

Which description most accurately describes rape?

a. It is a crime of deep passion.
b. It is associated with poverty.
c. It occurs in mentally ill adults.
d. It is a crime of violence.

Nursing Diagnoses and Related Interventions ✻

Nursing Diagnosis: Anxiety related to recent rape

Outcome Evaluation: Victim is able to discuss what happened and voice intense feelings about the crime; victim states ability to move forward with life.

One of the major needs of any victim after a violent act is to talk about what happened. A person who can describe an incident begins to "put a fence around" or contain the event. This process brings the event down from "something terrible has happened," a situation that leaves a person with a continuing high anxiety level, to "this specific thing has happened," a situation that allows the traumatic event to be examined and handled. Something that is concrete and describable is rarely as frightening as "something out there."

Ask the victim to describe the incident to you with an introduction such as, "Most people find that it helps to talk about what happened to them." Table 55.2 lists areas to explore with victims to help them reduce the incident to a size they can begin to handle.

Victims should be given the number of a counseling service to telephone before they leave the emergency department. Because genital bruising may not be apparent until 24 hours after the rape, they may be asked to return for a re-examination the next day so this can be documented. Syphilis will not be apparent for up to 6 weeks in serum, so they should return for a repeat VDRL at that time. They may be advised to return in 6 weeks and again in 6 months for HIV testing. Be certain that victims have a support person to accompany them home. Be sure they know that, if their distress becomes acute, they can return as needed to the health care facility for additional care or counseling. Inform them about any local support groups that provide follow-up counseling for victims of rape. One such organization, Women Organized Against Rape, is active in many communities.

Nursing Diagnosis: Disabling family coping related to recent rape of family member

Outcome Evaluation: Partner or other family members express feelings about the rape to health care provider; states confidence in ability to support rape victim.

In many instances, the victim's usual sexual partner has difficulty being a support person after a rape because they have as much difficulty dealing with the rape as the victim. Not infrequently, a relationship that was meaningful before the rape deteriorates because the partner now sees the victim as "soiled" or mistakenly believes the victim was somehow responsible for the trauma or actually enjoyed the experience. In

TABLE 55.2 ✻ Areas to Explore in Rape Counseling

Area	Considerations
The event	Where did the attack occur? What was happening at the time? This information is important for the victim to discuss and work through; otherwise, any time she is in similar circumstances again, she may have uncontrollable fears related to the attack. Walking home from school or waiting for an elevator in a public building are everyday actions that she will repeat often during her life. If she was raped in such circumstances, she can be reassured that she was acting sensibly and that the rape was not her fault.
The assailant	Allowing the victim to review the description of the rapist may help her to realize that she may react in negative ways in the future to a man with the same build or description. For example, the man may have approached her with a simple gesture, such as a hand on her shoulder. Others will perform this gesture again. She must work through her revulsion to handle it when it occurs in friendly circumstances.
The conversation	Describing the conversation with the rapist helps the victim to accept that she did not provoke the attack.
Details of the assault	Describing the actual assault is extremely difficult for most victims, but doing so allows them to work through it. Until they can describe the attack or the sexual act to which they had to submit, they may have difficulty in performing similar acts with persons of their choice.
Resistance to the assault	Many victims do not struggle during an assault because they realize that it could result in further harm to them. If someone asks them what they did to try to fight off the assailant, they may feel again that they provoked or agreed to the attack. Reassure them that no action was probably the best action and the reason they are still alive. To improve self-esteem, counsel victims that rape is a violent crime and that usually the strength of an attacker is far too great for any woman to resist effectively.

other instances, the partner may become so overprotective (not allowing the victim to go out alone; checking on her constantly) that she is not free to maintain her identity. Parents of a young adolescent may feel the same way. Counseling for the victim's partner or family may be necessary to help them to be truly supportive (Box 55.10).

What if... A stepbrother rapes his younger stepsibling? Because they are not blood relatives, would this be considered incest?

INTIMATE PARTNER ABUSE

Intimate partner abuse is abuse by a family member against another adult living in the household, such as a spouse or significant other. That spouse abuse and child abuse may both exist in a family strengthens the importance of providing family-centered nursing care so that both these situations can be identified and halted. As many as 20% to 30% of women seen in emergency departments are there because they have been abused by their intimate partner. Common injuries suffered by abused women include burns, lacerations, bruises, and head injuries. Asking all women at physical examinations to account for any bruise they have helps detect physical abuse. Asking them whether they are ever concerned about their safety or well-being helps detect emotional abuse. In addition, screening for intimate partner abuse is important when parents bring children for health care visits.

Intimate partner abuse occurs at a higher rate during pregnancy than other times (Shoffner, 2008). Homicide from partner abuse is the number-one cause of death in pregnant women. This probably happens because stress is often a trigger to abuse, and pregnancy, with all that an expected new child entails (another mouth to feed, body to clothe, or dependent to protect), can increase stress.

Abused women may have an unintended and unwanted pregnancy because they were unable to resist sexual advances from their abusive partner. Another woman may desire the pregnancy very much even with such a poor beginning because she believes having a child will change the partner and make him a better person. She may be grateful for the pregnancy, thinking that by having an infant she will have someone to love her.

Although it is impossible to predict how any individual woman will respond, pregnant abused women may demonstrate behaviors that reveal abuse. A woman may come for care late in pregnancy or not at all, for example, because her partner controls her transportation or money; she may fear that a health care provider will identify and report the abuse; or she may have been pretending the pregnancy did not exist to reduce stress in her home. She may be noticeable in a prenatal setting because she has purchased no maternity clothing (she has no funds for herself and asking for money may incite violence). She may decline laboratory tests if they involve additional transportation or money for the same reason.

An abused woman may have difficulty following recommended pregnancy nutrition (she must cook what her partner wants or she will be beaten). She may grow anxious if her appointment is running late (she must be home to cook dinner or risk a beating). She may call and cancel appointments frequently (or simply not keep appointments) because she has an obvious black eye or a bleeding facial laceration she does not want to reveal. She may dress inappropriately for

BOX 55.10 ✻ Goals of Crisis Intervention for Families of Rape Victims

- Help the family to express openly their immediate feelings in response to a rape as a shared life crisis.
- Help the family to be supportive of and reassuring to the victim.
- Help the family work through immediate practical matters and initiate problem-solving techniques.
- Help the family develop cognitive understanding of what the rape experience actually means to the victim and to the family.
- Explain the possibility of future psychological and somatic symptoms that characterize a rape trauma syndrome and what the family can do to minimize these symptoms.
- Activate qualities characteristic of healthy family functioning during the impact and resolution phases of the shared crisis.
- Educate the family about rape as a *violent crime,* not a sexually motivated act, and eliminate focus on the victim's guilt or responsibility.
- Eliminate the family's sense of guilt for not protecting the victim by assuring them that they could not have anticipated or prevented the rape.
- Discourage violent, destructive, or irrational retribution toward the rapist (under the guise of being on the victim's behalf) by encouraging sharing of feelings of helplessness, sadness, hurt, and anger.
- Encourage discussion of the sexual relationship between partners; suggest that the victim's partner let her know (a) that his feelings have not changed (if this is true) and that he still sexually desires her, (b) that he will wait for her to approach him, and (c) that sex therapy is available if they have persistent difficulties and want assistance in re-establishing normal sexual relations.
- Explain the possibility of sexually transmitted disease and pregnancy that may result from a rape, the preventive care necessary for the victim and spouse or boyfriend, and the follow-up care indicated.
- Explain that early crisis intervention often prevents long-term problems in resolving the crisis, and that to seek counseling at this time does not imply inadequacy (specify that crisis intervention usually lasts for 3–6 hr during the first few weeks after the rape).
- Refer the family for direct counseling if members' shared responses to the crisis interfere with their ability to cope adaptively.
- Provide factual data, resource lists for counseling, and follow-up care *in writing* (because highly stressed persons do not hear or recall information verbally communicated).
- Let families know that some decisions, such as whether to prosecute the rapist or move to a safer residence, can be postponed while more immediate needs, such as medical care, are taken care of. (This action helps the family set priorities and organize decisions about what has to be done now and gain emotional distance from the urgency and confusion felt during a crisis state to permit sound decision-making later.)
- Identify how the family has handled crises in the past, and encourage members to use adaptive coping mechanisms for this crisis.
- Encourage contact with persons identified as supportive to the family, and offer to contact such persons.
- Assign a primary nurse to spend time talking with the family in the emergency department waiting room while the victim receives medical care.
- Allow time for thoughts and feelings in the decision-making process.
- Use empathic listening to convey understanding of the family's feelings and concerns.
- Ask if you can check back with the family the next day to see how they are getting along and answer any questions they may have.

warm weather, wearing long-sleeved, tight-necked blouses to cover up bruises on her neck or arms. When undressed for a physical examination, there may be bruises or lacerations on her breasts, abdomen, or back she cannot explain. Her neck may reveal linear bruises from strangulation. Ask any woman with bruises to account for them. Determine whether the explanation correlates with the extent and placement of a bruise or laceration (Box 55.11).

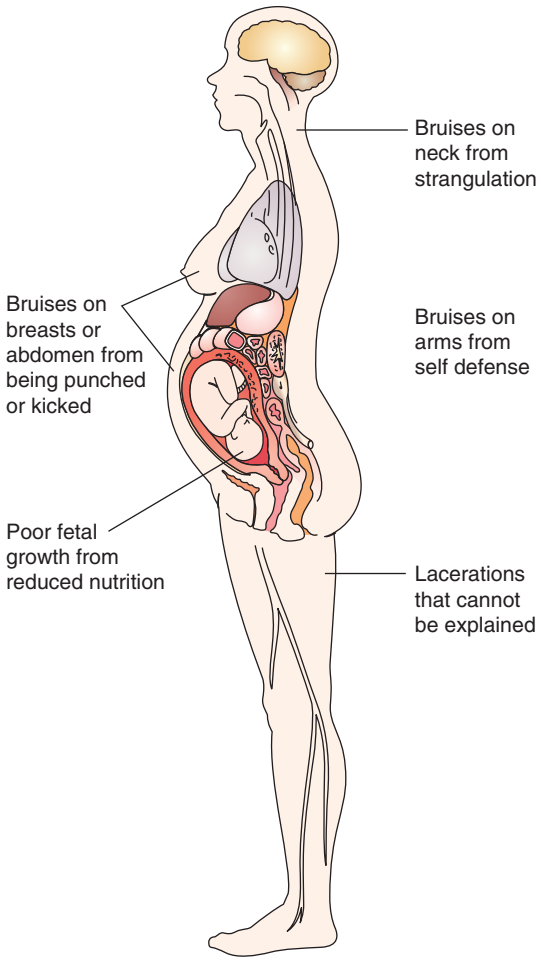
A woman who has experienced abuse may be anxious to listen to the baby's heartbeat at prenatal visits because her partner recently punched or kicked her in the abdomen and she is worried the fetus has been hurt. If abdominal trauma is suspected, an ultrasound may be done because this is the most accurate method of assessing fetal health after trauma. An ultrasound may reveal minimal placental infarcts from blunt abdominal trauma. This can lead to poor placental perfusion and low birth weight. Fetal heart tones and fundal height should also be recorded.

Nursing Diagnoses and Related Interventions ✻

Nursing diagnoses for an abused woman may pertain to physical injuries sustained, but they should also address the emotional manifestations of abuse. Some examples include:

- Powerlessness related to perception that it is impossible to break away from abusing partner
- Fear related to constant threat of violence

Box 55.11 Assessment
Assessing the Pregnant Woman For Intimate Partner Abuse



- Social isolation related to client's need to hide evidence of her abuse
- Ineffective denial related to inability to face the fact partner is abusive
- Compromised family coping related to dysfunctional relationship between client and abusive partner

Expected outcomes should address specific tasks a woman could accomplish to keep herself safe from further abuse, such as:

- Client carries telephone number of home for abused women with her.
- Client and abusive partner continue to attend counseling sessions.
- Client states she has filed restraining order against abusive partner.
- Client states she feels secure living at safe house.

It may be difficult to work with an abused woman who will not leave an abusive relationship because it is so hard to understand why she stays in the situation. A common finding is that a woman cannot leave because of fear of the abusive person (he has threatened that if she leaves, he will find her and kill her) and the guilt and low self-esteem she feels (he has told her so many times this is her fault and she deserves to be treated this way that she believes it). To free herself from this emotional paralysis, she needs outside help. Unfortunately, her low self-esteem and depression lead her to believe that no one would be interested in helping her.

Nursing Diagnosis: Chronic low self-esteem related to continuing physical and mental abuse

Outcome Evaluation: Client identifies positive traits about self; begins to discuss possible reasons why she has remained in an abusive situation; makes concrete, realistic plans for future; states she feels able, with continuing help and outside resources, to protect herself in the future.

Until she can develop better self-esteem, an abused woman may need support to make even simple decisions. Support any ability she has to make constructive decisions. Be familiar with shelters for abused women in your community; discuss with her how she can call the police at any time and they will take her to the shelter. Help her to file charges or obtain a restraining order to keep the abusive person from coming near her again if this is necessary.

Be careful not to blame the victims. Battered and emotionally abused individuals are often so immobilized by a sense of guilt: they believe that if they were better people, their partners would not resort to beatings or verbal badgering. Because victims may have no access to money and no skills to earn any, they need a great deal of support to be able to leave their partners. Even if they have a skill and have supported themselves in the past, their self-esteem may be so low that they no longer believe they can put the skill to use. As the abuse becomes more violent, they may be afraid that their abusers will follow and kill them and their children if they leave. Other extended family members may be unwilling to shelter the victims for fear of being included in the violence. An important role for nurses is helping an abused family find a shelter where they can feel safe. Treatment for abusers needs to be scheduled, but safety is the first priority.

After the birth of her child, assuming a woman moved away from the abuser, she may begin to feel a sense of depression from loneliness. This can lead to her having unrealistic expectations of her child, trying to make the infant smile at her and interact with her more than a newborn is capable of to have someone to love her. Caution her that her newborn does love her but she has to give the child some time to grow. Demonstrate all the things the child can do, such as attend to the sound of her voice or cuddle against her. Without this awareness, her unrealistic expectations can lead to disappointment and can interfere with mothering.

Do not leave an abused woman without a support system after the birth of her child. If she was depending on prenatal personnel during her pregnancy, the

gap must be filled with another support system. This could be a social agency that deals specifically with abused women; it could be a community health nurse who will be visiting her after she returns home. If she is left without a support person, her low self-esteem may not allow her to reach out and seek help. She may decide that suicide or returning to the abuser is her best recourse. If a woman does return to live with an abusive partner, both she and the infant need frequent health care visits scheduled so their health and welfare can be monitored. A child raised in a home where the mother is abused will learn that this is acceptable conduct, and the abuse may extend to yet another generation.

Children who are exposed to intimate partner abuse may demonstrate conduct problems, noncompliance, and aggression. They may develop low levels of empathy, or they may display distress behaviors such as clinging, crying, abdominal pain, or sleeping disorders. They may regress in language or social developmental milestones. Effects may be long term if the abuse causes teenage girls to shy away from relationships with boys, afraid that they will be exposed to abuse in the same way as their mother was, or if they develop a lack of respect for the abused parent because they blame that person for the abuse.

Like child abuse, intimate partner abuse affects all ethnic and social groups. If it appears to be more prevalent in lower socioeconomic neighborhoods, it is because these families are more visible to service organizations and law enforcement officials. When it occurs in middle-class or upper-class houses, wives are often too embarrassed to let people know and tend to keep the violence hidden longer.

Theories About Intimate Partner Abuse

Violent family situations can be divided into two groups: those in which violence preceded the relationship or children and those in which the violence developed after the relationship was established or children were born.

In the first situation, which is more common, violence is usually brought into the family by a man with a history of violence (although the woman may be the offender). His violence-prone characteristics usually erupt early in the courtship and grow progressively worse. He uses violence to handle even small conflicts that instills a pervasive feeling of powerlessness in the people around him. Such men usually have a history of early and prolonged exposure to family violence as children; alcohol is frequently associated with the expression of violence.

Intimate partner abuse often follows a cycle of violence that includes three phases: tension-building, acute violence, and a "honeymoon" or tranquil, loving phase. During the first phase, the abuser displays actions such as anger, arguing, and blaming the victim for external problems or for provoking the abuse. The acute violence phase can be triggered by an internal response in the abuser or by an external crisis. It can result in extreme physical harm to the victim. The tranquil, loving phase, characterized by kind and contrite behavior, follows the violence, lulling the victim into forgiveness and a wish to continue the relationship. Without intervention, however, this phase ends at some point, and the cycle of violence repeats (Kramer, 2007).

TABLE 55.3 ✻ Levels of Intimate Partner Abuse

Level	Description
I	Abuse is occasional; consists of slapping, punching, kicking, verbal abuse. Contusions occur.
II	Abuse is becoming more frequent; beatings are sustained and cause fractures, such as a broken jaw or rib fracture.
III	Abuse is even more frequent, perhaps daily. A weapon, such as a gun, baseball bat, or broom handle, may be used. Permanent disability or death from injuries, such as intracranial hemorrhage or concussion, may occur.

Partners react to the situation in three phases (Table 55.3). During the impact phase (stage I), a light level of abuse, the victim uses denial as a defense mechanism. If she does not end the relationship at this point, the abuse grows more frequent and more violent; by not stopping it, she is indirectly giving the offender permission to continue. During the second stage, the victim can no longer deny that the violence is occurring. At the same time, she cannot stop it because she does not provoke the violence; she is only a convenient recipient of poorly controlled violent behavior. She is forced to use coping mechanisms such as becoming very obedient and cooperative and doing everything her abuser asks in a desperate effort to reduce the violence. This phase is termed psychological infantilism or **learned helplessness.** The level of abuse can continue until the woman is being almost constantly physically abused (stage III). During this stage, the woman is forced to become isolated; she sinks into hopelessness and depression. She has difficulty seeking help because she is unable to believe that outside people might want to help her.

In the second type of violent family, in which violence begins late in a relationship, violence occurs as a last resort after all other attempts at communication have failed. The behavior of one partner threatens the psychological defenses of the other, and each projects feelings and shortcomings onto the other. Such a situation, however, is not typical of intimate partner abuse: in most instances, one partner brings violence into the family.

✔ Checkpoint Question 55.4

You care for a woman who has been injured by intimate partner abuse. What is a typical characteristic of an intimate partner abuser?

a. A man was raised in a family where his father abused his mother.
b. A woman wants to earn more money but has no education.
c. A father earns under $20,000 a year and has four credit cards.
d. A man has over four children and all are under school age.

Key Points for Review

- Child abuse can exist in many forms. It may be physical, emotional, or sexual and may encompass neglect.
- A high suspicion for child abuse should be present if burns, head injury, or rib fractures are present or if the history of the accident seems out of proportion to the injury.
- Shaken baby syndrome involves repetitive, violent shaking of a small infant by the arms or shoulders, causing a whiplash injury to the neck, edema to the brainstem, and distinct retinal hemorrhages.
- A triad of "special parent, special child, special circumstance" is characteristic of the family in which child abuse occurs.
- Failure to thrive is a syndrome in which an infant falls below the 5th percentile for weight and height on a standard growth chart. It is associated with a disturbance in the parent–child relationship.
- Children who comfort parents in emergency settings may just be sensitive children, or they may be demonstrating role reversal, a behavior characteristic of abused children.
- In families in which a child is abused, a parent may also be a victim of abuse. Ask enough questions at health care visits to be certain that this problem does not exist as well.
- Child abuse is reportable by law. Nurses can initiate reporting as an independent action or through their health agency's referral network.
- Methods to prevent abuse in which nurses can actively participate include teaching about the expected growth and development of children, educating teenage parents for parenting roles, and teaching empowerment, or a sense that children and adults have control of their own lives.
- Sexual abuse of children can be prevented by teaching children to recognize abnormal advances and to know it is right to speak out about wrongs against them.
- Abuse is a family problem, not an individual problem. Therapy must include all family members to be effective.
- Rape is a crime of violence, not of sexual intent. Rape victims need both short-term and long-term counseling.
- Pregnant women with traumatic injuries need to be carefully assessed to determine if intimate partner abuse was the cause of the trauma.

CRITICAL THINKING EXERCISES

1. Hillary is the 3-year-old you met at the beginning of the chapter. Although her mother told you that Hillary fell from a swing, Hillary has a broken forearm, a broken rib, and multiple bruises on her chest and back. Her mother tells you, "Hillary isn't pretty. I guess she's also clumsy." What additional questions would you want to ask to determine whether Hillary has been abused?
2. You weigh a baby at a well-child conference and discover that the infant's weight is below the 2nd percentile on a standardized growth chart. What questions would you want to ask the mother to see if you can account for this? What particular areas would you want to assess on a physical examination?
3. Physical examination determines that a 4-year-old girl has a purulent vulvovaginitis. A culture reveals this infection is gonorrhea. What questions would you want to ask her to determine how she contracted this infection? Suppose her parents are influential people in your community. Would this fact influence what questions you ask?
4. Examine the National Health Goals related to family violence. Most government-sponsored funds for nursing research are allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to Hillary's family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to nursing care of families when abuse or violence occurs. Confirm your answers are correct by reading the rationales.

Chapter 56

Nursing Care of a Family When a Child Has a Long-Term or Terminal Illness

KEY TERMS

- anticipatory grief
- death
- grief process
- vulnerable children

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe common concerns of parents of children with a long-term or terminal illness.
2. Identify National Health Goals related to children with long-term or terminal illnesses that nurses could help the nation achieve.
3. Use critical thinking to analyze ways that nursing care of a child with a long-term or terminal illness can be more family centered.
4. Assess adjustment of a child or family to a long-term or terminal illness.
5. Formulate nursing diagnoses for a child with a long-term or terminal illness.
6. Identify expected outcomes for a child with a long-term or terminal illness.
7. Plan nursing care for a child with a long-term or terminal illness.
8. Implement nursing care for a child with a long-term or terminal illness such as helping parents with time management.
9. Evaluate expected outcomes for effectiveness and achievement of care.
10. Identify areas related to the care of children with long-term or terminal illnesses that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of long-term and terminal illness in children with nursing process to achieve quality maternal and child health nursing care.

Charlie is a 3-year-old who has had a relapse after 18 months of chemotherapy for leukemia. You meet him in the emergency department because he has developed a severe cough and high fever. He is diagnosed as having pneumonia. "He's been sick for so long," his mother tells you. "We're all so tired, and he's been through so much. How could he develop something else?"

Previous chapters described the growth and development of well children and the care of children with specific disorders. This chapter adds information about the care of chronically and terminally ill children. This is important information because it builds a base for care and health teaching and support for the parents and child.

How could you best help this parent? What would be important topics to talk to her about?

When children have acute illnesses, both they and their parents become frightened by the sudden onset and severity of symptoms. Because human beings have a great capacity for coping with stress, however, as long as they are given adequate support, they can usually adjust to the strain of disrupted daily routines, hospital visits, and home care.

When a child's illness becomes long term or is one that is projected to have a terminal outcome, a family's capacity to cope can become stretched beyond its limits. Support is essential for such a family if it is to survive under this level of pressure and stress (Rabow & Pantilat, 2009).

People cope with situations depending on their perception of the event, the type and kind of support they receive from people around them, and the ways that they have found to be successful in coping with stressful situations in the past. When working with parents of a child with a long-term or terminal illness, discovering how the parents perceive the problem, what resources they have available, and how they plan to use these resources are crucial in planning effective nursing care.

BOX 56.1 ✻ Focus on National Health Goals

Long-term illness or early death in children is a major cost to the nation and individual families because it has the potential to reduce the earning power and contribution of future citizens. Several National Health Goals address this:

- Reduce the proportion of children and adolescents with disabilities who are reported to be sad, unhappy, or depressed from a baseline of 31% to 17%.
- Increase the proportion of children and youth with disabilities who spend at least 80% of their time in regular education programs from a baseline of 45% to 60%.
- Reduce the rate of infant deaths from a baseline of 7.2 per 100,000 to a target rate of 4.5 per 100,000.
- Reduce the death rate for children 1 to 4 years of age from a baseline of 34.1 per 100,000 to no more than 20 per 100,000 children, and for children aged 5 to 9 years, from a baseline of 17.2 per 100,000 to 13 per 100,000.
- Reduce the death rate for children 10 to 14 years of age, from a baseline of 21.5 per 100,000 to no more than 16.5 per 100,000, and the death rate for adolescents 15 to 19 years of age, from a baseline of 69.5 per 100,000 to 38 per 100,000 (http://www.nih.gov).

Nurses can help the nation achieve these goals by educating women to seek care during pregnancy so that congenital anomalies, a common cause of infant morbidity and mortality, are less frequent and to seek immunizations for their children so that diseases that can lead to long-term illness, such as rubeola and meningitis, can be prevented. Nursing research on the following areas would further these goals: What are special techniques for preparing children who are physically challenged to be more independent? How can children who use a wheelchair maintain a high sense of self-esteem? What specific measures are most helpful to parents when they learn their child has a terminal illness?

Whether the medical diagnosis involves a permanent disability or impending death, parents' first response may be grief. The parents have either lost the "perfect" child imagined during pregnancy or the well child they had up to the time of diagnosis. Depending on their age and maturity, children may also experience a grief response. National Health Goals related to the care of children with a long-term or terminal illness are shown in Box 56.1.

Nursing Process Overview

For Care of a Family Coping With a Long-Term or Terminal Illness

Assessment

Because a family's coping abilities are best assessed gradually, over a period of many contacts, nurses' assessments of the degree of a family's coping are often the most thorough and meaningful of all health care providers.

Observing children at home, where they are most comfortable, or at school in a familiar atmosphere, often reveals a great deal more about a child's present disease status or coping potential than does a formal test situation. Often a toy offered by a parent, sister, or brother will be grasped and manipulated by a child with a chronic disability, whereas the same toy offered by a stranger will not be accepted. Children with a long-term illness, on the whole, have probably been through many tests and procedures in the diagnosis of their disorder; they may have reason to think of health care providers as hurting people, not people for whom they wish to achieve. It may be possible to change their perception by maintaining a reassuring, gentle manner during assessment and subsequent care procedures.

Nursing Diagnosis

Long-term illness takes many forms. A condition that requires daily attention, such as diabetes (managing an insulin pump), but that is stabilized may not be as stressful to parents as an illness, such as muscular dystrophy, that slowly progresses in severity. In the former, although the child and family must adjust their lifestyle to incorporate the child's daily needs, they feel they have some control over the course of the illness and the child's overall health. In the latter, the child and family feel powerless, lacking any ability to alter the course of the disease; they must simply wait for the next acute crisis to develop. Nursing diagnoses for children with long-term or terminal illnesses need to address both the child and the family as a whole. Some examples when a long-term illness is present are:

- Interrupted family processes related to recent diagnosis of chronic illness in oldest child
- Compromised family coping related to child's disability
- Disabling family coping related to parents' inability to accept child's long-term illness
- Anticipatory grieving related to chronicity of the child's illness
- Risk for delayed growth and development related to lack of age-appropriate stimulation because of disability

New issues develop when the child's disorder becomes terminal. The family must learn to accept not only the child's illness, but also its eventual outcome. Some examples of nursing diagnoses when a terminal illness is present are:

- Hopelessness related to steady progression of child's disease
- Anticipatory grieving related to child's terminal illness
- Powerlessness related to inability to prolong child's life
- Decisional conflict related to treatment options and choice of setting for child's final care

Outcome Identification and Planning

Be certain when planning care for children with a chronic or fatal illness that outcomes established are realistic. You probably cannot alter the course of a child's illness, but you can help parents cope with signs and symptoms of the illness or the impending death and its aftermath.

Parents who have not yet accepted the seriousness of their child's illness may make plans that the child cannot possibly accomplish. These parents hold on to the hope that their child will eventually be cured or restored to full health. Sometimes this level of denial is essential to the parents' ability to cope with the child's daily needs and the needs of the rest of the family. They may believe that they must shield the child or other family members from the truth. Focusing on hopeful but realistic outcomes, such as the desire that the child will go through the day without experiencing pain or that the child will learn how to move about independently in a wheelchair, can help a family move forward toward final, realistic acceptance of a child's illness.

The following organizations are helpful for referral: Candlelighters Childhood Cancer Foundation (http://www.candlelighters.org), The Compassionate Friends (http://www.compassionatefriends.org), National Association of School Psychologists (http://www.nasponline.org), and Centers for Loss in Multiple Births (CLIMB) (http://www.climb-support.org).

Implementation

When children have a long-term or terminal illness, parents may begin to overprotect them so much that they neglect to encourage their growth. They may forget to provide play materials or other stimulation appropriate for their age. Helping parents to look at their child's capabilities and arranging appropriate activities for the child are ways in which nurses can facilitate parents' acceptance of the diagnosis and the road ahead. Suggestions for helping children achieve developmental milestones are discussed for each age group in Chapters 29 through 33.

Helping parents learn better coping strategies and teaching them ways to remember to give medication for several years, ways to maintain quality care without becoming exhausted, and the importance of maintaining a lifestyle of their own are other important measures.

Outcome Evaluation

Children with a long-term or terminal illness need periodic follow-up care, because plans made for a newborn may no longer be suitable as soon as the child becomes a toddler. Plans made in the early school years may need to be modified by the time the child is 12 years old, and they must change again with adolescence. In addition to follow-up of specific therapy by a specialty clinic, children also need routine health maintenance care. Otherwise, children will be well protected from the complications of their special illness but unprotected from common childhood illnesses that could be even more devastating.

Evaluation of whether expected outcomes for the family of a child who died were met helps to strengthen your planning with the next dying child you care for, improve your self-esteem, and build confidence in your ability to care for dying children. When evaluation reveals discrepancies between the wish and the reality of care, identifying areas you need to strengthen helps you to grow as a health care provider. Some examples suggesting achievement of outcomes are:

- Parents state realistic plans for their child regarding school placement.
- Parents state they have been able to deal with their grief over child's diagnosis to maintain normal family functioning.
- Parents state they are able to cope with present stressors.
- Child states he is aware his illness is chronic (long term) but thinks of self as a person who will be able to accomplish many things in life.

THE CHILD WITH A LONG-TERM ILLNESS

Because families have different resources and everyone reacts to situations differently, each child with a long-term illness and the family need to be assessed for their potential to cope with the illness and provide necessary care (Rabow & Pantilat, 2009). Through such assessment, appropriate interventions to help the family adapt can be started early in the course of the illness (Farasat & Hewitt-Taylor, 2007).

The Parents' Adjustment

Children have difficulty adjusting to events without good role modeling from their parents. Therefore, assessment begins with a look at how well the parents are responding to the diagnosis of a long-term illness.

Grief Response

Parents can be expected to experience a **grief process**, or regulated steps in grieving, when they are told their child will be physically or cognitively challenged or is terminally ill. The most commonly accepted steps or stages of grief are those outlined by Kübler-Ross (1969). Table 56.1 summarizes these stages. Most parents with a child who is physically or cognitively challenged never arrive at the final stage of acceptance or develop chronic sorrow (Hobdell et al., 2007). For parents with a terminally ill child, this may come only with the child's death. Reaching a final stage may be particularly difficult when parents grieve in different ways or at different paces (Wijngaards-de Meij et al., 2008).

During the first stage of grief (shock or denial), parents are unable to plan past immediate or short-term actions (learning to change a dressing or which pills to give each day). Trying to establish long-term outcomes at this point (what type of school the child will attend, vocations that will be open) is rarely

TABLE 56.1 ✻ Stages of Grief

Stage	Parents' Reaction	Description
1	Denial	Parents have difficulty realizing what has occurred. They ask, "How could this have happened?"
2	Anger	Parents react to the injustice of being singled out this way. They say, "It isn't fair this is happening."
3	Bargaining	Parents attempt to work out a "deal" to buy their way out of the situation. They say, "If my child gets well, I'll devote the rest of my life to doing good."
4	Depression	Parents begin to face what is happening. They feel sad and unprotected.
5	Acceptance	Acceptance is being able to say, "Yes, this is happening, and it is all right that it is happening." With a child with long-term illness, parents may never reach this stage but will always remain in the chronic sorrow of the depression stage.

productive, because this must all be done again when parents are truly ready to look this far ahead. During the second stage, anger, parents may be unwilling to learn (the whole thing is so unfair; planning is asking too much of them; how can they trust you? If you were really helpful, you would cure their child). This becomes a time of waiting also, therefore. During the bargaining stage of grief, parents are still not ready for planning. They believe that if their bargain is fulfilled (let their child be able to walk, and they will spend the rest of their life doing good), they do not have to make plans now such as purchasing a wheelchair because these will be unnecessary after the child's condition improves.

During the next stage of grief, depression, parents are ready to make plans but need a great deal of help in planning because they feel so fatigued. Be careful in working with people who are so depressed that you do not totally plan *for* them rather than *with* them. Many parents of children who are physically or cognitively challenged develop low self-esteem (they believe that if they were as good as others, they would have had a normal child). This makes them feel that your suggestions must be better than any they could make. After they return home, however, they are the ones who must live with these plans, so they should participate in making them.

Even after parents reach the final stage of grief—acceptance—some parents need guidance in making plans to avoid becoming so self-sacrificing that the needs and wishes of the spouse and other children are ignored. For example, parents may spend every waking moment with their ill child. Being a martyr this way is a method to ease guilt, a part of grief bargaining, a way of proving that they are equal to others—perhaps even the best parents in the entire world. These parents need time to talk about possible reasons why they feel they must push themselves in this manner. Perhaps they can find a middle-of-the-road approach to a child's care that allows time for all family members. Helping them to plan a respite from the care of a sick child, such as an evening out while a babysitter cares for the child, is a part of this approach.

By the time a child who is physically or cognitively challenged is of school age, parents need to begin to make some concrete plans regarding who will care for the child after they die. This is very difficult for parents; it asks them to contemplate their own mortality (something that people rarely want to do) as well as the vulnerability of their children when it occurs. They might consult with family members about guardianship and with a lawyer to help them write a will that will provide future caretaking and economic support for the chronically ill child.

Factors Influencing Parental Adjustment

Certain circumstances appear to increase parents' difficulty in adjusting to a disabling or long-term illness in their child. These include the degree and timing of the illness, the experience of the parents, the availability of support people, and the ability to make long-term plans.

Degree of Illness. The seriousness of an illness obviously affects the ability of parents to adjust (Eddy & Engel, 2008). A child who needs total care, for example, requires a much more radical readjustment of the parents' lives than a child who only needs additional speech therapy for an hour a day. In most instances, the parents' perception of the child's illness is as important as the child's condition itself (Fig. 56.1). For example, a parent who envisioned a son as someday becoming an Olympic runner may perceive a son with developmental hip dysplasia as having a serious physical challenge; a parent whose mental image of the child was that of a lawyer doing mainly desk work may not view the hip problem as a serious illness.

Many parents are not aware of the mental image that they carry of their child, an image that began to form the moment

FIGURE 56.1 A parent's perception of a child's disability is important to how well the family adjusts. Often it is easier to accept a disability that allows for greater functioning in everyday activities. (© Bachman/Science Source/Photo Researchers.)

the woman realized she was pregnant. Hidden desires are often revealed if you ask parents, "If things could have been different, what kind of person would you have liked your child to be?" A parent who answers, "a kind person" can still have that wish fulfilled, no matter what the degree of illness. A parent who says, "I always assumed my child would take over my business someday" may have some major mental readjustments to make.

Whether an illness is noticeable (spastic cerebral palsy) or not noticeable (controlled seizures) also can make a difference in how parents adjust to the illness. A mother who takes her child with cerebral palsy shopping (a child who walks unsteadily and knocks over a display) may hear other shoppers say, "Wouldn't you think a mother would watch her child more carefully?" On days that her child uses a wheelchair, however, shoppers' comments are more apt to be, "Poor little thing. Isn't it wonderful that his mother brings him shopping with her?" She is happy to have a signal (the wheelchair) that announces that her child is different and cannot be held to the same standards as other children. Other parents might be more grateful that a child's illness is not a visible one: it makes the illness seem lesser in extent, and therefore easier for them to accept.

BOX 56.2 * Focus on Evidence-Based Practice

What are the hardest challenges families face when adjusting to a child with chronic kidney failure?

Because kidneys that are damaged by disease cannot be made to function again, kidney failure can create an extreme burden for both children and their families that persists for the life of the child. To discover what makes adjusting to this chronic illness most difficult, researchers examined 11 studies that focused on the care of children with chronic kidney failure, published since 1980. Reviews of these studies revealed that parents reported high levels of stress, depression, and anxiety. They described uncertainty, social isolation, and increased caretaking duties as contributing to the burden. Families with children receiving dialysis reported increased disruption in family life and increased marital stress. They found that the parents of children receiving home dialysis had increased rates of depression and a lower quality of life when compared to parents of healthy children. Mothers often worried about the possibility of death and became very vigilant in monitoring their child's health. They checked on their children frequently at night so easily became fatigued. In addition, the mothers found that friends and family members were less likely to visit because of an ill child in the home, which led to social isolation. Those parents with lower socioeconomic status had the most difficulty adjusting.

Based on the above literature review, what questions would you want to ask the parents of a child who is scheduled to begin peritoneal dialysis at home?

Source: Aldridge, M. D. (2008). How do families adjust to having a child with chronic kidney failure? A systematic review. *Nephrology Nursing Journal, 35*(2), 157–162.

Relationship With Own Parents. When adults are able to relate well to their parents it suggests that they were raised in an atmosphere of love or were able to develop a sense of trust (Erikson, 1993). People with a sense of trust are able to form a firm sense of intimacy as adults and so be able to give love to children even when the children are handicapped in some way.

Onset of the Illness. Whether a condition is apparent at birth (such as a myelomeningocele) or occurs at a later time (a child is struck by a car at school age) may make a difference in the parents' ability to adjust. For some parents, never having had a well child can make the child's illness easier to accept. In any event, the need for long-term care of a child can totally change the parents' lifestyle. They may no longer be able to live in a high-rise apartment because it is not wheelchair accessible; a parent may have to reduce work hours or give up a career to devote full time to the child's care. They may devote their lives to becoming spokespersons for children with their child's illness as they seek second or third opinions (Davies et al., 2008).

Effect of Parental Experience. First-time parents may have more difficulty caring for a child with a long-term illness than older, more experienced parents, because all phases of parenting are more difficult for them. They might have difficulty evaluating how much activity a child needs or what toys are appropriate, for example. On the other hand, first-time parents, because they have no preconceived opinions, may be more flexible than other parents. A young parent who has just this one child may have more time to spend in a daily exercise program than does a parent with four other children.

Availability of Support People. A family that has few close friends and lives some distance from relatives is apt to have more difficulty adjusting to illness in a child than a family which has close support people. People who have secondary support systems in the community, such as an organization for parents of children who are physically or cognitively challenged or a local church or synagogue, usually do better than parents who are without these resources. People who are able to use health care resources effectively adjust more easily than those who cannot do so. The ability to use health care resources depends on several factors, including:

- Transportation (it is difficult to take a child in a 50-lb cast on a bus)
- Language barriers (it is frustrating to go for care and be unable to make your needs known)
- Finances and insurance coverage (it is disturbing to be told that you need to see a specialist when you have no money or your health coverage does not pay for one)
- Past experience with health care providers (if the best advice that has been given to the parents up to this point has been, "Take your baby home and treat him as near normally as possible," the parents may not see health care providers as a source of useful information or help)

Life Events. A child's illness usually appears to be more acute at times when the child would normally reach developmental milestones than at other times: at 12 months, for example, when the baby should be taking a first step; 6 years, when the child should begin school; the time for first communion or bar mitzvah; time for a driver's license; or voting age. When the child does not reach these milestones, parents are reminded of the illness in a particularly painful way (Box 56.2).

TABLE 56.2 ✻ Factors That Ease Parental Adjustment to a Child's Long-term Illness

Factor	Rationale
Support people are available.	Caring for a child is a series of crises during which support people become very important.
A strong marital bond exists between the parents.	A marriage partner can serve as the strongest support person.
A good relationship exists between the child's parents and their parents.	The parents (because they had good care) have a firm sense of trust and the ability to give care to another.
The child is other than the first-born.	The parents have had practice parenting.
The family lives close to shopping, schools, and transportation.	The family is not isolated.
The family has a strong religious faith.	Secondary support systems are important in times of stress.
The parents are told of the child's disability as soon as possible.	A handicap is easier to accept if the parents never thought of the child as totally well.

Factors that indicate that a family will probably be able to adjust to caring for a child with a long-term illness are summarized in Table 56.2.

✔ Checkpoint Question 56.1

What factor is most apt to help parents accept long-term illness in their child?

a. The parents are isolated so cannot compare their child to others.
b. The parents have good relationships with their own parents.
c. The parents are wealthy so have few worries other than the child.
d. Parents believe in alternative therapies so have many options.

The Child's Adjustment

A child's reaction to being physically or cognitively challenged or having a long-term illness is strongly influenced by the family's reaction to the illness. Family reactions may range from overprotectiveness to rejection and from denial to acceptance. The child's adjustment may also be influenced by peers and other support people, such as school personnel or health care providers. Social exclusion, discrimination, and physical barriers at school make it difficult for a child to adjust to a physical challenge or long-term illness. On the other hand, inclusion in school and social activities, acceptance by peers and support people, and the ability to function as normally as possible help the child adjust.

A child's ability to cope is further influenced by personal attitude and temperament, self-concept, age and development, understanding of the condition, and degree of the disorder. As the child grows and life situations change, the ability to cope may improve or worsen. For example, an adolescent who is physically challenged may become more optimistic about her condition because she is successfully working at her first job; another adolescent may become angered by his deteriorating condition because he is suddenly confined to a wheelchair.

The degree of fatigue that a child experiences is also instrumental in how well a child adjusts to a chronic illness as chronic fatigue can play a large role making even simple tasks seem monumental (Eddy & Cruz, 2007). Nursing interventions to help a child better adjust to a chronic condition include encouraging optimal growth and development (see Chapters 29 to 33), promoting self-care activities, enhancing self-esteem, preventing social isolation, providing health teaching, preventing fatigue, and aiding the child and family to accept the child's condition.

Siblings' Adjustment

Siblings' reactions to a child with a long-term or terminal illness are influenced by individual circumstances; however, their chief reaction is most profoundly affected by the reactions and perceptions of the parents. Without counseling, siblings may react with jealousy, anger, hostility, resentment, competition, guilt, or withdrawal. They may feel that they take second place to the child who needs more care. These reactions are common when parents focus most of their attention on the ill child, allow the health problem and its treatment to disrupt family life significantly, or grant the ill child special privileges and minimal discipline.

With counseling and support, siblings can develop acceptance, care, concern, and cooperation (Way, 2008). Such reactions are common when parents make it a point to set aside time each day for special activities with the well siblings such as playing a table game, walking in the park, teaching a child to swim, carefully explaining the condition and the necessity for special care, including siblings in the care of the ill child, providing siblings with respite from care if needed, and establishing realistic rules for all family members.

At any one time, the siblings may experience a mixture of feelings. For example, if a boy's parents must take his sister for chemotherapy during his swim meet, the boy may feel both resentment that his parents missed the meet and sadness that his sister could not compete in that meet or in any others.

The Nurse and the Ill Child

Caring for children with long-term illnesses can be a stressful role for nurses (Pontin & Lewis, 2008). To help the parents and child with a long-term illness, learn specific aspects of the child's condition and the possible complications that could occur. Over a period of years, parents become experts on the care of a child with a particular condition (Box 56.3). This can make them grow impatient with health care providers who appear to be unaware of things that they know well.

BOX 56.3 * Focus on Communication

Charlie is admitted to the hospital and intravenous therapy is started. You notice that his skin where the adhesive tape was removed is unusually reddened. He cries when you touch the irritated skin.

Less Effective Communication

Nurse: Look at Charlie's skin. It looks really red and sore.
Mrs. Circuso: That's from the adhesive tape.
Nurse: Oh, I don't think so. I tape this way all the time.
Mrs. Circuso: I never use it, even on myself.
Nurse: Well, it usually works really well. I'll ask the doctor what she recommends.

More Effective Communication

Nurse: Look at Charlie's skin. It looks so red and sore.
Mrs. Circuso: That's from the adhesive tape.
Nurse: Oh, has Charlie had this type of reaction before?
Mrs. Circuso: All the time. That's why I never use it, even on myself.
Nurse: I should have asked you how you usually do things for Charlie. You've been caring for him longer than I have.

It is easy to believe that a fellow nurse who has spent a great deal of time caring for a child has become an expert in a child's care. It is often more difficult to remember that a parent can easily become this type of expert also. Asking parents of children with long-term illness for their input not only can simplify care but also adds to the parents' feeling of self-esteem, improving their parenting.

When young children are seen at an ambulatory care setting or admitted to a hospital for care, review with the parents their typical way of carrying out a procedure so that you can continue to care for their child in the same way. As the child grows older, do this same review with the child. On the other hand, be available to show a parent or a child an easier way to do something if it seems appropriate. Frankly admitting to parents, "You're more familiar with Jennifer's care than I am; you'll have to teach me some things" is a refreshing approach; it not only allows parents to feel confidence in you (you are honest), but it also increases their self-esteem (they are knowledgeable people).

Also, familiarize yourself with the community resources that are available for children with long-term illnesses. Advising parents to see a dentist who specializes in caring for children with cerebral palsy when there is no one of that description less than 200 miles away, for example, is not only unhelpful but is actually destructive. It raises expectations in parents that cannot be met—accentuating, not solving, a problem.

Sometimes parents of children with long-term illnesses do not adhere well to instructions or do not keep health care appointments consistently. This inability to adhere usually is related to their stage of adjustment to the illness. As long as denial, anger, bargaining, or depression is functioning (and there is rarely a parent who has successfully moved completely through these stages of grief to acceptance), coming in for health care or evaluation is a major demand. Each visit is more a reminder of the child's illness than a time of reassuring health assessment.

Developmental Tasks

Children with long-term illnesses often do not meet developmental milestones on schedule; achieving developmental tasks can be difficult. When you are helping parents teach a child who is physically or cognitively challenged a developmental task, such as toilet training or using a spoon, help them to break the task down into its component parts such as reach for the spoon; grasp it; move it toward you; push it under the chosen food; lift it toward the mouth, etc. Breaking a task down into steps this way allows parents to appreciate that they are asking their child to learn a task that, although it looks easy, actually encompasses 20 or more coordinated motions. Helping them learn this technique enables them to be patient in teaching additional tasks in future years.

Ways to help children who are physically challenged achieve developmental tasks are discussed in Chapters 29 to 33. These include exposing them to normal events during a hospital stay or an ambulatory health care visit (Fig. 56.2).

Education

Children with a long-term illness often need special education programs or at least separate hours of individualized instruction to achieve in school. Most children benefit from preschool programs; these programs offer them a head start on school adjustment and learning. Children with a long-term illness tend to miss school more often than do their healthier classmates because of health care visits, and exacerbations of the illness. This can cause them to fall behind in school unless individualized plans to keep them with their school group are made. By federal law (Public Law 99-457, Education of the Handicapped Amendment), a school system must provide educational opportunities in the least structured setting possible for physically and cognitively challenged children, beginning with preschool. You may have to be a strong child advocate to see that the best educational program available is being provided for an individual child.

FIGURE 56.2 Ronald McDonald, a familiar face to many children, visits a young boy with a long-term illness. This interaction helps him keep active and in touch with usual events during hospitalization. (© Bob Kramer.)

Home Care

Most children with a long-term illness receive care at home today (Remke & Chrastek, 2007).

Planning for this care is discussed in Chapter 4. Important aspects to consider include the best school setting (home or away?), ways to involve the family in community activities, ways to include the child in a play group (children as young as preschool age may not choose an ill child as a playmate), how much self-care the child can achieve, and future plans, such as preparing a child for puberty or college. Home care or community health nurses can be instrumental in planning this type of care (Pontin & Lewis, 2008).

Many parents today seek complementary or alternative therapies for children with long-term illnesses. Always ask what therapies and medications they are using, to document the full extent of treatment that a child is receiving (Vlieger et al., 2008).

What if... You arrange for Charlie's mother to spend an afternoon shopping so she can have some respite time away from her ill child, but she spends the time cleaning her kitchen cupboards instead? Would you consider this a good use of respite time?

THE CHILD WHO IS TERMINALLY ILL

Death comes suddenly to some families, such as when an adolescent commits suicide or is killed in an automobile accident, providing no time for parents to prepare for the death (Melhem et al., 2007). Most children die after a terminal illness, however, so steps can be taken to help prepare parents for the coming death. This can be one of the hardest tasks in nursing. Most people are raised to accept the fact that elderly people die, but such people have also lived a long life. Most people can accept the death of middle-aged people with the same philosophy—they experienced at least a portion of their life. It is often more difficult to accept the death of children because they have had so little opportunity to live. This can make it difficult to work though your own feelings about a child's dying, so you can find the strength to care for the child or support the parents.

Parental Grief Responses

The way that death is viewed and the manner in which people express grief differ greatly across cultures. Some people are very expressive with grief; some are very restrained. The way a child's body is handled after death also differs. Some religions, for example, forbid organ donations or transplants. Autopsies are not approved because it is important that children be buried quickly after death. Cremation is not permitted. Being aware that people have different expectations for final care and that grief is expressed differently by different cultures enables better understanding of parents' concerns and reactions during a child's terminal illness and when death occurs.

Although reactions to learning that a child has a terminal illness are strongly culturally influenced, each family reacts in a unique way. Being aware of the usual grief response that occurs in anticipation of a child's death helps in recognizing such a response as grief and supporting a family through this very difficult period.

Denial

A parent's usual response to the diagnosis of a terminal illness in a child is denial, the first stage of grief (see Table 56.1). Although people are aware that children die, most proceed through life thinking, "It won't happen to my child." When they learn it may, they respond with disbelief or denial. The likelihood of this response is enhanced by the fact that many terminal illnesses, such as brain tumor or leukemia, begin insidiously ("How can a few black-and-blue marks be the symptoms of a potentially terminal disease?").

How the parents handle this initial disbelief has a great deal to do with their relationship with health care personnel. If they have trusted health care personnel up to this point, they may be able to accept the diagnosis without questioning any further. If they do not have this relationship, they may feel the need to obtain a second opinion. This often involves considerable expense, but for many parents it is a necessary step in moving past this first reaction. Parents who feel a need for a third, fourth, or fifth opinion may be having an unusually difficult time resolving a "surely not me" response. They need a factual explanation of why it is certain that their child has this disease, such as a copy of the blood report or the pathologist's biopsy report. They need time to talk about how they feel. Only after people can grasp that the illness is definitely present can they begin to accept that the disease will ultimately prove fatal.

During this stage of denial, parents' actions may be inappropriate to the child's condition. They may talk of an "upset stomach from the flu" when the child is vomiting blood or "his cold" when the child has cystic fibrosis. It is easy to view such denial as a step that should be hurried, because parents cannot begin to deal with the problem as long as they deny that there is a problem. This is true, but neither can they deal with a problem when it hurts as much as this one. Denial is a temporary pain-relief measure that is a necessary step on the way to acceptance.

Anger

Parents can be expected to enter a stage of anger soon—a change from "Surely not me" to "It's not right that this is happening to me." When parents are angry about a diagnosis, they may be unable to direct their anger appropriately. They may find themselves angry with the child (scolding the child for crying during a painful procedure). One parent may be angry with the other parent (criticizing the other for reckless driving or for eating a fattening food for lunch). They may be angry with you (for not answering the child's call light immediately). They may be angry with the medical, x-ray, laboratory, and dietary staff or with the entire health care system. It can be difficult to react to this kind of angry attack, because it seems unjustified (after all, you came as soon as you could). Be certain that your first reaction is not to be angry in return. This could result in your avoiding the child's room for the rest of the day, so as not to undergo that kind of unfair criticism again, and therefore not meeting the child's basic need to have support people nearby.

A more therapeutic reaction is to accept this angry response as the stage of grief that it is and respond accordingly: "I'm

sorry it seemed to take me so long to answer your call bell, but you seem angry about more than just the light. Would it help to talk about it?"

Parents may "shop" for another health care provider during the stage of anger, although their reaction will depend to a great extent on their experience with death in the past and the meaning this child has to them. Because grandparents live longer today, for some parents fatal illness in a child is their first contact with death. Another influential factor is that different children mean different things to parents. A child born to them at a happy time can represent all that is good and happy in their life, so loss of that child could also mean loss of all the joy the child represents.

When you ask grieving parents to talk, therefore, they may talk not about the child, but about how they felt when a parent died, how hard their job is for them, or how they feel their marriage is failing. This is part of grief: gathering resources, reworking stress from the past, and arming themselves to face stress in the near future. Parents often receive support from other parents on the hospital unit whose children also are terminally ill. They are helped by seeing parents of other children adjusting to approaching death—or, if not adjusting, at least functioning in what passes for a normal manner.

Bargaining

Although not everyone progresses through a grief response in a linear fashion, instead going back and forth between stages, bargaining is often the next stage to occur. Bargaining is an intermediate step in grief, a time when parents try to correct what is happening by making a bargain to be better people (a change from "This isn't right" to "I can make it right"). They vow to be better people or to function in a different way in exchange for their child's life. When parents realize that bargaining is ineffective, they are at a very low point: they have been let down not only by health care providers, but also by the superior power with whom they tried to bargain. They may need more support after bargaining fails than at any other point.

Depression

When parents have passed through stages of denial, anger, and bargaining, a further step occurs: developing awareness of the true meaning of what is happening, with accompanying depression. This is a change from "I can keep it from happening" to "It is happening." Behavior such as crying is the most common sign that this stage has been reached. Parents may ask more questions about care, procedures, or medications than before. Be careful that you do not interpret this questioning as criticism. Parents are asking why a child must have continuous dialysis not to criticize care, but because this is the first time they are fully aware of its serious implication.

Parents may work through the expected loss of a child by talking about their plans for the child or how the child was doing in school. They may suddenly shower the child with expensive gifts or trips. They may have a great deal of difficulty leaving the child after visiting hours. On the surface, this reaction appears to be a step backward (they were accepting the diagnosis so well; now they seem demanding and overwhelmed by it). Actually, this is the first time they have actually begun to appreciate the diagnosis and what it means.

At about this stage, parents need to think about preparing other children in the family for the death of the ill child. If the ill child is hospitalized and siblings have not been allowed to visit, they may interpret this as meaning that death is such a horrible sight that they are not allowed to be exposed to it, rather than that visiting is against hospital rules. You may need to advocate for sibling visitation to overcome this concern.

Some siblings feel responsible for the death of the ill child. They may have wished the child dead, for example, so that they could have a room all by themselves or so they could have the child's bicycle. They were told not to wrestle with the ill sibling, and they did anyway. These children need reassurance that wishing for something does not make it come true, and that the sibling's death is uncontrollable: it will happen no matter what they or their parents did or will do.

Acceptance

The acceptance stage of the grief process is resolution that the child will die (a change from "This is happening" to "It's all right that this is happening"). Few parents reach this stage by the time of the child's death; grief work will need to continue for years past the time of the death until this stage is reached.

✔ Checkpoint Question 56.2

Charlie's parents are starting to grieve because they fear he will not survive this recurrence of his illness. During which stage of grief do parents usually feel saddest?

a. The first stage, because everything is such a shock.
b. The last stage, because they fully accept the death.
c. The fourth stage, as they realize death is happening.
d. The stage at which the child talks about death.

Parental Coping Responses

Throughout the stages of grieving, parents are developing important coping mechanisms to see them through this crisis. They may have already learned to cope positively with their child's illness and treatment measures, but the determination that the illness is terminal requires yet another step. Promoting the development of positive coping strategies while being sensitive to the unique needs of each family member is an important nursing responsibility. It may be difficult to determine when a coping strategy is truly helpful and when it has become maladaptive. For instance, seeking information, such as surfing the Internet and asking to have medical library access, is generally a very useful strategy for parents with ill children: knowing what to expect reduces anxiety. Some parents, however, continue these seeking procedures past the point at which information is helpful to them. They may believe that if they look hard enough, they'll discover a way to cure their child (prolonged denial), or they may "overintellectualize" their child's illness and impending death to block feelings of sadness.

Problem-solving is always an effective coping strategy as long as the parents are realistic about which problems they can solve. Seeking the support of others, including health care providers and families with similar needs, is another positive strategy to encourage; providing the names of support groups or individual families (with their permission) who have gone through similar experiences can be a helpful

nursing action. Nurses may also need to help parents who are not comfortable accepting the help of others to learn how to do so or simply learn how to feel comfortable expressing their feelings to others (Edwards et al., 2008).

Assuring parents that their child will be kept comfortable and will not die in pain can be extremely comforting. Parents may also be able to cope by searching for the meaning of their child's impending death in philosophical, spiritual, or religious terms. For these parents, body organ donation may be a meaningful way to give themselves some solace that their child will in some way continue to live and contribute to others.

Anticipatory Grief

Parents who have some warning that death is expected may begin a preparatory or **anticipatory grief** phase in which they gradually incorporate the reality of their child's fate into their thoughts. Anticipatory mourning prepares parents for their child's death and spares them the abrupt, devastating, intolerable grief reaction that comes to parents whose child dies suddenly from trauma, such as a car accident, or sudden infant death syndrome (see Focus on Nursing Care Planning Box 56.4).

Although anticipatory grief does not shield parents from experiencing renewed grief once their child has died, it can be a useful process for them. A danger of anticipatory grief is that a parent may reach the acceptance stage of the grief process too far in advance of the child's death. If this happens, parents may accept the child's death so thoroughly that they begin to treat the child as if the child has already died. They stop visiting, or when they do visit, spend most of their time visiting other children on the unit or sitting in the waiting room talking to other parents. Once they spent time comforting their child; now they may fail to rock or touch the child as much. They may clean out the child's room and throw out or give away toys. Gradually they are drawing back from emotional attachment, to shield themselves from the abrupt, stabbing pain that death will bring.

Children need a great deal of support if this happens, just as they did during the initial denial stage. Parents cannot help that the grief process did not time itself to coincide exactly with the child's death. They need understanding and not criticism for this reaction.

For some parents, when the child actually dies, the event seems anticlimactic. They have anticipated death so long that, when it does occur, they cannot believe that it has actually happened. They may be so used to thinking constantly

BOX 56.4 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for the Family of a Child With a Potentially Fatal Illness

Charlie is a 3-year-old who has had a relapse after 18 months of chemotherapy for leukemia. His parents have arranged for hospice care for him at home. They state, "He's been through so much already. We just want him to die at home, close to us."

Family Assessment ✻ Child lives with parents on their llama ranch. Two older siblings (ages 20 and 26 years) have left home. Parents report finances as "tight." They have no health insurance because they are self-employed.

Client Assessment ✻ Child cachexic. Physiologic parameters deteriorating. Skin cool, damp, and mottled. Pulse rate, 62 bpm and weak; respirations, 8 breaths/min. Rattling sounds noted from chest. Responsive only to deep pain stimuli. Parents at bedside; older siblings (20-year-old brother and 26-year-old sister) absent.

Nursing Diagnosis ✻ Anticipatory grieving related to impending death of child

Outcome Criteria ✻ Parents express feelings about anticipated death; demonstrate positive coping mechanisms.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Assess whether parents have any concerns about child's final days of care.	Stay with the family and sit with them quietly if they prefer not to talk; allow them to cry.	Staying with the family demonstrates caring and concern for their well-being and wishes and offers support.	Parents discuss any concerns they have with care.
		Consultations		
Nurse	Assess whether parents would like a final visit from their clergy.	Arrange for visit by clergy if desired.	A visit by clergy provides the family with spiritual support.	Parents state whether a clergy visit would be helpful to them.

		Procedures/Medications		
Nurse	Assess whether child appears comfortable.	Provide for the child's comfort, including positioning, turning, changing linen, applying lotion, and alleviating pain.	Providing comfort to the child is comforting to the family.	Parents state they feel child is comfortable.
		Procedures/Medications		
Nurse	Ask whether parents would like to provide final care.	Allow family members to provide care as desired without forcing them.	Allowing family participation in care provides them with some sense of control over the situation, decreasing their feelings of powerlessness.	Parents state they feel they have had a voice in and are satisfied with child's care.
		Nutrition		
Nurse	Assess whether child could be hungry.	Child is too comatose for oral feeding. IV fluid prescribed only as maintenance.	Hunger is an uncomfortable sensation.	Parents agree they feel child is comfortable.
		Patient/Family Education		
Nurse	Assess whether parents have any questions about what actions they should take when the child dies.	Inform the family about what to expect. Explore their expectations and clarify any misconceptions.	Providing information helps to ease the family's fears and anxiety about the unknown.	Parents state they feel comfortable caring for child in final minutes and immediately afterward.
		Psychosocial/Spiritual/Emotional Needs		
Nurse	Assess whether parents need any type of additional emotional support. Question why older siblings are not present.	Explore as far as parents are willing whether support from their other children would be helpful.	Close family members can supply the most meaningful type of emotional support.	Parents state that their other children do not support hospice care and that, although they are disappointed, they are managing well.
Nurse	Ask whether parents have begun "grief work" such as reviewing and preserving memories of child.	Provide the family with opportunities to review special memories or experiences with the child.	Reviewing memories and special experiences provides a positive method for coping with grief.	Parents report they have begun a scrapbook of favorite photos they anticipate will give them solace in years to come.
		Discharge Planning		
Nurse	Assess whether parents have made final arrangements for child's burial; responsibility for reporting death to hospice group.	Assist family with making arrangements for what to do when the child dies.	Assistance with planning provides support and aids in grieving, allowing time to be spent with the child rather than on arrangements.	Parents state that they understand obligations for reporting death; have good relationship with hospice group to answer questions.
Nurse	Assess whether parents have contacted a community support group other than hospice group.	If not already accomplished, initiate referral to community organizations as appropriate.	Community organizations can supply long-term support after child dies.	Parents state they have the name of a community support group and will contact group if they feel need in future.

about their child's needs and having their child dependent on them that they do not know what to do. Some parents are reluctant to leave the hospital this final time as leaving with the child's possessions is the step that will make the death real.

The Vulnerable or Fragile Child Syndrome

When anticipatory grief proceeds so effectively that parents begin to think of a youngster as already dead but then the child does not die, parents may find that their grief reaction was so complete that they are unable to reverse it; they cannot view the child as they did before. They begin to treat the child in a cold and unfeeling way, as if the child were not really there but actually did die. Such children are termed **vulnerable children**, or fragile children (Green & Solnit, 1964). They may develop behavior problems as they grow older (acting-out behavior, such as temper tantrums, stealing in school, shoplifting as adolescents) as if to say, "Notice me! I'm not dead!" They require skilled counseling so that they can feel secure that they are still loved and learn to react effectively with others.

Children's Reactions to Impending Death

Children's reactions to death are strongly influenced by their previous experiences and the family's attitudes toward death. If children have had little or no exposure to death, it can be a strange and frightening phenomenon. This often happens when children are reared without pets or older relatives, forbidden to visit a dying relative, excluded from the rites of death, or discouraged from discussing the death of a loved one. To help ease the fear of death, encourage parents to maintain an open attitude, even if it is painful or uncomfortable. Children's reactions to death are also influenced by their stage of development and cognitive ability. Children's ability to understand death and the steps families can take to help their children cope with death are summarized in Box 56.5.

Infants and Toddlers

Infants and toddlers are certainly too young to appreciate that their death is about to occur. If the person who cared for them dies, they experience deep loss and a void in their life. If such a loss interferes with the development of a sense of trust, its implications for the child's ability to achieve warm, close relationships could last a lifetime.

Preschoolers

Preschoolers usually learn about the concept of death when a pet dies or they discover a dead bird or mouse. They envision death as temporary, however, and appear to have little of adults' fear of it. This casualness toward death is sometimes interpreted as callousness. For example, the first response of a child who is told that his brother has just been killed in an automobile accident might be to ask if he can have his brother's radio. This happens because he thinks of his brother as being gone for only a short time, making this a chance to take advantage of his property. This concept is strengthened by children's cartoons, in which characters frequently are killed and then immediately revive and go on with the story.

Because preschoolers fear separation greatly, they are stunned by the death of a parent. If children grasp the concept that they are dying, their major worry might be that they will be alone and separated. These children may need someone to stay with them constantly to reassure them that they are not alone.

School-Age Children

School-age children begin to have additional experience with death, so their knowledge of it as a final measure increases. They may think of it, however, as something that happens only to adults. Children's books tend to deal only shallowly with the subject, although many books that deal specifically with death are available for children (Box 56.6). As children near 8 or 9 years of age, they begin to appreciate that death is permanent. It is the same lonesome feeling they experienced

BOX 56.5 ❊ Focus on Family Teaching

Guidelines to Help Children Cope With Death

Q. Charlie's mother asks you, "Suppose Charlie doesn't get better? How can we help him cope with dying?"

A. Here are some helpful guidelines for each age level:

- Infants have no understanding of their impending death. Important points for caring for an infant who is dying are to keep the infant comfortable and secure and to remain nearby to prevent loneliness and insecurity.
- Toddlers, likewise, do not understand death. Even though a close relative or friend may have died, they are unable to relate this to what is about to happen to them. Toddlers like routine, so allowing them opportunities to make choices and providing consistent care are the most important measures for them.
- Preschool children probably envision death as a long sleep. This way of understanding death makes them fear separation much more than the thought of dying. Urge parents or family members to spend time with them.
- Early school-age children understand death as separation but tend to view the separation as temporary. After 9 years of age, children are able to realize that death is final. They still are not as fearful of death, however, as they are sad at the thought of being away from their parents and frightened as to how they will manage without their parents. Answer questions about death honestly (no one knows what it is really like, but because it happens to everyone, it must not be anything to be fearful of). It is important to praise children for accomplishments to help them maintain their self-esteem so they can face this coming change.
- Adolescents have adult concerns and understanding of death. They may ask if it will be painful; they may feel angry about all that they will miss in life by dying. They may be concerned that they will need to answer for past ill deeds after death. Providing time and opportunities for them to ask and talk about death is important to help them work through the coming change. Allowing them to continue their usual activities as much as possible helps them maintain self-esteem.

when their parents left them at camp or went away for a weekend, but this time the separation will be permanent.

Most children of school age are aware of what is happening to them when their disorder has a fatal prognosis. They may learn from other children on the unit ("Are you the kid who's dying?"), from their parents' strange responses to questions, or from overhearing snatches of conversation about reports or physical findings. Children, however, are accustomed to meeting new situations—starting school, visiting a museum for the first time, boarding an airplane for the first time—and they cope with these experiences very well, as long as they know that someone they care about will be there to support them. Dying can be viewed in this same light, as another new experience for them. They are able to cope with it well if they know that there will be someone with them. If the parents become unable to relate to a child this age because of their grief, a nurse may need to fill the gap (Fig. 56.3).

Many children associate death with sleep (perhaps that was the explanation they were given for a grandparent's death), so they may be afraid to fall asleep without someone near them. They may need the light left on to fall asleep because death is associated with darkness. They may need to have you sit with them while they fall asleep. Often a child who is dying is moved to the end of the hallway, away from the nurses' station. This move frees the nearby room for a child who needs frequent procedures (a justifiable move in terms of efficiency). However, it further isolates both a child who needs support and the child's parents, who also need your support and your presence nearby. Advocate as necessary for continued interaction with a child who is dying.

Adolescents

Although adolescents have an adult concept of death, they also may feel immune to death. Risky activities such as driving at high speeds reflect this judgment. They may deny symptoms for longer than usual because they believe it is impossible that anything serious could be happening to them. They appreciate time provided for discussion of how they view death and the ways they have contributed to their family even though they are dying young. Continuing to participate in typical activities helps them maintain a sense of control.

FIGURE 56.3 A one-to-one nursing relationship helps children with long-term illnesses not to feel deserted.

Environment for Death

The environment in which children die can influence their acceptance and their family's acceptance of death.

The Hospital

A few children who have a terminal illness need such a great deal of physical care (have a new tracheotomy, need lung ventilation) that they may remain in a hospital for care because their family does not have the skill, energy, or money necessary to care for them at home. In a hospital setting, be certain that visiting hours are extended to parents and other family members so that children are not left alone when they need people around the most. Be certain also that children have opportunities to maintain contact with peers.

The Home

Today, most children with terminal illnesses are not kept in the hospital past the time when it is determined that therapy is no longer effective. Many families prefer that a child die at home, surrounded by family and familiar possessions, rather than in a hospital. Time spent talking about arrangements—such as whom the parents should contact if the child suddenly becomes more ill than usual, how they will manage periodic checkups, or how they will purchase medicine or supplies—is important preparation for home care. Assess how the family will schedule its time to have some leisure periods free so they can balance the care of the ill child in their lives.

Home care can be an extremely satisfying experience, both for a child who is dying and for the family, as long as safeguards exist for protecting the caregivers' health and for providing good care for the child. This is discussed further in Chapter 4.

The Hospice

In 1967, St. Christopher's Hospice in London opened as a facility for people who wanted to die in a homelike setting while still receiving skilled professional health care. Most large communities today have hospice settings, although places specifically for children, and especially infants, are still not available in many communities (Roush et al., 2007). In a hospice, friends and family and even younger children and pets are allowed unlimited visiting. Children are invited to bring possessions with them that are important to them. They are urged to choose the degree of pain relief they want. Strong analgesia is often used to make a child pain-free (a criticism of hospice care is that this level of analgesia slows the respiratory rate and actually hastens death).

A basic philosophy of hospice care is that death is an extension or part of life, not a separate entity; therefore, it can be accepted not with separate or awkward rituals but with the same warm concern as other situations in everyday life. For many children, hospice care is furnished as part of home care, so that they are not separated from their families.

Preparation for a Nursing Role With Dying Children and Their Families

Caring for dying clients can be an emotionally draining experience for health care providers as well as family members (Hogan, 2007). Although it is best that nursing assignments be consistent so that a child has meaningful support, for everyone there is a point at which a health care provider may need a respite from caring for a certain child or help in offering support for the parents. This is not admitting weakness but recognizing humanness and a sense of compassion that interferes with client need.

Self-Awareness

Before you can offer support to children in any circumstance, be aware of your own reactions and feelings. To offer support to a child who is dying, examine how you feel about caring for someone who is dying.

Fear. Fear is a natural response to death, because the phenomenon is new and strange. To overcome this fear, put it into perspective. In nursing, you care for many people who have illnesses and experiences you will never have; so, caring for people with experiences beyond your own is not really strange but almost routine in nursing.

People who have never seen someone die are often afraid that the moment of death will be terrifying to watch. Death usually occurs gently, however, with body functioning gradually lessening until it stops in a pain-free, quiet manner. People who have been declared dead and were then resuscitated by heroic measures report that death was not frightening but involved a feeling of exceptional calm and comfort; some people have said afterward that they wished they had been allowed to die rather than being called back to their body, because death seemed so appealing (Belanti, Perera, & Jagadheesan, 2008).

Failure. Some health care professionals find themselves drawing back from caring for dying children because death symbolizes failure to them. This can make children feel as if they have failed—they have not been able to keep their body from dying despite everyone's best efforts.

Remind yourself that death is the ultimate outcome for everyone. At the point that death becomes unpreventable, the only failure that can exist is the failure of health care professionals to help a child achieve death with dignity and consideration, free of guilt that the child failed caregivers.

Grief

Nursing care is so intense that the relationship formed may be closer than you realize until a child is diagnosed as having a terminal illness or dies; only then do you experience the depth of the relationship. Because nurses develop such close bonds with terminally ill children, they may experience profound grief when a child dies or no longer requires their care. The grief that accompanies caring for dying children can be broken down into the same stages of grief experienced by the children themselves when they learn that they are dying.

Denial. There is a danger that a nurse who is in a stage of denial may care for children without mentioning that they have more than a simple illness. This includes omitting the use of such common expressions as, "How are you this morning?" to avoid having to hear the answer. Denial may be so extensive that you avoid going into a child's room unless an important procedure must be done. This is confusing and lonely for children, because they miss the normal exchange of conversation and contact.

Nurses sometimes change professions after the death of a child to whom they felt close, because they are unwilling to submit themselves to that level of hurt again.

Anger. Anger may be intense when a young child dies, because the death seems so unfair. Nurses who are angry have difficulty offering effective care: they may perceive themselves as giving thorough, comforting care, but actually they inflict discomfort with sharp, abrupt movements. Anger clouds a nurse's judgment, such as which analgesic would be best to administer. Dying children cannot approach angry caregivers or ask questions; they are left alone and perhaps feeling guilty that they have caused this anger.

Bargaining. Caregivers begin to bargain for life just as children do. A statement such as, "If Tommy just makes it through the weekend while I'm off, I'll spend all my extra time with him next week" is a bargaining statement. Statements of this kind are easy to overlook in your coworkers or yourself. Listening for them helps you to evaluate when a fellow worker is having difficulty caring for a particular patient and perhaps needs to change assignments. Hearing yourself say them should alert you that you are more involved with a child than you perhaps have realized. You need to talk to someone about your feelings or ask for help. Remember that when bargaining fails, people reach their lowest point in grief. Recognizing bargaining statements in yourself helps you to be prepared for the depression that will follow.

Depression. Nurses who enter this phase may be ineffective caregivers, because depressed people are poor problem solvers (everything becomes a crisis). Nurses may make unwise decisions in their personal lives (such as drop out of a night school course, file for divorce) because they cannot solve problems effectively.

Depression is doubly destructive because when you are depressed, your reasoning processes are so distorted that you lose the ability to recognize that depression is the problem. When

FIGURE 56.4 Good communication skills help build a trusting relationship, allowing a child to share feelings about being terminally ill. (© Caroline Brown, RNC, MS, DEd.)

caring for a child who is expected to die, monitor your usual behavior to see if you are following your usual pattern. If irregularities occur (sleeping a great deal, not sleeping, loss of appetite), assess whether depression has overwhelmed you. When depressed, try to make no major decisions for at least a week, to give your perspective time to change, or you may find later that you have made an unwise, irreversible decision.

Acceptance. The average person can reach a stage of acceptance in grief because people are subjected to few true losses in a lifetime. As a nurse on a unit where many terminally ill children come for care, you may find yourself facing loss or death repeatedly. Therefore, a stage of acceptance may never be reached. A caregiver who cannot reach a stage of acceptance is left in a stage of depression and has extreme difficulty functioning.

To achieve a stage of acceptance, you may need to modify what it is you are accepting. You cannot accept the unfairness of death in children, but you can accept your ability to offer care that gives death dignity and compassion. Do not compensate for being unable to feel good by not feeling. This is a dangerous attitude, because it also blocks your ability to feel happiness, love, and trust. You may need to ask for a temporary change of assignment to re-establish your perspective. You may need to concentrate on self-esteem therapy for yourself (doing something special for yourself, such as taking an evening to do nothing but meet your own needs).

What if... While caring for Charlie for an extended period, you notice yourself making poor judgments in your personal life such as not following through on projects or spontaneous buying? Could this be an expression of grief?

Caring for the Dying Child

A child may live for days, weeks, or even months in a "dying phase." Attentive physical and emotional care is essential to a child's maintaining a sense of security and positive self-esteem during this time. It is also essential to the grieving process for both the child and the child's family. Frequent and substantive communication is a major part of providing this care. Children, like their parents, need the opportunity to talk about their fears and feelings about death. Practicing good communication skills when providing any care such as when administering pain medication, starting intravenous lines, or providing basic comfort measures such as a bath help to establish a trusting relationship with the child, making the child feel more comfortable about sharing feelings with you (Fig. 56.4). Box 56.7 provides some specific guidelines about communicating with a child who is dying.

BOX 56.7 ✻ Approaches to Communicating With Dying Children

1. *Continue active conversation.* Children who are dying need to receive stimulation in as near normal a way as possible.
2. *Use moments of silence therapeutically.* Such moments occur normally just as speech occurs normally. Do not feel you have to chatter to fill quiet intervals.
3. *Use the words death and dying as appropriate in conversation.* Trying to avoid a word makes interchanges awkward. Statements such as, "These flowers are dying," "That's a dead-end job," or "I'm dying to try that" may make it acceptable for the child you are caring for to voice for the first time what is happening —"I'm dying, too; let me tell you about dead-ending."
4. *Preserve dying children's defenses.* If they are using denial or bargaining, do not try to push them to the next step of grieving by confrontation. Children will move on to the next step when they are psychologically ready.
5. *Remember that many children assume that they will die at night.* Therefore, night is "owned" by the dying. A child may talk more freely at night about fears or an unfulfilled life ambition than during the day. Children may also be more frightened at night and enjoy having someone sit beside them until they fall asleep.
6. *Be supportive, not trite.* A statement such as "All of us are dying" is true but not helpful. A supportive statement such as, "This must be hard for you" is better.
7. *Be aware that not all people's beliefs are the same as yours.* A statement such as, "God works in mysterious ways" may explain death for you but can be little comfort to a family who does not envision that as true. A statement such as, "I believe God made some children die early to teach us to appreciate life" may evoke an angry response such as, "Who could believe in a God like that?" rather than be comforting.

The Child's Family

For many children, terminal illness involves a series of hospital admissions interspersed with ambulatory care or home visits. Parents need time during these visits to talk about the problems they are having, not only with physical care (Should the child attend regular school? Could he come on vacation? How many times a day are they supposed to give the immunosuppressant?) but also about how it feels to live with a child who is dying (How should they answer the child's or siblings' questions about dying?). Although many parents are reluctant to tell a child that he is dying, this is probably the soundest course once the child can see that his condition is deteriorating. There is often less anxiety in knowing what is happening than in hearing people whispering or spelling out words around you.

If a child experiences an exacerbation of the disease, parents may again begin an anticipatory grief reaction: anger, bargaining, depression, acceptance. The process will be cut short by improvement, only to begin again at the next exacerbation. For this reason, the parents of a child who is being admitted to the hospital for the 12th time for a fatal illness may be in the same stage of grief as the parents of a child with a newly diagnosed fatal illness.

During health supervision visits, ask parents how other children in the family are managing. The parents may need to be reminded that, although the dying child does need a lot of their time, other children find this illness in a sibling as baffling as do the parents. When the ill child dies, siblings need the same active support to help them grieve.

The Onset of Death

As death nears in children, physiologic changes, such as slowed metabolism, decreased cell oxygenation, and cell dysfunction, begin to occur, changing their appearance.

Stroke volume of the heart decreases, so the power to circulate blood is reduced. The child's skin feels cool and may appear mottled or cyanotic because blood can no longer be pushed to distal sites. Just before death, blood begins to pool in dependent body parts, making them appear purple. As circulation fails, absorption of a drug from a muscle becomes virtually impossible; emergency drugs need to be administered intravenously to have an effect.

As peripheral circulation fails, less heat is lost from the body, and the internal temperature rises. The child's body compensates for this by increased perspiration to increase heat loss through evaporation. This makes the child's skin feel cool and damp. You may need to change linens frequently because of the increased moisture on the skin. Because perfusion of distal body parts is impaired, turn the child slowly to allow the circulatory system to accommodate to the change in position.

Slowed respirations lead to increased secretions in the lungs and the appearance of rales, the sound of air being pulled through fluid in the alveoli. To compensate for a few minutes of very slow respirations, a child may take several quick or extremely deep inhalations periodically. Be certain the child's chest is not compressed, so that the child has optimal lung expansion to do this.

A decrease in muscular function leads to severe weakness and fatigue. More and more, children maintain the exact position into which they are placed. As the throat muscles become lax, the possibility of aspiration increases. Assess a child carefully for an intact gag reflex before offering oral fluid. If the gag or swallowing reflex is impaired, position the child on the side to allow saliva to drain from the mouth, to prevent aspiration. An often-noticed phenomenon is constant hand movement—picking at bedclothes, for example—which probably represents the loss of upper centers of voluntary muscular control. Neurologically, deep reflexes, such as the Achilles tendon reflex, begin to fade.

As children grow closer and closer to death, they begin to demonstrate a lessened level of consciousness, although they may remain perfectly alert until seconds before death. Vision apparently blurs, because children tend to turn their head toward a light. Touch seems to remain intact, because they often quiet to a gentle stroking of the arm or shoulder; they grasp your hand meaningfully, as if touch is appreciated and felt. Hearing remains intact; remind family members and, on occasion, other health care personnel of this. Continue to explain procedures to unconscious children as if they were conscious, because they undoubtedly do hear you. Never make any comment in their presence that you would not make if they were alert. Continue to use the same gentle touch and nonverbal communication motions, such as holding a hand or brushing hair from the forehead, as if children were fully conscious. They may be fully aware of your actions even though they can give no indication of it.

Digestion slows as total body metabolism slows. Constipation because of poor bowel tone and decreased peristaltic action will occur. The abdomen may become distended from intestinal flatus. Dehydration with dry mucous membranes and conjunctivae will occur unless intravenous fluid replacement is initiated. Mouth dryness will lead to cracking and secondary infection and pain; prevent this by frequent cleaning of the mucous membrane with clear water and applications of petroleum jelly to the lips. If the conjunctivae appear dry, ask the physician to prescribe moistening eye drops; keep any crusting at the eyelids washed away so that optimal vision is possible.

Keep skin surfaces from rubbing against one another by using supportive pillows and good positioning. Keep the skin free of urine or feces from incontinence; this prevents the development of painful ulcers. These are normally not a major concern in children, but they are a concern here because of the lessened peripheral blood perfusion. Assess for pain (thrashing or moaning), and provide relief with appropriate comfort measures.

Documentation of Death

Defining when death occurs is controversial and involves both legal and ethical issues. Signs of death in a child not receiving ventilatory or mechanical assistance are the same as in adults:

- Absence of respirations
- No audible heart sounds by stethoscope
- No pulse by palpation
- No apparent blood pressure
- Absence of body movement or reflexes
- Dilated, fixed pupils

Death is officially determined by unreceptivity and unresponsivity; no spontaneous muscular movement or breath; no reflex response; and a flat electroencephalogram—again, the same as in adults. Emergency medical technicians make a

preliminary assessment in the home or hospice setting, and then death is confirmed by a physician.

Organ Donation

Parents may be asked by their physician or by a specifically designated transplantation team before a child's death to grant permission for body organs to be transplanted into other children after death occurs. This is particularly important for liver and kidney transplants, because it is difficult to transplant adult-size organs into children. If parents decide to allow organ donation, mark this information on the child's plan of care in a conspicuous place, and alert the physician about the decision. When death does occur, the child's body will be maintained by a life-support system to ensure that the organ remains perfused until it can be removed. The donation of body organs may help parents accept their child's death more easily, because they can feel their child has helped another person live. On the other hand, if parents are reluctant to agree to organ donation, you may need to advocate for them. Donating their child's organs is not a practice for everyone (Bellali, Papazoglou, & Papadatou, 2007).

Aftercare

Before beginning any aftercare for a child who has died in a health care facility or at home, check with family members to see if they want to spend a few minutes with the child or if there are any religious rites they want to complete before the body is transported to the morgue. Some parents need this time to comprehend that death has really occurred. Some people have special prayers they want to say; others want to say a final, private goodbye. In the hospital, check that the child's bed and room look neat and clean before you ask family whether they would like to spend some time in the room, particularly if a final resuscitation attempt resulted in blood-soaked sponges or scattered equipment.

Remain in the room with the family in case they need your support, but be unobtrusive. Some parents fear touching a child's body after death, but touch is a strong and intimate communication technique that a family member may appreciate being shown how to use. Role model touching by holding the child's hand or brushing hair away from the forehead as if the child were still alive. Some parents may seem unable to leave the room or to let go of the child's hand. You may need gradually to separate their hands, saying something such as, "I'll always remember Molly the way she was when I first met her—so full of life and always laughing. I'm sure that's how you'll always remember her, too." This helps parents begin to accept the fact that, in more than a physical sense, it is time to let go.

As a rule, crying is helpful for parents. You may need to tell them that it is all right to cry. On the other hand, do not interpret a lack of tears as a lack of feeling, because crying is not everyone's response to death. It is not unprofessional for nurses to cry when a child dies. A parent's warmest memory of a hospital experience may be that a nurse cried as she said goodbye to their child—the implication being that the child made an important impact on people other than family.

Autopsy Permission

If a child's death is a result of homicide, suicide, death within 24 hours after a hospital admission, suspected harmful death, or death in an institution or home where the child was not under a physician's care, an autopsy is required by law; parents have no input regarding whether this is done. In other instances, it would be helpful to medical progress or to research if an autopsy could be done, but parents must give permission for one. Parents may refuse to allow an autopsy for a child, believing that doing so will protect the child from any more hurt, or out of religious convictions. Autopsies advance medical science, so they should be done if at all possible; on the other hand, parents have every right to refuse permission without being made to feel guilty for their actions. You may need to advocate for them.

✔ Checkpoint Question 56.3

Suppose parents are told their child will die, but then the child does not die. What is an unexpected consequence of anticipatory grieving?

a. It has no effect, because the child does not die.
b. It can disrupt the parent–child relationship.
c. It teaches the child that parents can be wrong.
d. It breaks parents' confidence in their religion.

Key Points for Review

- Children with long-term illnesses need continual reassessment because, like all children, their needs change as they grow older. Larger doses of medicine will become necessary; care such as additional muscle-strengthening exercises may be necessary.
- Factors that make it easier for parents to accept a long-term illness in a child include having support people present and being told about the child's condition as early as possible.
- Long-term illness in a child is often most difficult for parents to accept at times when the child would have been achieving specific milestones of development. Extra support for both the parents and the child may be necessary at these times.
- Help children to do as much care for themselves as possible within the limits of their illnesses. Self-care empowers them to be as independent as possible.
- Children are about 9 years old before they are able to understand the meaning of death and that it is permanent. A child and parents can be expected to move through the stages of grief (denial, anger, bargaining, depression, and acceptance) on learning about a potentially fatal diagnosis.
- Children and parents are apt to need help to face a terminal diagnosis in a child. Urge the parents and the child to ask for help to see them through this very difficult time in their lives.

CRITICAL THINKING EXERCISES

1. Charlie is the 3-year-old boy with leukemia you met at the beginning of the chapter. His parents tell you that

Charlie's disease has put them through a great deal of strain. What would be important topics to discuss with these parents?

2. Charlie's parents are both 50 years old and live on a ranch; finances are tight, and they have no health insurance. Two grown children have expressed resentment at their parents for spending so much time and money trying to find a cure for Charlie. What risk factors does to this family have that might make adjusting to a child with a long-term illness more difficult than usual?
3. You notice Charlie's parents in the waiting room of the hospital comforting parents whose child was just hit by a car and killed instantly; you hear them say that losing a child suddenly is better than what they are experiencing. Why do you think these parents feel this way? What stage of grief could they be experiencing? How could you help them with their feelings?
4. Examine the National Health Goals related to long-term or terminal care of children. Most government-sponsored funds for nursing research are allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to Charlie's family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the patient scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX types of questions related to children with a long-term or terminal illness. Confirm your answers are correct by reading the rationales.

Appendix

A The Rights of Children and Childbearing Women

THE RIGHTS OF CHILDBEARING WOMEN

We must ensure that all childbearing women have access to information and care that is based on the best scientific evidence now available, and that they understand and have opportunities to exercise their right to make health care decisions. Women whose rights are violated need access to legal or other recourse to address their grievances.

Every Woman's Rights

Consideration and respect for every woman under all circumstances is the foundation of this statement of rights.

1. Every woman has the right to health care before, during, and after pregnancy and childbirth.
2. Every woman and infant has the right to receive care that is consistent with current scientific evidence about benefits and risks.* Practices that have been found to be safe and beneficial should be used when indicated. Harmful, ineffective, or unnecessary practices should be avoided. Unproven interventions should be used only in the context of research to evaluate their effects.
3. Every woman has the right to choose a midwife or a physician as her maternity care provider. Both caregivers skilled in normal childbearing and caregivers skilled in complications are needed to ensure quality care for all.
4. Every woman has the right to choose her birth setting from the full range of safe options available in her community, on the basis of complete, objective information about benefits, risks and costs of these options.*
5. Every woman has the right to receive all or most of her maternity care from a single caregiver or a small group of caregivers, with whom she can establish a relationship. Every woman has the right to leave her maternity caregiver and select another if she becomes dissatisfied with her care.* (Only second sentence is a legal right.)
6. Every woman has the right to information about the professional identity and qualifications of those involved with her care, and to know when those involved are trainees.*
7. Every woman has the right to communicate with caregivers and receive all care in privacy, which may involve excluding nonessential personnel. She also has the right to have all personal information treated according to standards of confidentiality.*
8. Every woman has the right to receive maternity care that identifies and addresses social and behavioral factors that affect her health and that of her baby.** She should receive information to help her take the best care of herself and her baby and have access to social services and behavioral change programs that could contribute to their health.
9. Every woman has the right to full and clear information about benefits, risks, and costs of the procedures, drugs, tests and treatments offered to her, and of all other reasonable options, including no intervention.* She should receive this information about all interventions that are likely to be offered during labor and birth well before the onset of labor.
10. Every woman has the right to accept or refuse procedures, drugs, tests and treatments, and to have her choices honored. She has the right to change her mind.* (Please note that this established legal right has been challenged in a number of recent cases.)
11. Every woman has the right to be informed if her caregivers wish to enroll her or her infant in a research study. She should receive full information about all known and possible benefits and risks of participation, and she has the right to decide whether to participate, free from coercion and without negative consequences.*
12. Every woman has the right to unrestricted access to all available records about her pregnancy, her labor, and her infant; to obtain a full copy of these records; and to receive help in understanding them, if necessary.*
13. Every woman has the right to receive maternity care that is appropriate to her cultural and religious background, and to receive information in a language in which she can communicate.*
14. Every woman has the right to have family members and friends of her choice present during all aspects of her maternity care.**
15. Every woman has the right to receive continuous social, emotional, and physical support during labor and birth from a caregiver who has been trained in labor support.**
16. Every woman has the right to receive full advance information about risks and benefits of all reasonably available methods for relieving pain during labor and birth, including methods that do not require the use of drugs. She has the right to choose which methods will be used and to change her mind at any time.*
17. Every woman has the right to freedom of movement during labor, unencumbered by tubes, wires, or other apparatus. She also has the right to give birth in the position of her choice.*
18. Every woman has the right to virtually uninterrupted contact with her newborn from the moment of birth, as long as she and her baby are healthy and do not need care that requires separation.**

(At this time in the United States, childbearing women are legally entitled to those rights marked with *. The legal system would probably uphold those rights marked with **.)

From the Maternity Center Association. (2004.) *The rights of childbearing women.* New York: MCA.

19. Every woman has the right to receive complete information about the benefits of breastfeeding well in advance of labor, to refuse supplemental bottles and other actions that interfere with breastfeeding, and to have access to skilled lactation support for as long as she chooses to breastfeed.**
20. Every woman has the right to decide collaboratively with caregivers when she and her baby will leave the birth site for home, based on their condition and circumstances.**

UNITED NATIONS DECLARATION OF THE RIGHTS OF THE CHILD†

Preamble

Whereas the peoples of the United Nations have, in the Charter, reaffirmed their faith in fundamental human rights, and in the dignity and worth of the human person, and have determined to promote social progress and better standards of life in larger freedom,

Whereas the United Nations has, in the Universal Declaration of Human Rights, proclaimed that everyone is entitled to all the rights and freedoms set forth therein, without distinction of any kind, such as race, color, sex, language, religion, political or other opinion, national or social origin, property, birth, or other status,

Whereas the child, by reason of his physical and mental immaturity, needs special safeguards and care, including appropriate legal protection, before as well as after birth,

Whereas the need for such special safeguards has been stated in the Geneva Declaration of the Rights of the Child of 1924, and recognized in the universal Declaration of Human Rights and in the statutes of specialized agencies and international organizations concerned with the welfare of children,

Whereas mankind owes to the child the best it has to give.

Now therefore the general assembly proclaims

This Declaration of the Rights of the Child to the end that he may have a happy childhood and enjoy for his own good and for the good of society and rights and freedoms herein set forth, and calls upon parents, upon men and women as individuals, and upon voluntary organizations, local authorities, and national governments to recognize these rights and strive for their observance by legislative and other measures progressively taken in accordance with the following principles:

Principle 1

The child shall enjoy all the rights set forth in this Declaration. All children, without any exception whatsoever, shall be entitled to these rights, without distinction or discrimination on account of race, color, sex, language, religion, political or other opinion, national or social origin, property, birth, or other status, whether of himself or of his family.

Principle 2

The child shall enjoy special protection, and shall be given opportunities and facilities, by law and by other means, to enable him to develop physically, mentally, morally, spiritually, and socially in a healthy and normal manner and in conditions of freedom and dignity. In the enactment of laws for this purpose, the best interests of the child shall be the paramount consideration.

Principle 3

The child shall be entitled from his birth to a name and a nationality.

Principle 4

The child shall enjoy the benefits of social security. He shall be entitled to grow and develop in health; to this end special care and protection shall be provided both to him and to his mother, including adequate prenatal care. The child shall have the right to adequate nutrition, housing, recreation, and medical services.

Principle 5

The child who is physically, mentally, or socially handicapped shall be given the special treatment, education, and care required by his particular condition.

Principle 6

The child, for the full and harmonious development of his personality, needs love and understanding. He shall, wherever possible, grow up in the care and under the responsibility of his parents, and in any case in an atmosphere of affection and of moral and maternal security; a child of tender years shall not, save in exceptional circumstances, be separated from his mother. Society and the public authorities shall have the duty to extend particular care to children without a family and to those without adequate means of support. Payment of state and other assistance toward the maintenance of children of large families is desirable.

Principle 7

The child is entitled to receive education, which shall be free and compulsory, at least in the elementary stages. He shall be given an education that will promote his general culture and enable him on a basis of equal opportunity to develop his abilities, his individual judgment, and his sense of moral and social responsibility and to become a useful member of society.

The best interests of the child shall be the guiding principle of those responsible for his education and guidance; that responsibility lies in the first place with his parents.

The child shall have full opportunity for play and recreation, which shall be directed to the same purposes as education; society and the public authorities shall endeavor to promote the employment of this right.

Principle 8

The child shall in all circumstances be among the first to receive protection and relief.

†United Nations. (1959). *Declaration of the rights of the child.* Geneva: The United Nations. Reaffirmed by the Universal Declaration of Human Rights, 2004.

Principle 9

The child shall be protected against all forms of neglect, cruelty, and exploitation. He shall not be the subject of traffic, in any form.

The child shall not be admitted to employment before an appropriate minimum age; he shall in no case be caused or permitted to engage in any occupation or employment that would prejudice his health or education, or interfere with his physical, mental, or moral development.

Principle 10

The child shall be protected from practices that may foster racial, religious, and any other form of discrimination. He shall be brought up in a spirit of understanding, tolerance, friendship among peoples, peace, and universal brotherhood and in full consciousness that his energy and talents should be devoted to the service of his fellow men.

Appendix

B Composition of Infant Formulas (per 100 mL)

Name (Manufacturer)	CHO (% of Kcal/ozcal/type)	Fat (% of cal/type)	PRO (% of cal/type)	FE (mg)	VIT D(IU)	mg Ca/mg PO_4
Cow's Milk–based Standard Formulas						
Enfamil (Mead Johnson) with/without iron	20[a] 44%[a] Lactose	48% Palm olein, coconut oil, soy oil, sunflower oil	8% Cow's milk	1.22/0.34	41	52/36
Similac (Ross); with/without iron	20[a] 43% Lactose	48% Soy oil, coconut oil	9% Cow's milk	1.2/0.15	40	49/38
PM 60/75 (Ross)[b]	20 41% Lactose	50% Coconut oil, corn oil	9% Lactalbumin, casein	0.15	40	75/20
Gerber; with/without iron (Gerber)	20[c] 43% Lactose	49% Corn oil, coconut oil	9% Cow's milk	1.21/0.11	40	50/39
Good Start (Carnation)[b]	20[c] 44% Lactose, soy maltodextrin	46% Palm oil, safflower oil, coconut oil	10% Whey and whey protein	1.01	41	43/24
Soy-Based Standard Formulas						
Isomil (Ross)	20 41% Corn syrup, sucrose	49% Coconut oil, soy oil	10% Soy protein isolate	1.2	40	70/50
ProSobee (Mead Johnson)	20 40% Corn syrup solids	48% Coconut oil, soy oil, palm oil	12% Soy protein isolate	1.3	42	63/49
Preterm Formulas						
Similac Special Care (Ross)	24[d] 42% Lactose (50%), Polycose glucose polymers (50%)	47% MCT oil (50%), soy oil (30%), coconut oil (20%)	11% Nonfat milk whey (60%), casein (75%)	1.5/0.3	122	146/81
Enfamil Premature (Mead Johnson); with/without iron	24[d] 44% Lactose (50%), corn syrup solids	44% MCT oil (75%), soy oil (75%), coconut oil (20%)	12% Lactalbumin (60%), casein (75%)	1.5/0.2	219	134/75
Similac Neocare (Ross)[e]	22 41% Lactose (50%), glucose polymers (50%)	49% MCT oil (25%), LCT oil (75%)	10% Whey (50%), casein (50%)	1.3	59	78/46
Special Formulas[f]						
Nutramigen (Mead Johnson)	20 54% Modified corn starch, corn syrup solids	35% Corn oil, soy oil	11% Casein hydrolysate and amino acids	1.25	42	63/42
Pregestimil (Mead Johnson)	20 41% Corn syrup solids, modified cornstarch, dextrose	48% MCT oil (60%), corn oil, soy oil, safflower oil	11% Casein hydrolysate, amino acids	1.25	50	63/42
Portagen (Mead Johnson)	20 46% Corn syrup solids, sucrose	75% MCT oil (85%), corn oil, lecithin	14% Sodium caseinate	1.25	52	63/47

CHO, carbohydrate; CF, cystic fibrosis; FE, iron; LCT, long-chain triglyceride; MCT, medium-chain triglyceride; PRO, protein.

[a]Also available as 24 kcal/oz and 27 kcal/oz.

[b]Formula with a low renal solute load.

[c]Also available as 24 kcal/oz.

[d]Also available as 20 kcal/oz.

[e]Available only as ready-to-feed.

[f]Indications for Special Formulas

Alimentum (Ross)[e]	20	41% Sucrose, modified tapioca starch	48% MCT oil (50%), safflower oil (75%), soy oil (10%)	11% Casein hydrolysate, amino acids	1.2	30	70/50
LactoFree (Mead Johnson)	20	42% Corn syrup solids	49% Palm olein, soy oil, coconut oil, sunflower oil	9% Cow's milk protein isolate	1.2	75	55/37
Neocate (Scientific Hospital Supplies, Inc.)	20	47% Corn syrup solids, dextrose, maltose, maltriose, oligosaccharides	41% Hybrid safflower oil, coconut oil, soy oil	12% Synthetic free amino acids	1.2	58	83/62

Name	Indications[F]
Nutramigen	Cow's milk allergy, severe or multiple food allergies, severe or persistent diarrhea, galactosemia
Pregestimil	Malabsorption, intestinal resection, severe or persistent diarrhea, food allergies
Portagen	Steatorrhea secondary to CF, intestinal resections, pancreatic insufficiency, biliary atresia, lymphatic anomalies, celiac disease
Alimentum	Problems with digestion or absorption, severe or prolonged diarrhea, CF, steatorrhea, food allergies, intestinal resection
Lactofree	Lactose intolerance *without* cow's milk protein intolerance
Neocate	Cow's milk allergy, soy and protein hydrolysate intolerance, multiple food protein intolerance

Appendix C

Drug Effects in Lactation

Women who are breastfeeding should ask their health care providers about the safety of any medicine or alternative therapy during breastfeeding.

Adrenergics	Parenteral *epinephrine* (Adrenalin) is excreted in breast milk; the status of other adrenergic bronchodilators is not known. *Albuterol* (Proventil, Ventolin) has tumorigenic effects in animals; if considered necessary, breastfeeding should be discontinued. Oral drugs used as nasal decongestants (e.g., *pseudoephedrine* [Sudafed], others) are contraindicated in nursing mothers because of higher than usual risks to infants from sympathomimetic drugs.
Analgesics	*Most nonsteroidal anti-inflammatory drugs, such as ibuprofen (Motrin, Advil), are excreted in breast milk, and nursing is not recommended. However, occasional use of therapeutic doses is probably acceptable. Acetaminophen* (Tylenol) is excreted in breast milk in low concentrations. No adverse effects have been reported, and it is probably the analgesic-antipyretic drug of choice for nursing mothers. Salicylates (e.g., *aspirin*) are excreted in breast milk in small amounts. Adverse effects on nursing infants have not been reported but are a potential risk. Narcotic analgesics such as *meperidine* (Demerol) are excreted in breast milk, but amounts may not be enough to cause adverse effects in the nursing infant. Some authorities recommend waiting 4 to 6 h after a dose before nursing. *Alfentanil* (Alfenta) should probably not be given. Significant amounts have been found in breast milk 4 h after a dose.
Angiotensin-converting enzyme (ACE) inhibitors	*Captopril* (Capoten) is excreted in breast milk, but effects on the infant are unknown. It is not known whether *enalapril* (Vasotec) or *lisinopril* (Prinivil, Zestril) is excreted in breast milk. In general, nursing is not recommended while taking these drugs.
Antianginal agents (nitrates)	Safety for use in the nursing mother has not been established.
Antianxiety and sedative-hypnotic agents (benzodiazepines)	*Diazepam* (Valium) and other benzodiazepines should generally be avoided. They are excreted in breast milk and may cause lethargy and weight loss in the infant. The drugs and their metabolites may accumulate to toxic levels in neonates because of slow drug metabolism.
Antiarrhythmics	When these agents are required for a nursing mother, breastfeeding should generally be discontinued. *Quinidine* (Quinaglute), *disopyramide* (Norpace), and *mexiletine* (Mexitil) are excreted in breast milk; it is unknown whether *procainamide* (Pronestyl, Procan), *lidocaine* (Xylocaine), and *flecainide* (Tambocor) are excreted. Potential exists for serious adverse effects in infants.
Antibiotics	Read the labeling on all antibiotics, antifungals, and antivirals to be certain they are safe for lactating women and infants. Examples of those commonly prescribed for women are: *Penicillins* are excreted in breast milk in low concentrations and may cause diarrhea, candidiasis, or allergic responses in nursing infants. *Cephalosporins* are excreted in small amounts and may alter bowel flora, cause pharmacologic effects, and interfere with interpretation of culture reports with fever or infection. *Aztreonam* (Azactam) is excreted in small amounts; discontinuing breastfeeding temporarily is probably indicated. It is unknown whether *imipenem/cilastatin* (Primaxin) is excreted. The aminoglycosides *netilmicin* (Netromycin) and *streptomycin* are excreted in small amounts. Because these drugs are nephrotoxic and ototoxic, the immature kidney function of neonates and infants should be considered. *Tetracyclines* are excreted in breast milk and should be avoided. *Sulfonamides* are excreted and generally contraindicated. They may cause kernicterus in the neonate and diarrhea and skin rash in the nursing infant. *Erythromycin* is excreted and may become concentrated in breast milk. No adverse effects on nursing infants have been reported. However, the potential exists for alteration in bowel flora, pharmacologic effects, and interference with fever workup. *Nitrofurantoin* (Macrodantin) is excreted in very small amounts.

	However, safety for use in nursing mothers has not been established, and infants with glucose-6-phosphate dehydrogenase (G-6-PD) deficiency may be adversely affected. *Clindamycin* (Cleocin) is excreted. Breastfeeding is probably best discontinued if the drug is necessary, to avoid potential problems in the infant. *Cinoxacin* (Cinobac) and *norfloxacin* (Noroxin) are probably excreted, and there is a potential for severe adverse effects in nursing infants. Depending on the mother's need for the drug, either the drug or breastfeeding should be discontinued. *Isoniazid* (INH) and *rifampin* (Rifadin) are excreted in breast milk, and nursing infants should be observed for adverse drug effects. *Trimethoprim* (Proloprim, Bactrim) is excreted and may interfere with folic acid metabolism in the infant.
Anticholinergics	*Atropine* and others are excreted and may cause infant toxicity or decreased breast milk production. Safety for use is not established.
Anticoagulants	*Heparin* is not excreted in breast milk; *warfarin* (Coumadin) is excreted, but some evidence suggests no harm to the nursing infant. More data are needed, and heparin is preferred if anticoagulant therapy is required.
Anticonvulsants	*Phenytoin* (Dilantin) and other hydantoins are excreted and may cause serious adverse effects in nursing infants. The drug or breastfeeding should be discontinued. *Phenobarbital* is excreted in small amounts and may cause drowsiness in the infant.
Antidepressants	Tricyclic antidepressants such as *amitriptyline* (Elavil) and others are excreted in small amounts; effects on nursing infants are not known. Other antidepressants have not been established as safe for use.
Antidiabetic drugs	*Insulin* does not enter breast milk and is not known to affect the nursing infant. However, insulin requirements of the mother may be decreased while breastfeeding. Oral agents *chlorpropamide* (Diabinese) and *tolbutamide* (Orinase) are excreted in breast milk; the status of other sulfonylureas is unknown. There is a potential for hypoglycemia in nursing infants.
Antidiarrheals	*Diphenoxylate* (Lomotil) and *loperamide* (Imodium) should be used cautiously during lactation; effects on the nursing infant are unknown.
Antiemetics	Although information is limited, most of the drugs (e.g., phenothiazines such as *promethazine* [Phenergan] and antihistamines such as *dimenhydrinate* [Dramamine]) are apparently excreted in breast milk and may cause drowsiness and possibly other effects in nursing infants. Antihistamines used for antiemetic effects also may inhibit lactation. *Metoclopramide* (Reglan) is excreted and concentrated in breast milk; it should be used cautiously, if at all.
Antihistamines	Histamine$_1$ receptor antagonists such as *diphenhydramine* (Benadryl) may inhibit lactation by their drying effects and may cause drowsiness in nursing infants. For most of the commonly used drugs, including over-the-counter allergy and cold remedies, little information is available about excretion in breast milk or effects on nursing infants. Histamine$_2$ receptor antagonists such as *cimetidine* (Tagamet) and *ranitidine* (Zantac) are excreted in breast milk. *Famotidine* (Pepcid) is excreted in animals, but it is not known whether it is excreted in human breast milk. It is generally recommended that either the drug or nursing be discontinued.
Antihypertensives	Beta-adrenergic blocking agents should generally be avoided by nursing mothers. *Propranolol* (Inderal) and *metoprolol* (Lopressor) are excreted in low concentrations; *acebutolol* (Sectral) and its major metabolite are excreted; it is unknown whether *nadolol* (Corgard) and *timolol* (Blocadren) are excreted. *Methyldopa* (Aldomet) is excreted; effects on nursing infants are unknown. It is unknown whether *hydralazine* (Apresoline) is excreted; safety for use is not established. *Captopril* (Capoten), *clonidine* (Catapres), *guanabenz* (Wytensin), and *guanfacine* (Tenex) are not generally recommended, because information about effects on nursing infants is limited. Calcium channel blocking drugs should not be given to nursing mothers. *Verapamil* (Calan) and *diltiazem* (Cardizem) are excreted in breast milk.

(continued)

Antimanic agent	*Lithium* is excreted in breast milk and reaches about 40% of the mother's serum level. Infant serum and milk levels are about equal. If the drug is required, nursing should be discontinued.
Antipsychotic drugs	Little information is available considering the extensive use of these drugs. *Chlorpromazine* (Thorazine) and *haloperidol* (Haldol) have been detected in breast milk in small amounts. Safety has not been established.
Antithyroid drugs	Nursing is contraindicated for clients on the antithyroid drugs *propylthiouracil* and *methimazole* (Tapazole).
Beta-adrenergic blocking agents	See **Antihypertensives.**
Bronchodilators (Xanthine)	*Theophylline* (Theo-Dur) enters breast milk readily; use with caution.
Calcium channel blocking agents	See **Antihypertensives.**
Corticosteroids	*Prednisone* (Deltasone), *dexamethasone* (Decadron), and others appear in breast milk and could suppress growth, interfere with endogenous corticosteroid production, or cause other adverse effects in nursing infants. Advise mothers taking pharmacologic doses not to breastfeed.
Digitalis	*Digoxin* (Lanoxin) is excreted. However, infants receive very small amounts, and no adverse effects have been reported.
Diuretics	If diuretic drug therapy is required, nursing mothers should discontinue breastfeeding. Thiazide diuretics such as *hydrochlorothiazide* (HydroDIURIL) and the loop diuretic *furosemide* (Lasix) are excreted in breast milk. It is unknown whether *bumetanide* (Bumex) and ethacrynic acid (Edecrin) are excreted. Little information is available about potassium-sparing diuretics, such as *amiloride* (Midamor), *triamterene* (Dyrenium, Dyazide, Maxide), and *spironolactone* (Aldactone). They are not recommended for use.
Laxatives	*Cascara sagrada* is excreted in breast milk and may cause diarrhea in the nursing infant. It is not known whether *docusate* (Colace) is excreted.
Nonsteroidal anti-inflammatory drugs	See **Analgesics.**
Thyroid hormones	Small amounts are excreted in breast milk. The drugs are not associated with adverse effects on nursing infants but should be used with caution in nursing mothers.

To use this chart: Find weight in pounds in the left-hand column; find weight in ounces in the top row. Where they intersect is weight in grams. For example, 1 lb 4 oz = 567 g.

Conversion of Fahrenheit to Celsius

Celsius	Fahrenheit	Celsius	Fahrenheit	Celsius	Fahrenheit
34.0	93.2	37.0	98.6	40.0	104.0
34.2	93.6	37.2	99.0	40.2	104.4
34.4	93.9	37.4	99.3	40.4	104.7
34.6	94.3	37.6	99.7	40.6	105.2
34.8	94.6	37.8	100.0	40.8	105.4
35.0	95.0	38.0	100.4	41.0	105.9
35.2	95.4	38.2	100.8	41.2	106.1
35.4	95.7	38.4	101.1	41.4	106.5
35.6	96.1	38.6	101.5	41.6	106.8
35.8	96.4	38.8	101.8	41.8	107.2
36.0	96.8	39.0	102.2	42.0	107.6
36.2	97.2	39.2	102.6	42.2	108.0
36.4	97.5	39.4	102.9	42.4	108.3
36.6	97.9	39.6	103.3	42.6	108.7
36.8	98.2	39.8	103.6	42.8	109.0

(° C) × (9/5) + 32 = ° F.
(° F − 32) × (5/9) = ° C.

Calculation of body mass index (BMI) is recommended by the National Heart, Lung, and Blood Institute as a practical means of assessing body fat. Persons with a BMI of 18.5 to 24.9 are considered to be of normal weight. Those with a BMI of 25.0 to 29.9 are overweight. Patients with a BMI of 30.0 to 34.9 or 35.0 to 39.9 are in obesity class I or II, respectively; and those with a BMI of 40 and over are considered extremely obese (obesity class III).

From National Heart, Lung, and Blood Institute (2008). *Clinical guidelines on the identification, evaluation, and treatment of overweight and obesity in adults: The Evidence Report.* Bethesda, MD: National Institutes of Health.

Appendix F Standard Laboratory Values

Pregnant and Nonpregnant Women

Values	Nonpregnant	Pregnant
Hematologic		
Complete blood count (CBC)		
Hemoglobin, g/dL	12–16*	11.5–14*
Hematocrit, PCV, %	37–47	32–42
Red cell volume, mL	1600	1900
Plasma volume, mL	2400	3700
Red blood cell count, million/mm^3	4–5.5	3.75–5.0
White blood cells, total per mm^3	4500–10,000	5000–15,000
Polymorphonuclear cells, %	54–62	60–85
Lymphocytes, %	38–46	15–40
Erythrocyte sedimentation rate, mm/h	≤0–20	30–90
MCHC, g/dL packed RBCs (mean corpuscular hemoglobin concentration)	30–36	No change
MCH (mean corpuscular hemoglobin per picogram)	29–32	No change
MCV/μm^3 (mean corpuscular volume per cubic micrometer)	82–96	No change
Blood Coagulation and Fibrinolytic Activity†		
Factors VII, VIII, IX, X		Increase in pregnancy, return to normal in early puerperium; factor VIII increases during and immediately after delivery
Factors XI, XIII		Decrease in pregnancy
Prothrombin time (protime)	60–70 sec	Slight decrease in pregnancy
Partial thromboplastin time (PTT)	12–14 sec	Slight decrease in pregnancy and again decrease during second and third stage of labor (indicates clotting at placental site)
Bleeding time	1–3 min (Duke) 2–4 min (Ivy)	No appreciable change
Coagulation time	6–10 min (Lee/White)	No appreciable change
Platelets	150,000 to 350,000/mm^3	No significant change until 3–5 days after delivery, then marked increase (may predispose woman to thrombosis) and gradual return to normal
Fibrinolytic activity		Decreases in pregnancy, then abrupt return to normal (protection against thromboembolism)
Fibrinogen	250 mg/dL	400 mg/dL
Mineral and Vitamin Concentrations		
Serum iron, μg	75–150	65–120
Total iron-binding capacity, μg	250–450	300–500
Iron saturation, %	30–40	15–30
Vitamin B_{12}, folic acid, ascorbic acid	Normal	Moderate decrease
Serum protein		
Total, g/dL	6.7–8.3	5.5–7.5
Albumin, g/dL	3.5–5.5	3.0–5.0
Globulin, total, g/dL	2.3–3.5	3.0–4.0
Blood sugar		
Fasting, mg/dL	70–80	65
2-hour postprandial, mg/dL	60–110	Under 140 after a 100-g carbohydrate meal is considered normal

Values	Nonpregnant	Pregnant
Cardiovascular		
Blood pressure, mm Hg	120/80‡	114/65
Peripheral resistance, dyne/s · cm^{-5}	120	100
Venous pressure, cm H_2O		
Femoral	9	24
Antecubital	8	8
Pulse, rate/min	70	80
Stroke volume, mL	65	75
Cardiac output, L/min	4.5	6
Circulation time (arm-tongue), sec	15–16	12–14
Blood volume, mL		
Whole blood	4000	5600
Plasma	2400	3700
Red blood cells	1600	1900
Plasma renin, units/L	3–10	10–80
Chest radiograph studies		
Transverse diameter of heart	—	1–2 cm increase
Left border of heart	—	Straightened
Cardiac volume	—	70-mL increase
Electrocardiogram	—	15° left axis deviation
V_1 and V_2	—	Inverted T-wave
kV_4	—	Low T
III	—	Q + inverted T
aVr	—	Small Q
Hepatic		
Bilirubin total	Not more than 1 mg/dL	Unchanged
Cephalin flocculation	Up to 2+ in 48 h	Positive in 10%
Serum cholesterol	110–300 mg/dL	↑ 60% from 16–32 weeks of pregnancy; remains at this level until after delivery
Thymol turbidity	0–4 units	Positive in 15%
Serum alkaline phosphatase	2–4.5 units (Bodansky)	↑ from week 12 of pregnancy to 6 weeks after delivery
Serum lactate dehydrogenase		Unchanged
Serum glutamic-oxaloacetic transaminase		Unchanged
Serum globulin albumin	1.5–3.0 g/dL 4.5–5.3 g/dL	↑ slight ↓ 3.0 g by late pregnancy
A/G ratio		Decreased
α_2-globulin		Increased
β-globulin		Increased
Serum cholinesterase		Decreased
Leucine aminopeptidase		Increased
Sulfobromophthalein (5 mg/kg)	5% dye or less in 45 min	Somewhat decreased
Renal		
Bladder capacity	1300 mL	1500 mL
Renal plasma flow (RPF), mL/min	490–700	Increase by 25%, to 612–875
Glomerular filtration rate (GFR), mL/min	105–132	Increase by 50%, to 160–198
Nonprotein nitrogen (NPN), mg/dL	25–40	Decreases
Blood urea nitrogen (BUN), mg/dL	20–25	Decreases
Serum creatinine, mg/kg/24 hr	20–22	Decreases
Serum uric acid, mg/kg/24 hr	257–750	Decreases
Urine glucose	Negative	Present in 20% of gravidas
Intravenous pyelogram (IVP)	Normal	Slight to moderate hydroureter and hydronephrosis; right kidney larger than left kidney

(continued)

Pregnant and Nonpregnant Women (continued)

Values	Nonpregnant	Pregnant
Miscellaneous		
Total thyroxine concentration	5–12 μg/dL thyroxine	↑ 9–16 μg/dL thyroxine (however, unbound thyroxine not greatly increased)
Ionized calcium		Relatively unchanged
Aldosterone		↑ 1 mg/24 hr by third trimester
Dehydroisoandrosterone	Plasma clearance 6–8 L/24 hr	↑ plasma clearance tenfold to twentyfold

* At sea level. Permanent residents of higher levels (e.g., Denver) require higher levels of hemoglobin.
From Scott, J. R., et al. (2007). *Danforth's obstetrics and gynecology.* Philadelphia: Lippincott Williams & Wilkins.
† Pregnancy represents a hypercoagulable state.
‡ For the woman about 20 years of age.
10 years of age: 103/70.
30 years of age: 123/82.
40 years of age: 126/84.

INFANTS AND CHILDREN

The following reference values for laboratory tests represent guidelines only, since the reference range from one institution to the next will vary, depending on the laboratory method used. To simplify the interpretation of laboratory results reported in International System (SI) units, conversion factors (from SI to conventional units) are provided. SI base units are the gram (g), the liter (L), and the mole (mol). Other abbreviations used throughout this table are listed below.

SI Prefixes

Factor	Prefix	Symbol
10^{3}	kilo	k
10^{-1}	deci	d
10^{-2}	centi	c
10^{-3}	milli	m
10^{-6}	micro	μ
10^{-9}	nano	n
10^{-12}	pico	p
10^{-15}	femto	f

Abbreviations

CI	confidence interval
D	day
F	female
H	hour
Hb	hemoglobin
M	male
MCHC	mean corpuscular hemoglobin concentration
MCV	mean corpuscular value
mEq	milliequivalent
min	minute
RBC	red blood cell
s	second
SD	standard deviation
U	unit
WBC	white blood cell
yr	year

Blood

Test	SI Reference Range	Conversion Factor	Conventional Units Reference Range
Adrenocorticotropic hormone (ACTH)	Cord: 130–160 ng/L 1st week: 100–140 Adult 0800 h: 25–100 1800 h: <50		Cord: 130–160 pg/mL 1st week: 100–140 Adult 0800 h: 25–100 1800 h: <50
Alanine aminotransferase (ALT)	<1 yr: 5–28 U/L >1 yr: 820		Same as SI

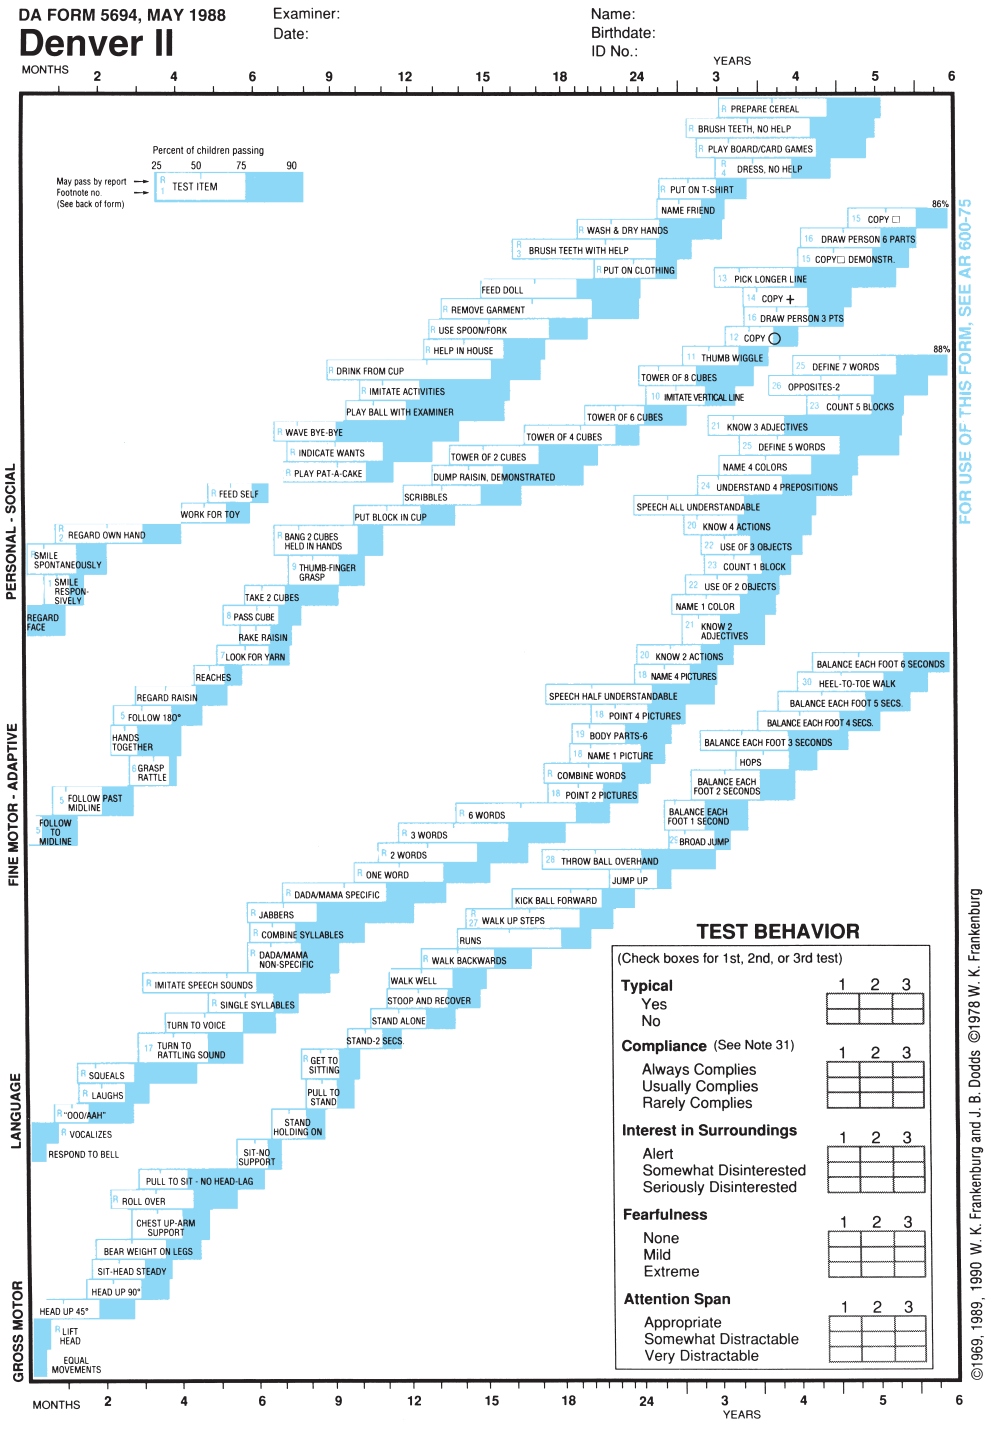
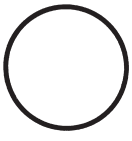
H Denver II



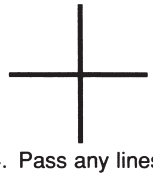
DIRECTIONS FOR ADMINISTRATION

1. Try to get child to smile by smiling, talking, or waving. Do not touch him/her.
2. Child must stare at hand several seconds.
3. Parent may help guide toothbrush and put toothpaste on brush.
4. Child does not have to be able to tie shoes or button/zip in the back.
5. Move yarn slowly in an arc from one side to the other, about 8" above child's face.
6. Pass if child grasps rattle when it is touched to the backs or tips of fingers.
7. Pass if child tries to see where yarn went. Yarn should be dropped quickly from sight from tester's hand without arm movement.
8. Child must transfer cube from hand to hand without help of body, mouth, or table.
9. Pass if child picks up raisin with any part of thumb and finger.
10. Line can vary only 30 degrees or less from tester's line.
11. Make a fist with thumb pointing upward and wiggle only the thumb. Pass if child imitates and does not move any fingers other than the thumb.

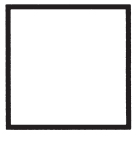


12. Pass any enclosed form. Fail continuous round motions.

13. Which line is longer? (Not bigger.) Turn paper upside down and repeat. (pass 3 of 3 or 5 of 6)



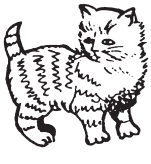
14. Pass any lines crossing near midpoint.

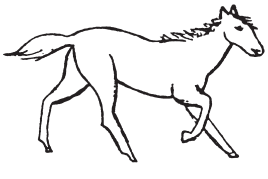


15. Have child copy first. If failed, demonstrate.

When giving items 12, 14, and 15, do not name the forms. Do not demonstrate 12 and 14.

16. When scoring, each pair (2 arms, 2 legs, etc.) counts as one part.
17. Place one cube in cup and shake gently near child's ear, but out of sight. Repeat for other ear.
18. Point to picture and have child name it. (No credit is given for sounds only.)
    If less than 4 pictures are named correctly, have child point to picture as each is named by tester.





19. Using doll, tell child: Show me the nose, eyes, ears, mouth, hands, feet, tummy, hair. Pass 6 of 8.
20. Using pictures, ask child: Which one flies?... says meow?... talks?... barks?... gallops? Pass 2 of 5, 4 of 5.
21. Ask child: What do you do when you are cold?... tired?... hungry? Pass 2 of 3, 3 of 3.
22. Ask child: What do you do with a cup? What is a chair used for? What is a pencil used for? Action words must be included in answers.
23. Pass if child correctly places and says how many blocks are on paper. (1, 5).
24. Tell child: Put block **on** table; **under** table; **in front of** me, **behind** me. Pass 4 of 4. (Do not help child by pointing, moving head or eyes.)
25. Ask child: What is a ball?... lake?... desk?... house?... banana?... curtain?... fence?... ceiling? Pass if defined in terms of use, shape, what it is made of, or general category (such as banana is fruit, not just yellow). Pass 5 of 8, 7 of 8.
26. Ask child: If a horse is big, a mouse is __? If fire is hot, ice is __? If the sun shines during the day, the moon shines during the __? Pass 2 of 3.
27. Child may use wall or rail only, not person. May not crawl.
28. Child must throw ball overhand 3 feet to within arm's reach of tester.
29. Child must perform standing broad jump over width of test sheet (8 1/2 inches).
30. Tell child to walk forward,  heel within 1 inch of toe. Tester may demonstrate. Child must walk 4 consecutive steps.
31. In the second year, half of normal children are non-compliant.

OBSERVATIONS:

Appendix

Standard Infection Precautions

Standard precautions are specific steps to prevent the transmission of infectious agents. Use Standard Precautions, or the equivalent, for the care of all patients.

A. Handwashing

(1) Wash hands after touching blood, body fluids, secretions, excretions, and contaminated items, whether or not gloves are worn. Wash hands immediately after gloves are removed, between patient contacts, and when otherwise indicated to avoid transfer of microorganisms to other patients or environments. It may be necessary to wash hands between tasks and procedures on the same patient to prevent cross-contamination of different body sites.

(2) Use a plain (nonantimicrobial) soap for routine handwashing.

(3) Use an antimicrobial agent or a waterless antiseptic agent for specific circumstances (e.g., control of outbreaks or hyperendemic infections), as defined by the infection control program.

B. Gloves

Wear gloves (clean, nonsterile gloves are adequate) when touching blood, body fluids, secretions, excretions, and contaminated items. Put on clean gloves just before touching mucous membranes and nonintact skin. Change gloves between tasks and procedures on the same patient after contact with material that may contain a high concentration of microorganisms. Remove gloves promptly after use, before touching noncontaminated items and environmental surfaces, and before going to another patient, and wash hands immediately to avoid transfer of microorganisms to other patients or environments.

C. Mask, Eye Protection, Face Shield

Wear a mask and eye protection or a face shield to protect mucous membranes of the eyes, nose, and mouth during procedures and patient-care activities that are likely to generate splashes or sprays of blood, body fluids, secretions, and excretions.

D. Gown

Wear a gown (a clean, nonsterile gown is adequate) to protect skin and to prevent soiling of clothing during procedures and patient-care activities that are likely to generate splashes or sprays of blood, body fluids, secretions, or excretions. Select a gown that is appropriate for the activity and amount of fluid likely to be encountered. Remove a soiled gown as promptly as possible, and wash hands to avoid transfer of microorganisms to other patients or environments.

E. Patient-Care Equipment

Handle used patient-care equipment soiled with blood, body fluids, secretions, and excretions in a manner that prevents skin and mucous membrane exposures, contamination of clothing, and transfer of microorganisms to other patients and environments. Ensure that reusable equipment is not used for the care of another patient until it has been cleaned and reprocessed appropriately. Ensure that single-use items are discarded properly.

F. Environmental Control

Ensure that the hospital has adequate procedures for the routine care, cleaning, and disinfection of environmental surfaces, beds, bedrails, bedside equipment, and other frequently touched surfaces, and ensure that these procedures are being followed.

G. Linen

Handle, transport, and process used linen soiled with blood, body fluids, secretions, and excretions in a manner that prevents skin and mucous membrane exposures and contamination of clothing, and that avoids transfer of microorganisms to other patients and environments.

H. Occupational Health and Bloodborne Pathogens

(1) Take care to prevent injuries when using needles, scalpels, and other sharp instruments or devices; when handling sharp instruments after procedures; when cleaning used instruments; and when disposing of used needles. Never recap used needles, or otherwise manipulate them using both hands, or use any other technique that involves directing the point of a needle toward any part of the body; rather, use either a one-handed "scoop" technique or a mechanical device designed for holding the needle sheath. Do not remove used needles from disposable syringes by hand, and do not bend, break, or otherwise manipulate used needles by hand. Place used disposable syringes and needles, scalpel blades, and other sharp items in appropriate puncture-resistant containers, which are located as close as practical to the area in which the items were used, and place reusable syringes and needles in a puncture-resistant container for transport to the reprocessing area.

(2) Use mouthpieces, resuscitation bags, or other ventilation devices as an alternative to mouth-to-mouth resuscitation methods in areas where the need for resuscitation is predictable.

I. Patient Placement

Place a patient who contaminates the environment or who does not (or cannot be expected to) assist in maintaining appropriate hygiene or environmental control in a private room. If a private room is not available, consult with infection control professionals regarding patient placement or other alternatives.

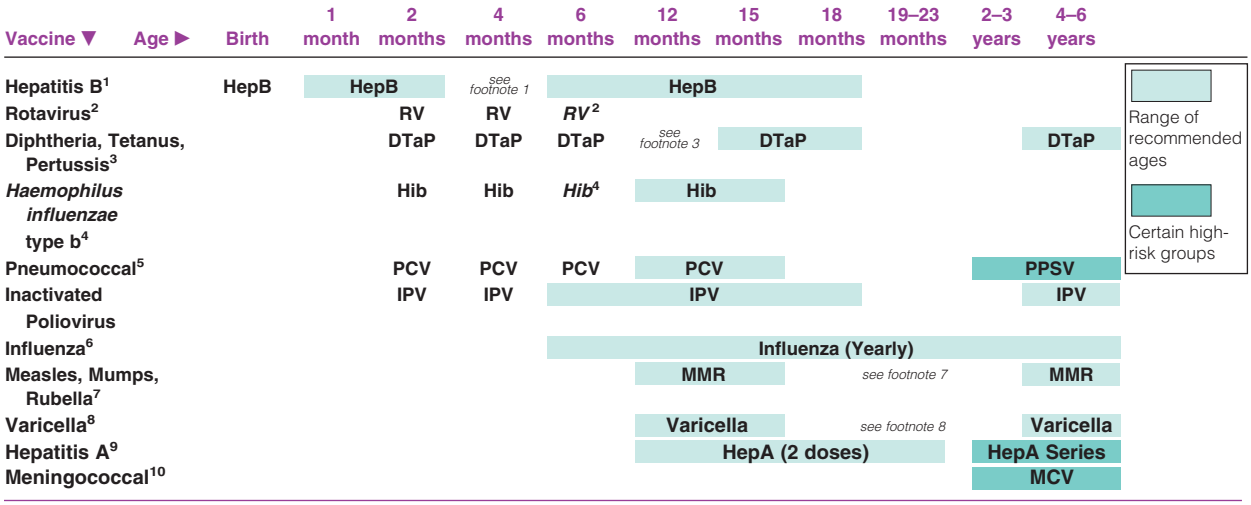
From Guideline for isolation precautions in hospitals developed by the Centers for Disease Control and Prevention and the Hospital Infection Control Practices Advisory Committee (HICPAC), update 2004.

Appendix J

Recommended Childhood and Adolescent Immunization Schedule, United States, 2009

Recommended Immunization Schedule for Persons Aged 0 Through 6 Years—United States • 2009

(For those who fall behind or start late, see the catch-up schedule)



This schedule indicates the recommended ages for routine administration of currently licensed vaccines, as of December 1, 2008, for children aged 0 through 6 years. Any dose not administered at the recommended age should be administered at a subsequent visit, when indicated and feasible. Licensed combination vaccines may be used whenever any component of the combination is indicated and other components are not contraindicated and if approved by the Food and Drug Administration for that dose of the series. Providers should consult the relevant Advisory Committee on Immunization Practices statement for detailed recommendations, including high-risk conditions: http://www.cdc.gov/vaccines/pubs/acip-list.htm. Clinically significant adverse events that follow immunization should be reported to the Vaccine Adverse Event Reporting System (VAERS). Guidance about how to obtain and complete a VAERS form is available at http://www.vaers.hhs.gov or by telephone, 800-822-7967.

1. Hepatitis B vaccine (HepB). ***(Minimum age: birth)***

At birth:

- Administer monovalent HepB to all newborns before hospital discharge.
- If mother is hepatitis B surface antigen (HBsAg)-positive, administer HepB and 0.5 mL of hepatitis B immune globulin (HBIG) within 12 hours of birth.
- If mother's HBsAg status is unknown, administer HepB within 12 hours of birth. Determine mother's HBsAg status as soon as possible and, if HBsAg-positive, administer HBIG (no later than age 1 week).

After the birth dose:

- The HepB series should be completed with either monovalent HepB or a combination vaccine containing HepB. The second dose should be administered at age 1 or 2 months. The final dose should be administered no earlier than age 24 weeks.
- Infants born to HBsAg-positive mothers should be tested for HBsAg and antibody to HBsAg (anti-HBs) after completion of at least 3 doses of the HepB series, at age 9 through 18 months (generally at the next well-child visit).

4-month dose:

- Administration of 4 doses of HepB to infants is permissible when combination vaccines containing HepB are administered after the birth dose.

2. Rotavirus vaccine (RV). ***(Minimum age: 6 weeks)***

- Administer the first dose at age 6 through 14 weeks (maximum age: 14 weeks 6 days). Vaccination should not be initiated for infants aged 15 weeks or older (i.e., 15 weeks 0 days or older).
- Administer the final dose in the series by age 8 months 0 days.
- If Rotarix® is administered at ages 2 and 4 months, a dose at 6 months is not indicated.

3. Diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP). ***(Minimum age: 6 weeks)***

- The fourth dose may be administered as early as age 12 months, provided at least 6 months have elapsed since the third dose.
- Administer the final dose in the series at age 4 through 6 years.

4. *Haemophilus influenzae* type b conjugate vaccine (Hib). ***(Minimum age: 6 weeks)***

- If PRP-OMP (PedvaxHIB® or Comvax® [HepB-Hib]) is administered at ages 2 and 4 months, a dose at age 6 months is not indicated.
- TriHiBit® (DTaP/Hib) should not be used for doses at ages 2, 4, or 6 months but can be used as the final dose in children aged 12 months or older.

5. Pneumococcal vaccine. ***(Minimum age: 6 weeks for pneumococcal conjugate vaccine [PCV]; 2 years for pneumococcal polysaccharide vaccine [PPSV])***

- PCV is recommended for all children aged younger than 5 years. Administer 1 dose of PCV to all healthy children aged 24 through 59 months who are not completely vaccinated for their age.
- Administer PPSV to children aged 2 years or older with certain underlying medical conditions (see *MMWR* 2000;49[No. RR-9]), including a cochlear implant.

6. Influenza vaccine. ***(Minimum age: 6 months for trivalent inactivated influenza vaccine [TIV]; 2 years for live, attenuated influenza vaccine [LAIV])***

- Administer annually to children aged 6 months through 18 years.
- For healthy nonpregnant persons (i.e., those who do not have underlying medical conditions that predispose them to influenza complications) aged 2 through 49 years, either LAIV or TIV may be used.
- Children receiving TIV should receive 0.25 mL if aged 6 through 35 months or 0.5 mL if aged 3 years or older.
- Administer 2 doses (separated by at least 4 weeks) to children aged younger than 9 years who are receiving influenza vaccine for the first time or who were vaccinated for the first time during the previous influenza season but only received 1 dose.

7. Measles, mumps, and rubella vaccine (MMR). ***(Minimum age: 12 months)***

- Administer the second dose at age 4 through 6 years. However, the second dose may be administered before age 4, provided at least 28 days have elapsed since the first dose.

8. Varicella vaccine. ***(Minimum age: 12 months)***

- Administer the second dose at age 4 through 6 years. However, the second dose may be administered before age 4, provided at least 3 months have elapsed since the first dose.
- For children aged 12 months through 12 years the minimum interval between doses is 3 months. However, if the second dose was administered at least 28 days after the first dose, it can be accepted as valid.

9. Hepatitis A vaccine (HepA). ***(Minimum age: 12 months)***

- Administer to all children aged 1 year (i.e., aged 12 through 23 months). Administer 2 doses at least 6 months apart.
- Children not fully vaccinated by age 2 years can be vaccinated at subsequent visits.
- HepA also is recommended for children older than 1 year who live in areas where vaccination programs target older children or who are at increased risk of infection. See *MMWR* 2006;55(No. RR-7).

10. Meningococcal vaccine. ***(Minimum age: 2 years for meningococcal conjugate vaccine [MCV] and for meningococcal polysaccharide vaccine [MPSV])***

- Administer MCV to children aged 2 through 10 years with terminal complement component deficiency, anatomic or functional asplenia, and certain other high-risk groups. See *MMWR* 2005;54(No. RR-7).
- Persons who received MPSV 3 or more years previously and who remain at increased risk for meningococcal disease should be revaccinated with MCV.

The Recommended Immunization Schedules for Persons Aged 0 Through 18 Years are approved by the Advisory Committee on Immunization Practices (www.cdc.gov/vaccines/recs/acip), the American Academy of Pediatrics (http://www.aap.org), and the American Academy of Family Physicians (http://www.aafp.org).

Department of Health and Human Services • Centers for Disease Control and Prevention

Recommended Immunization Schedule for Persons Aged 7 Through 18 Years—United States • 2009

(For those who fall behind or start late, see the schedule below and the catch-up schedule)

Vaccine ▼ Age ►	7–10 years	11–12 years	13–18 years
Tetanus, Diphtheria, Pertussis[1]	*see footnote 1*	Tdap	Tdap
Human Papillomavirus[2]	*see footnote 2*	HPV (3 doses)	HPV Series
Meningococcal[3]	MCV	MCV	MCV
Influenza[4]	Influenza (Yearly)		
Pneumococcal[5]	PPSV		
Hepatitis A[6]	HepA Series		
Hepatitis B[7]	HepB Series		
Inactivated Poliovirus[8]	IPV Series		
Measles, Mumps, Rubella[9]	MMR Series		
Varicella[10]	Varicella Series		

Range of recommended ages

Catch-up immunization

Certain high-risk groups

This schedule indicates the recommended ages for routine administration of currently licensed vaccines, as of December 1, 2008, for children aged 7 through 18 years. Any dose not administered at the recommended age should be administered at a subsequent visit, when indicated and feasible. Licensed combination vaccines may be used whenever any component of the combination is indicated and other components are not contraindicated and if approved by the Food and Drug Administration for that dose of the series. Providers should consult the relevant Advisory Committee on Immunization Practices statement for detailed recommendations, including high risk conditions: http://www.cdc.gov/vaccines/pubs/acip-list.htm. Clinically significant adverse events that follow immunization should be reported to the Vaccine Adverse Event Reporting System (VAERS). Guidance about how to obtain and complete a VAERS form is available at http://www.vaers.hhs.gov or by telephone, 800-822-7967.

1. **Tetanus and diphtheria toxoids and acellular pertussis vaccine (Tdap).** ***(Minimum age: 10 years for BOOSTRIX® and 11 years for ADACEL®)***
   - Administer at age 11 or 12 years for those who have completed the recommended childhood DTP/DTaP vaccination series and have not received a tetanus and diphtheria toxoid (Td) booster dose.
   - Persons aged 13 through 18 years who have not received Tdap should receive a dose.
   - A 5-year interval from the last Td dose is encouraged when Tdap is used as a booster dose; however, a shorter interval may be used if pertussis immunity is needed.
2. **Human papillomavirus vaccine (HPV).** ***(Minimum age: 9 years)***
   - Administer the first dose to females at age 11 or 12 years.
   - Administer the second dose 2 months after the first dose and the third dose 6 months after the first dose (at least 24 weeks after the first dose).
   - Administer the series to females at age 13 through 18 years if not previously vaccinated.
3. **Meningococcal conjugate vaccine (MCV).**
   - Administer at age 11 or 12 years, or at age 13 through 18 years if not previously vaccinated.
   - Administer to previously unvaccinated college freshmen living in a dormitory.
   - MCV is recommended for children aged 2 through 10 years with terminal complement component deficiency, anatomic or functional asplenia, and certain other groups at high risk. See *MMWR* 2005;54(No. RR-7).
   - Persons who received MPSV 5 or more years previously and remain at increased risk for meningococcal disease should be revaccinated with MCV.
4. **Influenza vaccine.**
   - Administer annually to children aged 6 months through 18 years.
   - For healthy nonpregnant persons (i.e., those who do not have underlying medical conditions that predispose them to influenza complications) aged 2 through 49 years, either LAIV or TIV may be used.
   - Administer 2 doses (separated by at least 4 weeks) to children aged younger than 9 years who are receiving influenza vaccine for the first time or who were vaccinated for the first time during the previous influenza season but only received 1 dose.
5. **Pneumococcal polysaccharide vaccine (PPSV).**
   - Administer to children with certain underlying medical conditions (see *MMWR* 1997;46[No. RR-8]), including a cochlear implant. A single revaccination should be administered to children with functional or anatomic asplenia or other immunocompromising condition after 5 years.
6. **Hepatitis A vaccine (HepA).**
   - Administer 2 doses at least 6 months apart.
   - HepA is recommended for children older than 1 year who live in areas where vaccination programs target older children or who are at increased risk of infection. See *MMWR* 2006;55(No. RR-7).
7. **Hepatitis B vaccine (HepB).**
   - Administer the 3-dose series to those not previously vaccinated.
   - A 2-dose series (separated by at least 4 months) of adult formulation Recombivax HB® is licensed for children aged 11 through 15 years.
8. **Inactivated poliovirus vaccine (IPV).**
   - For children who received an all-IPV or all-oral poliovirus (OPV) series, a fourth dose is not necessary if the third dose was administered at age 4 years or older.
   - If both OPV and IPV were administered as part of a series, a total of 4 doses should be administered, regardless of the child's current age.
9. **Measles, mumps, and rubella vaccine (MMR).**
   - If not previously vaccinated, administer 2 doses or the second dose for those who have received only 1 dose, with at least 28 days between doses.
10. **Varicella vaccine.**
    - For persons aged 7 through 18 years without evidence of immunity (see *MMWR* 2007;56[No. RR-4]), administer 2 doses if not previously vaccinated or the second dose if they have received only 1 dose.
    - For persons aged 7 through 12 years, the minimum interval between doses is 3 months. However, if the second dose was administered at least 28 days after the first dose, it can be accepted as valid.
    - For persons aged 13 years and older, the minimum interval between doses is 28 days.

The Recommended Immunization Schedules for Persons Aged 0 Through 18 Years are approved by the Advisory Committee on Immunization Practices (www.cdc.gov/vaccines/recs/acip), the American Academy of Pediatrics (http://www.aap.org), and the American Academy of Family Physicians (http://www.aafp.org).

DEPARTMENT OF HEALTH AND HUMAN SERVICES • CENTERS FOR DISEASE CONTROL AND PREVENTION

Catch-up Immunization Schedule for Persons Aged 4 Months Through 18 Years Who Start Late or Who Are More Than 1 Month Behind—United States • 2009

The table below provides catch-up schedules and minimum intervals between doses for children whose vaccinations have been delayed. A vaccine series does not need to be restarted, regardless of the time that has elapsed between doses. Use the section appropriate for the child's age.

CATCH-UP SCHEDULE FOR PERSONS AGED 4 MONTHS THROUGH 6 YEARS

VACCINE	Minimum Age for Dose 1	Minimum Interval Between Doses			
		Dose 1 to Dose 2	Dose 2 to Dose 3	Dose 3 to Dose 4	Dose 4 to Dose 5
Hepatitis B[1]	**Birth**	**4 weeks**	**8 weeks** (and at least 16 weeks after first dose)		
Rotavirus[2]	**6 wks**	**4 weeks**	**4 weeks**[2]		
Diphtheria, Tetanus, Pertussis[3]	**6 wks**	**4 weeks**	**4 weeks**	**6 months**	**6 months**[3]
***Haemophilus influenzae* type b**[4]	**6 wks**	**4 weeks** if first dose administered at younger than age 12 months **8 weeks (as final dose)** if first dose administered at at age 12–14 months **No further doses needed** if first dose administered at age 15 months or older	**4 weeks**[4] if current age is younger than 12 months **8 weeks (as final dose)**[4] if current age is 12 months or older and second dose administered at younger than age 15 months **No further doses needed** if previous dose administered at age 15 months or older	**8 weeks (as final dose)** This dose only necessary for children aged 12 months through 59 months who received 3 doses before age 12 months	
Pneumococcal[5]	**6 wks**	**4 weeks** if first dose administered at younger than age 12 months **8 weeks (as final dose for healthy children)** if first dose administered at age 12 months or older or current age 24 through 59 months **No further doses needed** for healthy children if first dose administered at age 24 months or older	**4 weeks** if current age is younger than 12 months **8 weeks (as final dose for healthy children)** if current age is 12 months or older **No further doses needed** for healthy children if previous dose administered at age 24 months or older	**8 weeks (as final dose)** This dose only necessary for children aged 12 months through 59 months who received 3 doses before age 12 months or for high-risk children who received 3 doses at any age	

1. **Hepatitis B vaccine (HepB).**
   - Administer the 3-dose series to those not previously vaccinated.
   - A 2-dose series (separated by at least 4 months) of adult formulation Recombivax HB® is licensed for children aged 11 through 15 years.
2. **Rotavirus vaccine (RV).**
   - The maximum age for the first dose is 14 weeks 6 days. Vaccination should not be initiated for infants aged 15 weeks or older (i.e., 15 weeks 0 days or older).
   - Administer the final dose in the series by age 8 months 0 days.
   - If Rotarix® was administered for the first and second doses, a third dose is not indicated.
3. **Diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP).**
   - The fifth dose is not necessary if the fourth dose was administered at age 4 years or older.
4. ***Haemophilus influenzae* type b conjugate vaccine (Hib).**
   - Hib vaccine is not generally recommended for persons aged 5 years or older. No efficacy data are available on which to base a recommendation concerning use of Hib vaccine for older children and adults. However, studies suggest good immunogenicity in persons who have sickle cell disease, leukemia, or HIV infection, or who have had a splenectomy; administering 1 dose of Hib vaccine to these persons is not contraindicated.
   - If the first 2 doses were PRP-OMP (PedvaxHIB® or Comvax®), and administered at age 11 months or younger, the third (and final) dose should be administered at age 12 through 15 months and at least 8 weeks after the second dose.
   - If the first dose was administered at age 7 through 11 months, administer 2 doses separated by 4 weeks and a final dose at age 12 through 15 months.
5. **Pneumococcal vaccine.**
   - Administer 1 dose of pneumococcal conjugate vaccine (PCV) to all healthy children aged 24 through 59 months who have not received at least 1 dose of PCV on or after age 12 months.

(continued)

Catch-up Immunization Schedule for Persons Aged 4 Months Through 18 Years Who Start Late or Who Are More Than 1 Month Behind—United States • 2009 (continued)

CATCH-UP SCHEDULE FOR PERSONS AGED 4 MONTHS THROUGH 6 YEARS					
VACCINE	Minimum Age for Dose 1	Minimum Interval Between Doses: Dose 1 to Dose 2	Dose 2 to Dose 3	Dose 3 to Dose 4	Dose 4 to Dose 5
Inactivated Poliovirus[6]	**6 wks**	**4 weeks**	**4 weeks**	**4 weeks**[6]	
Measles, Mumps, Rubella[7]	**12 mos**	**4 weeks**			
Varicella[8]	**12 mos**	**3 months**			
Hepatitis A[9]	**12 mos**	**6 months**			

CATCH-UP SCHEDULE FOR PERSONS AGED 7 THROUGH 18 YEARS					
Tetanus, Diphtheria/ Tetanus, Diphtheria, Pertussis[10]	**7 yrs**[10]	**4 weeks**	**4 weeks** if first dose administered at younger than age 12 months **6 months** if first dose administered at age 12 months or older	**6 months** if first dose administered at younger than age 12 months	
Human Papillomavirus[11]	**9 yrs**	**Routine dosing intervals are recommended**[11]			
Hepatitis A[9]	**12 mos**	**6 months**			
Hepatitis B[1]	**Birth**	**4 weeks**	**8 weeks** (and at least 16 weeks after first dose)		
Inactivated Poliovirus[6]	**6 wks**	**4 weeks**	**4 weeks**	**4 weeks**[6]	
Measles, Mumps, Rubella[7]	**12 mos**	**4 weeks**			
Varicella[8]	**12 mos**	**3 months** if the person is younger than age 13 years **4 weeks** if the person is aged 13 years or older			

- For children aged 24 through 59 months with underlying medical conditions, administer 1 dose of PCV if 3 doses were received previously or administer 2 doses of PCV at least 8 weeks apart if fewer than 3 doses were received previously.
- Administer pneumococcal polysaccharide vaccine (PPSV) to children aged 2 years or older with certain underlying medical conditions (see *MMWR* 2000;49[No. RR-9]), including a cochlear implant, at least 8 weeks after the last dose of PCV.

6. Inactivated poliovirus vaccine (IPV).
- For children who received an all-IPV or all-oral poliovirus (OPV) series, a fourth dose is not necessary if the third dose was administered at age 4 years or older.
- If both OPV and IPV were administered as part of a series, a total of 4 doses should be administered, regardless of the child's current age.

7. Measles, mumps, and rubella vaccine (MMR).
- Administer the second dose at age 4 through 6 years. However, the second dose may be administered before age 4, provided at least 28 days have elapsed since the first dose.
- If not previously vaccinated, administer 2 doses with at least 28 days between doses.

8. Varicella vaccine.
- Administer the second dose at age 4 through 6 years. However, the second dose may be administered before age 4, provided at least 3 months have elapsed since the first dose.
- For persons aged 12 months through 12 years, the minimum interval between doses is 3 months. However, if the second dose was administered at least 28 days after the first dose, it can be accepted as valid.
- For persons aged 13 years and older, the minimum interval between doses is 28 days.

9. Hepatitis A vaccine (HepA).
- HepA is recommended for children older than 1 year who live in areas where vaccination programs target older children or who are at increased risk of infection. See *MMWR* 2006;55(No. RR-7).

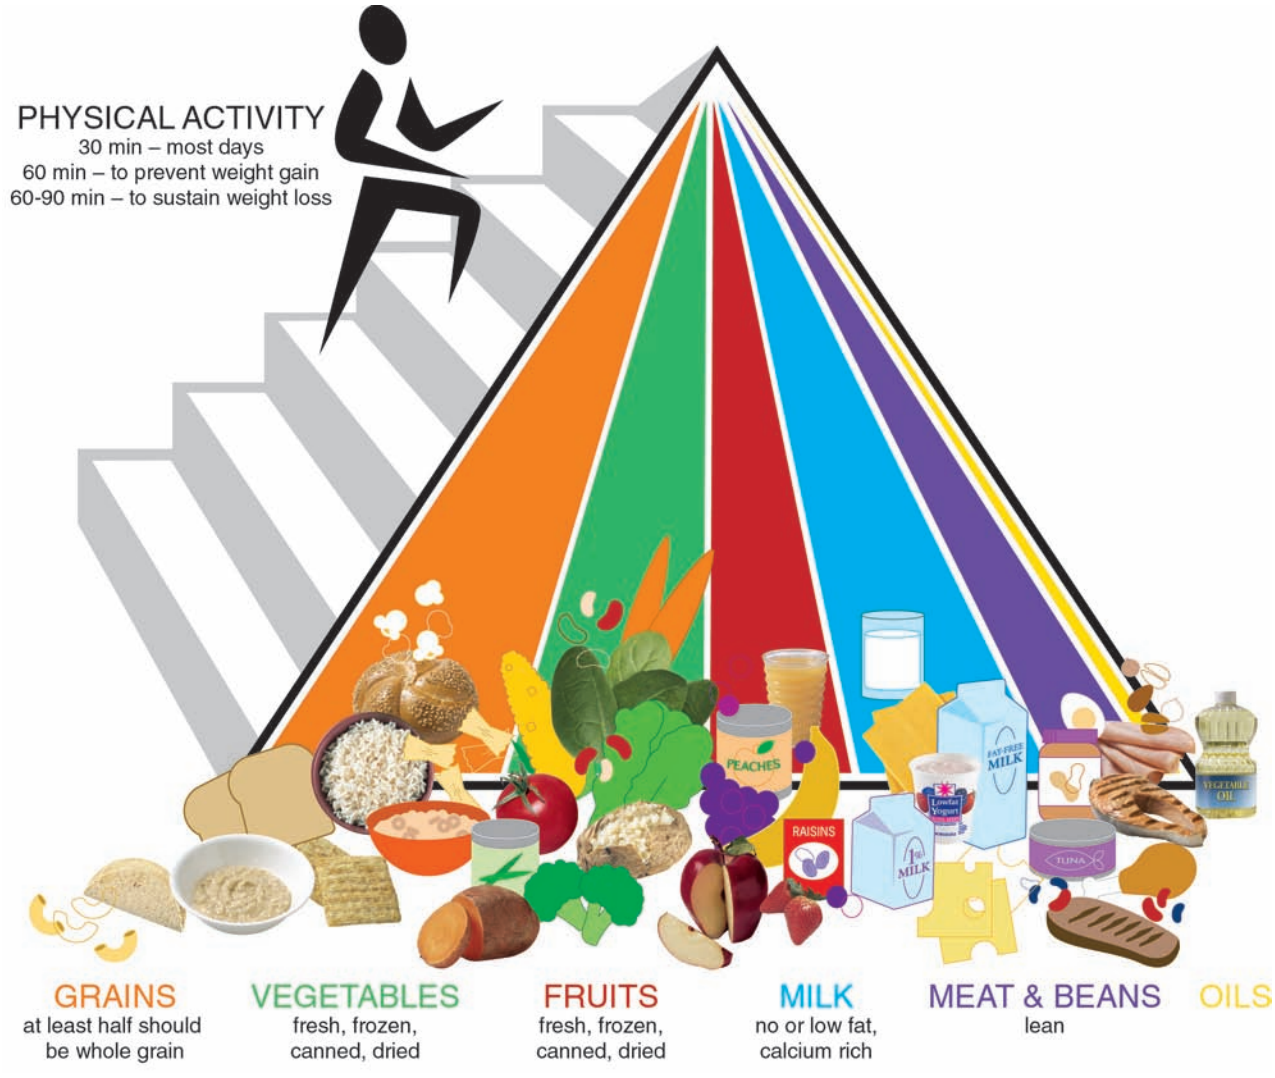
10. Tetanus and diphtheria toxoids vaccine (Td) and tetanus and diphtheria toxoids and acellular pertussis vaccine (Tdap).
- Doses of DTaP are counted as part of the Td/Tdap series
- Tdap should be substituted for a single dose of Td in the catch-up series or as a booster for children aged 10 through 18 years; use Td for other doses.

11. Human papillomavirus vaccine (HPV).
- Administer the series to females at age 13 through 18 years if not previously vaccinated.
- Use recommended routine dosing intervals for series catch-up (i.e., the second and third doses should be administered at 2 and 6 months after the first dose). However, the minimum interval between the first and second doses is 4 weeks. The minimum interval between the second and third doses is 12 weeks, and the third dose should be given at least 24 weeks after the first dose.

Information about reporting reactions after immunization is available online at **http://www.vaers.hhs.gov** or by telephone, **800-822-7967**. Suspected cases of vaccine-preventable diseases should be reported to the state or local health department. Additional information, including precautions and contraindications for immunization, is available from the National Center for Immunization and Respiratory Diseases at **http://www.cdc.gov/vaccines** or telephone, **800-CDC-INFO (800-232-4636).**

Appendix

K The Food Guide Pyramid



GRAINS Make half your grains whole	VEGETABLES Vary your veggies	FRUITS Focus on fruits	MILK Get your calcium-rich foods	MEAT & BEANS Go lean with protein
Eat at least 3 oz. of whole-grain cereals, breads, crackers, rice, or pasta every day 1 oz. is about 1 slice of bread, about 1 cup of breakfast cereal, or ½ cup of cooked rice, cereal, or pasta	Eat more dark-green veggies like broccoli, spinach, and other dark leafy greens Eat more orange vegetables like carrots and sweetpotatoes Eat more dry beans and peas like pinto beans, kidney beans, and lentils	Eat a variety of fruit Choose fresh, frozen, canned, or dried fruit Go easy on fruit juices	Go low-fat or fat-free when you choose milk, yogurt, and other milk products If you don't or can't consume milk, choose lactose-free products or other calcium sources such as fortified foods and beverages	Choose low-fat or lean meats and poultry Bake it, broil it, or grill it Vary your protein routine – choose more fish, beans, peas, nuts, and seeds
For a 2,000-calorie diet, you need the amounts below from each food group. To find the amounts that are right for you, go to MyPyramid.gov.				
Eat 6 oz. every day	Eat 2½ cups every day	Eat 2 cups every day	Get 3 cups every day; for kids aged 2 to 8, it's 2	Eat 5½ oz. every day

Find your balance between food and physical activity

- Be sure to stay within your daily calorie needs.
- Be physically active for at least 30 minutes most days of the week.
- About 60 minutes a day of physical activity may be needed to prevent weight gain.
- For sustaining weight loss, at least 60 to 90 minutes a day of physical activity may be required.
- Children and teenagers should be physically active for 60 minutes every day, or most days.

Know the limits on fats, sugars, and salt (sodium)

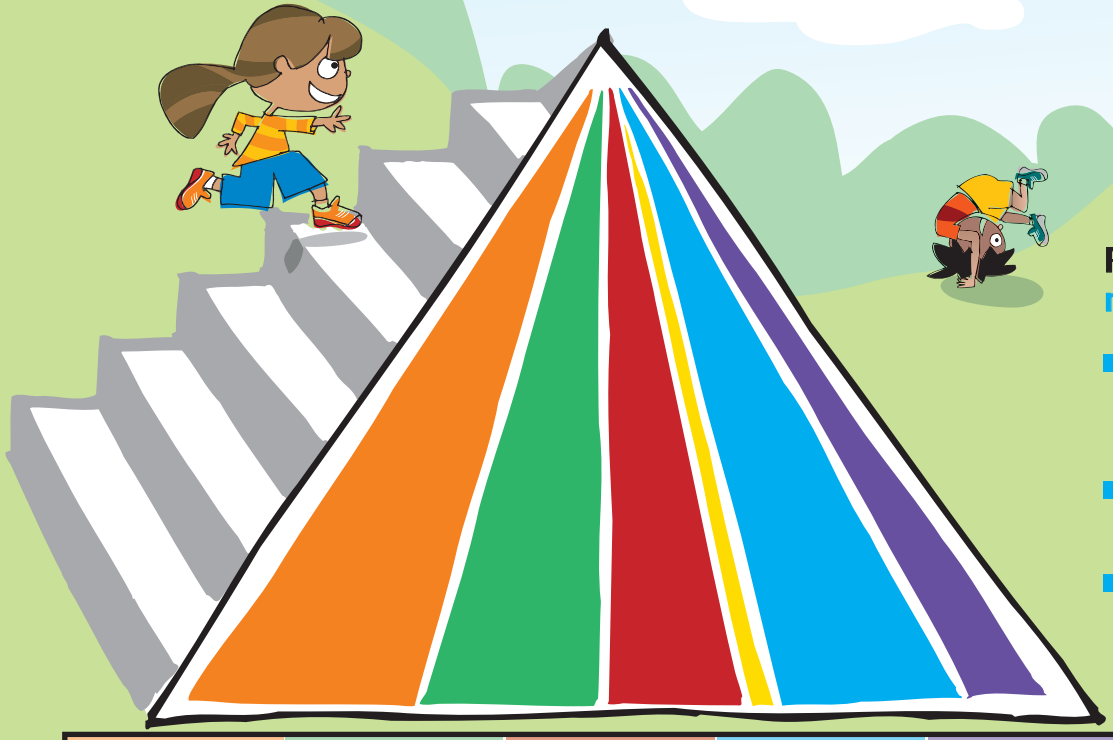
- Make most of your fat sources from fish, nuts, and vegetable oils.
- Limit solid fats like butter, margarine, shortening, and lard, as well as foods that contain these.
- Check the Nutrition Facts label to keep saturated fats, *trans* fats, and sodium low.
- Choose food and beverages low in added sugars. Added sugars contribute calories with few, if any, nutrients.

From the U.S. Department of Agriculture, Center for Nutrition Policy and Promotion, 2005. Washington, DC: Author.

MyPyramid Plan for Preschoolers

for: _____

Here is a customized MyPyramid Plan for your preschooler. Use it as a general guide for what and how much to feed your child each day. You don't have to be exact in these amounts every day. Try to balance the amounts over a few days or a week.



Put this Plan into action with meal and snack ideas.

- Offer different foods from day to day. Encourage your child to choose from a variety of foods.
- Serve foods in small portions at scheduled meals and snacks.
- Beverages count too. Make smart beverage choices.

Grains | Vegetables | Fruits | Milk | Meat & Beans

Learn more about the food groups and see what counts as a cup or an ounce in each group.
Click on the food group name or go "Inside the Pyramid" at www.MyPyramid.gov.

Limit Extras (solid fats & added sugars) to calories. Use the MyPyramid Menu Planner to find the number of calories from Extras in your meals.

Oils are different from solid fats. Your child's allowance is teaspoons of Oils a day.

Choose and prepare foods with little or no salt.

MyPyramid.gov
STEPS TO A HEALTHIER YOU

Glossary

abortion: any interruption of a pregnancy before the fetus is viable (a stage of development that will enable the fetus to survive outside the uterus if born at that time)
absorption: transfer of a drug from its point of entry in the body into the bloodstream
abstinence: refraining from sexual intercourse
abstract thought: final stage in cognitive thought processes; allows problem solving and creating hypotheses
abuse: willful injury by one person of another
accommodation: adjustment of the eye to focus on a close image (ophthalmology); the ability to adapt thought processes to fit what is perceived (Piaget)
acculturation: the process of losing cultural beliefs and values to those of a dominant society
achalasia: inability of a muscle to relax, particularly the cardiac sphincter
acrocyanosis: cyanosis (blue color) in the feet and hands
acute pain: sharp pain, generally occurring abruptly after an injury
acute transplant rejection: reaction to a transplanted organ, usually occurring within the first 3 months after transplantation
acyanotic heart disorders: heart or circulatory anomalies that involve either a stricture to the flow of blood or a shunt that moves blood from the arterial to the venous system (oxygenated to unoxygenated blood, or **left-to-right shunts**)
adaptability: the ability to change one's reaction to stimuli over time
adolescence: the time period between 13 years and 18 to 20 years
adrenarche: pubic and axillary hair that occur with puberty
adventitious sounds: extra or abnormal breathing sounds
affective learning: learning that involves a change in attitude
afterload: the resistance against which the cardiac ventricles must pump
afterpains: intermittent cramping due to uterine contraction during involution in the postpartal period
aganglionic megacolon: (Hirschsprung's disease) absence of ganglionic innervation to the muscle of a section of the bowel
age of viability: the earliest age at which fetuses could survive if they were born at that time; generally accepted as 24 weeks, or fetuses weighing more than 400 g
agranulocytes: white blood cells without granules in the cell cytoplasm
alleles: two like genes
allergen: antigen that causes the release of mediating substances causing tissue injury and allergic symptoms
allogeneic transplantation: transfer of body tissues from an immune-compatible (histocompatible) donor
allografting: transfer of body tissue between two genetically dissimilar individuals
Alport's syndrome: a progressive chronic glomerulonephritis inherited as an autosomal dominant disorder
alternative birthing center: a setting for birth separate from a hospital
amblyopia: reduced vision in one eye; "lazy eye"
amenorrhea: absence of a menstrual flow
amniocentesis: the withdrawal of amniotic fluid from the uterus by means of introduction of a needle through the abdominal and uterine wall
amnioinfusion: enlarging the amount of amniotic fluid by administration of normal saline or lactated Ringer's solution intravaginally into the uterus
amniotic cavity: the space in the developing conceptus from which the ectodermal cells develop
amniotic fluid embolism: condition in which amniotic fluid is forced into maternal circulation and travels to the lungs as small emboli
amniotic membrane: the innermost membrane surrounding the fetus; it secretes amniotic fluid
analgesia: a medication that reduces or decreases awareness of pain
anaphylaxis: acute hypersensitivity (type I) reaction characterized by extreme vasodilation that leads to circulatory shock and extreme bronchoconstriction that decreases the airway lumens
andrology: the branch of medicine that treats the male and diseases specific to the male sex
anesthesia: a medication that causes partial or complete loss of sensation
angioedema: edema of the skin and subcutaneous tissue
anhedonia: inability to remember the last time when a person felt happy or had a good time
ankle clonus: continued motion of the foot
ankyloglossia: an abnormal restriction of the tongue caused by an abnormally tight frenulum
anovulation: faulty or inadequate release of ova
anteflexion: a uterus that is bent forward just above the cervix
anteversion: a uterus that is tipped abnormally forward including the cervix
anticipatory grief: preparatory phase in which people gradually incorporate the reality of impending death into their thoughts

antigen: any foreign substance (molecule) capable of stimulating an immune response
antitoxins: antibodies against toxin-producing bacteria
aplastic anemia: depression of hematopoietic activity in bone marrow affecting all blood cells
apnea: pause in respirations longer than 20 seconds with accompanying bradycardia
apparent life-threatening event (ALTE): infant who is cyanotic and limp in bed but survives after mouth-to-mouth resuscitation
appendicitis: inflammation of the appendix
apposition: the amount of end-to-end contact of bone fragments
approach: a child's response on initial contact with a new stimulus
appropriate for gestational age (AGA): newborn who falls between the 10th and 90th percentile of weight for age regardless of gestational age
areola: the pigmented circle surrounding the nipple
arthroscopy: direct visualization of a joint with a fiber-optic instrument
aspermia: absence of sperm
aspiration: inhalation of a foreign object into the airway
aspiration studies: studies involving the removal of body fluids by such techniques as lumbar puncture or bone marrow aspiration
assimilation: changing a situation or one's perception of it to fit one's thoughts
astereognosis: difficulty identifying objects placed in the hand when the eyes are closed
astigmatism: congenital or acquired unevenness of the curvature of the cornea
atelectasis: collapse of alveoli
atresia: complete closure of a body opening
attention span: the time interval a person can maintain interest in a topic or object
attitude: the degree of head flexion a fetus assumes during labor, or the relation of the fetal parts to each other
audiogram: a test to measure hearing
augmentation of labor: assisting labor that has started spontaneously to be more effective
auscultation: listening with the aid of a stethoscope
autografting: transplantation of tissue from one part of the body to another in the same individual
autoimmunity: an inability to distinguish self from non-self, causing the immune system to carry out immune responses against normal cells and tissue
autologous transplantation: transplantation using the person's own previously removed tissue
automatisms: complex purposeless movements, such as lip smacking or fumbling hand movements
autonomic dysreflexia: a powerful sympathetic reflex reaction that causes signs of hypertension, tachycardia, flushed face, and severe occipital headache
autonomy: independence
azotemia: accumulation of nitrogen waste in the bloodstream
B lymphocytes: lymphocytes formed in the bone marrow; responsible for antibody formation
baby-bottle syndrome: decay of all the upper teeth and the lower posterior teeth, usually due to putting an infant to bed with a bottle
balloon angioplasty: procedure usually by way of cardiac catheterization in which a catheter with an uninflated balloon at its tip is inserted and passed through the heart into a stenosed valve. As the balloon is inflated, it breaks valve adhesions and may relieve the stenosis.
ballottement: the sensation of an object rebounding after being pushed by an examining hand; used for pregnancy diagnosis
barium contrast studies: x-ray involving the use of barium, a radiopaque substance to outline the gastrointestinal tract
barrier method: a method of reproductive life planning in which sperm are prevented from entering the cervix
basal body temperature method: a method of natural family planning based on the use of the body temperature on arising
battledore placenta: a placenta with the cord inserted marginally rather than centrally
behavior modification: a system of rewarding a person for desired behavior and ignoring or punishing the person for undesired behavior
beriberi: deficiency of vitamin B_1 involving tingling and numbness of extremities, heart palpitations, and exhaustion
bicornuate uterus: a uterus that has two fundal horns; it may have an accompanying septum
bifidus factor: specific growth-promoting factor for the bacteria *Lactobacillus bifidus* whose presence in breast milk interferes with colonization of pathogenic bacteria in the gastrointestinal tract
binge eating: episodes of uncontrollable intake of large amounts of food over a specified period of time
binocular vision: ability to fuse two images into one
biologic gender: a person's chromosomal sexual designation of being male (XY) or female (XX)
biopsy: surgical removal of tissue cells for laboratory analysis
birthing bed: a bed specifically prepared for birth
birthing chair: a chair used in labor and birth
birthing room: a specifically prepared room for aiding comfort, safety, and conduct of birth
blastocyst: a hollow sphere of cells that forms in early fetal development
blood dyscrasias: hematologic disorders
blood plasma: liquid portion containing proteins, hormones, enzymes, and electrolytes
body mass index: determination of body weight by comparing height to weight (weight divided by height squared)

Bowman's capsule: double-walled chamber enclosing the glomerulus of the kidney
Braxton Hicks contractions: painless, erratic uterine contractions that occur toward the end of pregnancy. They ready the cervix for labor, but cervical dilation does not occur with them.
breech presentation: fetal presentation in which either the buttocks or feet are the first body parts to contact the cervix
broken fluency: repetition and prolongation of sounds, syllables, and words
bronchoscopy: a procedure in which a bronchoscope, a specially designed tube, is passed through the nose or mouth to observe the larynx, trachea, bronchi, and alveoli
brown fat: the special tissue present in newborns to maintain body temperature
bruit: a swishing or blowing sound that occurs with turbulent blood flow, such as if there is an outpouching of the aorta
bruxism: grinding the teeth during sleep
calendar method: a method of natural family planning based on the determination of fertile and nonfertile days each month
calorie counting: counting the number of calories that a person ingests in 1 day
caput succedaneum: edema of the scalp at the presenting part of the head
cardiac catheterization: a procedure in which a small radiopaque catheter is passed through a major vein in the arm, leg, or neck into the heart to secure blood samples or inject dye, to evaluate cardiac function
cardinal movements of labor: position changes to keep the smallest diameter of the fetal head (in cephalic presentations) always presenting to the smallest diameter of the birth canal (descent, flexion, internal rotation, extension, external rotation, and expulsion)
caries: dental cavities
carpal spasm: hand spasm involving abduction of the hand and flexion of the wrist with the thumb positioned across the palm
cartilage: connective tissue
case management nursing: one nurse being in charge of a patient's care from admission to discharge
catarrhal stage: inflammation of the nose and throat during infectious diseases
catatonia: immobility
caudal regression syndrome: hypoplasia of the lower extremities occurring primarily in infants of diabetic mothers
cavernous hemangioma: type of birthmark evidenced as a dilated vascular space
celiac disease: sensitivity or immunologic response to protein, particularly the gluten factor of protein found in grains—wheat, rye, oats, and barley
cell-mediated immunity: type of immune response due to T-lymphocyte activity
centering: focusing on only one aspect of an object or situation
central cyanosis: cyanosis of the trunk
central nervous system (CNS): the brain, the spinal cord, and the surrounding membranes or meninges that protect the delicate tissues from normal trauma
cephalhematoma: a collection of blood under the periosteum of the skull bone
cephalic presentation: fetal presentation in which the head is the body part that first contacts the cervix
cephalocaudal: relating to head and tail; progression of development in a fetus and child
cephalopelvic disproportion: inability of the fetal head to pass through the maternal pelvis due to a discrepancy in size
cerebrospinal fluid (CSF): the fluid in the subarachnoid space, which serves as a cushion to the spinal cord
cervical cap: a latex barrier method of contraception that fits over the uterine cervix
cervical cerclage: suturing of the cervix to maintain a pregnancy to prevent premature cervical dilatation
cervical ripening: change in cervical consistency from firm to soft
cesarean birth: birth accomplished through an abdominal incision into the uterus
Chadwick's sign: discolorization of vaginal walls from pink to violet
chain of infection: method by which organisms are spread and enter a new individual to cause disease
chemotaxis: "calling" leukocytes into the area
chemotherapeutic agent: one that is capable of destroying malignant cells
chief concern: the reason the parents or patient has come to the health care agency
chloasma: extra pigment on the face
choreiform movements: aimless movements
choreoathetosis: rapid, purposeless movements
choreoid: irregular and jerking movements
chorioamnionitis: infection of the fetal membranes and amniotic fluid
chorionic membrane: the outer fetal membrane
chorionic villi: projections of the trophoblast that produce human chorionic gonadotropin and begin osmosis of nutrients to the embryo
chromosome: the structure that weaves genes into strands in the nucleus of all body cells
chronic pain: pain that lasts for a prolonged period of time (often defined as 6 months' time)
clarifying: repeating statements others have made so that you and they can be certain that you understood
class inclusion: the ability to understand that objects can belong to more than one classification
classic cesarean incision: an incision that is made vertically through both the abdominal skin and the uterus

clean-catch specimen: urine specimen obtained after the urinary meatus has been cleaned
cleansing breath: a deep breath taken at the beginning and end of breathing exercises during labor that helps prevent hyperventilation
cleft lip: failure of the maxillary and median nasal processes to fuse normally
cleft palate: an opening of the palate
clinical nurse specialist: a nurse prepared at the master's degree level who is capable of acting as a consultant in an area of expertise, as well as serving as a role model, researcher, and teacher of quality nursing care
clubbing: a change in the angle between the fingernail and nailbed because of increased capillary growth in the fingertips; a response to hypoxia
celiocentesis: the transvaginal aspiration of fluid collected in the extraembryonic cavity early in pregnancy for analysis
cognitive development: the acquisition of the ability to think and reason
cognitive learning: learning that involves a change in the individual's level of understanding or knowledge
coitus interruptus: a method of contraception in which the penis is withdrawn from the vagina before ejaculation
colonoscopy: a procedure in which a colonoscope, a specially designed tube, is passed through the anus to examine the rectum or colon
colostrum: a thin, watery, yellow fluid composed of protein, sugar, fat, water, minerals, vitamins, and maternal antibodies that precedes breast milk
comedones: the lesions of acne vulgaris; "blackheads"
communication: the exchange of ideas between two or more persons
community: a limited geographic area in which the residents relate to and interact among themselves
complement: a special body protein that is capable of lysing cells; composed of 20 different proteins that are normally nonfunctional molecules but become active with the immune response
complete miscarriage: the entire products of conception (fetus, membranes, and placenta) are expelled spontaneously without any assistance
complete protein: a protein that supplies all of the essential amino acids
complex vocal tics: repeated use of words or phrases out of context
computed tomography (CT): x-ray procedure in which many views of an organ or body part are made to represent what the organ would look like if it were cut into thin slices
concrete operational thought: typical thought pattern of school-age children, preceding abstract thought
conditioned reflex: a reflex to respond to a specific stimulus developed by training
condom: a latex barrier method of contraception worn on the penis (a male condom) or inserted vaginally (a female condom); provides some protection against STIs as well
conduction: transfer of body heat to a cooler solid object in contact with the body
congestive heart failure: a condition in which the myocardium of the heart cannot pump and circulate enough blood to supply oxygen and nutrients to body cells
conjugate vera: true conjugate; measurement between the anterior surface of the sacral prominence and the posterior surface of the inferior margin of the symphysis pubis
conjunctivitis: commonly called "pink eye" by parents; an infection of the conjunctiva that covers the eye
conscious relaxation: deliberate relaxation
conscious sedation: a state of depressed consciousness obtained by IV analgesia therapy
consciously controlled breathing: deliberately spaced breathing to achieve a desired rate
conservation: property of an object when a change in form does not equate to a change in size or amount
constriction ring: a simple type of contraction ring that occurs at any point in the myometrium and at any time during labor
contact dermatitis: example of a delayed or type IV hypersensitivity response; it is a reaction to skin contact with an allergen (a substance irritating only to the person with prior sensitization)
contraceptive: a method or device to prevent the fertilization of the human ovum
contractility: the ability of the ventricles to stretch; refers to the force of contraction generated by the myocardial muscle
contraction: a rhythmic tightening of the uterus that aids in achieving cervical dilatation and effacement
contrecoup injury: an injury resulting from a blow to one side of the skull that causes the brain to rebound and then injure the opposite side
convalescent period: interval between when infectious symptoms begin to fade and the child returns to full wellness
convection: flow of heat from the body surface to cooler surrounding air
conventional development: adult level of moral development (Kohlberg)
coordination of secondary schema: stage associated with infant's development of object permanence (Piaget)
coprolalia: use of socially unacceptable words, usually obscenities
corona radiata: the crown-like grouping of cells that surrounds the ovum immediately after ovulation
cotyledons: subdivisions of the maternal surface of the placenta; filled with maternal blood to allow for osmosis of nutrients to the fetal placental villi

couvade syndrome: somatic symptoms experienced by the father during pregnancy simulating those of the pregnant mother
Couvelaire uterus: uteroplacental apoplexy due to blood entering the uterine musculature
crackles: the sound of rales
Crohn's disease: inflammation of segments of the intestine, affecting any part of the gastrointestinal tract, but most commonly the terminal ileum
crowning: the appearance of the fetal head at the perineum just before birth
cryptorchidism: failure of one or both testes to descend from the abdominal cavity to the scrotum
culdoscopy: the introduction of an endoscope through the posterior vaginal wall to view the pelvic organs
cultural values: beliefs generally held by the majority of people in a community or society
culture: the learned way of life of a community or society
cutaneous pain: pain that arises from superficial structures such as the skin and mucous membrane
cyanosis: a blue tinge to the skin indicating hypoxia
cyanotic heart disease: cardiac anomaly when blood is shunted from the venous to the arterial system as a result of abnormal communication between the two (deoxygenated blood to oxygenated blood; **right-to-left shunt**)
cystocele: a pouching of the bladder into the anterior vaginal wall
cytomegalovirus: a member of the herpes virus family; teratogen that can cause extensive damage to a fetus yet causes few symptoms in the woman
cytotoxic (cell-destroying) **response:** cells are detected as foreign and immunoglobulins directly attack and destroy the cells without harming surrounding tissue
cytotoxic (killer) **T cells:** T lymphocytes that have the specific feature of binding to the surface of antigens and directly destroying the cell membrane and therefore the cell
death: end of life; officially determined by unreceptivity and unresponsivity; no spontaneous muscular movement or breath; no reflex response; and a flat electroencephalogram
débridement: the removal of foreign material from a burn or wound
decenter: to project the self into other peoples' situations and see the world from their viewpoint
decerebrate posturing: typical posture occurring when the midbrain is not functional; characterized by rigid extension and adduction of arms and pronation of the wrists with the fingers flexed; legs extended and the feet plantar flexed
decidua basalis: the endometrium portion under the implanted blastocyst
decidua capsularis: the endometrium portion that covers the blastocyst
decidua vera: the endometrium portion that covers the nonimplanted portion of the uterus
deciduous teeth: temporary teeth that are replaced by permanent teeth at around age 6 to 7 years
decorticate posturing: a child's arms adducted and flexed on the chest with wrists flexed, hands fisted; lower extremities extended and internally rotated; feet plantar flexed; denotes brainstem involvement
deep tendon reflexes: neurologic reflexes such as triceps, biceps, patellar, and Achilles reflexes
deep vein thrombosis (DVT): formation of thrombus (blood clot) in the deep veins secondary to stasis, vessel damage, and hypercoagulation
deferred imitation: ability to remember an action and imitate it later
dehiscence: the separation of a muscle or surgical incision
dehydration: an excessive loss of body water
delayed hypersensitivity: T-lymphocyte activity occurring solely without an accompanying humoral response
demonstration: the showing of a procedure to stimulate learning
dermatoglyphics: the study of surface markings of the skin
development: an increase in ability (a qualitative change)
developmental care: care designed to meet the specific needs of each infant
developmental hip dysplasia: (often referred to as *congenital hip dysplasia*) improper formation and function of the hip socket
developmental milestone: major marker of normal development
developmental task: a skill or a growth responsibility arising at a particular time, the successful achievement of which will provide a foundation for the accomplishment of future tasks
diagonal conjugate: distance between the anterior surface of the sacral prominence and the anterior surface of the inferior margin of the symphysis pubis
dialysis: separation and removal of solutes from body fluid by diffusion through a semipermeable membrane
diaphragm: a mechanical barrier contraceptive device fitted over the cervix in the woman
diaphragmatic excursion: distance the diaphragm moves as measured from inspiration to expiration
diaphysis: central shaft of a long bone
diastasis recti: overstretching and separation of the abdominal musculature
diastole: relaxation of the heart chambers
dilatation: widening of the opening of the cervix in labor
diplegia: (paraplegia); paralysis of the lower extremities
diplopia: double vision

direct bilirubin: water-soluble end breakdown product of heme that is combined and excreted in bile
direct care: a nurse remains in continual attendance or visits frequently and actually administers care
discipline: setting rules so people know what is expected
disorganization phase: first phase of rape trauma syndrome in which victims feel a combination of humiliation, shame and guilt, embarrassment, anger, and vengefulness
distractibility: the ability to shift concentration from one focus to another
distraction: (a) a technique that allows the cells of the brainstem that register an impulse as pain to be preoccupied with other stimuli so the pain impulse cannot register; (b) use of an external device to separate opposing bones, thus encouraging new bone growth
distribution: movement of a drug through the bloodstream to the specific site of action
dominant gene: expressed in preference to the other genes
doula: a person without professional experience who guides and assists a woman in labor
drowning: asphyxiation because of submersion in a liquid
ductus arteriosus: a blood vessel joining the pulmonary artery and aorta in fetal life; closes at birth
ductus venosus: a blood vessel joining the umbilical vein and the inferior vena cava in fetal life; closes at birth
dysfunctional labor: previously termed *inertia;* occurrence of sluggishness of contractions, or the force of labor
dyskinetic: disordered muscle tone
dyslexia: reading impairment disorder in which letters or words are reversed
dysmature: newborn who is before term or post-term or is underweight or overweight for gestational age
dysmenorrhea: painful menstruation
dyspareunia: pain on sexual intercourse
dystocia: difficult labor
echocardiography: ultrasound involving the use of high-frequency sound waves to locate and study the movement and dimensions of the cardiac structures
echolalia: repetitive words or phrases spoken by others
eclampsia: development of a seizure from hypertension of pregnancy
ecomap: a diagram of the family's interactions within the community
ectoderm: one of the layers of primary germ cell tissue in the embryo
ectomorphic: having a slim body build
ectopic pregnancy: one in which implantation occurs outside the uterine cavity
effacement: thinning of the cervix in labor
effleurage: light massage done by the fingertips
egocentrism: perceiving that one's thoughts and needs are better or more important than those of others
eighth-month anxiety: fear of strangers that peaks during the eighth month
elective termination of pregnancy: termination of a pregnancy by medical intervention
Electra complex: strong emotional attachment of a preschool girl to her father (Freud)
electrical impulse studies: those that include electrical conduction
electrocardiogram (ECG): written record of the electrical voltages generated by the contracting heart
emancipated minor: a person before the age of majority who is free from the custody, care, and control of his or her parents and is capable of health care decisions; a pregnant adolescent
embryo: the intrauterine growth period from the time following implantation until organogenesis is complete (tenth day to 5 to 8 weeks)
empathy: the ability to put yourself in another's place and experience a feeling as that person does
en face position: a position in which a caregiver's face and an infant's face look directly at each other
enanthem: rash on the mucous membrane
endocervix: the inner surface of the cervix
endometriosis: abnormal growth of extrauterine endometrial cells, often in the cul-de-sac of the peritoneal cavity, the uterine ligaments, and the ovaries
endometritis: an infection of the endometrium, the lining of the uterus
endometrium: the inner layer of the uterus that is shed with menstruation
endomorphic: having a large body build
endorphins: naturally occurring opiate-like substances in the body
endoscopy: a procedure in which an endoscope, a specially designed tube, is passed through the mouth to examine the gastrointestinal tract
engagement: settling of the fetal head into the pelvis during labor
engorgement: breast distention with swelling caused by vascular and lymphatic congestion arising from an increase in the blood and lymph supply to the breasts
engrossment: staring at the newborn in the en face position for long intervals
entoderm: one of the layers of primary germ cells in the embryo
enucleation: eye removal
enuresis: involuntary passage of urine past the age when a child should be expected to have attained bladder control
environmental control: as many common allergens as possible are removed from the environment
epidural analgesia: injection of an analgesic agent into the epidural space just outside the spinal canal, to provide analgesia to the lower body for 12 to 24 hours
epiphyseal plate: area where the increase in the length of long bones occurs
epiphysis: rounded end portion of a long bone

episiotomy: surgical incision of the perineum to prevent tearing and to release pressure on the fetal head with birth
epispadias: opening of the urinary meatus on the dorsal or superior surface of the penis
erectile dysfunction: impotence; the inability to achieve erection in order to complete a sex act
erosion: inflammation of the epithelium of the cervical canal spreading onto the area surrounding the os, giving the cervix a reddened appearance
erythema toxicum: newborn rash that usually appears in the 1st to 4th day of life; sometimes called a flea-bite rash
erythroblastosis fetalis: see *hemolytic disease of the newborn*
erythroblasts: large, nucleated early red blood cells
erythrocytes: red blood cells
erythropoietin: a hormone produced by the kidneys that stimulates red blood cell development
escharotomy: a surgical incision into the hard crust that forms over a burn
esotropia: condition in which the eye is always turning in
estimated date of birth: the predicted date on which a baby will be born (also estimated date of confinement, or EDC)
ethnicity: the cultural group into which a person is born
ethnocentrism: the belief that one's own values or beliefs are superior to others
evaporation: loss of heat through conversion of a liquid to a vapor
evidence-based practice: the use of research or controlled investigation of a problem using a scientific method in conjunction with clinical expertise as acquired through experience and practice as a foundation for action
Ewing's sarcoma: malignant tumor occurring most often in the bone marrow of the diaphyseal area (midshaft) of long bones
exanthem: a skin rash
excretion: elimination of raw drug or drug metabolites, a process that largely prevents properly administered drugs from becoming toxic
exophthalmos: protrusion of the eyeballs
exotoxins: poisons produced by some bacteria
exotropia: condition in which the eye is always turning outward
expected date of birth: calculated date on which birth can be predicted to occur (EDB)
expiration: carbon dioxide–filled air discharged to the outside
exstrophy of the bladder: midline closure defect occurring during the embryonic period of gestation (first 8 weeks) and resulting in the bladder lying open and exposed on the abdomen
external cephalic version: turning of a fetus from a breech to a cephalic position before birth
extracorporeal membrane oxygenation (ECMO): mechanical means of oxygenating blood
extremely-very-low-birth-weight (EVLBW) infant: an infant weighing 500 to 1000 g
extrusion reflex: a tongue reflex in infants that expels solid objects from the mouth; fades at 4 months
failure to thrive: also called reactive attachment disorder; unique syndrome in which an infant falls below the fifth percentile for weight and height on a standard growth chart or is falling in percentiles on a growth chart
family: two or more people who live in the same household (usually), share a common emotional bond, and perform certain interrelated social tasks
family nurse practitioner: nurse who provides health care not only to women but all persons throughout the age span; in conjunction with a physician, an FNP can provide prenatal care for the woman with an uncomplicated pregnancy
family nursing: the concept that clients do not exist outside a family; the family rather than an individual is considered the client
family of orientation: one's birth family: oneself, mother, father, and siblings
family of procreation: one's marriage family: oneself, spouse, and children
family theory: a way of analyzing problems or concerns from a family's point of view
feedback: a reply to communication indicating that the message has been received and interpreted
fertility awareness: a method of contraception based on analyzing the consistency of vaginal secretions
fertility rate: the proportion of women who could have babies who are having them
fertilization: the union of the sperm and ovum
fetal alcohol syndrome: condition associated with an infant born to a woman who uses alcohol during pregnancy; infant typically is small for gestational age, cognitively challenged, and has a characteristic craniofacial deformity including short palpebral fissures, thin upper lip, and upturned nose
fetal descent: sinking of the fetus in the birth canal just prior to birth (one of six cardinal movements of labor)
fetoscopy: the visualization of the fetus by inspection through a fetoscope
fetus: the developing structure from the eighth week postfertilization until birth
fibrocystic breast disease: benign multiple cysts in the breasts
fine motor development: ability to accomplish smaller, more defined body movement; measured by observing or testing prehensile ability
fistula: abnormal opening
flat affect: not revealing feelings
fluoroscopy: a radiologic serial-images technique
focusing: helping a person to center on a subject

fomites: inanimate objects, such as soil, food, water, bedding, towels, combs, or drinking glasses, that provide a means of infection transmission
foramen ovale: an opening between the atria of the heart during intrauterine life
forceps birth: birth using forceps (steel double-bladed instruments used to prevent pressure on the fetal head); forceps outlet procedure when the forceps are applied after the fetal head reaches the perineum
foremilk: constantly forming breast milk
formal operational thought: final stage of cognitive development, involving the ability to think in abstract terms and use the scientific method to arrive at conclusions
fovea centralis: (the center of the macula); an area of closely packed cones on the retinas where color is best perceived
fracture: break in the continuity or structure of bone
frenulum: the membrane attached to the lower anterior tip of the tongue
gamma globulin: serum obtained from the pooled blood of many people; rich in antibodies
gastroesophageal reflux: (commonly called achalasia in infants) a neuromuscular disturbance in which the gastroesophageal (cardiac) sphincter and the lower portion of the esophagus are lax, allowing easy regurgitation of gastric contents into the esophagus
gate control theory: a theory of how pain impulses can be interrupted before they travel between a site of injury and the brain where the impulse is actually registered as pain
gavage feedings: nasogastric tube feedings given to an infant
gender identity: the inner sense of being male or female, which may be the same as or different from biologic gender
gender role: the behavior a person conveys about being male or female
genes: basic units of heredity that determine both the physical and mental characteristics of people
genetics: study of how and why chromosomal disorders occur; the science of heredity
genogram: a diagram of family structure depicting essential family relationships; the interactive roles that exist in a family
genome: complete set of genes present
genotype: actual gene composition
genu valgus: knock-knees
geographic tongue: term for the rough-appearing tongue surface that often accompanies general symptoms of illness such as fever
gestational age: number of weeks fetus remained in utero
gestational trophoblastic disease: proliferation and degeneration of the trophoblastic villi
glomerular filtration rate: rate at which substances are filtered from the blood to the urine
glomerulonephritis: inflammation of the glomeruli of the kidney
glucose tolerance test: a test of the body's ability to metabolize carbohydrate by measuring the serum glucose level after ingestion of a fixed amount of glucose
glycogen loading: depleting, then replenishing glycogen stores by altering carbohydrate intake, to store extra glycogen for the purpose of sustaining energy through an athletic event
glycosuria: excess glucose in the urine
glycosylated hemoglobin: measure of the amount of glucose attached to hemoglobin
gonad: a sex gland; an ovary in the female; a testis in the male
goniotomy: surgical procedure used to treat congenital glaucoma
Goodell's sign: softening of the cervix; a probable sign of pregnancy
granulocytes: white blood cells with granules in the cell cytoplasm
graphesthesia: ability to recognize a shape that has been traced on the skin
gravida: number of times a woman has been pregnant, including the present pregnancy; a pregnant woman
grief process: regulated steps in grieving
gross motor development: ability to accomplish large body movements
growth: an increase in size; a quantitative change
gynecology: the study of the female reproductive organs and female disorders
gynecomastia: enlargement of the breasts; excess development of male breast tissue; a transient occurrence in normal adolescence
hand regard: infants holding their hands in front of their face and studying their fingers for long periods of time
hapten formation: process whereby a substance, not antigenic in itself, becomes antigenic when combined with a higher-weight molecule, usually a protein
Hawthorne effect: an improvement in behavior because of being studied
health fair: a display to teach healthful behaviors
Hegar's sign: softening of the lower uterine segment; a probable sign of pregnancy
Heinz bodies: oddly shaped particles in red blood cells
HELLP syndrome: a variation of hypertension of pregnancy named for the common symptoms that occur: *h*emolysis, *e*levated *l*iver enzymes, and *l*ow *p*latelets
helper T cells: lymphocytes that stimulate B lymphocytes to divide and mature into plasma cells and begin secretion of immunoglobulins
hemangioma: vascular tumor of the skin
hemiplegia: paralysis of both extremities on one side
hemochromatosis: deposition of iron in body tissues from destruction of red blood cells
hemoglobin: a complex protein that is the oxygen-carrying component of red blood cells

hemolysis: destruction of red blood cells
hemolytic disease of the newborn: condition involving red blood cell destruction in the fetus who is Rh positive and whose mother is Rh negative
hemorrhagic disease of the newborn: newborn bleeding disorder resulting from a deficiency of vitamin K
hemosiderosis: deposition of iron in body tissues
hepatitis: inflammation and infection of the liver
hermaphrodite: having both ovaries and testes
heterograft: tissue from another species (such as a pig) used as a temporary skin covering
heterosexual: an individual whose sexual relations are with persons of the opposite sex
heterozygous trait: having two different or unlike genes for a designated characteristic
hiatal hernia: intermittent protrusion of the stomach up through the esophageal opening in the diaphragm
high-risk pregnancy: one in which a concurrent disorder, pregnancy-related complication, or external factor jeopardizes the health of the mother and/or fetus
hind milk: new breast milk formed after the let-down reflex
Homans' sign: pain in the calf on dorsiflexion of the foot
home care: care of people in their own home, provided by or supervised through a certified home health care or community health care agency
homosexual: an individual whose sexual relations are with persons of his or her own sex
homozygous trait: having two like genes for a designated characteristic
hordeolum: an infection of an eyelash
hormones: chemicals produced by ductless glands of the endocrine system
hospice care: care of the person with a terminal disease; can be cared for at home
humoral immunity: immunity created by antibody production or B-lymphocyte involvement
hydramnios: an excessive amount of amniotic fluid (generally over 2000 mL)
hydrocele: collection of fluid in the scrotal sac
hydrocephalus: an excess of cerebrospinal fluid (CSF) in the ventricles and subarachnoid spaces of the brain
hydronephrosis: enlargement of the pelvis of the kidney with urine as a result of back-pressure in the ureter
hydrops fetalis: old term for the appearance of a severely involved infant with Rh incompatibility at birth
hyperactivity: excess movement
hyperbilirubinemia: increased serum bilirubin
hypercholesterolemia: greater than usual levels of cholesterol in the blood
hyperfunction: overfunction of a gland or organ
hyperglycemia: increased blood glucose level
hyperopia: farsightedness
hyperplasia: an increase in the number of cells of a body part
hyperptyalism: excessive secretion of saliva
hypersensitivity response: excessive antigen-antibody response when the invading organism is an allergen rather than a simple immunogen
hypertension: elevated blood pressure
hypertonic uterine contractions: contractions with an increase in resting tone to more than 15 mm Hg
hypertrophy: an increase in the size of an organ because the cells have increased in size rather than number
hypocalcemia: decreased serum calcium level
hypodermoclysis: subcutaneous infusion
hypofunction: underfunction of a gland or organ leading to acute or chronic insufficiency
hypoglycemia: decreased blood glucose level
hyposensitization: immunotherapy; a process to diminish an allergic response
hypospadias: urethral defect in which the urethral opening is not at the end of the penis but on the ventral (lower) aspect of the penis
hypothalamus: an organ located in the center of the brain that is the regulator of the autonomic nervous system
hypotonic uterine contractions: the number of contractions are low or infrequent (not increasing beyond two or three in a 10-minute period) or ineffective
hypoxemia: deficient oxygenation of the blood
hypoxia: inadequate oxygenation of body tissue
identity: developmental task of adolescence; determining who one is
imminent or inevitable miscarriage: a threatened miscarriage accompanied by uterine contractions and cervical dilation
immune response: body's action plan devised to combat invading organisms or substances by leukocyte and antibody activity
immune serum: serum that provides passive immunity
immunity: the ability to destroy invading antigens
immunocompetent cells: cells capable of resisting foreign invaders
immunogen: substance (antigen) that can be readily destroyed by an immune response
immunoglobulins: antibodies that bind to and destroy specific antigens
implantation: nidation; the attachment of the zygote to the uterine endometrium
imprinting: differential expression of genetic material that allows researchers to identify whether the chromosomal material has come from the male or female parent
incest: sexual activity between family members
inclusion: children with physical or cognitive challenges attending regular schools and classes
incompetent cervix: a cervix that dilates and causes birth of a fetus before term
incomplete miscarriage: part of the conceptus (usually the fetus) is expelled, but the membranes or placenta is retained in the uterus

incomplete protein: a protein that does not contain all of the essential amino acids
incubation period: time between the invasion of an organism and the onset of symptoms of infection
indirect care: the nurse plans and supervises care given by others, such as home health care aides or parents
induction of labor: labor that is artificially started
industry: the developmental task of the school-age child, according to Erikson; to learn how to do things well
infant mortality rate: percent of infants who die during the first year of life per 1000 births
infantile spasms: a form of generalized seizures—"salaam" and "jackknife"—or infantile myoclonic seizures, characterized by very rapid movements
infertility: the inability to produce children
inguinal hernia: protrusion of a section of the bowel into the inguinal ring
initiative: the developmental task of the preschooler, according to Erikson; to learn how to do things
innocent heart murmur: heart murmur of no significance; also called insignificant or functional heart murmur
insensible fluid loss: fluid loss occurring as a result of evaporation from skin and lungs and from saliva
inspection: visual observation to determine health
inspiration: delivery of warmed moistened air via the respiratory system to the alveoli
insulin pump: an automatic pump about the size of a transistor radio used to deliver insulin continuously
intelligence: ability to think abstractly, to adjust to new situations, and to profit from experience
intercostal spaces: spaces between the ribs
interferon: a protein that protects against viruses
intermittent infusion devices: (heparin locks) devices that maintain open venous access for medicine administration, yet allow patients to be free of intravenous tubing so that they can be out of bed and more active
intimate partner abuse: abuse by a significant other
intracath: a slim, pliable catheter threaded into a vein
intrauterine device (IUD): a contraceptive device inserted into the uterine cavity
intrauterine growth restriction or retardation (IUGR): failure to grow at the expected rate in utero
intuitive thought: a stage of preschool thinking in which children can only see one characteristic of an object (centering)
intussusception: invagination of one portion of the intestine into another
involution: the process whereby the reproductive organs return to their nonpregnant state
irritable bowel syndrome: presence of either intermittent episodes of loose and normal stools or recurrent abdominal pain
ischial tuberosity diameter: distance between the ischial tuberosities, or the transverse diameter of the outlet (the narrowest diameter at that level or the one most apt to cause a misfit)
isoimmunization: production of antibodies against Rh-positive blood in a fetus by a woman's immunologic system
jaundice: yellowing of the skin
kangaroo care: placing a newborn against a parent's skin to transfer heat from the parent to the newborn, thus conserving body heat
karyotype: a visual presentation of chromosomes
keratomalacia: necrosis of the cornea with perforation, loss of ocular fluid, and blindness
kernicterus: permanent brain cell damage secondary to elevated bilirubin levels
ketoacidosis: a lowered serum pH resulting from accumulation of ketones
kinesthesia: ability to distinguish movement
Koplik's spots: small, irregular, bright red spots with a blue-white center point, appearing on the buccal membrane with measles
kwashiorkor: disease caused by protein deficiency
labile mood: sudden mood changes (e.g., crying occurs, followed immediately by giggling or laughing)
labor-delivery-recovery room: a hospital room specifically designed to accommodate labor and birth so that a separate delivery room is not needed
labor-delivery-recovery-postpartum room: a specifically designed room that serves as the location not only for labor and birth but also for the postpartum recovery period
lactase: the enzyme that converts lactose to glucose and galactose
lactiferous sinuses: reservoirs for milk located behind the breast nipple
lactoferrin: iron-binding protein in breast milk that interferes with growth of pathogenic bacteria
Lamaze method of childbirth: a method of childbirth based on conditioned reflexes using paced breathing and relaxation techniques
Landau reflex: develops at 3 months; when held in ventral suspension, the infant's head, legs, and spine extend. When the head is depressed, the hips, knees, and elbows flex.
lanugo: fine, downy hair that covers a newborn's shoulders, back, and upper arms
laparoscopy: examination of the abdominal cavity and organs by insertion of a surgical instrument through the anterior abdominal wall
large-for-gestational-age (LGA) infant: an infant who falls above the 90th percentile in weight
latchkey child: a child who is without adult supervision for a part of each weekday
latent tetany: neuromuscular irritability associated with hypocalcemia
learned helplessness: psychological infantilism; phase of intimate partner violence in which the partner is forced to use coping mechanisms such as becoming very obedient and cooperative in a desperate effort to reduce the violence

Leboyer method: a birth method encouraging a quiet, darkened room and maternal-infant bonding
left-to-right shunts: heart or circulatory anomalies that involve blood movement from the arterial to the venous system (oxygenated to unoxygenated blood)
Leopold's maneuvers: a method of observation and palpation to determine fetal presentation and position
lesbian: a female homosexual
let-down reflex: collecting sinuses of the mammary glands contract, forcing milk forward through the nipples, thus making it available for the baby
letting-go phase: the third phase of the postpartal period in which the woman redefines her new role
leukemia: distorted and uncontrolled proliferation of white blood cells (leukocytes)
leukocytes: white blood cells
leukopenia: a decrease in the number of white blood cells
leukorrhea: a whitish, viscous vaginal discharge or an increase in the amount of normal vaginal secretions
libido: sexual nature
lie: the relationship between the long axis of the fetus and the long axis of the mother
light refraction: manner that light is bent as it passes through the lens of the eye
lightening: descent of the fetus into the pelvis at about 2 weeks prior to birth; also called engagement
lithotomy position: a position with a woman on her back with her thighs flexed and her feet resting in the examining table stirrups
liver transplantation: surgical replacement of a malfunctioning liver by a donor liver
lochia: uterine flow, consisting of blood, fragments of decidua, white blood cells, mucus, and some bacteria following childbirth
lochia alba: colorless or white vaginal discharge occurring about the 10th postpartal day
lochia rubra: vaginal discharge consisting almost entirely of blood with only small particles of decidua and mucus, occurring from days 1 to 3 of the postpartal period
lochia serosa: pink or brownish vaginal discharge beginning at about the 4th postpartal day
lordosis: forward curve of the spine
low segment incision: an incision made horizontally across the abdomen just over the symphysis pubis and also horizontally across the uterus just over the cervix
low-birth-weight infant: an infant weighing under 2500 g
lymphokine: a substance that contains or prevents migration of antigens
lymphoma: malignancy of the lymph or reticuloendothelial system
lysis: killing
lysozyme: enzyme found in breast milk that apparently actively destroys bacteria by lysing (dissolving) their cell membranes, possibly increasing the effectiveness of antibodies
macronutrient: mineral with a daily requirement greater than 100 mg
macrophages: mature white blood cells
macrosomia: birth weight above the 90th percentile on an intrauterine growth chart for that gestational age
magnetic resonance imaging (MRI): combination of a magnetic field, radio frequency, and computer technology to produce diagnostic images
malleoli: rounded prominence on either side of the ankles
malocclusion: deviation from normal teeth positioning
mandatory reporters: persons who are required to report suspected child abuse when they identify it
manifest tetany: muscular twitching and carpopedal spasms from hypocalcemia
mastitis: infection of the breast
maternal and child health nursing: the full scope of nursing that deals with families during childbearing and childrearing periods
maturation: reaching adulthood
McBurney's point: one third of the way between the anterior superior iliac crest and the umbilicus; location of the appendix
McDonald's Rule: the fundus-to-symphysis distance in cm is equal to the week of gestation between the 20th to 31st week of pregnancy
means of transmission: method of spread of pathogens that cause infectious disease
Meckel's diverticulum: the remains of a small pouch of the omphalomesenteric (vitelline) duct off the ileum, approximately 18 inches from the ileum-colon junction
meconium: a sticky, tarlike, blackish-green, odorless material formed from mucus, vernix, lanugo, hormones, and carbohydrates that accumulates during intrauterine life in the intestine
meconium plug: extremely hard portion of meconium that completely obstructs the intestinal lumen, causing bowel obstruction
megakaryocytes: immature thrombocytes
megaloblastic anemia: enlarged red blood cells
meiosis: type of cell division in which the number of chromosomes in the cell is reduced to the haploid (half) number for reproduction (23 rather than 46 chromosomes)
melasma: excessive body pigment on the face that occurs during pregnancy
memory cells: B lymphocytes that are responsible for retaining the formula or ability to produce specific immunoglobulins
menarche: the first menstrual period
menopause: the cessation of ovarian function
menorrhagia: an abnormally heavy menstrual flow
mesoderm: one of the layers of primary germ cell tissue in the embryo

metabolism: conversion of a drug into an active form (biotransformation) or an inactive form (inactivation)
metaphysis: thin area between the diaphysis and epiphysis in long bones
metastasis: tumors that have extended beyond the original site or have spread systemically
metrorrhagia: bleeding between menstrual periods
micronutrient: mineral with a daily requirement less than 100 mg
milia: pinpoint white papule (a plugged or unopened sebaceous gland) that can be found on the cheek or across the bridge of the nose of newborns
missed miscarriage: now more commonly referred to as early pregnancy failure; the fetus dies in utero but is not expelled
mittelschmerz: abdominal pain during ovulation from the release of accompanying prostaglandins
molding: change in shape of the fetal skull due to uterine contractions pressing the vertex against the not-yet-dilated cervix
molestation: vague term that includes "indecent liberties," such as oral-genital contact, genital fondling and viewing, and masturbation
Mongolian spot: collection of pigment cells (melanocytes); slate-gray patches across the sacrum or buttocks and possibly the arms and legs of newborns
monophasic oral contraceptive: birth control pills that contain the same amount of estrogen and progestin content in each pill throughout the cycle
Montgomery's tubercles: sebaceous glands of the areola of the breast
mood quality: a person's usual emotional state
mores: customs generally accepted as right to follow by a community or society
mortality rate: the number of deaths per 1000 persons
morula: the developing blastomere structure as it multiplies rapidly and forms a bumpy surface
motor tics: eye blinking, neck jerking, and facial grimacing
multigravida: woman who has been pregnant more than once
multipara: a woman who has given birth to more than one child past the age of viability
mumps orchitis: testicular inflammation and scarring due to the mumps virus
Munchausen syndrome by proxy: parent who repeatedly brings a child to a health care facility, reporting symptoms of illness when in fact the child is well
myometrium: the muscle layer of the uterus
myopathy: disease of the muscular system
myopia: nearsightedness
natal teeth: teeth present at birth
natural family planning: contraception involving no medical devices or chemicals
near drowning: a state in which a person has survived drowning
neck righting reflex: turning of shoulders, trunk, and pelvis in the same direction when the infant turns the head to the side
necrotizing enterocolitis (NEC): development of necrotic patches in the bowel, interfering with digestion and possibly leading to a paralytic ileus; seen in infants in intensive care nurseries
neonatal nurse practitioner: nurse skilled in the care of the newborn, both well and ill
neonatal period: the interval from birth to 28 days of age
neonatal teeth: teeth erupting in the first 4 weeks of life
neonate: a baby in the neonatal period, the first 28 days of life
neoplasm: new growth, usually referring to new *abnormal* growth that does not respond to normal growth-control mechanisms
nephrosis: altered glomeruli permeability due to fusion of the glomeruli membrane surfaces causing abnormal loss of protein in urine
neural plate: the embryonic structure from which the nervous system develops
neuroblastomas: tumors that arise from the cells of the sympathetic nervous system
neurons: nerve cells
nevus flammeus: a macular purple or dark red lesion (sometimes called a *port-wine stain* because of its deep color) that is present at birth
nociceptors: specialized group of sensory receptors for pain
nocturnal emissions: ejaculation during sleep
nondisjunction: uneven cell division that leads to abnormal chromosome divisions
non–rapid-eye movement (NREM) sleep: first stage of sleep; type of sleep that occurs in up to 80% of total sleep time
nonstress test: assessment of fetal well-being determined from examination of the fetal heart rate in relationship to fetal activity
nontherapeutic communication: communication that lacks deliberate purpose (e.g., socializing)
normoblast: a developmental stage of RBC after erythroblast
norms: customs generally accepted as right to follow by a community or society
nulligravida: woman who is not or never has been pregnant
nurse-midwife: nurse who assists women with pregnancy and childbearing either independently or in association with an obstetrician; can assume full responsibility for the care and management of women with uncomplicated pregnancies
nursing research: controlled investigation of problems that have implications for nursing practice
nutritional marasmus: disease caused by deficiency of all food groups; basically a form of starvation

nystagmus: rapid, irregular eye movement
obese: a body mass index over 30.0 or, in a child, a weight over the 90th percentile on a weight chart
object permanence: awareness that an object exists even when it is out of sight
Oedipus complex: strong emotional attachment of a preschool boy to his mother (Freud)
oligohydramnios: a decreased amount of amniotic fluid
omphalocele: protrusion of abdominal contents through the abdominal wall at the point of the junction of the umbilical cord and abdomen
oncogenic viruses: viruses associated with causing cancer due to their ability to change the structure of DNA or RNA
oocyte: an immature ovum
operculum: the mucous plug formed in the cervical canal during pregnancy
ophthalmia neonatorum: eye infection at birth or during the first month, most commonly caused by *Neisseria gonorrhoeae* or *Chlamydia trachomatis*
orchiectomy: removal of the testis
orchiopexy: surgery to repair undescended testes
orchitis: inflammation of the testes
organic heart murmur: murmur occurring as the result of heart disease or a congenital defect
organogenesis: organ formation
orthopnea: position with the head and chest elevated to ease breathing
orthoptics: eye exercises
osteogenic sarcoma: malignant tumor of long bone involving rapidly growing bone tissue (mesenchymal-matrix forming cells)
otorrhea: discharge from the external ear
overhydration: excess body fluid, usually extracellular fluid
overweight: a body mass index between 25.0 and 29.9
oxytocin: a pituitary hormone that initiates or sustains uterine contractions
pain: an unpleasant sensation caused by pressure, injury, or tissue anoxia; whatever the person experiencing it says it is, and existing whenever he or she says it does
pain threshold: the point at which the individual reports that a stimulus is painful
pain tolerance: the point at which an individual withdraws from a stimulus or seeks relief
palilalia: repeating one's own words
palpation: an assessment technique that yields information on warmth and edema through touching
pancytopenia: reduction of all blood cell components
para: number of children above the age of viability a woman has previously birthed
parachute reaction: arm extension seen in 6- to 9-month-old infants who are suddenly lowered toward an examining table from ventral suspension, as if to protect themselves from falling
parallel play: playing alongside, not with, other children; characteristic of toddlers
paraphrasing: restating what a person has said not only to assure the person that you have heard correctly (as in clarifying), but to help explain what the person was trying to say
paraplegia (diplegia)**:** paralysis of the lower extremities
paroxysmal coughing: series of expiratory coughs after a deep inspiration
paroxysmal nocturnal dyspnea: suddenly waking at night short of breath
passage: the birth canal
passenger: the fetus
patent urachus: failure of the urachus (narrow tube that joins the bladder to the umbilicus in utero) to close properly during embryologic development, leading to the development of a fistula between the bladder and umbilicus
pathologic retraction ring (Bandl's ring): a type of contraction ring that occurs at the juncture of the upper and lower uterine segments; a warning sign that severe dysfunctional labor is occurring
patient-controlled analgesia (PCA): form of administration that allows self-administration of IV boluses of medication, usually opioids, with a medication pump
pedal (foot) spasm: foot spasm manifested as the foot is extended, the toes are flexed, and the sole of the foot is cupped
pediatric nurse practitioner: an advanced nursing role that specializes in the well care of children
pedophile: adult who seeks out children for sexual gratification
pellagra: deficiency of niacin involving dermatitis and resembling a sunburn
pelvic inflammatory disease (PID): infection of the pelvic organs: the uterus, fallopian tubes, ovaries, and their supporting structures
peptic ulcer: shallow excavation formed in the mucosal wall of the stomach, the pylorus, or the duodenum
perception checking: documenting a feeling or emotion
percussion: a chest physiotherapy technique that uses a cupped or curved palm against the chest; an assessment technique that helps determine the consistency of tissue beneath the surface area
perimetrium: the outer coat of the uterus
perinatal home health care: care at home during pregnancy or the neonatal period
periodic respirations: irregular breathing pattern typically seen in newborns
periosteum: outside sensitive layer covering of central shafts of long bones
peripartal cardiomyopathy: myocardial failure apparently due to the effect of the pregnancy on the circulatory system
peripheral nervous system (PNS): the cranial nerves, the spinal nerves, and the somatic and visceral divisions

peritonitis: infection of the peritoneal cavity
periventricular leukomalacia (PVL): abnormal formation of the white matter of the brain
permanence: the awareness that objects exist when out of sight
permissive reporters: people who may, but are not legally required to, report child abuse
petechiae: pinpoint, macular, purplish-red spots caused by intradermal or submucous hemorrhage
phagocytosis: destruction of invading substances
pharmacokinetics: the way a drug is absorbed, distributed throughout the body, metabolized, inactivated, and excreted
phenotype: outward appearance or the expression of the genes
phonocardiogram: diagram of heart sounds translated into electrical energy by a microphone placed on the chest and then recorded as a diagrammatic representation of heart sounds
photophobia: sensitivity to light
physiologic jaundice: yellowing of the skin occurring on the 2nd or 3rd day of life as a result of the breakdown of fetal red blood cells
physiologic retraction ring: ridge on the inner uterine surface marking the boundary between the upper and lower segments of the uterus during labor
physiologic splitting: term to denote closure of the pulmonary valve slightly later than the aortic valve
pica: indiscriminate eating of nonfood substances
pincer grasp: ability to bring the thumb and first finger together to pick up small objects
placenta accreta: an unusually deep attachment of the placenta to the uterine myometrium
placenta circumvallata: the fetal side of the placenta is covered with chorion membrane
placenta marginata: the fold of chorion reaches just to the edge of the placenta
placenta previa: low implantation of the placenta
placenta succenturiata: one or more accessory lobes connected to the main placenta by blood vessels
plasma cells: B lymphocytes that secrete large quantities of immunoglobulins
play therapy: a psychoanalytic technique used by psychiatrists to help children better understand their feelings and thoughts and motivations
plethora: marked reddened appearance of the skin
plumbism: lead poisoning
pneumothorax: the presence of atmospheric air in the pleural space
poikilocytic: irregular in shape
point of maximum impulse (PMI): the point on the chest where the apical heartbeat can be heard best
polycystic kidney: large, fluid-filled cysts forming in place of normal kidney tissue
polycythemia: an increase in the number of red blood cells that results as a compensatory response to insufficient oxygenation of the blood
polydactyly: presence of one or more additional fingers
polydipsia: excessive thirst
polyuria: excessive urination
portal of entry: means by which a pathogen can enter a person's body
portal of exit: method by which organisms leave an infected person's body to be spread to others
position: the relationship of a specific fetal part to the maternal pelvis
positive reinforcement: rewarding someone for demonstrating desired behavior
positive signs of pregnancy: findings that definitely indicate a pregnancy is present
positron emission tomography (PET): CT scan involving the use of an injectable radioactive contrast medium
postcardiac surgery syndrome: febrile illness with pericarditis and pleurisy that appears to be a benign inflammatory response to a surgical procedure, developing at the end of the first postoperative week
postconventional development: the mature form of moral reasoning in which standards of conduct are internalized (Kohlberg)
postpartal depression: overall feeling of sadness in a woman accompanied by extreme fatigue, an inability to stop crying, increased anxiety about her own or her infant's health, insecurity (unwilling to be left alone or unable to make decisions), psychosomatic symptoms, and either depressive or manic mood fluctuations during the first year following birth
postpartal psychosis: psychiatric illness occurring during the postpartum period
postperfusion syndrome: a complication after cardiac surgery manifested by fever, splenomegaly, general malaise, maculopapular rash, hepatomegaly, and leukocytosis
post-term infant: infant born after the onset of week 43 of pregnancy
post-term pregnancy: a pregnancy that exceeds the limit of 42 weeks
post-term syndrome: infant who stays in utero past week 42 of pregnancy and demonstrates the characteristics of malnourishment
postural proteinuria: also called postural albuminuria; condition in which albumin spills into the urine when children stand upright for an extended period and decreases when resting in the supine position
powers of labor: labor contractions
precipitate labor: uterine contractions so strong that the woman gives birth with only a few rapidly occurring contractions
preconventional reasoning: stage of moral development centering on "niceness" or "fairness"
pre-eclampsia: in pregnancy-induced hypertension, the phase before the pregnant woman experiences a seizure
prehensile ability: ability to coordinate hand movements

preload: volume of blood in the ventricles at the end of diastole (the point just before contraction)
premature cervical dilatation: previously termed an incompetent cervix; refers to a cervix that dilates prematurely and therefore cannot hold a fetus until term
premature ejaculation: deposition of sperm before vaginal penetration or the full enjoyment of the sexual partner
premature separation of the placenta: also called abruptio placentae; separation of the placenta before birth of the fetus
premenstrual dysphoric disorder (PDD): condition occurring in the luteal phase of the menstrual cycle and relieved by the onset of menses that has both behavioral and physiologic symptoms
preoperational thought: period of cognitive development at the end of the toddler stage; the child begins to use assimilation (Piaget)
prereligious stage: the infant period of moral reasoning, according to Kohlberg
pressure anesthesia: a natural yet simplest form of pain relief for birth that results from the fetal head pressing against the stretched perineum
presumptive signs of pregnancy: findings, largely subjective in nature, that suggest but do not confirm that a pregnancy is present
preterm infant: infant born before term (less than the full 37th week of pregnancy)
preterm labor: labor that occurs before the end of week 37 of gestation
preterm rupture of membranes: rupture of fetal membranes with loss of amniotic fluid during pregnancy
priapism: persistent, painful erection
primary apnea: period of halted respirations during the first few seconds of life
primary circular reaction: infant's exploration of objects by grasping them with the hands or by mouthing them
primary engorgement: feeling of tension in the breasts on the 3rd or 4th day postpartum
primary subfertility: no previous conceptions have occurred
primary nursing: a nursing pattern in which one nurse assumes complete responsibility for the care of a patient
primigravida: a woman during her first pregnancy
primipara: a woman who has given birth to one viable infant
probable signs of pregnancy: findings, largely objective in nature, that suggest but do not confirm that a pregnancy is present
prodromal period: a time between the beginning of nonspecific symptoms and specific infectious symptoms
prolactin: an anterior pituitary hormone that acts on the acinar cells of the mammary glands to stimulate the production of milk
proteinuria: protein in the urine
prune belly syndrome: severe urinary tract dilation that develops as early as intrauterine life from an unknown cause
pseudoanemia: the apparent anemia that occurs early in pregnancy due to rapid expansion of blood volume
pseudocyesis: false pregnancy
pseudohermaphrodite: a child with some external features of both sexes, although only either ovaries or testes (or neither) are present
pseudomenstruation: mucous vaginal secretion in female newborns, which is sometimes blood-tinged
psychomotor learning: learning that requires a change in an individual's ability to perform a skill
psychoprophylactic method: the Lamaze method of childbirth
ptosis: drooping of the eyelid
puberty: the stage at which a person first becomes capable of sexual reproduction
pudendal nerve block: the injection of a local anesthetic near the right and left pudendal nerves at the level of the ischial spine
puerperium: the first 6 weeks following childbirth
pulse pressure: the gap between systolic and diastolic blood pressure
punishment: a consequence that results from a breakdown in discipline (disregarding the rules)
purging: self-induced vomiting or the use of laxatives, enemas, or diuretics
purpura: hemorrhagic rash or small hemorrhages occurring in the superficial layer of skin
pyloric stenosis: hypertrophy or hyperplasia of the muscle surrounding the pyloric sphincter (opening between the lower portion of the stomach and the beginning portion of the intestine, the duodenum), making it difficult for the stomach to empty
pyrosis: heartburn
quadriplegia: paralysis of all four extremities
quickening: the first movement of the fetus perceived by the mother
radiation: transfer of body heat to a cooler solid object not in contact with the baby
radiopharmaceuticals: radioactive-combined substances that, when given orally or by injection, flow to designated body organs
rales: fine crackling lung sound; denotes fluid in alveoli
rape trauma syndrome: a form of posttraumatic stress syndrome consisting of two phases: disorganization and reorganization
rapid eye movement (REM): last stage of sleep lasting 10 to 30 minutes in which eyes move in rapid, involuntary motions and respirations are irregular; body turnings, movements, and penile erections may occur
recessive gene: gene that is not dominant
rectocele: a herniation of the rectum into the posterior vaginal wall

recurrent pregnancy loss: having three spontaneous miscarriages that occurred at the same gestation age in three pregnancies
redemonstration: returning a demonstration to show competency of the skill
referred pain: pain that is perceived at a site distant from its point of origin
reflecting: technique for therapeutic communication that involves restating the last word or phrase a person has said
remodeling: new bone tissue replacing old bone tissue
reorganization phase: second phase of rape trauma syndrome that may last for months or years; rape victims possibly continue to report recurring nightmares, perhaps sexual dysfunction, and continuing inability to relate to men or face new and surprising situations. They may continue to have a great deal of difficulty discussing the rape.
reproductive life planning: planning to space children or prevent children from being conceived
reservoir: container or place in which organisms grow and reproduce
resorption: the breakdown of bone cells
reticulocyte: a developmental stage of red blood cells prior to the formation of mature RBCs
retinopathy of prematurity (ROP): an acquired ocular disease that leads to partial or total blindness in children, due to vasoconstriction of immature retinal blood vessels; commonly caused by use of too-high oxygen levels
retractions: indentation of intercostal spaces reflecting difficulty breathing
retractors: long, metal, curved instruments used to aid birth
retroflexion: a uterus that is bent backward just above the cervix
retroversion: a uterus that is tipped abnormally backwards
reversibility: the ability to retrace steps
review of systems: summary of body symptoms as the last step in a health interview
Rh incompatibility: an Rh-negative mother (one negative for a D antigen or one with a dd genotype) is carrying a fetus with an Rh-positive blood type (DD or Dd genotype)
rhabdomyosarcoma: tumor of striated muscle
rhinorrhea: discharge from the nose
rhythmicity: a regular rhythm in physiologic functions
rickets: deficiency of vitamin D involving poor bone formation
right-to-left shunt: cardiac anomaly when blood is shunted from the venous to the arterial system as a result of abnormal communication between the two (deoxygenated blood to oxygenated blood)
ripening: softening of the cervix with the approach of labor
role confusion: characteristic of people who do not develop a sense of identity; uncertainty about what kind of person one is
role fantasy: a method of thinking that changes perceptions to how the child would like things to turn out (magical thinking)
rooming-in: a hospital pattern in which an infant stays in the room with the mother
sarcomas: tumors derived from connective tissue, such as bone and cartilage, muscle, blood vessels, or lymphoid tissue
schemas: the means by which thoughts are organized (Piaget)
scope of practice: range of activity
scurvy: vitamin C deficiency involving muscle tenderness and petechiae
seborrhea: a scaly scalp condition, often called cradle cap
secondary apnea: weakening of a newborn's respiratory effort after attempts to initiate respirations with a few strong gasps after 1 to 2 minutes of apnea
secondary circular reaction: infant's ability to realize that his or her actions can initiate pleasurable sensations
secondary subfertility: a couple is unable to conceive at present although they have had a previous viable pregnancy
secondary stuttering: stuttering that develops after a child learns to speak without stuttering
sella turcica: a depression of the sphenoid bone
sensorimotor stage: the period from birth to 2 years of age (Piaget)
sensory deprivation: loss of environmental stimuli
sensory overload: receiving more stimulation than can be tolerated or processed
septicemia: pathogenic organisms in the bloodstream
sequestrum: dead bone tissue detached from adjoining healthy bone
sexually transmitted infections (STIs): those spread through sexual contact with an infected partner
shaken baby syndrome: repetitive, violent shaking of a small infant by the arms or shoulders causing a whiplash injury to the neck, edema to the brainstem, and distinct retinal hemorrhages
shoulder dystocia: an infant's wide shoulders are unable to pass through the outlet of the pelvis
sickle-cell crisis: term used to denote a sudden, severe onset of sickling with sickle-cell anemia
sickle-cell trait: the existence of hemoglobin AS (normal hemoglobin and abnormal hemoglobin S); a disease carrier
silent rape syndrome: long-term effects in victims who do not report rape and receive no counseling
Sims' position: turned to the left side with the weight of the uterus resting on the bed
single-photon emission computerized tomography (SPECT): CT scan involving the use of an injectable iodine-based contrast medium

sinus arrhythmia: a marked heart rate increase occurring as the child inspires and a marked decrease in heart rate as the child expires
sitz bath: small, portable basin that fits on a toilet seat to provide a constant supply of water to the perineal area. It soothes healing tissue and decreases inflammation by vasodilation to the area.
skilled home care: care that includes physician-prescribed procedures such as dressing changes, administration of drugs, health teaching, and observation of the client's progress
sleep deprivation: lack of adequate amount of sleep leading to difficulty in concentrating and episodes of disorientation and misperception
small-for-gestational-age (SGA) infant: an infant who falls below the 10th percentile of weight for age
social smile: a definite response (smiling) to an interaction occurring at about 6 weeks of age
somatic pain: pain that originates from deep body structures such as muscles or blood vessels
Somogyi phenomenon: rebound hyperglycemic response, typically manifested with nighttime hypoglycemia and early morning hyperglycemia
speculum: a metal or plastic instrument with movable flat blades used for pelvic examinations
sperm count: the number of sperm present in a measured amount of semen
sperm motility: whether sperm are seen to be active
spermatogenesis: production of sperm cells
spina bifida: Latin for "divided spine"; most often used as a collective term for all spinal cord disorders
spontaneous miscarriage: pregnancy interruption due to natural causes
stalking: repetitive, intrusive, and unwanted actions directed at an individual to gain the individual's attention or evoke fear
station: the relationship of the presenting part of the fetus to the level of the ischial spines
status epilepticus: a seizure that lasts continuously for more than 30 minutes or a series of seizures from which the child does not return to his or her previous level of consciousness
steatorrhea: large, bulky, greasy stools
stenosis: narrowing
stereognosis: the ability to recognize an object by touch
stereopsis: depth perception; the ability to locate an object in space relative to another object
stereotyping: applying a fixed conception
strabismus: crossed eye
strawberry hemangioma: a type of birthmark identified as an elevated area formed by immature capillaries and endothelial cells
striae gravidarum: reddish steaks appearing on the abdominal wall during pregnancy
stridor: a harsh, strident breath sound on inspiration
stupor: lethargy and unresponsiveness
subconjunctival hemorrhage: rupture of a conjunctival capillary appearing as a red spot on the sclera, frequently seen in newborns
substance abuse: the use of chemicals to improve a mental state or induce euphoria
substance dependent: when a person has withdrawal symptoms following discontinuation of the substance, and such activities as abandonment of important activities, spending increased time in activities related to substance use, using substances for a longer time than planned, and continued use despite the existence of worsening problems due to substance use
substitution of meaning: also called guided imagery; distraction technique to help a person place another meaning (a nonpainful one) on a painful procedure
suppressor T cells: T cells that reduce the production of immunoglobulins against a specific antigen and prevent their overproduction
surfactant: a lipoprotein secreted by the alveoli cells to reduce surface tension in alveoli
susceptible host: individual more prone to infection than others
syndactyly: fusing of the fingers
synergeneic transplantation: transplantation between a donor and recipient who are genetically identical (i.e., identical twins)
systole: contraction of the heart chambers
T lymphocytes: lymphocytes that are produced by the bone marrow but mature under the influence of the thymus gland (hence the term *T cells*)
taboos: actions that are prohibited in a specific culture
tachypnea: an increased respiratory rate
taking-hold phase: the second phase of the postpartal period where the woman begins to initiate action
taking-in phase: the first phase of the postpartal period experienced when the woman is reflective and plays a largely passive role
teaching plan: a design of content to be taught and the teaching–learning techniques to be used
temperament: a child's innate behavioral characteristics such as activity level, rhythmicity, tendency to approach or withdraw, and adaptability to situations
teratogen: substance that causes fetal harm
teratogenicity: capable of causing fetal harm
term infant: an infant born after the beginning of week 38 and before week 42 of pregnancy
tertiary circular reaction stage: a stage of development in which the child discovers new properties of objects (Piaget)
thelarche: breast development changes at puberty
theory: a systematic statement of principles that provides a framework for explaining some phenomenon
therapeutic communication: an interaction between two people that is planned, has structure, and is helpful and constructive

therapeutic play: play technique that can be used by nurses to better understand children's feelings and thoughts and relieve their anxiety
thought stopping: technique whereby children are taught to stop anxious thoughts by substituting a positive or relaxing thought
threatened miscarriage: pregnancy interruption manifested by vaginal bleeding, initially beginning as scant bleeding, and usually bright red in color
threshold of response: the intensity level of stimulation that is necessary to evoke a reaction
threshold sensation: the amount of stimulus that results in pain
thrombocytes: platelets
thrombocytopenia: decreased platelet count
thrombophlebitis: inflammation of the lining of a blood vessel with the formation of blood clots
thrush: a *Candida* infection that usually appears on the tongue and sides of the cheeks as white or gray patches
thumb opposition: ability to bring the thumb and fingers together
tocolytic agent: a drug to halt labor
tolerance: a state of not responding to an allergen
total parenteral nutrition (TPN): concentrated hypertonic solutions of intravenous fluid containing glucose, vitamins, electrolytes, trace minerals, fat, and protein to meet all of the child's nutritional needs
toxic shock syndrome (TSS): an infection usually caused by toxin-producing strains of *Staphylococcus aureus* organisms
toxoid: extract of a toxin with reduced virulence
toxoplasmosis: a protozoan infection spread most commonly through contact with uncooked meat; also contracted through handling cat stool in soil or cat litter
tracheostomy: an opening into the trachea to create an artificial airway
tracheotomy: procedure to create an airway
traction: pulling on a body part in one direction against a counterpull exerted in the opposite direction to reduce dislocations and immobilize fractures
transcultural nursing: a philosophy of nursing that focuses on the unique cultural beliefs of people
transcutaneous electrical nerve stimulation (TENS): pain relief measure that achieves its effect by counterirritation on nociceptors by use of a light electric current
transillumination: holding a bright light such as a flashlight or a specialized light—a Chun gun—against a body part to reveal fluid inside
transition: the end of the first stage of labor, just before the woman experiences pushing sensations
transitional stool: green and loose stool passed on the second to third day of the newborn's life
transsexual: a person of one sex whose perceived identity is of the opposite sex
transvestite: a person who engages in the practice of dressing in the clothes of the opposite sex for sexual gratification
triphasic oral contraceptives: birth control pills in which the estrogen and progestin content varies throughout the cycle
trophoblast: the outer layer of the blastocyst
true conjugate: conjugate vera; measurement between the anterior surface of the sacral prominence and the posterior surface of the inferior margin of the symphysis pubis
trust: the developmental task of the infant, according to Erikson; learning to love and be loved
tubal ligation: a method of contraception in which the fallopian tubes are cauterized, tied, or clamped to prevent sperm from reaching the discharged oocyte
tumor staging: procedure by which a malignant tumor's extent and progress are determined
turgor: skin characteristic reflecting the amount of fluid in body tissue
tympanocentesis: withdrawal of fluid from the middle ear through the tympanic membrane
ulcerative colitis: inflammation of continuous intestinal segments, typically the colon and rectum, with the distal colon and rectum most severely affected
ultrasound: painless diagnostic procedure in which pictures of internal tissue and organs are produced by high-frequency sound waves
umbilical cord: the structure composed of one vein and two arteries that connects the placenta to the fetus
umbilical cord prolapse: a loop of the umbilical cord slipping down in front of the presenting fetal part
underweight: a body mass index under 18.5
urticaria: swelling and itching caused by capillary dilatation
uterine atony: relaxation of the uterus in the postpartal period
uterine inversion: a rare phenomenon in which the uterus turns inside out
vacuum extraction: birth of a fetus by means of vacuum pressure
vaginal birth after cesarean birth (VBAC): a vaginal birth in a woman who previously had a child by cesarean birth
vaginismus: painful, involuntary spasms of the vagina
varicocele: abnormal dilation of the veins of the spermatic cord
vascular access port (VAP): small device (infusion port) implanted under the skin, usually on the anterior chest just under the clavicle to allow for circulatory access
vasculitis: inflammation of blood vessels
vasectomy: a surgical ligation of the vas deferens that results in male sterility
ventral suspension: infant's appearance when held in midair on a horizontal plane, supported by a hand under the abdomen

vernix caseosa: a white, cream cheese–like substance that serves as a skin lubricant; usually noticeable on a newborn's skin at birth in a term neonate
very-low-birth-weight infant: infant weighing less than 1500 g
vesicoureteral reflux: retrograde flow of urine from the bladder into the ureters
vibration: a chest physiotherapy technique that involves pressing a vibrating hand against a child's chest during exhalation to loosen and raise mucus
visceral pain: involves sensations that arise from internal organs such as intestines
vocal tics: coughing, throat clearing, snorting, and barking
volvulus: a twisting of the bowel causing obstruction
voyeurism: the practice of obtaining sexual pleasure by looking at the nude body of another
vulnerable or fragile children: children whose parents were told they would die, but who lived and are treated in a cold and unfeeling way—as if they actually did die
vulvovaginitis: inflammation of the vulva or vagina
Wharton's jelly: the gelatinous substance that gives bulk to the umbilical cord
wheezing: whistling expiratory sound
women's health nurse practitioner: an advanced practice nurse who specializes in the health care of women
xerophthalmia: dry and lusterless conjunctivae caused by vitamin A deficiency
yolk sac: the space in the blastocyst from which the hemopoietic system develops
zona pellucida: a layer of fluid that surrounds the ovum at ovulation
zygote: a fertilized ovum
