Observe the Pattern: Lochia is red for the first 1 to 3 days (lochia rubra), pinkish-brown from days 4 to 10 (lochia serosa), and then white (lochia alba) for as long as 6 weeks after birth. The pattern of lochia (rubra to serosa to alba) should not reverse. A red flow after a pink or white flow may indicate that placental fragments have been retained or that uterine contraction is decreasing and new bleeding is beginning.

Assess the Odor: Lochia should not have an offensive odor. Lochia has the same odor as menstrual blood. An offensive odor usually indicates that the uterus has become infected. Immediate intervention is needed to halt postpartal infection.

Watch for Absence: Lochia should never be absent during the first 1 to 3 weeks. Absence of lochia, like presence of an offensive odor, may indicate postpartal infection. Lochia may be scant in amount after cesarean birth, but it is never altogether absent.

and estradiol are all at prepregnancy levels. Estrol may be elevated for an additional week before it reaches prepregnancy levels. Follicle-stimulating hormone (FSH) remains low for about 12 days and then begins to rise as a new menstrual cycle is initiated.

The Urinary System

During pregnancy, as much as 2000 to 3000 mL excess fluid accumulates in the body. An extensive diuresis begins to take place almost immediately after birth to rid the body of this fluid. This easily increases the daily output of a postpartal woman from a normal level of 1500 mL to as much as 3000 mL/day during the second to fifth day after birth. This marked increase in urine production causes the bladder to fill rapidly.

During a vaginal birth, the fetal head exerts a great deal of pressure on the bladder and urethra as it passes on the bladder's underside. This pressure may leave the bladder with a transient loss of tone that, together with the edema surrounding the urethra, decreases a woman's ability to sense when she has to void. A woman who has undergone epidural or spinal anesthesia can feel no sensation in the bladder area until the anesthetic has worn off.

To prevent permanent damage to the bladder from overdistention, assess a woman's abdomen frequently in the immediate postpartal period. On palpation, a full bladder is felt as a hard or firm area just above the symphysis pubis. On percussion (placing one finger flat on the woman's abdomen over the bladder and tapping it with the middle finger of the other hand), a full bladder sounds resonant, in contrast to the dull, thudding sound of non–fluid-filled tissue. Pressure on this area may make a woman feel as if she has to void, but she is then unable to do so. As the bladder fills, it displaces the uterus; uterine position is therefore a good gauge of whether a bladder is full or empty. If the uterus is becoming uncontracted or feels soft on palpation and is pushed to the side, the usual cause is an overfilled bladder.

The hydronephrosis or increased size of ureters that occurred during pregnancy remains present for about 4 weeks after birth. The increased size of these structures, in conjunction with reduced bladder sensitivity, increases the possibility of urinary stasis and urinary tract infection in the postpartal period.

During the entire postpartal period, urine tends to contain more nitrogen than normal. This is probably due in part to a woman's increased muscle activity during labor and in part to the breakdown of protein in a portion of the uterine muscle that occurs during involution. Lactose levels in the urine are slightly elevated the same as during pregnancy, as the body prepares for breastfeeding. Diaphoresis (excessive sweating) is another way by which the body rids itself of excess fluid. This is noticeable in women soon after birth.

The Circulatory System

The diuresis that is evident between the second and fifth days after birth, as well as the blood loss at birth, acts to reduce the added blood volume a woman accumulated during pregnancy. This reduction occurs so rapidly, in fact, that the blood volume returns to its normal prepregnancy level by the first or second week after birth.

The usual blood loss with a vaginal birth is 300 to 500 mL. With a cesarean birth, it is 500 to 1000 mL. A 4-point decrease in hematocrit (proportion of red blood cells to circulating plasma) and a 1-g decrease in hemoglobin value occur with each 250 mL of blood lost. For example, if an average woman enters labor with a hematocrit of 37%, it will be about 33% on the first postpartal day, and hemoglobin will fall from 11 to 10 g/dL. If the woman was anemic during pregnancy, she can expect to continue to be anemic afterward. As excess fluid is excreted, the hematocrit gradually rises (because of hemoconcentration), reaching prepregnancy levels by 6 weeks after birth.

Women usually continue to have the same high level of plasma fibrinogen during the first postpartal weeks as they did during pregnancy. This is a protective measure against hemorrhage. However, this high level also increases the risk of thrombus formation. There is also an increase in the number of leukocytes in the blood. The white blood cell count may be as high as 30,000 cells/mm^3 (mainly granulocytes) compared to a normal level of 5000 to 10,000 cells/mm^3, particularly if labor was long or difficult. This, too, is part of the body's defense system, a defense against infection and an aid to healing.

Any varicosities that are present will recede, but they rarely return to a completely prepregnant appearance. Although vascular blemishes, such as spider angiomas, fade slightly, they may not disappear completely either.

The Gastrointestinal System

Digestion and absorption begin to be active again soon after birth unless a woman has had a cesarean birth. Almost immediately, the woman feels hungry and thirsty and she can eat without difficulty from nausea or vomiting during this time.

Hemorrhoids (distended rectal veins) that have been pushed out of the rectum because of the effort of pelvic-stage pushing often are present. Bowel sounds are active, but passage of stool through the bowel may be slow because of the still-present effect of relaxin on the bowel. Bowel evacuation may be difficult because of the pain of episiotomy sutures or hemorrhoids.

The Integumentary System

After birth, the stretch marks on a woman's abdomen (striae gravidarum) still appear reddened and may be even more prominent than during pregnancy, when they were tightly stretched. Typically, in a Caucasian woman, these will fade to a pale white over the next 3 to 6 months; in an African American woman, they may remain as areas of slightly darker pigment. Excessive pigment on the face and neck (chloasma) and on the abdomen (linea nigra) will become barely detectable in 6 weeks' time. If **diastasis recti** (overstretching and separation of the abdominal musculature) is present, the area will appear slightly indented. If the separation is large, it will appear as a bluish area in the abdominal midline. Modified sit-ups help to strengthen abdominal muscles and return abdominal support to its prepregnant level. Both the abdominal wall and the ligaments that support the uterus, which were obviously stretched during pregnancy, usually require the full 6 weeks of the puerperium to return to their former state.

Effects of Retrogressive Changes

The overall effects of postpartal retrogressive changes are exhaustion and weight loss.

Exhaustion

As soon as birth is completed, a woman experiences total exhaustion. For the last several months of pregnancy, she probably has experienced some difficulty sleeping. Near the end of pregnancy, she probably was unable to find a comfortable position to sleep because of the fetus' activity or the presence of back or leg pain. All during labor, she worked hard with little or no sleep. Now she has "sleep hunger," which may make it difficult for her to cope with new experiences and stressful situations until she has enjoyed a sustained period of sleep.

Weight Loss

The rapid diuresis and diaphoresis during the second to fifth days after birth usually result in a weight loss of 5 lb (2 to 4 kg), in addition to the approximately 12 lb (5.8 kg) lost at birth. Lochia flow causes an additional 2- to 3-lb (1-kg) loss, for a total weight loss of about 19 lb. Additional weight loss is most dependent on the amount of pregnancy weight gain and on whether a woman takes active measures to lose weight. It is also influenced by nutrition, exercise, and breastfeeding. The weight a woman reaches at 6 weeks after birth becomes her baseline postpartal weight unless she takes active measures to lose the weight (Box 17.5). In many women, this baseline is higher than their prepregnancy weight and one of the reasons that obesity has become a national health concern (Ebbeling et al., 2007).

BOX 17.5 ✻ Focus on Evidence-Based Practice

What is an effective action for women to do to lose the additional weight they gained during pregnancy?

Women are usually interested in losing the weight they gained during pregnancy. It is not always easy to lose those extra pounds they gained, though, because they are exhausted from labor and their days are filled with new baby care. To investigate whether lack of sleep, a common postpartal concern, is linked to obesity, researchers selected 940 participants who were enrolled in prenatal care and assessed them for their sleep pattern and whether they lost their pregnancy weight during their postpartal period. Of the 940 women, 124 (13%) developed postpartum weight retention or were 5 kg or more above pregravid weight at 1 year postpartum. Of these 940 women, 114 (12%) women slept 5 hours or less per day, 280 (30%) slept 6 hours per day, 321 (34%) slept 7 hours per day, and 225 (24%) slept more than 8 hours per day. The women who slept the most (8 hours) were most apt to have lost their pregnancy weight gain at 1 years time; those who slept the least (under 5 hours) were most apt to retain their additional pregnancy weight.

The researchers suggest that interventions to prevent postpartum obesity should consider strategies to obtain optimal maternal sleep during the year after birth.

Would this study be helpful when talking to postpartum women about their need to rest to prevent exhaustion?

Vital Sign Changes

Vital sign changes in the postpartum period reflect the internal adjustments that occur as a woman's body returns to its prepregnant state.

Temperature

Temperature is always taken orally or tympanically (never rectally) during the puerperium, because of the danger of vaginal contamination and the discomfort involved in rectal intrusion.

A woman may show a slight increase in temperature during the first 24 hours after birth because of dehydration that occurred during labor. If she receives adequate fluid during the first 24 hours, this temperature elevation will return to normal. Most women are thirsty immediately after birth and are eager to take in fluid. This makes drinking a large quantity of fluid not a problem unless the woman is nauseated from a birth anesthetic.

Any woman whose oral temperature rises above 100.4° F (38° C), excluding the first 24-hour period, is considered by criteria of the Joint Commission on Maternal Welfare to be febrile. In such women, a postpartal infection may be present (Poggi, 2007).

Occasionally, when a woman's breasts fill with milk on the third or fourth postpartum day, her temperature rises for a period of hours because of the increased vascular activity involved. If the elevation in temperature lasts longer than a few hours, however, infection is a more likely reason. Infection is a major cause of postpartal mortality and morbidity. Because nurses play a major role in assessing postpartum temperature, they have the important role of being the health care providers who may first detect the problem.

Pulse

A woman's pulse rate during the postpartal period is usually slightly slower than normal. During pregnancy, the distended uterus obstructed the amount of venous blood returning to the heart; after birth, to accommodate the increased blood volume returning to the heart, stroke volume increases. This increased stroke volume reduces the pulse rate to between 60 and 70 beats per minute. As diuresis diminishes the blood volume and causes blood pressure to fall, the pulse rate increases accordingly. By the end of the first week, the pulse rate will have returned to normal.

Evaluate pulse rate conscientiously in the postpartal period, because a rapid and thready pulse during this time could be a sign of hemorrhage. Be certain to compare a woman's pulse rate with the slower range expected in the postpartal period, not with the normal pulse rate in the general population. Otherwise, this important finding of hemorrhage may be missed.

Blood Pressure

Blood pressure should also be monitored carefully during the postpartal period, because a decrease in this can indicate bleeding. In contrast, an elevation above 140 mm Hg systolic

or 90 mm Hg diastolic may indicate the development of postpartal pregnancy-induced hypertension, an unusual but serious complication of the puerperium (Bailis & Witter, 2007) (see Chapter 21).

To evaluate blood pressure, compare a woman's pressure with her prepregnancy level if possible, rather than with standard blood pressure ranges; otherwise, if her blood pressure rose during pregnancy, a significant postpartal decrease in pressure could be missed.

Oxytocics, drugs frequently administered during the postpartal period to achieve uterine contraction, cause contraction of all smooth muscle, including blood vessels (Subramanian et al., 2008). Consequently, these drugs can increase blood pressure. To prevent blood pressure from rising too high, always measure it before administering one of these agents. If the blood pressure is greater than 140/90 mm Hg, withhold the agent and notify the woman's physician or nurse-midwife to prevent hypertension and, possibly, a cerebrovascular accident.

A major complication in women who have lost an appreciable amount of blood with birth is orthostatic hypotension, or dizziness that occurs on standing because of the lack of adequate blood volume to maintain nourishment of brain cells. To test whether a woman will be susceptible to orthostatic hypotension, assess her blood pressure and pulse while she is lying supine. Next, raise the head of the bed fully upright, wait 2 or 3 minutes, and reassess these values. If the pulse rate is increased by more than 20 beats per minute and blood pressure is 15 to 20 mm Hg lower than formerly, the woman might be susceptible to dizziness and fainting when she ambulates. Advise her to always sit up slowly and "dangle" on the side of her bed before attempting to walk. If she notices obvious dizziness on sitting upright, support her during ambulation to avoid the possibility of a fall. Caution her not to attempt to walk carrying her newborn until her cardiovascular status adjusts better to her blood loss. Inform the woman's physician or nurse-midwife of these findings.

What if... Joan Cooper, now 12 hours postpartum, has an oral temperature of 99° F (37.2° C) and is uncomfortable from profuse diaphoresis and extreme fatigue. What actions would you take?

Progressive Changes

Two physiologic changes that occur during the puerperium involve progressive changes, or the building of new tissue. Because building new tissue requires good nutrition, caution women against strict dieting that would limit cell-building ability during the first 6 weeks after childbirth (Rolfes, Pinna, & Whitney, 2009).

Lactation

The formation of breast milk (lactation) begins in a postpartal woman whether or not she plans to breastfeed (Pavone, Purinton, & Petersen, 2007). Early in pregnancy, the increased estrogen level produced by the placenta stimulates the growth of milk glands; breasts increase in size because of the larger glands, accumulated fluid, and some extra adipose tissue. For the first 2 days after birth, an average woman notices little change in her breasts from the way they were during pregnancy. Since midway through pregnancy, she has been secreting colostrum, a thin, watery, prelactation secretion. She continues to excrete this fluid the first 2 postpartum days. On the third day, her breasts become full and feel tense or tender as milk forms within breast ducts.

Breast milk forms in response to the decrease in estrogen and progesterone levels that follows delivery of the placenta (which stimulates prolactin production and, consequently, milk production). When breast milk first begins to form, the milk ducts become distended. The nipple secretion changes from the clear colostrum to bluish white, the typical color of breast milk. A woman's breasts become fuller, larger, and firmer. In many women, breast distention becomes marked, and this often is accompanied by a feeling of heat or throbbing pain. Breast tissue may appear reddened, simulating an acute inflammatory or infectious process. The distention is not limited to the milk ducts but occurs in the surrounding tissue as well, because blood and lymph enter the area to contribute fluid to the formation of milk. This feeling of tension in the breasts on the third or fourth day after birth is termed primary **engorgement.** It fades as the infant begins effective sucking and empties the breasts of milk. Whether milk production continues depends on the sucking of the infant at the breasts as this releases oxytocin and causes new milk to form. Whether women continue to breastfeed after hospital discharge is influenced by such factors as employment, personal habits, and how important they view breastfeeding to be (Abdulwadud & Snow, 2009). They must be certain to drink adequate fluid daily, eat a nutritious diet, and check with their health care provider before ingesting alternative therapies such as herbs as most of these can be found in breast milk and could be toxic to a newborn (Seely et al., 2008). Techniques of breastfeeding are discussed in Chapter 19.

Return of Menstrual Flow

With the delivery of the placenta, the production of placental estrogen and progesterone ends. The resulting decrease in hormone concentrations causes a rise in production of FSH by the pituitary, which leads, with only a slight delay, to the return of ovulation. This initiates the return of normal menstrual cycles.

A woman who is not breastfeeding can expect her menstrual flow to return in 6 to 10 weeks after birth. If she is breastfeeding, a menstrual flow may not return for 3 or 4 months (lactational amenorrhea) or, in some women, for the entire lactation period. However, the absence of a menstrual flow does not guarantee that a woman will not conceive during this time, because she may ovulate well before menstruation returns (Van der Wijden, Kleijnen, & Van den Berk, 2009).

NURSING CARE OF A WOMAN AND FAMILY DURING THE FIRST 24 HOURS AFTER BIRTH

A woman remains in a birthing room for at least the first hour after birth so she has time to become acquainted with her newborn and to provide for careful health care team observation. After this initial hour, teach perineal care and

encourage a woman to shower. She then remains in the room as a postpartal patient or is transferred to a separate postpartal room. The most dangerous hour in childbearing—the first hour after birth—has passed.

Hemorrhage is still a possibility for the first 2 or 3 days after birth, until the myometrial vessels have sclerosed. One of the worries for a woman giving birth at home is that she will not appreciate how dangerous a time this is. With attention focused more on the newborn than on her, postpartal hemorrhage could occur. In the hospital, various health care personnel may be involved in caring for a woman: be sure all members of the health care team are knowledgeable about this danger.

Assessment

Assessment of a postpartal woman includes history, physical examination, and analysis of laboratory findings.

Health History

The technical aspects of a woman's pregnancy, labor, and birth can be learned from her pregnancy, labor, and birth charts. Most of this information is best obtained from a woman herself, however, because this supplies not only information on the events of her pregnancy and labor but also her emotions and impressions about them. If you previously cared for a woman during labor and birth and gained this information, then it is unnecessary to do so again.

Family Profile. Information for a family profile includes age, support persons, other children, type of housing and community setting, occupation, education level, and socioeconomic level or the information necessary to evaluate the impact a new child will have on the woman and her family. This information also lays a foundation for teaching self-care and child care specific to the woman's knowledge level and needs.

Pregnancy History. Information for a pregnancy history includes para and gravida status (and the reason for any discrepancy), expected date of birth, whether the pregnancy was planned, and any problems or complications such as spotting or pregnancy-induced hypertension that occurred. This information helps you to gauge a woman's potential for bonding, because an unplanned pregnancy or complications arising during pregnancy can interfere greatly with bonding.

Labor and Birth History. It is important to gather information on the length of labor, position of the fetus, type of birth, any analgesia or anesthesia used, problems during labor such as fetal distress, supine hypotension syndrome, and the presence of perineal sutures. This information helps in planning for necessary procedures.

Infant Data. The sex and weight of the infant, any difficulty at birth such as the need for resuscitation, plans to breastfeed or formula feed, and any congenital anomalies present are the major facts to obtain. This information helps in planning care for the infant and promoting bonding with the parents.

Postpartal Course. Ask about a woman's general health; her activity level since the birth; a description of lochia; the presence of perineal, abdominal, or breast pain; difficulty with elimination; success with infant feeding; and response of her support person to parenting. This information helps in planning what anticipatory guidance will be needed for home care.

Laboratory Data

Women routinely have their hemoglobin and hematocrit levels measured 12 to 24 hours after birth, to determine whether blood loss at birth has left them anemic. If the hemoglobin finding is lower than 10 g/100 mL, supplementary iron is usually prescribed. Take note of the laboratory reports on a postpartal woman, and make certain that any abnormal finding, such as low hemoglobin, is brought to the attention of the woman's physician or nurse-midwife. The responsibilities of being a new mother, coupled with the additional burden of an undetected low hemoglobin level, can severely tax a woman's energy levels (Dodd, Dare, & Middleton, 2009).

If a woman required catheterization during labor or had a urinary tract infection during pregnancy, a urinalysis or urine culture may be ordered in the postpartal period. Obtain the urine specimen with a clean-catch technique, using a sterile cotton ball tucked in the vaginal introitus to prevent lochia from contaminating the specimen. In some women, it may be necessary to obtain a specimen by urinary catheterization to rule out urinary infection.

Physical Assessment

During early labor, a woman is given a fairly complete physical examination. During the immediate postpartal period, therefore, repetition of a complete examination is not necessary. Crucial assessments examining particular aspects of health, such as an estimation of nutrition and fluid state, energy level, presence or absence of pain, breast health, fundal height and consistency, lochia amount and character, perineal integrity, and circulatory adequacy, are required.

General Appearance. A woman's general appearance in the postpartal period reveals a great deal about her energy level, her self-esteem, and whether she is moving into the taking-hold phase of recovery. Before beginning assessment, ask a woman to void so that she has an empty bladder. Observe how much energy she uses when reaching for her robe or walking to the bathroom—does she struggle or move listlessly, or does she accomplish this task quickly? Observe for a cringing expression or hand pressure against her abdomen that suggests pain on movement. Observe whether she has combed her hair, applied makeup, and put on her own clothing or an agency gown. Many women choose to sleep in an agency gown to prevent lochia stains on their own clothing, but a woman who is pleased with herself, her pregnancy, and her birth experience is usually anxious to wear her own clothing and "fuss" with her appearance within an hour after birth. A woman who is extremely exhausted or depressed probably will not bother with her appearance this way. Keep in mind that a woman whose labor progressed so rapidly that she came to a health care agency as an emergency admission may not have had time to pack a comb and brush or her own clothing. Cultural variations also affect appearance and actions.

In the United States, the postpartal period is generally regarded as a time of wellness; early ambulation and eating a

varied diet are encouraged. In other cultures, the period after childbirth may be regarded primarily as a time of rest. Cultural differences include restricting certain foods, reducing activity levels, or both; taboos and rituals are not uncommon. Assessing women in the postpartal period for cultural variations of these types is important, because such variations explain why a woman might be reluctant to ambulate or why she leaves a lunch of food she views as unacceptable uneaten although she said she was hungry.

Hair. Palpate the woman's hair to determine its firmness and strength. Whenever a diet is deficient in nutrients, hair becomes listless and "stringy." A woman who had good nutritional intake during pregnancy has firm, crisp hair. Many women begin to lose a quantity of hair in the postpartal period. This is because, during pregnancy, metabolism was increased and hair growth was rapid, so many hairs reached maturity at the same time. As the woman's body returns to a normal metabolism level, this hair is lost. You may need to reassure a woman that hair loss is not a sign of illness but just another aspect of return to her prepregnant state.

Face. Assess the woman's face for evidence of edema such as puffy eyelids or a prominent fold of tissue inferior to the lower eyelid. Normally, this is negligible. However, in a woman who had pregnancy-induced hypertension and accumulated excessive fluid, it may be evident. It also will become evident in a woman who is developing postpartal pregnancy-induced hypertension, although this condition is rare. Facial edema is most apparent early in the morning if a woman has been lying supine with her head level during the night.

Eyes. Inspect the color and texture of the inner conjunctiva. If a woman is dehydrated, the area appears dry. A woman who is anemic from poor pregnancy nutrition or excessive blood loss at birth has pale conjunctiva. Be alert to possible variations because of skin color, however. The conjunctiva always appears lightly shaded in fair-skinned women. Dark-skinned women may have a ruddy conjunctiva appearance even with anemia. Check the hemoglobin level of any woman with paler than usual conjunctivae to determine whether anemia is present.

Breasts. Breast tissue increases in size as breast milk forms, so a bra that was adequate during pregnancy may no longer be adequate by the second or third postpartal day. Use of a bra supports breast tissue that feels heavy because of increased fluid accumulation and aids comfort. Advise a woman to buy a nursing bra for the postpartal period that is one to two sizes larger than her pregnancy size to allow for this increase. Properly fitted, a bra should fit firmly and snugly. The straps of a bra should not leave erythematic marks on a woman's shoulders.

To assess breasts, ask a woman to remove her bra and cover her breasts with a towel or folded sheet to protect modesty. Ask her to raise her hands over her head and then tuck them under her head, because this stretches and thins breast tissue. Inspect and then palpate for breast size, shape, and color.

Breast tissue should feel soft on palpation on the first and second postpartal day. On the third day, it should begin to feel firm and warm (described as *filling*). On the third or fourth day, breasts appear large and reddened, with taut, shiny skin (engorgement). On palpation, they feel hard and tense and are painful. Normally, engorgement causes the entire breast to feel warm or appear reddened. If only one portion of a breast is warm or reddened, mastitis or inflammation or, possibly, infection of glands or milk ducts is suggested (Deshpande, 2007).

Occasionally, a firm nodule is detected on palpation. Usually, this is only a temporarily blocked milk duct or milk contained in a gland that is not flowing forward to the nipple. However, the location of the nodule should be noted and reported to the woman's physician or nurse-midwife, so that it can be reassessed before discharge from the hospital. Such blocking of breast milk usually is relieved by the infant's sucking. Nevertheless, any nodule needs reassessment, because a fibrocystic or malignant growth unrelated to the pregnancy could be present.

Note whether the breast nipples are normally erect and not inverted. Assess for any cracks, fissures, or the presence of caked milk. Avoid squeezing the nipples, because this can be painful. Unnecessary nipple manipulation also may increase the risk of mastitis by providing a portal for infection.

Uterus. For uterine assessment, position the woman supine so that the height of the uterus is not influenced by an elevated position. Observe her abdomen for contour, to detect distention, and for the appearance of striae or a diastasis. If a diastasis is present (a slightly indented, possibly bluish-tinged groove in the midline of the abdomen), measure the width and length by fingerbreadths.

Palpate the fundus of the uterus by placing one hand on the base of the uterus, just above the symphysis pubis, and the other at the umbilicus. Press in and downward with the hand at the umbilicus until you "bump" against a firm globular mass in the abdomen: the uterine fundus (Fig. 17.5). Assess consistency (firm, soft, or boggy), location (midline), and height. For the first hour after birth, the height of the fundus is at the umbilicus or even slightly above it. It decreases one fingerbreadth in size daily. Measure the height in fingerbreadths, such as "2 F↓ umbilicus" (2 cm beneath the umbilicus). Although this measurement seems less scientific than a measurement of the height of the uterus from the pubis might be, it is the most useful measurement because it shows the gradual decline in size or distance from the umbilicus.

Never palpate a uterus without supporting the lower segment, because the uterus potentially could invert if not stabilized (resulting in a massive hemorrhage).

Palpation of a fundus should not cause pain as long as the action is done gently. If the uterus is not firm on palpation, massage it gently with the examining hand. This usually causes the uterus to contract and become firm immediately. Use a gentle rotating motion, never a hard or forceful touch, so that you do not cause pain or cause the uterus to expend excess energy in contracting. If the uterine fundus does not grow firm with massage, extreme atony, possibly retained placenta fragments, or an excess amount of blood loss may be occurring. Notify the woman's physician or nurse-midwife. Administer PRN oxytocin as ordered. In addition, placing the woman's infant at breast will cause endogenous release of oxytocin and achieve the same effect as oxytocin administration.

FIGURE 17.5 To palpate a uterus, be certain to place one hand at the base of the uterus. This fundus measures about two fingerbreadths below the umbilicus.

If massage appears ineffective, a clot may be present in the cavity of the uterus. The clot may be expressed from the uterus by gentle pressure on the fundus, but only after the uterus has been massaged. If the uterus is totally relaxed, fundal pressure could cause inversion of the uterus, an extremely serious complication that leads to rapid hemorrhage. Another reason the uterus may not be well contracted is that a rapidly filling bladder is preventing contraction. If contraction remains inadequate, a uterine ultrasound may be ordered to help detect any abnormalities.

A woman who received no oxytocin after birth to help her uterus contract is at greater risk for poor uterine contraction than is a woman who did receive this. If no oxytocin was given, assess the woman's uterine fundus every 10 to 15 minutes immediately after birth, to evaluate and assist the fundus to contract should it become soft or relaxed.

Once the first hour after birth has passed, a woman's uterus may be evaluated for height and consistency less frequently, depending on institutional policy. By the ninth or tenth day after delivery, the uterus will have become so small it is no longer palpable above the symphysis pubis.

Lochia. A woman can expect to have lochia for 2 to 6 weeks. Characteristics of normal lochia and the change in pattern from red to pink to white were described in Table 17.1.

During the first hour after birth, when the fundus is checked every 15 minutes, also remove the mother's perineal pad and evaluate lochia character, amount, color (rubra, serosa, or alba), odor, and presence of any clots. Be certain that a pad is not adhering to perineal stitches before removing it.

When you ask a woman to turn so you can inspect her perineum, be sure to check under her buttocks to observe any blood that may be pooling beneath her. If you observe a constant trickle of vaginal flow or a woman is soaking through a pad every 60 minutes, she is losing more than the average amount of blood. She needs to be checked by a physician or nurse-midwife to be certain that there is no cervical or vaginal tear causing excessive bleeding.

While a woman is at the health care facility, inspect her lochia discharge once every 15 minutes for the first hour, and then according to the institution's policy. Make certain a woman understands that she must wash her hands after handling pads and must use only her own personal care equipment so that she does not contract or spread infection. Demonstrate good role modeling for handwashing and equipment use. Encourage a woman to change perineal pads frequently as she begins self-care, because lochia is an excellent medium for bacterial growth that could spread through the vagina to the uterus. The presence of constantly wet pads against an episiotomy suture line also slows healing. Changing pads frequently is not a problem for a woman while she is at the health care facility, but if she is trying to save money, she may try to conserve on the number of pads she uses at home. Be certain she knows not to use tampons until after she returns for her postpartal checkup, to diminish the risk for infection and toxic shock syndrome (see Chapter 47). Ensure that women know the criteria for judging the amount and type of normal lochia (see Box 17.4), so they can do this accurately.

Perineum. While evaluating lochia, also inspect the perineum. Ask a woman to turn on her side, into a Sims' position with her back toward you. If a midline episiotomy was performed, position the mother on either side. If a mediolateral incision is present, turning her so that the incision is on the bottom buttock often causes less pain and offers better visibility. Gently lift the upper buttock and inspect the perineum. Observe for ecchymosis, hematoma, erythema, edema, intactness, and presence of drainage or bleeding from any episiotomy stitches.

An episiotomy is usually 1 or 2 inches long. However, if a laceration was involved, stitches may extend from the vagina back to the rectum. Rarely, they extend forward toward the urethra. An episiotomy incision is usually fused (edges sealed) by 24 hours after birth; if it is a midline incision, it may be almost invisible because the perineal fold obscures it. A hematoma (blood-filled, protruding sphere) could be present if surface capillaries were broken during the pressure of birth; this should be noted as a potential complication. If there is clotted lochia along the incision line, review postpartal perineal care so that this does not continue to occur. Before discharge, teach a woman who has episiotomy stitches how to lie on her back and view her perineum with a handheld mirror, so that, once a day while at home, she can inspect her perineum for redness, sloughing of sutures, pus formation, or drainage at the suture line.

After perineal assessment, assess the rectal area for the presence of hemorrhoids. If any are present, document their number, appearance, and size in centimeters.

What if... Joan Cooper, at 18 hours postpartum, states that she has had to change her perineal pads twice in the last 30 minutes because they were saturated. She noticed two large clots on the last pad. What assessment should you first perform on her, and why?

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Pain related to uterine cramping (afterpains)

Outcome Evaluation: Client states degree of pain is tolerable; demonstrates knowledge of measures for adequate pain relief.

Provide Pain Relief for Afterpains. Pain from uterine contractions can be intense, but you can assure a woman that this type of discomfort is normal and rarely lasts longer than 3 days. If necessary, either ibuprofen (such as Motrin), which has anti-inflammatory properties, or a common analgesic such as acetaminophen (such as Tylenol) is effective for pain relief. As with any abdominal pain, heat to the abdomen should be avoided, because it could cause relaxation of the uterus and subsequent uterine bleeding.

Relieve Muscular Aches. Many women feel sore and aching after labor and birth because of the excessive energy they used for pushing during the pelvic division of labor. They describe feeling as if they have "run for miles." A woman may need a mild analgesic such as acetaminophen for the pain. A backrub is effective for relieving an aching back or shoulders. Carefully assess a woman who states that she has pain on standing. Pain in the calf of the leg on standing (a position that dorsiflexes the foot) is a sign similar to Homans' sign suggesting thrombophlebitis may be present (see later discussion).

Administer Cold and Hot Therapy. Applying an ice or cold pack to the perineum during the first 24 hours reduces perineal edema and the possibility of hematoma formation, thereby reducing pain and promoting healing and comfort. Be certain not to place ice or plastic directly on the woman's perineum. Wrap an ice bag first in a towel or disposable pad, to decrease the chance of a thermal burn (risk of injury increases because the perineum has decreased sensation from edema after birth). Commercial cold packs combined with perineal pads also are available. For a low-cost alternative, a rubber glove may be partially filled with ice chips, provided latex allergy is not a concern.

Ice to the perineum after the first 24 hours is no longer therapeutic. After this time, healing increases best if circulation to the area is encouraged by the use of heat. Dry heat in the form of a perineal hot pack or moist heat with a sitz bath is an effective way to increase circulation to the perineum, provide comfort, reduce edema, and promote healing.

Commercial hot packs are available, which grow warm after they are "cracked" and the chemicals in them combine. Caution women to use a washcloth or gauze square between the pack and their skin, to prevent a possible burn.

Promote Perineal Exercises. Some women find that carrying out perineal exercises three or four times a day can greatly relieve perineal edema. The exercise consists of contracting and relaxing the muscles of the perineum 5 to 10 times in succession, as if trying to stop voiding (Kegel exercises). This aids comfort by improving circulation to the area and decreasing edema. When repeated frequently, Kegel exercises also help a woman regain her prepregnant muscle tone and help prevent urinary incontinence (Hay-Smith & Dumoulin, 2009).

Give Episiotomy Care. Although relatively small in size, episiotomy sutures can cause considerable discomfort, because the perineum is an extremely tender area and the muscles of the perineum are involved in so many activities such as sitting, walking, stooping, squatting, bending, urinating, and defecating.

Most women expect labor to be painful. They usually do not anticipate the pulling pain from perineal stitches in the postpartal period, discomfort that interferes with their rest and sleep, with eating, and with being able to sit and hold their baby comfortably.

Because the perineal area heals rapidly, you can assure a woman that this discomfort is normal and does not usually last longer than 5 or 6 days. Many physicians and nurse-midwives order a soothing cream or anesthetic spray to be applied to the suture line to reduce discomfort. A cortisone-based cream or sitz bath helps to decrease inflammation and relieve tension in the area. Because of their cooling effect, witch hazel preparations are a mainstay for relief of both perineal and hemorrhoidal discomfort. A woman may worry that she will experience additional discomfort when the episiotomy sutures are removed. Explain that these sutures are made of an absorbable material so will not need to be removed. Sutures usually dissolve within 10 days.

Administer Sitz Baths. A **sitz bath** is a portable basin that fits on a toilet seat. A reservoir filled with water provides a constant supply of swirling water to the basin. The movement of water soothes healing tissue, decreases inflammation by causing vasodilation in the area, and thereby effectively reduces discomfort and promotes healing.

Sitz baths usually use water that is maintained at 100° to 105° F (38° to 41° C). Be certain that the water in a sitz bath is not too hot before you help a woman to use it; it should feel pleasantly warm, not hot. The woman may not be sensitive to the temperature herself, because healing surfaces are not good indicators of temperature. This caution applies particularly to a woman who is using an analgesic cream or spray on her perineum or who has a great deal of generalized perineal edema. Both situations make her prone to burns from scalding water unless you act to protect her (Box 17.6).

Women should use a sitz bath three to four times a day for a maximum of 20 minutes each time. Because of the soothing effect of the warm water and the sitting position, alert a woman that she may feel extremely tired and unsteady on her feet after using a sitz bath and may need help in getting back to bed.

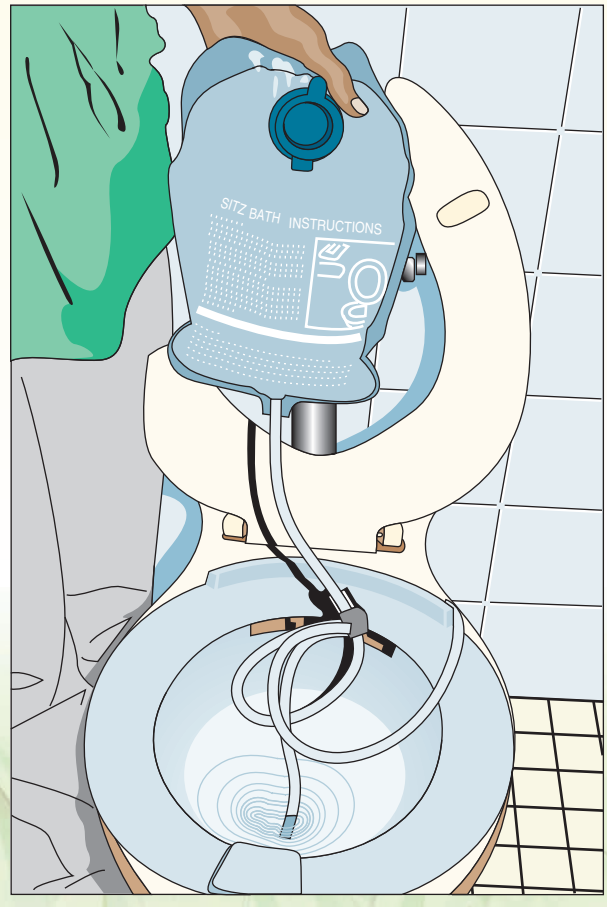
Provide Pain Management. Several topical medications with lidocaine (Xylocaine) bases, such as gels or

Box 17.6 Nursing Procedure ✻ Sitz baths

Purpose: To aid healing of the perineum through application of moist heat

Procedure

1. Wash your hands; identify client and explain procedure.
2. Assess client's condition; ascertain whether client is able to ambulate to bathroom; assist and modify as necessary.
3. Assemble equipment, including sitz bath, clean towel, perineal pad.
4. Place sitz bath on toilet seat. Fill collecting bag with warm water at a temperature of 100° F to 105° F (38° C to 41° C). Hang the bag overhead so a steady stream of water will flow from the bag, through the tubing, and into the basin.



Principle

1. Handwashing prevents the spread of infection; identification ensures that procedure is performed on correct client, thereby promoting safety; explanation assists in alleviating any anxiety.
2. A sitz bath can make a woman feel lightheaded, increasing her risk of injury. Fatigue and exhaustion may interfere with client's ability to ambulate or tolerate procedure, also increasing her risk for injury.
3. Organization of equipment increases efficiency of the procedure.
4. Using correct temperature of water (pleasantly warm) eliminates risk of thermal injury. Adequate flow of warm water increases circulation to the perineum, thereby reducing inflammation and aiding healing.

Box 17.6 Nursing Procedure ✻ Sitz baths (continued)

Procedure	Principle
5. Assist client with ambulating to bathroom; help with removal of perineal pad from front to back. Assist client to sit in basin.	**5.** Assisting ambulation minimizes risk of injury. Removing pad from front to back minimizes risk of infection transmission. Proper placement ensures effectiveness of treatment.
6. Instruct client to use clamp on tubing to regulate water flow; use robe or blankets to prevent chilling and provide for privacy. Have call bell within reach.	**6.** Continuous swirling water aids in reducing edema and promoting comfort. Privacy enhances self-esteem. Quick, easy access to call bell allows for prompt intervention should problems arise.
7. After 20 minutes, assist client with drying perineum and applying clean pad (holding pad by the bottom side or ends).	**7.** After 20 minutes, heat is no longer therapeutic because vasoconstriction occurs. Proper handling of pad prevents contamination and possible risk of infection.
8. Assist client with ambulating back to room.	**8.** Client may become fatigued from the procedure or lightheaded from the warm water, increasing her risk of falling.
9. Evaluate client's tolerance and response to procedure; ask client to report how she feels. Institute health teaching, such as continuing sitz baths when at home.	**9.** Evaluation assists with determining effectiveness of procedure and making any changes. Health teaching helps to promote continuity of care after discharge.
10. Record completion of procedure, condition of perineum, and client's condition and response.	**10.** Documentation provides additional means for evaluation of care and client outcomes.

sprays, are available to relieve perineal pain. These are applied to the incision line with a clean gauze square or via a spray. Because of their anesthetic action, they instantly reduce incision line pain. Tucks, a commercial form of soft pad impregnated with witch hazel that can be tucked between the perineum and a sanitary pad, also are effective in relieving perineal pain. Some women doubt the efficacy of suture-line medications or worry that applying the cream will hurt more than not applying it. They may need extra encouragement to try these helpful aids.

In addition to local perineum creams or sprays, many women require an oral or parenteral analgesic to relieve their episiotomy discomfort. Most physicians and nurse-midwives order a moderate-strength analgesic such as propoxyphene/acetaminophen (Darvocet) or codeine for the first 24 hours, then a milder one such as acetaminophen for the remainder of the first week. Ibuprofen also is widely prescribed. Advise a woman not to use aspirin for pain relief during the postpartal period, because it interferes with blood clotting and may increase her risk for hemorrhage from the denuded placental site (Karch, 2009).

Nursing Diagnosis: Risk for infection (uterine) related to lochia and denuded uterine surface

Outcome Evaluation: Client's temperature remains below 100.4° F; lochia is present and without foul odor.

Provide Perineal Care. Postpartal women are particularly prone to perineal infection because lochia, if allowed to dry and harden on the vulva and perineum, furnishes a rich bed for bacterial growth, which then can spread to the uterus. Because the vagina lies in close proximity to the rectum, there is also always the danger that bacteria will spread from the rectum to the vagina. Interruption in skin integrity from an episiotomy also increases the client's risk for infection.

Teach a woman to include perineal care as part of her daily bath or shower and after every voiding or bowel movement. If the woman is on bed rest during the first hour after birth, you will need to provide perineal care for her.

Before beginning perineal care, wash your hands and pull on clean gloves to prevent the risk of infection transmission. Place a plastic-covered pad under the woman's buttocks to protect the bed during the procedure. With the woman lying in a supine position, remove the perineal pad from the front to back; the direction is important to prevent the portion of the pad that was over her rectal area from sliding forward to contaminate the vaginal opening.

Perineal care is a clean but not a sterile procedure. Agencies differ as to the type of cleansing that is done and the articles and solutions used. If actual washing is to be done, use a clean gauze square or a clean portion of a washcloth with soap and water for each stroke, always washing from front to back, from the pubis toward the rectum. Rinse the area in the same manner, and dry it.

A second common method is to spray the perineum with clear tap water from a spray bottle. Direct the spray toward the front of the perineum, and allow

it to flow from front to back. Be certain that none of the solution enters the vagina, as it could be a source of contamination. The labia have a tendency to close and cover the vaginal opening, which normally prevents solution from entering the vagina. Do not separate the labia; instead, allow them to perform this protective function. Spray gently to avoid splashing any blood-tinged solution on yourself (to guard against contacting body secretions).

It may be advantageous to have a woman turn on her side in a Sims' position, to permit better visualization of an episiotomy area. In some women, better cleaning of this area can also be done in this position.

Promote Perineal Self-Care. As soon as a woman is allowed to get up to go to the bathroom (if her infant was born without an anesthetic, this is within the first hour after birth), teach her how to carry out her own perineal care.

The bathroom should have an area close to the toilet where a woman can place the equipment she needs for care: a spray bottle, sponges to dry, clean pads, and so forth. Instruct her how to remove the soiled perineal pad and where to dispose of it. Remind her of the importance of using any cream or medication that has been prescribed. Caution her not to flush the toilet until she is standing upright. Otherwise, the flushing water might spray her perineum and cause infection.

If women are given a clear explanation as to why perineal care is important, they perform it well. However, self-care does not eliminate a nurse's responsibility for checking a woman's perineum to assess its condition and the amount and type of lochia flow present. By continuing with these assessments, a nurse remains a woman's first line of defense against postpartal complications such as infection and hemorrhage.

Nursing Diagnosis: Disturbed sleep pattern related to exhaustion from and excitement of childbirth

Outcome Evaluation: Client states she is able to sleep and feels rested during postpartal period.

After birth, a woman is a paradox. She is excited. She has a baby and she wants to hold and be with this new person in her life. She wants to talk to her support person about the experience, their child, and their future. At the same time, she is so exhausted that she falls asleep easily.

Allow a woman to have time with her expanded family in the birthing room immediately after the baby's birth so she can then enjoy sound rest.

Promote Rest in the Early Postpartal Period. Few women are prepared for the degree of fatigue they experience after childbirth. Try to do all procedures swiftly yet gently, to allow as much time for sleep as possible. If a woman has discomfort from hemorrhoids, perineal stitches, or afterpains, be sure she has pain relief so that she can rest comfortably or sleep. Urge her not to fall asleep in a narrow hospital bed with her new infant. Sharing bed space is controversial even in a large bed (Horsley et al., 2007). A newborn in a narrow bed could easily fall and be injured.

Some women experience shaking chills immediately or within a half-hour after birth. This is caused in part by the pressure changes in the abdomen that occur with reduction in the bulk of the uterus and temperature readjustment in response to the diaphoresis of labor. It also may result from the exhilaration the woman is feeling, combined with exhaustion. In any event, shaking chills at this point are common. Reassure the woman that chills are common, so that she will not attribute them to a developing cold or infection. Cover her with a warm blanket, offer her a warm drink, and assure her the occurrence is normal. These actions are usually enough to make the chill transient and allow the woman to fall into a sound, much-needed sleep of about an hour.

Although a woman may choose any position to sleep, she may enjoy being able to sleep on her stomach, something she was not able to do during pregnancy.

Promote Rest Throughout the Puerperium. The importance of rest throughout the entire puerperium cannot be stressed enough. As long as a woman is in the health care facility, reserve time for naps. Include suggestions for getting adequate rest while at home in discharge instructions, because rest may prove difficult. The newborn will wake at least twice a night, and relatives and friends will be coming to see the baby during the day.

Many women do not realize how long it will take to fully return to their previous level of functioning. When families were closely knit and neighborhoods were smaller, a new mother had someone in her family or neighborhood to look after the baby while she napped. Today, many couples do not have family or close friends nearby. If the parents have not thought through this problem before birth, you can help them look at their situation and see what is available to them. Perhaps the woman's mother, a sister, her partner's mother, or another relative could come and stay with them for the first week. Perhaps the father could take a week off from work or school to help out at home; many employment benefit programs provide for this time. If none of these solutions seems appropriate, the couple might appreciate being given the name of a community service agency that supplies homemakers on a short-term basis. A referral to a community health agency for an early home visit is yet another suggestion.

A woman without support has many demands for her new role—being a mother instead of a daughter; a mother as well as a wife; a mother of three, not two. If she is overcome by sleep hunger, her judgment and sense of balance can be blurred. Although it is not the only contributing factor, extreme fatigue is associated with the development of postpartal depression (Corwin & Arbour, 2007).

Nursing Diagnosis: Risk for bathing/hygiene self-care deficit related to exhaustion from childbirth

Outcome Evaluation: Client takes daily responsibility for own hygiene. Client appears clean, dressed, and well groomed.

After childbirth, women often report that their hospital or birthing center room is being kept too warm; to

prove it, they point out how heavily they are perspiring. Postpartal rooms often are kept warm so that newborns will be comfortable, but the profuse perspiration a woman is experiencing normally comes from her body's attempt to regulate fluid, not from the heat of the environment.

You can assure a woman that sweating is a normal postpartal event that helps to bring her body back to its prepregnant state. If she has profuse diaphoresis, particularly at night, she usually prefers to wear a hospital gown rather than one of her own. She may need frequent gown changes during the day to be comfortable and not become chilled.

A daily shower is refreshing. Be certain to accompany a woman for a shower on her first postpartal day, because she often is more fatigued than she realizes. Standing under warm water may also make her dizzy, and she may need help to walk safely back to bed.

Formerly, women were not allowed to take tub baths after birth, for fear that bacteria from the bath water would enter the vagina and cause infection. There appears to be little evidence that this is a real danger, however, so if a woman wants to bathe instead of shower, she may do so.

Nursing Diagnosis: Imbalanced nutrition, less than body requirements, related to lack of knowledge about postpartal needs

Outcome Evaluation: Client ingests a 2200- to 2700-kcal diet and drinks 6 to 8 glasses of fluid daily.

Postpartal menu planning should include a diet of between 2200 and 2300 calories daily. Foods should be high in protein and in the vitamins and minerals needed for good tissue repair. An adequate supply of roughage is important to help restore the peristaltic action of the bowel. A woman who is breastfeeding needs an additional 500 calories (i.e., a 2700-kcal diet) and an additional 500 mL of fluid (these may be from the same source) each day to encourage the production of high-quality breast milk. Most mothers are hungry during the immediate postpartal period and consume an adequate diet without urging.

Teach a woman to continue to eat a nutritious diet after she returns home. This can be a problem, because some women become so fatigued during their first weeks at home that they feel unable to prepare adequate meals. Neglecting to eat properly leads to more fatigue and, ultimately, to an even less nutritious diet.

If a woman has any prenatal vitamins or supplementary iron preparations left over from pregnancy, she should, as a rule, continue to take them until her supply is used. If she needs further supplements, her physician or nurse-midwife will prescribe them for her, either on discharge or when she returns for her postpartum checkup (Lipscomb & Novy, 2007).

Promote Adequate Fluid Intake. The rapid diuresis and diaphoresis that occur during the second to fifth postpartal days ordinarily result in a weight loss of 5 lb in addition to the approximately 12 lb lost at childbirth.

Women often feel thirsty during this period of rapid fluid loss and want additional fluid. It seems a paradox that while the body is ridding itself of unwanted fluid, it should also demand fluid. Part of this paradox stems from a woman's having had little to drink during labor. She may say immediately after the birth, "I don't think I'll ever get enough to drink again." Part of the need for fluid stems from the increased amount of nitrogen being released from catabolized uterine cells. A woman needs to increase her fluid intake to rid her body of these wastes.

You may need to encourage some women to drink adequate fluid during the first few postpartum days because they are restricting fluid in the hope of preventing their breasts from becoming engorged. Other mothers are beginning diets that they hope will bring their bodies more quickly back to their nonpregnant slim state. However, fluid restriction does little to deter breast engorgement, and overall, this is not a good time for dieting. The postpartal period is a time of rebuilding and readjusting, for which a woman needs both ample nourishment and adequate fluid intake. Encourage her to drink at least three to four 8-oz glasses of fluid each day (six to eight glasses if breastfeeding).

Nursing Diagnosis: Risk for impaired urinary elimination or constipation related to loss of bladder and bowel sensation after childbirth

Outcome Evaluation: Client voids more than 30 mL/hr without urinary retention, beginning 1 hour after birth, and has a bowel movement by postpartum day 4. No urinary incontinence is noted.

Promote Urinary Elimination. Because the diuresis of the postpartal period begins almost immediately after birth, a woman's bladder begins filling almost immediately. A full bladder puts pressure on the uterus and causes difficulty with uterine contraction. An overdistended bladder may also damage bladder function. Women who have had epidural anesthesia are particularly prone to developing urinary retention (Musselwhite et al., 2007).

Professional judgment is necessary here to assess what is adequate voiding. A woman may report that she is out of bed and using the bathroom to void. However, only a person with knowledge of the extent of the diuresis being accomplished and the amount that should be voided during this time is able to estimate whether bladder function is adequate.

Encourage a woman to walk to the bathroom and void at the end of the first hour after birth, to help prevent bladder distention. Some women have too much perineal edema to be able to void this early. A woman with an episiotomy may be reluctant to void because she knows that acid urine against her sutures will sting. However, many women have enough residual effect of epidural or pudendal anesthesia at this time that voiding is painless. Assist by providing privacy (but remain in close proximity in case a woman becomes dizzy if this is her first time out of bed), running water at the sink, or offering the woman a drink of water. Pouring warm tap water over the vulva, if consistent with the agency's policy for perineal care, also may help.

If the woman still has not been able to void by 4 to 8 hours after birth, and bladder distention is present,

she will need to be catheterized. Because the perineum is edematous after birth, the vulva in a postpartal woman appears out of proportion. This makes it difficult to locate the urethra for urinary catheterization. Be certain that, during catheterization, you do not invade the vagina by mistake and thereby carry contamination to the denuded uterus. Occasionally, because of poor tone, the bladder retains large amounts of residual urine after voiding. This urine harbors bacteria, which can cause bladder infection.

To detect whether urinary retention is occurring, be certain to measure the first voiding after birth. Whether the bladder is emptying also may be judged by measuring fundal height and position or by palpating or percussing bladder prominence in the lower abdomen. If a woman is voiding less than 100 mL at a time or has a displaced uterus or a palpable bladder, her physician or nurse-midwife may order catheterization for residual urine after a voiding. As a rule, if the residual urine is more than 150 mL, the catheter is left in place for 12 to 24 hours to give the bladder time to regain its normal tone and to begin to function efficiently.

Fortunately for most women who must be catheterized, the procedure needs to be done only once after birth. Usually, after another 6 to 8 hours has passed and the bladder has filled again, some of the perineal edema has subsided, the bladder has achieved better tone, and the woman is able to void by herself if helped to the bathroom.

Because catheterization can lead to urinary infection, it should not be used indiscriminately in the postpartal period. On the other hand, it should be done before the woman's bladder is injured or the uterus is displaced and uncontracted, resulting in bleeding.

Some women report urinary incontinence during the postpartal period, resulting from poor perineal tone and sensation. Kegel exercises are helpful to strengthen perineal muscles and eliminate incontinence in the future.

Prevent Constipation. Many women have difficulty moving their bowels during the first week of the puerperium, a condition that can be worrisome and uncomfortable. Constipation occurs because of relaxation of the abdominal wall and the intestine, now that they are no longer compressed by the bulky uterus. For a bowel movement, the abdominal wall must exert pressure. In its relaxed state, the pressure is not strong enough to be effective. Also, if hemorrhoids or perineal stitches are present, a woman may decline to try to move her bowels for fear of pain.

To prevent constipation, many women are prescribed a stool softener such as docusate sodium, beginning with the first day after birth (Box 17.7). If a woman has not moved her bowels by the third postpartum day, a mild laxative or cathartic may be prescribed. There is danger in giving cathartics before the third day, because the resulting increase in intestinal activity could cause uterine irritation and lead to insufficient contraction.

Early ambulation, a good diet with adequate roughage, and an adequate fluid intake all aid in preventing the problem of constipation.

BOX 17.7 ✻ Focus on Pharmacology

Docusate Sodium (Colace, Surfak)

Classification: Docusate sodium is a stool softener.

Action: Used in the postpartal period to prevent constipation. It works by lowering the surface tension of feces, allowing water and lipids to penetrate the stool and soften it (Karch, 2009).

Pregnancy Risk Category: C

Dosage: 50–100 mg PO daily.

Possible Adverse Effects: Occasional abdominal pain and diarrhea

Nursing Implications

- Encourage a woman to swallow the medication with a full glass of water or juice.
- Instruct a woman to consume high-fiber foods to encourage elimination.
- Encourage activity to promote intestinal motility.

Prevent Development of Hemorrhoids. The pressure of the fetal head on the rectal veins during birth tends to aggravate or produce hemorrhoids (swollen rectal veins) to such an extent that some women find hemorrhoidal discomfort to be their chief discomfort in the first few days after birth (Quijano & Abalos, 2009). This discomfort can be relieved by sitz baths, anesthetic sprays, witch hazel or astringent preparations, or preparations such as hydrocortisone acetate (Proctofoam). Gentle manual replacement of hemorrhoidal tissue may also give relief. Assuming a Sims' position several times a day aids in good venous return to the rectal area and also reduces discomfort. Increased fluid and the administration of a stool softener prevent the development of hardened stool, which can irritate hemorrhoids.

Nursing Diagnosis: Risk for ineffective peripheral tissue perfusion related to immobility and increased estrogen level

Outcome Evaluation: Client demonstrates negative Homans' sign and absence of erythema or pain in calves of legs.

Assess Peripheral Circulation. To determine whether peripheral circulation is adequate, assess a woman's thigh for skin turgor. Assess for edema at the ankle and over the tibia on the lower leg. Although this technique is not totally reliable, assess for thrombophlebitis by dorsiflexing a woman's ankle and asking her if she notices pain in her calf on that motion (**Homans' sign**). Assess also for redness in the calf area, because thrombophlebitis can be present even with a negative Homans' sign. Continue to assess for adequate peripheral circulation once every 8 hours during the woman's stay in a health care facility. If you suspect thrombophlebitis, do not massage the area—doing so could cause an embolus.

Be certain to allow a woman to dangle her legs on the edge of the bed for a few minutes to prevent

FIGURE 17.6 Ambulating postpartally is not always easy but helps to prevent complications.

dizziness before she gets up for the first time. Then, assist her as needed to take the few steps to a nearby bathroom. Remain with her to be certain that dizziness does not occur. After this, she may be up on her own as she wishes.

As a rule, women who ambulate quickly feel stronger and healthier by the end of their first week and have fewer bowel, bladder, and circulatory complications than those who do not (Fig. 17.6).

Nursing Diagnosis: Pain related to primary breast engorgement

Outcome Evaluation: Client states pain from breast engorgement is at a tolerable level.

Prevent/Alleviate Breast Engorgement. If a woman is breastfeeding, encouraging her newborn to suck at the breast is the main treatment for relief of the tenderness and soreness of primary breast engorgement (techniques of breastfeeding are discussed in Chapter 19).

Many women find the application of warm compresses or standing under a warm shower beneficial to relieve engorgement discomfort. Good support from a bra also offers relief because it prevents unnecessary strain on the supporting muscles of the breasts, positions the breasts in good alignment, and diminishes the amount of engorgement caused by blocked milk ducts. If the woman has not packed a bra in her suitcase, ask her to arrange to have one brought from home.

A woman who is not breastfeeding may experience even stronger discomfort. However, when little or no milk is removed from the breasts, the accumulation of milk inhibits further milk formation, and engorgement subsides in about 2 days. Cold compresses, applied to the breasts three or four times a day during the period of engorgement, or an oral analgesic, or both, provide relief. Wearing a snug-fitting bra and avoiding nipple stimulation may help. Restricting fluid and pumping milk from the breasts are not effective measures and are to some degree harmful, so these actions should be avoided.

Promote Breast Hygiene. Breast care during the postpartal period includes cleanliness and support. These issues are the same whether or not a woman is breastfeeding.

Teach a woman to wash her breasts daily with clear water at the time of her bath or shower and then dry them with a soft towel. She should avoid using soap, because it tends to dry and crack the nipples, possibly leading to fissures and breast abscess. It is not necessary for women to wash their breasts more often than daily, because excessive washing means unnecessary manipulation.

A woman who has a considerable discharge of colostrum or milk from her breasts (whether breastfeeding or not) should insert clean gauze squares or commercial nursing pads into her bra to absorb the moisture, changing them as often as necessary to keep the nipples dry. If the nipples remain wet for any length of time, fissures may form and lead to infection.

Nursing Diagnosis: Health-seeking behaviors related to future breast health

Outcome Evaluation: Client states the importance of once-yearly breast examination by a health care provider (or a yearly mammogram, if appropriate for her age) and her intention to schedule this examination yearly.

Because breast tumors are a major type of neoplasm in women, all women of childbearing age should know the importance of yearly breast assessment (Calhoun & Giuliano, 2007). Many women are not interested in hearing about cancer prevention measures during pregnancy; the possibility of developing cancer is too far removed from what they are doing during pregnancy—creating life. In the postpartal period they become conscious of the need to remain well to raise this new child to maturity. This makes them receptive to having you review with them or teach them the necessity for regular breast assessment at health care visits.

A breastfeeding woman will, of course, have a milk discharge from her nipples. She may occasionally discover a distended milk gland that feels very much like a cyst or tumor. You can assure her she should not worry about such distended glands unless they persist beyond two breastfeedings. Also, remind her that, if she does notice a lump or have an abnormal nipple discharge in a breast, she should call her health care provider about the finding but be aware that most lumps found in breasts are not cancerous. Also, breast carcinoma, if discovered early and treated promptly (often without removal of more than the local lesion), has a good cure rate.

Nursing Diagnosis: Health-seeking behaviors related to client's desire to return to prepregnant weight and appearance

Outcome Evaluation: Client states realistic goals for return to former appearance; is able to demonstrate appropriate exercises.

After childbirth, the abdominal wall and the uterine ligaments are stretched. The abdomen pouches forward.

Wearing a girdle may help a woman feel more comfortable during the first few weeks after birth, but it does not aid, and may actually hinder, strengthening the tone of the abdominal wall.

A woman can best help her abdominal wall to return to good tone by using proper body mechanics and posture, getting adequate rest, and performing prescribed exercises. Exercises to strengthen the abdominal and pelvic muscles may be started, with the consent of the woman's physician or nurse-midwife, as early as the first day after birth. She should continue these exercises until the end of the puerperium to derive the maximum benefit from them. Common abdominal and perineal strengthening exercises are described in Table 17.2. Many women find commercial abdominal exercisers helpful to fully strengthen their abdominal wall.

Teach Methods to Promote Uterine Involution. All during the postpartal period, lying on the abdomen gives support to abdominal muscles and may aid involution, because it tips the uterus into its natural forward position. If this puts too much pressure on sore breasts, placement of a small pillow under the abdomen usually solves the problem.

It may be dangerous for a woman to assume a knee–chest position until at least the third week after birth. In a knee–chest position, the vagina tends to open. Because the cervical os remains open to some extent until the third week, there is a danger that air will enter the vagina and the open cervix, penetrate the open blood sinuses inside the uterus, enter the circulatory system, and cause an air embolism.

Although this would be a rare occurrence, it is good practice for a woman to avoid this position until she returns for a postpartal examination and is assured that her cervix has closed. Women who have used a knee–chest position during pregnancy to relieve the pressure of hemorrhoids need to be cautioned that a modified Sims' position, such as they used for a rest position during pregnancy, is better for them now.

Nursing Diagnosis: Risk for ineffective sexuality patterns related to physiologic changes of postpartal period

Outcome Evaluation: Client states she has a satisfactory sexual relationship with her partner; demonstrates understanding of both coital and noncoital methods of sexual expression.

At one time, women were cautioned not to resume sexual relations after the birth of a baby until after their medical checkup at 6 weeks. However, there is no apparent physiologic reason to delay sexual relations this long. For most couples, coitus may be resumed as soon as lochia serosa has stopped—about 1 to 2 weeks after birth.

Caution women, however, that sex may be somewhat uncomfortable if it is begun this early. Tissue at an episiotomy site may be sensitive. Because the vaginal epithelium is still thin, vaginal tenderness may be noticed. Use of a lubricant will help any mucosal dryness. A female-superior position can be suggested because it allows the woman to control the depth of penile penetration.

A woman who is breastfeeding may notice that milk is released from her nipples with sexual arousal.

TABLE 17.2 ✻ Muscle-Strengthening Exercises

Exercise	Description
Abdominal breathing	Abdominal breathing may be started on the first day after birth, because it is a relatively easy exercise. Lying flat on her back or sitting, a woman should breathe slowly and deeply in and out 5 times, using her abdominal muscles. Check by watching her abdominal wall rise that she is actually using these muscles.
Chin-to-chest	The chin-to-chest exercise is excellent for the second day. Lying on her back with no pillow, a woman raises her head and bends her chin forward on her chest without moving any other part of her body while exhaling. She should start this gradually, repeating it no more than 5 times the first time and then increasing it to 10–15 times in succession. The exercise can be done 3 or 4 times a day. She will feel her abdominal muscles pull and tighten if she is doing it correctly.
Perineal contraction	If a woman is not already using this exercise as a means of alleviating perineal discomfort, it is a good one to add on the third day. She should tighten and relax her perineal muscles 10–25 times in succession as if she were trying to stop voiding (Kegel exercises). She will feel her perineal muscles working if she is doing it correctly.
Arm raising	Arm raising helps both the breasts and the abdomen return to good tone and is a good exercise to add on the fourth day. Lying on her back, arms at her sides, a woman moves her arms out from her sides until they are perpendicular to her body. She then raises them over her body until her hands touch and lowers them slowly to her sides. She should rest a moment, then repeat the exercise 5 times.
Abdominal crunches	It is advisable to wait until the 10th or 12th day after birth before attempting abdominal crunches. Lying flat on her back with knees bent, a woman folds her arms across her chest and raises herself to a sitting position. This exercise expends a great deal of effort and tires a postpartal woman easily. Caution her to begin very gradually and work up slowly to doing it 10 times in a row.

BOX 17.8 ✻ Signs of Good Parent–Child Adaptation

Good parent–child adaptation is demonstrated when a parent:

- Speaks of infant as desirable and attractive
- Is not upset by vomiting, drooling, and the like
- Holds the baby warmly
- Makes eye contact with the infant
- Plays with and soothes the infant
- Talks or sings to the baby
- Expresses confidence that the infant is well
- Finds physical or psychological attributes to admire about the baby
- Is able to discriminate between the baby's signs of hunger, sleep, and so on

Women may already be aware that their degree of exhaustion can make them less receptive to sexual arousal than before. Be sure that women receive adequate reproductive planning information, if desired, before they resume sexual relations (see Chapter 6).

Nursing Diagnosis: Risk for impaired parenting related to inadequate bonding behavior after childbirth

Outcome Evaluation: Parents hold and comfort their infant appropriately and voice positive characteristics of child.

To assess that bonding is occurring, listen to what parents say about their newborn in the immediate postpartal period. Do they make positive statements such as, "I'm glad he's a boy" or "She's cute," or negative ones such as, "I really hoped it would be a girl" or "She looks like a circus clown with no hair"? First impressions may not be lasting ones. However, negative comments need to be identified, so that extra discussion about things such as what it feels like to have four boys, or not to have the prettiest child in the nursery, can take place. Although brief hospital stays are advantageous in many ways, if such discussion does not occur, a family may be discharged from the health care agency with their needs unmet (Brown et al., 2009). At home, away from health care personnel who are attuned to how disappointment can interfere with parent–child interaction, parents may have great difficulty adjusting to and relating to this new child. Typical signs of good parent–child adaptation are shown in Box 17.8.

NURSING CARE OF A WOMAN AND FAMILY IN PREPARATION FOR DISCHARGE

The greatest need of a postpartal woman before discharge from a health care agency is education to prepare her to care for herself and her newborn at home (see Focus on Nursing Care Planning Box 17.9). She must be aware of danger signs to look for and know whom to call if she notices any of them. She must understand safe baby care. Because of shortened lengths of stay, every contact with a woman during a health agency stay should include some teaching information. At the same time, be aware that learning does not take place if the learner is overwhelmed and hurried. Use common sense to determine when it is time to teach and when it is time to observe or listen. Observation of mother–child or parent–child interactions and evaluation of a woman's support system at home are the basis for much of the teaching.

Most women attend classes in newborn care during their pregnancies. They remember many points from these classes, but when they actually have a newborn they can become worried that they do not remember enough. Many mothers say that child care did not seem real during pregnancy. The postpartal period is a time for teaching, reteaching, and offering anticipatory guidance to help in the new situations a family can expect when they go home.

During the taking-in phase of the puerperium, a woman may not show much interest in learning; she is more in need of the comfort of being taken care of. As she enters her taking-hold period, she grows increasingly receptive to advice and looks to nurses for the information she needs. Some nurses assume that multiparas will react negatively to child care suggestions. They are, after all, veterans of child care. If you listen carefully, however, you may discover that a mother of two girls feels insecure about the care of her new baby boy. A woman whose next youngest child is 5 years old may admit that in 5 years she has completely forgotten how small newborns are. She yearns to have a nurse who is comfortable with such small human beings reassure her that she is holding her new baby correctly and giving proper care. All mothers, whether primiparas or multiparas, need to be evaluated individually and helped whenever they ask or you find that they need guidance.

Group Classes

Providing group classes on bathing infants, breastfeeding techniques, minimizing jealousy in older children, and maintaining health in the newborn can be helpful to mothers and fathers, because in these settings they can learn not only from the instructor but also from other parents. Brain-storming this way is helpful to women who envision jealousy problems with older children or who plan to return to a full-time job and also breastfeed (Abdulwadud & Snow, 2009). Be certain that a time for questions and answers is planned at these sessions, so parents can apply what is being taught to their individual circumstances. Urging fathers to attend classes is helpful, because many fathers give direct child care for at least part of every day. Including the father in teaching is also important, because the problems that arise with newborn care are, by their nature, family problems, and every effort should be made by nursing personnel to help both parents prepare to deal with them.

Individual Instruction

Every family needs some individual instruction in how to care for their infant and how the woman can care for herself after discharge. How to bathe and feed the baby, how to care for the infant's cord and circumcision if the infant has this, a review of how much infants sleep during 24 hours, and how to fit a newborn into the family's pattern of living are topics

BOX 17.9 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Postpartal Woman

Joan Cooper is 6 hours postpartum after birth of an 8-lb 2-oz baby girl. She states, "I haven't urinated since before the birth. What kind of mother am I going to be if I can't even manage my own care?" Her husband Mike pulls you aside and says, "Sometimes, I see my wife crying for no reason. Why isn't she as happy as I am?"

Family Assessment ✻ Couple has been married for 3 years. Husband works as a pharmacist. Will be taking a week off from work to spend time with Joan and the new baby. Joan is on maternity leave from her job as a court reporter.

Client Assessment ✻ Labor and birth were without incident. Abdomen soft. Uterus ½ fingerbreadth above umbilicus, soft, and displaced to the right. Moderate lochia rubra. Bladder firm on palpation above symphysis pubis. Resonant on percussion. Vital signs within acceptable parameters.

Nursing Diagnosis ✻ Altered urinary elimination related to perineal edema and decreased bladder tone from fetal head pressure during labor and birth.

Outcome Criteria ✻ Client attempts common measures to initiate voiding; voids more than 100 mL within 2 hours' time. Voices that she understands that crying is a common reaction postbirth.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Assess amount of urine voided during labor, and reassess fundal height and position.	Discuss importance of continuing to drink to help initiate bladder reflex. Also discuss importance of emptying bladder.	Assessing fundal height and position provides evidence about the degree of bladder filling. Retention of urine in the bladder predisposes to infection.	Client voids a minimum of 100 mL by 2 hours' time, and fundal height returns to 1 fingerbreadth below umbilicus after voiding.
		Consultations		
Nurse	Determine which member of client's primary care team is on call.	If client has not voided by 8 hours after birth, notify team member on call and keep her or him informed.	Bladder distention can interfere with uterine involution and, if allowed to persist, may result in permanent loss of bladder tone.	Primary health care provider is notified of client's inability to void.
		Procedures/Medications		
Nurse	Assess what measures client thinks would help her to void.	Instigate measures client suggests, such as ambulating to bathroom or hearing water running. Respect privacy while staying nearby for support.	Respecting client's preferences helps her to maintain feeling of control. Remaining nearby ensures client safety.	Client ambulates to the bathroom to void with assistance from health care provider.
		Nutrition		
Nurse	Assess whether intake, both intravenous and oral, has been adequate since birth.	Stress importance of drinking extra water during the postpartum period.	Women should drink ample fluid during the postpartum period, to counteract normal diuresis and ensure good urine output.	Client confirms she has been drinking 1 glass of fluid an hour. Knows to drink 6 to 8 glasses of fluid daily.

(continued)

BOX 17.9 ✻ Focus on Nursing Care Planning (continued)

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Patient/Family Education		
Nurse	Assess client's knowledge of postpartal care measures.	Teach normal physiologic changes that occur after birth and the importance of preventing complications such as urinary retention or thrombophlebitis.	The more informed clients are, the more they can participate in self-care.	Client states that she understands the importance of a good fluid output to help prevent urinary tract infection.
		Psychosocial/Spiritual/Emotional Needs		
Nurse	Assess whether client can explain why she has episodes of crying.	Emphasize that "baby blues" are common during the postpartal period. Most difficulties are transitory and will not interfere with parenting.	Feeling of sadness is common. The change to being a parent is a major role change.	Client states that she views inability to void as a temporary setback and one that will not interfere with her success as she moves into a parenting role.
		Discharge Planning		
Nurse/nurse midwife	Assess client to see whether she understands the importance of monitoring voiding at home, maintaining perineal tone.	Once voiding pattern is re-established, instruct client in Kegel exercises.	Kegel exercises help strengthen perineal muscles.	Client describes Kegel exercises that she will continue to use to strengthen perineal muscles.

parents like to discuss. Teaching does not have to be formal. You can teach without lecturing by making a comment such as, "Notice how large all newborns' heads seem" while you are showing the parents how to bathe the baby, or "Babies like to be bundled firmly" while you are helping dress the child, or "Notice how uneven newborn respirations are." This kind of instruction saves parents many anxious moments when they are at home. Techniques for home care of the newborn are discussed in Chapter 18.

Discharge Planning

Before a postpartal family is discharged from the health care agency, a woman will be given instructions by her physician or nurse-midwife concerning her care at home. These instructions differ among health care providers but have common points that are summarized in Table 17.3.

Before discharge, make sure a woman is aware that she must return for an examination 4 to 6 weeks after birth, and that she should make an appointment to take her baby to a primary care provider for an examination at 2 to 4 weeks of age. If a woman does not have an adequate rubella antibody titer and anticipates further pregnancies, she may receive a rubella immunization before discharge. Women who are Rh negative and who have had an Rh-positive infant will receive RhiG or Rh antibodies to prevent problems in a future pregnancy (Crowther & Middleton, 2009).

Be certain that discharge instructions for the family are given both verbally and in writing. Getting ready to go home, dressing the baby, seeing him or her in new clothes for the first time, and experiencing the thrill of realizing the baby is really theirs to take home is so exciting that oral instructions may go unheard. On the other hand, parents should not simply be handed a list of printed material. Review the instructions with the parents to be sure they understand them.

Many health care agencies have a community liaison person, ideally a nurse, who calls or makes a home visit to mothers after discharge. This person helps the new mother assess her own health and that of her baby and answers questions from families who lose their instructions or are unable to interpret them after they have returned home.

Making a telephone call to or visiting a family 24 hours after discharge is the most helpful way to evaluate whether the family is able to continue self-evaluation and infant care and is able to integrate the new infant into the family. Such calls or visits may also reduce the number of acute care visits and rehospitalizations for newborns.

TABLE 17.3 ✻ Postpartal Discharge Instructions

Area	Instructions
Work	All women should avoid heavy work (lifting or straining) for at least the first 3 weeks after birth. Women differ in their concept of heavy work, so it is a good idea to explore what a woman considers heavy work. If she plans to do too much, you can perhaps help her to modify her plans. It is usually advised that a woman not return to an outside job for at least 3 weeks (or better, 6 weeks), not only for her own health but also for enjoyment of the early weeks with her newborn.
Rest	A woman should plan at least one rest period each day and try to get a good night's sleep. She can rest during the day when her newborn is sleeping, unless she has other children or an aged parent to care for. If she has others dependent on her, explore the possibility of having a neighbor, another family member, or a person from a community health agency relieve her.
Exercise	A woman should limit the number of stairs she climbs to one flight/day for the first week at home. Beginning the second week, if her lochial discharge is normal, she may start to increase this activity. This limitation will involve some planning on her part, especially if her washing machine is in the basement and she must wash diapers every day, or if she must go up and down stairs to check on her baby. It is probably better to arrange for a place for the baby to sleep downstairs as well as upstairs, so the baby must be taken upstairs only at bedtime. She should continue with muscle-strengthening exercises, such as abdominal crunches.
Hygiene	A woman may take either tub baths or showers. She should continue to apply any cream or ointment as ordered for the perineal area and cleanse her perineum from front to back. Any perineal stitches will be absorbed within 10 days. She should not use vaginal douches until she returns for her postpartal checkup.
Coitus	Coitus is safe as soon as a woman's lochia has turned to alba and, if present, the episiotomy is healed (usually about the first week after birth). Vaginal cells may not be as thick as formerly because prepregnancy hormone balance has not yet completely returned. Use of a contraceptive foam or lubricating jelly will aid comfort. Be certain she knows safer sex precautions.
Contraception	If desired, a woman should begin a contraception measure with the initiation of coitus. If she wishes an IUD, this may be fitted immediately after birth or at her first postpartal checkup. Oral contraceptives are begun about 2–3 weeks after birth. A diaphragm must be refitted at a 6-week checkup. Until she returns for this checkup, an over-the-counter spermicidal jelly and condoms can provide protection.
Follow-up	A woman should notify her physician or nurse-midwife if she notices an increase, not a decrease, in lochial discharge, or if lochia serosa or lochia alba becomes lochia rubra. Delayed postpartal hemorrhage can occur in women who become extremely fatigued. Getting adequate rest during her first weeks at home will do much to prevent the possibility of this complication. Four to 6 weeks after birth, a woman should return to her physician or nurse-midwife for an examination. This visit is important to ensure that involution is complete, immunization against the virus associated with cervical cancer (HPV), and reproductive life planning (if desired) can be discussed.

NURSING CARE OF A WOMAN AND FAMILY AFTER DISCHARGE

Postpartal Home Visits

In today's health care climate of cost containment, most women are discharged from a health care facility 2 to 3 days after childbirth. Such a practice has the advantage of allowing the family unit to be interrupted as little as possible. A new mother may rest better at home than in a strange setting, and she may eat better if she has cultural preferences for specific foods. The infant can be more quickly exposed to family routines rather than a superficial facility schedule. However, early discharge has the disadvantage of not allowing a new family to have the ready support of health care personnel if they have questions about their newborn or about the woman's condition. Although home visits are helpful for everyone, they should especially be planned for high-risk newborns, including newborns who are preterm, those born with a congenital anomaly, infants of adolescent mothers, and infants of mothers who have abused drugs during pregnancy.

The purposes of a home visit for the well postpartum woman and her newborn are to help integrate the infant into the family and to provide the family with additional information on newborn care that they may not have been able to learn during a brief hospital stay. Such a visit also allows for physical examination of the woman and newborn and for newborn screening procedures or bilirubin testing, if these were not done before hospital discharge.

Because women need to preserve their energy during the postpartal period, try to arrange a home visit at the woman's convenience. Preparation for home visiting is discussed in Chapter 4, with other aspects of home care. Important assessments to make at a postpartal home visit include:

Pregnancy History: Were there physical factors that could have interfered with pregnancy bonding, such as painful varicose veins or gestational diabetes? Were there psychosocial factors such as an unwelcome move or loss of an important support person? Ask the woman to describe her labor and birth, both to determine whether any complications were present and to evaluate her reaction to the event.

Newborn History: Has the baby had a return visit for a physical examination, and what were the findings? Is there anything about her infant for which a woman is concerned? Is the baby eating well? Sleeping at spaced intervals? Constantly fretful? Is the baby voiding?

Postpartal Course: Does a woman still have pain? Are there any concerns about her health? Is she managing to obtain adequate rest? A woman may be unprepared for feelings of postpartal depression ("baby blues") that she is experiencing. Ask whether she feels "blue" or extremely fatigued.

Future Plans: Will the woman be returning to work outside her home? If so, what plans has she made for child care?

Family Assessment: How are other children adapting? Does the client have adequate help with the new baby? How are her finances?

Physical Examination of the Mother: Assess temperature, pulse, and respiratory rate to detect possible infection or excessive blood loss. Assess uterine height and consistency (by the 10th day after delivery, the uterus should no longer be palpable as an abdominal organ). Assess the perineum to be certain there are no signs of infection in episiotomy stitches and that lochia color and odor are normal. Assess breasts for engorgement or any sign of infection.

Physical Examination of the Infant: Assess temperature, pulse, respiratory rate, and skin turgor. Assess the abdomen for distention. Inspect for any ecchymotic marks. Assess for full range of motion of extremities and that the child follows a moving light. Assess for jaundice. Inspect for possible diaper rash. Check that the skin around the cord is not reddened. (Full assessment of a newborn is discussed in Chapter 18.)

Follow-up Information: Be certain the family has made plans (or knows how to make plans) for continued care for both the infant and the mother. Be certain that they have the telephone number of a health care provider they can call if they have a concern before their next follow-up appointment.

Visiting a new family a few days after a hospital discharge this way is enjoyable, because most families have at least one question about their newborn that they are pleased to have answered. They are always pleased to be reassured that they are parenting well.

Postpartal Examination

Every newborn should have a health maintenance visit 2 to 4 weeks after birth (see Chapter 18). Every woman should have a checkup by her physician or nurse-midwife at 4 to 6 weeks after birth (the end of the postpartal period), to assure herself and her health care provider that she is in good health and has no residual problems from childbearing.

During this examination, the woman's abdominal wall is inspected for tone. Her breasts are inspected to see whether they have returned to their nonpregnant state if she is not breastfeeding or to see that they are unfissured and free of complications if she is breastfeeding. Most important, a thorough internal examination is performed to be certain that involution is complete, the ligaments and the pelvic muscle supports have returned to good functional alignment, and any lacerations sustained during birth have healed (Table 17.4). Ask about the possibility of intimate partner abuse, because it can increase during the postpartal period because of the added stress of forming a new family.

If a woman has hemorrhoids or varicosities as a result of the pregnancy, her physician or nurse-midwife will discuss with her whether further management of these conditions is necessary. You should review the necessity of having a breast examination, Papanicolaou (Pap) smear, and pelvic examination every year as a means of screening for breast, cervical, and uterine cancer. If a woman is older than 40 years, include a discussion about the need for mammogram examinations at least every other year. Encourage women who have stopped smoking during pregnancy to continue to be smoke free as yet another good health measure.

The postpartal examination should be a time for a woman to discuss any problems she had with childbearing and any she now has with childrearing, because these are a continuum. If reproductive life planning was not discussed immediately after birth, this visit is an opportune time for such a discussion. If a woman desires to use a diaphragm or a cervical cap, they can be fitted during this examination. Subcutaneous implanted hormonal contraception also can be inserted at this time. Women who are breastfeeding can begin on progesterone-only birth control pills (Truitt et al., 2009).

NURSING CARE OF A POSTPARTAL WOMAN AND FAMILY WITH UNIQUE NEEDS

A Woman Who Chooses Not to Keep Her Child

Although the availability of birth control information and the ability of women to secure abortions have reduced the number of unwanted or unplanned children, some women still may complete a pregnancy and then give up their child for adoption (Fontenot, 2007). There are numerous reasons for this decision: a woman may be unmarried, or her marriage may be failing, and she does not want to raise a child alone. She may feel that her family is already complete. She may want to finish school before having a child, or she may want to pursue a career.

During pregnancy, most women decide whether they will keep their child. During labor, they express confidence in their decision, but with the actual birth of their child, they may find that their resolve wavers. A woman who was certain she was going to surrender her child for adoption may realize she wants to keep the child. A woman who was certain she was going to keep her child could become aware for the first time of the responsibility involved and decide that the best course for the child is adoption. In either event, a woman's feelings can become confused.

For a woman who chooses not to keep her child, the wait in the birthing room for preparations to transfer the baby to a nursery may seem unusually long. She may also be alone, with no partner or support person with her during this time. Every woman has a right to see, hold, and feed her child if she wishes. A woman who is not going to keep her child may feel proud that she has produced a healthy baby. The realization that the baby is well can provide a foundation on which to build a sounder future so she does not have to make this choice again.

Do not attempt to change a woman's mind about keeping her child or placing the child for adoption during the post-

TABLE 17.4 ✻ Six-Week Physical Assessment

Area of Assessment	Data Collection
History	Assess chief concern, family profile (support system, bonding, self-esteem, family integrity), interval history, and review of systems (urinary system for pain, frequency, or stress incontinence along with gastrointestinal tract and reproductive tract in particular). Assess maternal intake. Some new mothers are too fatigued to eat well, so they eat mainly carbohydrate snack foods or, at least, not a balanced diet.
Physical Examination	Expected Findings
General appearance	Alert; positive mood. If not, woman is probably still extremely fatigued
Weight	Achievement of prepregnant weight; if not, this will be her baseline postpregnant weight
Hair	Healthy, firm hair; excess loss of hair from early postpartal period has halted
Eyes	Pink and moist conjunctiva; if pallor persists, diet may be inadequate because of fatigue
Breasts	
Nursing woman	Full and firm to palpation; blue veins prominent under skin; only slightly tender. No palpable nodules or lumps. If erythematous or tender, mastitis may be present. If fissures on nipples are present, the woman may need to expose her nipples to air or to apply additional cream. An occasional filled milk gland may present as a lump; re-examine after breastfeeding
Non-nursing woman	Return to prepregnant size; no palpable nodules or lumps
Abdomen	Striae less prominent; linea nigra fading, muscle tone improving. No distended bowel from constipation. No distended bladder from retention. No history of pain, frequency, or blood on urination. (If lax abdominal muscle tone is present, women need to increase abdominal exercises. For constipation, increase fluid and fiber. Urinary symptoms probably reflect urinary infection that needs specific treatment.)
Perineum and uterus	No lochia; cervix closed; uterus has returned to prepregnant size. Pap test is normal. Ask woman to bear down during pelvic examination to observe for uterine prolapse, rectocele, or cystocele. If involution is not complete, reason for subinvolution must be investigated
Lower extremities	Varicosities barely noticeable
Rectum	Hemorrhoids receded to prepregnant size or are no longer observable
Laboratory Report	
Laboratory values	Hct: 37%; Hgb: 11–12 g/100 mL. If these are low, reassess diet; possibly iron supplement may be needed Rubella antibody titer: 1:8; if low, additional immunization is recommended before a second pregnancy
Immunization status	Assess need for human papillomavirus (HPV) [Gardasil], or rubella vaccine

Hct, hematocrit; Hgb, hemoglobin.

partal period. She is extremely vulnerable to suggestion at this time, and such decisions are too long range and too important to be made at such an emotional time. Her earlier conclusions may be the sound ones. Instead, offer nonjudgmental support. Be especially aware of your own feelings about this issue, to avoid influencing a woman's decision making unnecessarily.

During the taking-in phase of the puerperium, be especially careful that you do not "lead" the woman's thinking. Women enjoy having decisions made for them during this time and may ask what you think is best. An answer such as, "You're the one who has to make this decision. What are your thoughts about it?" can help her begin to think through the problem.

It is not uncommon for women who surrender their infants for adoption to experience grief reactions, the same as those of women whose children have died. If a woman decides to surrender her child for adoption, refer her to an official adoption agency, if she has not contacted one already. An official agency gives a woman the best assurance that the parents chosen for her child will be appropriate. This assurance helps to relieve any misgivings or guilt she may have about surrendering the child and should reduce the moments of doubt that can come in future years, such as wondering whether the child is well cared for and is getting everything the mother could have given her.

Some women do not openly voice a wish to give up their child, but their actions demonstrate that they feel little attachment to their newborn. A woman who wants to keep her baby has a tentative but eager approach to her newborn, whereas a woman who has doubts is slow to make contact, barely touching the baby even by the time of discharge, and asking few questions about newborn care. When this happens, the hospital social service department can be of assistance in helping the woman plan the child's future. Either a single mother or a married couple may place an infant for adoption or into a foster home, although for some couples family counseling may be a greater need.

It is a fallacy to assume that everything will work out once the woman and infant arrive home. The number of abused children seen in hospital emergency departments is proof of the harm that can follow when assessment to detect poor parent–child bonding is inadequate in the first few days of life (Hicks & Stolfi, 2007).

A Woman Who Is Discharged but Whose Child Remains Hospitalized

Newborns who are ill at birth often are transported to a regional center or to a neonatal intensive care nursery for care, a move that automatically separates them from their parents. Many transport teams take an instant photograph of the baby and leave it with the mother. They also leave the nursery telephone number and the name of a nurse or physician to contact for questions or information. Most transport teams call the mother after they arrive at the distant hospital to assure her that her infant managed the stress of transport well.

Maintaining communication with the nursery is important so that parents can begin to bond with their child. Urge them to call the nursery at least once daily to ask about their infant. If the infant is hospitalized in the same hospital, help the mother arrange visiting time with the infant. Transport her to the nursery, so that she can see and, ideally, hold her child. Without this assistance, some women will not call or visit, because they are afraid that this is an imposition or inconvenience for the nursery. Assure the mother that her telephone calls and visits are expected (the nursery wants to encourage bonding). Visiting in an intensive care nursery is further discussed in Chapter 26.

It is easy for a woman who is separated from her newborn to feel despondent (Amankwaa, Pickler, & Boonmee, 2007). Some mothers whose infants are ill at birth feel uncomfortable sharing a hospital room with a postpartal roommate who is caring for a well baby. This is often a good time to arrange for a visit to the nursery or to suggest that you and the woman take a walk in the hallway to increase her amount of ambulation.

A Family Who Is Adopting a Child

A family who is adopting an infant may come into the hospital or birthing center to meet their new infant for the first time. Such a couple needs the same introduction to newborn care as biologic parents. Additional needs of adopting parents are discussed in Chapter 3.

✔ Checkpoint Question 17.3

You care for Joan Cooper at a 6-week postpartum visit. What should her fundal height be at this time?

a. Six fingerbreadths below the umbilicus.
b. No longer palpable on her abdomen.
c. One centimeter above the symphysis pubis.
d. Inverted and palpable at the cervix.

Key Points for Review

- The postpartal period (puerperium) is the 6-week period after childbirth. This is an important period, because it marks the child's introduction to the family. Women move through an initial "taking-in" phase, in which they are dependent; a "taking-hold" phase, in which they manifest independence; and a "letting-go" phase, in which the mother role is finally defined.
- Rooming-in is the preferred health care agency arrangement for postpartal families, because it allows a new family the best chance for quality interaction. The more time new parents spend with a newborn, the more likely it is that effective bonding will occur. Help parents to feel comfortable with their newborn by offering anticipatory guidance and role modeling infant care.
- "Postpartal blues" are a normal accompaniment to childbirth. You can assure a woman that her feelings are normal and offer supportive care until the emotion passes.
- Uterine involution is the process whereby the uterus returns to its prepregnant state. A uterus decreases in size one fingerbreadth a day until it disappears under the pubic bone at about day 10. Lochia is the name of the vaginal flow after childbirth: the flow is lochia rubra (red) for the first 1 to 3 days; lochia serosa (pink to brown) on days 4 through 10; and lochia alba (white) until 2 to 6 weeks after the birth.
- A woman is at great risk for hemorrhage in the postpartal period, so assessments done during this time are some of the most critical assessments made in nursing. Do not discount the importance of these assessments because the overall content of the postpartal period is so focused on wellness.
- Lactation is the production of breast milk. Colostrum is present immediately after birth; milk forms on the third to fourth postpartal day. A feeling of fullness and firmness on this day is termed *filling;* if warmth and discomfort occur, it is termed *engorgement.*
- Women may need various comfort measures to alleviate pain from sutures, uterine pain (afterpains), and breast tenderness. Application of cold or heat and administration of analgesics are important nursing interventions.
- Women need to learn about self-care before health care agency discharge, so that they can maintain self-care at home. A follow-up telephone call or home visit is helpful. All women should conscientiously return for a visit at 6 weeks after childbirth, to be certain their reproductive organs have returned to their nonpregnant state. A menstrual flow should return within 6 to 10 weeks in the non-breastfeeding mother, or 3 to 4 months in the breastfeeding mother.

CRITICAL THINKING EXERCISES

1. As the nurse working in a postpartum unit, you care for Mike and Joan Cooper, who have just become parents of an 8-lb 2-oz baby girl. Joan is on maternity leave from her job as a court reporter. Mike plans to take off a week from work to spend time with Joan and the new baby. As you prepare them for discharge, you notice they seem overwhelmed with the amount of information they have been provided. Joan says, trying to get the baby to nurse, "He's so big and my breasts are so small, will he get enough milk? I was hoping by breast-

feeding I wouldn't have to worry about birth control for a while, but I'm having so much trouble maybe that won't work out." Mike pulls you aside and says, "Sometimes, I see my wife crying for no reason. Why isn't she as happy as I am?" What additional postpartal teaching does the Cooper family need?

2. Suppose because Joan Cooper does not have an episiotomy incision, you expect her to have little perineal discomfort. Instead, she states that her perineal pain is excruciating. You notice she has hemorrhoids. You overhear her tell her husband that he is acting selfishly for paying more attention to their new daughter than to her. You observe her handing her baby roughly to her husband. What could you suggest to make her more comfortable?
3. Suppose you are present at Joan's 6-week postpartal checkup. What would you include in an assessment plan to ensure that she has physically and emotionally adjusted well to childbirth?
4. Examine the National Health Goals related to the postpartal period. Most government-sponsored funds for nursing research are allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to the Cooper family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to nursing care of the postpartal family. Confirm your answers are correct by reading the rationales.

Chapter

18 Nursing Care of a Family With a Newborn

KEY TERMS

- acrocyanosis
- caput succedaneum
- cavernous hemangioma
- central cyanosis
- cephalhematoma
- conduction
- convection
- erythema toxicum
- evaporation
- hemangiomas
- jaundice
- kernicterus
- lanugo
- meconium
- milia
- mongolian spot
- natal teeth
- neonatal period
- neonate
- nevus flammeus
- physiologic jaundice
- pseudomenstruation
- radiation
- strawberry hemangioma
- subconjunctival hemorrhage
- thrush
- transitional stool
- vernix caseosa

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe the normal characteristics of a term newborn.
2. Identify National Health Goals related to newborn care that nurses could help the nation achieve.
3. Use critical thinking to analyze ways that the care of a term newborn can be more family centered.
4. Assess a newborn for normal growth and development.
5. Formulate nursing diagnoses related to a newborn or the family of a newborn.
6. Identify expected outcomes for a newborn and family during the first 4 weeks of life.
7. Plan nursing care to augment normal development of a newborn, such as ways to aid parent–child bonding.
8. Implement nursing care of a normal newborn, such as instructing parents on how to care for their newborn.
9. Evaluate outcome criteria for the achievement and effectiveness of care.
10. Identify areas related to newborn assessment and care that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of newborn growth and development and immediate care needs with the nursing process to achieve quality maternal and child health nursing care.

Carlotta Ruiz has just given birth to her second child, a 6-lb 5-oz baby girl she named Beth. Apgar scores at 1 and 5 minutes were 6 and 8. Vital signs are temperature (axillary), 98.2° F (36.8° C); heart rate, 136 beats per minute; and respirations, 74 breaths per minute. She is 18.5 inches long, with a head circumference of 34 cm and a chest circumference of 32 cm. She has a small port-wine birthmark on her right thigh.

While Jose, Carlotta's husband, is in the room, Carlotta tells you she is a "veteran" at baby care. Jose adds, "Little Joe [their 3-year-old] will be so excited to see his new sister. That's all he's been talking about lately."

When Carlotta is alone, you notice she seems a little apprehensive about caring for her new daughter. She tells you, "She's so much smaller than Joe was. And why does it sound like she has a cold? And what is this rash all over her? Isn't it bad enough she has a birthmark?"

Previous chapters described the care of a pregnant woman and family during the antepartal, intrapartal, and postpartal periods. This chapter adds information about caring for a newborn and family. The newborn period is important to a family's well-being because it lays the foundation for the rest of the family's childrearing years.

Does Carlotta know as much about newborns as she thought? What additional teaching does this family need?

Newborns undergo profound physiologic changes at the moment of birth (and, probably, psychological changes as well), as they are released from a warm, snug, dark, liquid-filled environment that has met all of their basic needs into a chilly, unbounded, brightly lit, gravity-based, outside world. Within minutes after being plunged into this strange environment, a newborn has to initiate respirations and adapt a circulatory system to extrauterine oxygenation. Within 24 hours, neurologic, renal, endocrine, gastrointestinal, and metabolic functions must be operating competently for life to be sustained.

How well a newborn makes these major adjustments depends on his or her genetic composition, the competency of the recent intrauterine environment, the care received during the labor and birth period, and the care received during the newborn or **neonatal period** (from birth through the first 28 days of life) (Ruiz et al., 2009). Two thirds of all deaths that occur during the first year of life occur in the neonatal period. More than half occur in the first 24 hours after birth—an indication of how hazardous a time this is for an infant.

BOX 18.1 ✻ Focus on National Health Goals

Several National Health Goals deal directly with the newborn period:

- Increase to at least 75% the proportion of mothers who breastfeed their babies in the early postpartal period from a baseline of 64%.
- Increase to at least 50% the proportion of women who continue breastfeeding until their babies are 5 to 6 months old from a baseline of 29%.
- Increase to 70% the percentage of healthy full-term infants who are put to sleep on their backs from a baseline of 35%.
- Increase to 60% from a baseline of 43% the number of women who breastfeed exclusively until their infant is 3 months of age; from 13% to 25% for those who breastfeed exclusively until 6 months.
- Increase to at least 75% the proportion of parents and caregivers who use feeding practices that prevent baby-bottle tooth decay.
- Reduce the neonatal mortality rate to no more than 2.9 per 1000 live births from a baseline of 4.8 per 1000 live births (http://www.nih.gov).

Nurses can help the nation achieve these goals, by encouraging women not only to begin breastfeeding but also to continue it through the first 6 months of life; by advising parents on the advantage of placing infants on their backs to sleep and on the danger of tooth decay from letting a baby drink from a bottle of milk or juice while falling asleep; and by discussing with parents who use formula the proper methods for preparation so that gastrointestinal illness does not occur.

Areas that could benefit from additional nursing research include identifying the reasons why some women end breastfeeding shortly after discharge from a health care agency and investigating common methods of encouraging sleep in infants other than by bottle feeding or offering solid food.

Newborn health is so important that National Health Goals related to the first days of life have been devised. These are shown in Box 18.1. Nurses play a major role in achieving these goals because nurses are the people who provide newborn care and give newborn instructions to new parents.

Nursing Process Overview

For Health Promotion of the Term Newborn

Assessment

Assessment of a newborn or **neonate** (a baby in the neonatal period) includes a review of the mother's pregnancy history; physical examination of the infant; analysis of laboratory reports such as hematocrit and blood type, if indicated; and assessment of parent–child interaction for the beginning of bonding. Assessment begins immediately after birth and is continued at every contact during a newborn's hospital or birthing center stay, early home visits, and well-baby visits. Teaching parents to make assessments concerning their infant's temperature, respiratory rate, and overall health is crucial so that they can continue to monitor their infant's health at home (Box 18.2).

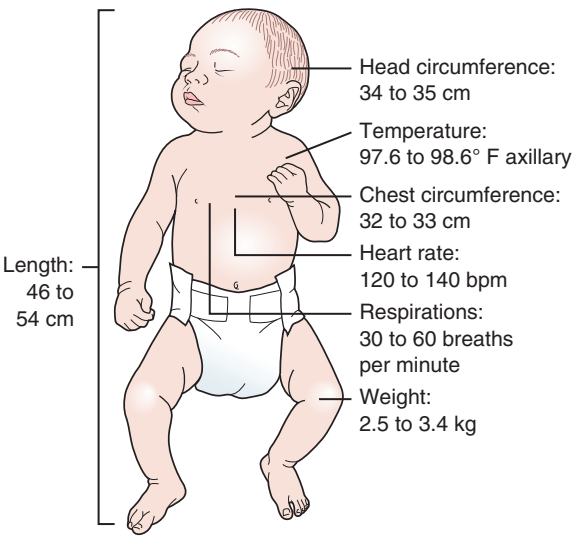
Nursing Diagnosis

Nursing diagnoses associated with a newborn often center on the problems of establishing respirations, beginning nutrition, and assisting with parent–newborn bonding. Examples are:

- Ineffective airway clearance related to mucus in airway
- Ineffective thermoregulation related to heat loss from exposure in birthing room
- Imbalanced nutrition, less than body requirements, related to poor sucking reflex

Box 18.2 Assessment

Assessing the Average Newborn



- Readiness for enhanced family coping related to birth of planned infant
- Health-seeking behaviors related to newborn needs

If a minor deviation from the normal is present, such as a hemangioma, a diagnosis such as "Parental fear related to hemangioma on left thigh of newborn" might be relevant.

Outcome Identification and Planning

Planning nursing care should take into account both the newborn's needs during this transition period and a mother's need for adequate rest during the postpartal period. Try to adapt teaching time to the schedules of the mother and her newborn. Although the woman must learn as much as possible about newborn care, she also must go home from the health care setting with enough energy to practice what she has learned. Important planning measures for newborns include helping them regulate their temperature and helping them grow accustomed to breastfeeding or bottle feeding. A helpful Internet site to recommend to parents is the Yale/New Haven Children's Hospital web site (http://www.ynhh.org).

Implementation

A major portion of implementation in the newborn period is role modeling to help new parents grow confident with their newborn. Be aware how closely parents observe you for guidance in newborn care. Conserving newborn warmth and energy, to help prevent hypoglycemia and respiratory distress, should be an important consideration to accompany all interventions.

Outcome Evaluation

Evaluation of expected outcomes should reveal that parents are able to give beginning newborn care with confidence. Be certain parents make arrangements for continued health supervision for their newborn, so that evaluation can be continued and the family's long-term health needs can be met. Examples indicating achievement of outcomes concerning newborns are:

- Infant establishes respirations of 30 to 60 per minute.
- Infant maintains temperature at 97.8° to 98.6° F (36.5° to 37° C).
- Infant bottle feeds or breastfeeds well with a strong sucking reflex.

PROFILE OF A NEWBORN

It is not unusual to hear the comment "all newborns look alike" from people viewing a nursery full of babies. In actuality, every child is born with individual physical and personality characteristics that make him or her unique right from the start (Fig. 18.1).

Some newborns are born stocky and short, some large and bony, some thin and rangy. Some have a temperament that causes them to feed greedily, protest procedures loudly, and respond to their parent's inexperienced handling with restlessness and spitting up. Other newborns sleep soundly, make no protest over procedures or diaper changes, and seem passive in accepting this new step in life. With experience in working with newborns, it becomes easier to differentiate

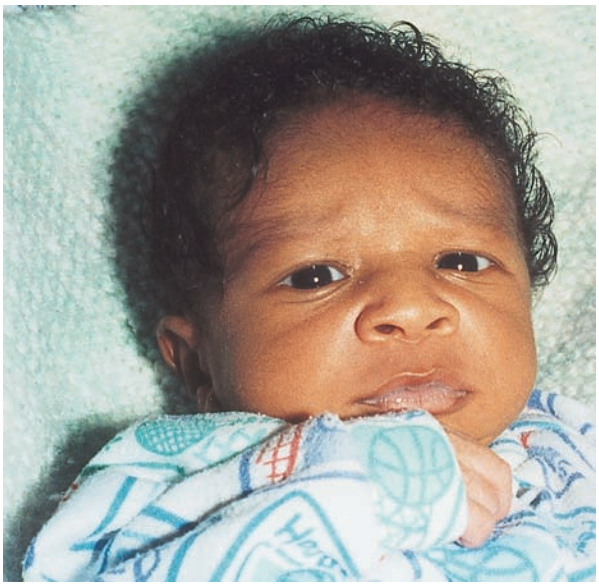


FIGURE 18.1 Personality is apparent in a newborn from the start. Note the alert, searching interest.

newborns who are merely demonstrating these extremes of normal behavior from those whose behavior or appearance indicates a need for more skilled care as their adjustment to independent life is not progressing smoothly.

Vital Statistics

Vital statistics measured in a newborn are weight, length, and head and chest circumference. The technique for obtaining these is shown in Chapter 34, along with other aspects of health assessment. Be sure all health care providers involved with newborns are aware of safety issues specific to newborn care when taking these measurements such as not leaving a newborn unattended on a bed or scale.

Weight

The birth weight of newborns varies depending on the racial, nutritional, intrauterine, and genetic factors that were present during conception and pregnancy. The weight in relation to the gestational age should be plotted on a standard neonatal graph, such as the one shown in Appendix E. Plotting weight this way helps identify newborns who are at risk because of their small size. This information also separates those who are small for their gestational age (newborns who have suffered intrauterine growth restriction) from preterm infants (infants who are healthy but small only because they were born early). These first measurements also establish a baseline for future evaluation.

Plotting weight in conjunction with height and head circumference is also helpful because it highlights disproportionate measurements (see Appendix E). All three of these measurements should fall near the same percentile in an individual child. For example, a newborn who falls within the 50th percentile for height and weight but whose head circumference is in the 90th percentile may have abnormal head growth. A newborn who is in the 50th percentile for weight and head circumference but in the 3rd percentile for height may have a growth problem.

The average birth weight (50th percentile) for a white, mature female newborn in the United States is 3.4 kg (7.5 lb); for a white, mature male newborn, it is 3.5 kg (7.7 lb). Newborns of other races weigh approximately 0.5 lb less. The arbitrary lower limit of normal for all races is 2.5 kg (5.5 lb). Birth weight exceeding 4.7 kg (10 lb) is unusual, but weights as high as 7.7 kg (17 lb) have been documented. If a newborn weighs more than 4.7 kg, the baby is said to be macrosomic and a maternal illness, such as diabetes mellitus, must be suspected (Kwik et al., 2007). Second-born children usually weigh more than first-born. Birth weight continues to increase with each succeeding child in a family.

During the first few days after birth, a newborn loses 5% to 10% of birth weight (6 to 10 oz). This weight loss occurs because a newborn is no longer under the influence of salt- and fluid-retaining maternal hormones. Diuresis begins to remove a part of the infant's high fluid load. A newborn also voids and passes stool. Because approximately 75% to 90% of a newborn's weight is fluid, all three of these measures reduce weight. In addition, breastfed newborns have a limited intake until about the third day of life because of the relatively low caloric content and amount of colostrum they ingest. If newborns are formula-fed, their intake during this time is also limited because of the time needed to establish effective sucking.

After this initial loss of weight, a newborn has 1 day of stable weight, then begins to gain weight. The breastfed newborn recaptures birth weight within 10 days; a formula-fed infant accomplishes this gain within 7 days. After this, a newborn begins to gain about 2 lb per month (6 to 8 oz per week) for the first 6 months of life.

Length

The average birth length (50th percentile) of a mature female neonate is 53 cm (20.9 in). For mature males, the average birth length is 54 cm (21.3 in). The lower limit of normal length is arbitrarily set at 46 cm (18 in). Although rare, babies with lengths as great as 57.5 cm (24 in) have been reported.

Head Circumference

In a mature newborn, the head circumference is usually 34 to 35 cm (13.5 to 14 in). A mature newborn with a head circumference greater than 37 cm (14.8 in) or less than 33 cm (13.2 in) should be carefully assessed for neurologic involvement, although occasionally a well newborn falls within these limits. Head circumference is measured with a tape measure drawn across the center of the forehead and around the most prominent portion of the posterior head (the occiput; see Fig. 34.6 in Chapter 34).

Chest Circumference

The chest circumference in a term newborn is about 2 cm (0.75 to 1 in) less than the head circumference. This is measured at the level of the nipples. If a large amount of breast tissue or edema of breasts is present, this measurement will not be accurate until the edema has subsided.

Vital Signs

Vital sign measurements begin to change from those present in intrauterine life at the moment of birth.

Temperature

The temperature of newborns is about 99° F (37.2° C) at birth because they have been confined in an internal body organ. The temperature falls almost immediately to below normal because of heat loss and immature temperature-regulating mechanisms. The temperature of birthing rooms, approximately 68° to 72° F (21° to 22° C), can add to this loss of heat.

Newborns lose heat by four separate mechanisms: convection, conduction, radiation, and evaporation (Fig. 18.2).

Convection is the flow of heat from the newborn's body surface to cooler surrounding air. The effectiveness of convection depends on the velocity of the flow (a current of air cools faster than nonmoving air). Eliminating drafts from windows or air conditioners reduces convection heat loss.

Conduction is the transfer of body heat to a cooler solid object in contact with a baby. For example, a baby placed on a cold counter or on the cold base of a warming unit quickly loses heat to the colder metal surface. Covering surfaces with a warmed blanket or towel helps to minimize conduction heat loss.

Radiation is the transfer of body heat to a cooler solid object not in contact with the baby, such as a cold window or air conditioner. Moving an infant as far from the cold surface as possible helps reduce this type of heat loss.

Evaporation is loss of heat through conversion of a liquid to a vapor. Newborns are wet, so they lose a great deal of heat as the amniotic fluid on their skin evaporates. To prevent this heat loss, dry newborns as soon as possible, especially their face and hair as the head, a large surface area in a newborn, can be responsible for a great amount of heat loss. Covering the hair with a cap after drying it further reduces the possibility of evaporation cooling. Be certain to remove any wet blankets used to dry the infant immediately and place the infant on a warm, dry blanket.

A newborn not only loses heat easily by the means just described but also has difficulty conserving heat under any circumstance. Insulation, an efficient means of conserving heat in adults, is not effective in newborns because they have little subcutaneous fat to provide insulation. Shivering, a means of increasing metabolism and thereby providing heat in adults, is rarely seen in newborns.

Newborns can conserve heat by constricting blood vessels and moving blood away from the skin. *Brown fat,* a special tissue found in mature newborns, apparently helps to conserve or produce body heat by increasing metabolism. The greatest amounts of brown fat are found in the intrascapular region, thorax, and perirenal area. Brown fat is thought to aid in controlling newborn temperature similar to temperature control in a hibernating animal. In later life, it may influence the proportion of body fat retained.

Newborns exposed to cool air tend to kick and cry to increase their metabolic rate and produce more heat. This reaction, however, also increases their need for oxygen and their respiratory rate increases. An immature newborn with poor lung development has trouble making such an adjustment. Newborns who cannot increase their respiratory rate in response to increased needs will be unable to deliver sufficient oxygen to their systems. In addition, a newborn becomes fatigued by rapid breathing, placing additional strain on an already stressed cardiovascular system. The resultant anaerobic catabolism of body cells releases acid. Every newborn is born

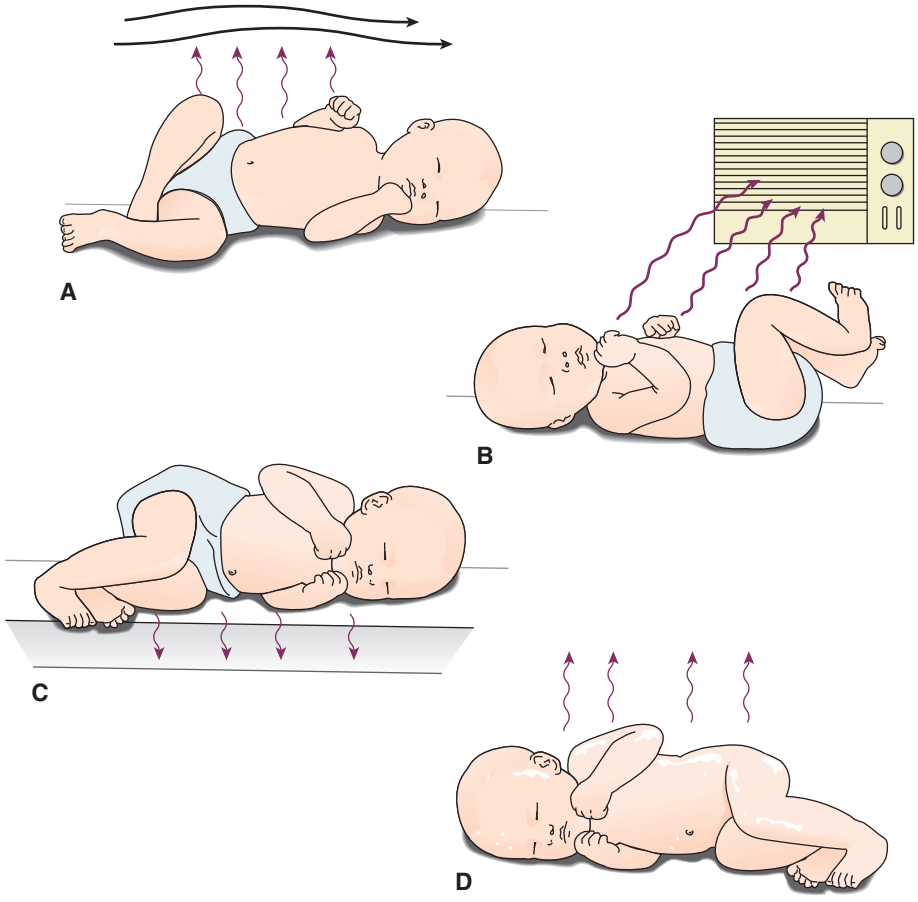

FIGURE 18.2 Heat loss in the newborn. (**A**) Convection. (**B**) Radiation. (**C**) Conduction. (**D**) Evaporation.

slightly acidotic. Any new buildup of acid may lead to severe, life-threatening acidosis.

Drying and wrapping newborns and placing them in warmed cribs, or drying them and placing them under a radiant heat source, are excellent mechanical measures to help conserve heat. In addition, placing a newborn against the mother's skin and then covering the newborn with a blanket helps to transfer heat from the mother to the newborn; this is termed skin-to-skin care (Moore, Anderson, & Bergman, 2009).

All early care of newborns should be done speedily to avoid exposing the newborn to cool air unnecessarily. Any procedure during which a newborn must be uncovered such as resuscitation or circumcision should be done under a radiant heat source to prevent damaging heat loss. If chilling is prevented, a newborn's temperature stabilizes at 98.6° F (37° C) within 4 hours after birth.

In contrast to an adult, a newborn with a bacterial infection may run a subnormal temperature. Therefore, if a newborn's temperature does not stabilize shortly after birth, the cause must be investigated to rule out infection.

Pulse

The heart rate of a fetus in utero averages 120 to 160 beats per minute (bpm). Immediately after birth, as the newborn struggles to initiate respirations, the heart rate may be as rapid as 180 bpm. Within 1 hour after birth, as the newborn settles down to sleep, the heart rate stabilizes to an average of 120 to 140 bpm.

The heart rate of a newborn often remains slightly irregular because of immaturity of the cardiac regulatory center in the medulla. Transient murmurs may result from the incomplete closure of fetal circulation shunts. During crying, the rate may rise again to 180 bpm. In addition, heart rate can decrease during sleep, ranging from 90 to 110 bpm.

You should be able to palpate brachial and femoral pulses in a newborn, but the radial and temporal pulses are more difficult to palpate with any degree of accuracy. Therefore, a newborn's heart rate is always determined by listening for an apical heartbeat for a full minute, rather than assessing a pulse in an extremity. Always palpate for femoral pulses, however, because their absence suggests possible coarctation (narrowing) of the aorta, a common cardiovascular abnormality.

Respiration

The respiratory rate of a newborn in the first few minutes of life may be as high as 80 breaths per minute. As respiratory activity is established and maintained, this rate settles to an average of 30 to 60 breaths per minute when the newborn is at rest. Respiratory depth, rate, and rhythm are likely to be irregular, and short periods of apnea (without cyanosis) which last less than 15 seconds, sometimes called *periodic respirations,* are normal. Respiratory rate can be observed most easily by watching the movement of a newborn's abdomen, because breathing primarily involves the use of the diaphragm and abdominal muscles.

Coughing and sneezing reflexes are present at birth to clear the airway. Newborns are obligate nose-breathers, however, and show signs of acute distress if their nostrils become obstructed. Short periods of crying, which increase the depth of respirations and aid in aerating deep portions of the lungs, may be beneficial to a newborn. Long periods of crying, however, can exhaust the cardiovascular system.

Blood Pressure

The blood pressure of a newborn is approximately 80/46 mm Hg at birth. By the 10th day, it rises to about 100/50 mm Hg. Because measurement of blood pressure in a newborn is somewhat inaccurate, it is not routinely measured unless a cardiac anomaly is suspected. For an accurate reading, the cuff width used must be no more than two thirds the length of the upper arm or thigh. Blood pressure tends to increase with crying (and a newborn cries when disturbed and manipulated by such procedures as taking blood pressure). A Doppler method may be used to take blood pressure (see Chapter 34). Hemodynamic monitoring is helpful when continuous assessment is necessary.

✔ Checkpoint Question 18.1

Beth Ruiz, like all newborns, can lose body heat by conduction. Under which condition is conduction most apt to occur?

a. The nursery is cooled by air conditioning.
b. The infant is wet from amniotic fluid.
c. There is a breeze from an open window.
d. Beth is placed in a cold bassinet.

Physiologic Function

Just as changes occur in vital signs after birth, so do changes occur in all the major body systems.

Cardiovascular System

Changes in the cardiovascular system are necessary after birth because now the lungs must oxygenate the blood that was formerly oxygenated by the placenta. When the cord is clamped, a neonate is forced to take in oxygen through the lungs. As the lungs inflate for the first time, pressure decreases in the pulmonary artery (the artery leading from the heart to the lungs). This decrease in pressure plays a role in promoting closure of the ductus arteriosus, a fetal shunt. As pressure increases in the left side of the heart from increased blood volume, the foramen ovale between the two atria closes because of the pressure against the lip of the structure (permanent closure does not occur for weeks). With the remaining fetal circulatory structures (umbilical vein, two umbilical arteries, and ductus venosus) no longer receiving blood, the blood within them clots, and the vessels atrophy over the next few weeks.

Figure 18.3 shows the respiratory and cardiovascular changes that occur at birth, beginning with the first breath. The peripheral circulation of a newborn remains sluggish for at least the first 24 hours. It is common to observe cyanosis in the infant's feet and hands **(acrocyanosis)** and for the feet to feel cold to the touch at this time.

Blood Values. A newborn's blood volume is 80 to 110 mL per kilogram of body weight, or about 300 mL total. The oxygen dissociation curve is shifted to the left; that is, the quantity of oxygen bound to hemoglobin and the partial pressure of oxygen are greater in newborn blood than in an adult's blood, or a newborn's hemoglobin carries a greater proportion of oxygen than adult hemoglobin.

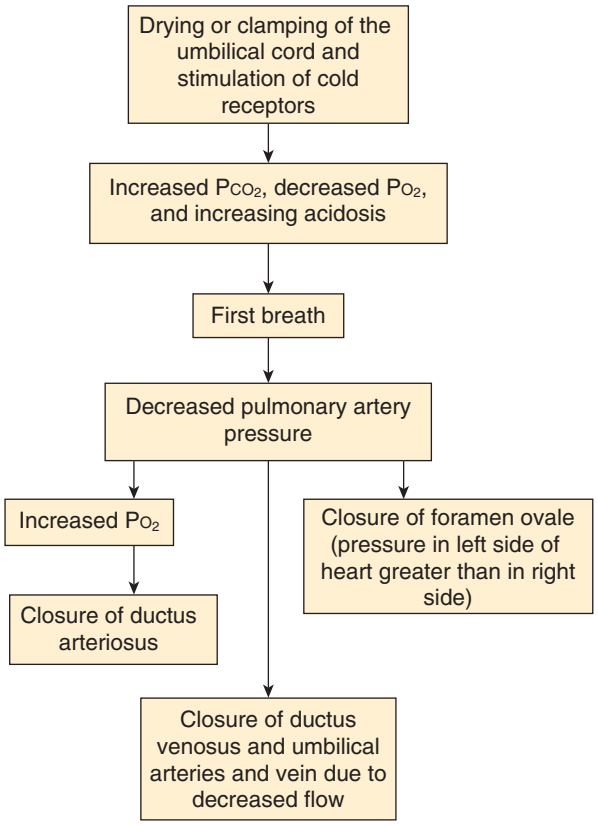

FIGURE 18.3 Circulatory events at birth.

Hemoglobin level averages 17 to 18 g/100 mL of blood. The hematocrit is between 45% and 50%. A newborn also has an elevated red blood cell count, about 6 million cells per cubic millimeter. Capillary heel-sticks may reveal a falsely high hematocrit or hemoglobin value because of sluggish peripheral circulation. Before obtaining a blood specimen from a heel, warm the foot by wrapping it in a warm cloth. This increases circulation and improves the accuracy of this value.

Once proper lung oxygenation has been established, the need for the high red cell count diminishes. Therefore, within a matter of days, a newborn's red cells begin to deteriorate. Bilirubin is a byproduct of the breakdown of red blood cells. An indirect bilirubin level at birth is 1 to 4 mg/100 mL. Any increase over this amount reflects the release of bilirubin as excessive red blood cells begin their breakdown (Chetham, 2007).

A newborn has an equally high white blood cell count at birth, about 15,000 to 30,000 cells/mm^3. Values as high as 40,000 cells/mm^3 may be seen if the birth was stressful. Polymorphonuclear cells (neutrophils) account for a large part of this leukocytosis, but by the end of the first month, lymphocytes become the predominant cell type. This leukocytosis is a response to the trauma of birth and is nonpathogenic; an increased white blood cell count should not be

taken as evidence of infection. On the other hand, although the high white blood cell count makes infection difficult to prove in a newborn, infection must not be dismissed as a possibility if other signs of infection such as pallor, respiratory difficulty, or cyanosis are present. Usual blood values in a newborn are summarized in Appendix F.

Blood Coagulation. Because most newborns are born with a lower than normal level of vitamin K, they have a prolonged coagulation or prothrombin time. Vitamin K, synthesized through the action of intestinal flora, is necessary for the formation of factor II (prothrombin), factor VII (proconvertin), factor IX (plasma thromboplastin component), and factor X (Stuart-Prower factor). Because a newborn's intestine is sterile at birth unless membranes were ruptured more than 24 hours before birth, it takes about 24 hours for flora to accumulate and for vitamin K to be synthesized. Because almost all newborns can be predicted to have this diminished blood coagulation ability, vitamin K (AquaMEPHYTON) is usually administered intramuscularly into the lateral anterior thigh, the preferred site for all injections in a newborn, immediately after birth.

Respiratory System

A first breath is a major undertaking because it requires a tremendous amount of pressure (about 40 to 70 cm H_2O). It is initiated by a combination of cold receptors; a lowered partial pressure of oxygen (P_{O_2}), which falls from 80 to as low as 15 mm Hg before a first breath; and an increased partial carbon dioxide pressure (P_{CO_2}), which rises as high as 70 mm Hg before a first breath. All newborns have some fluid in their lungs from intrauterine life that will ease the surface tension on alveolar walls and allows alveoli to inflate more easily than if the lung walls were dry. About a third of this fluid is forced out of the lungs by the pressure of vaginal birth. Additional fluid is quickly absorbed by lung blood vessels and lymphatics after the first breath.

Once the alveoli have been inflated with a first breath, breathing becomes much easier for a baby, requiring only about 6 to 8 cm H_2O pressure. Within 10 minutes after birth, most newborns have established a good residual volume. By 10 to 12 hours of age, vital capacity is established at newborn proportions. The heart in a newborn takes up proportionately more space than in an adult, so the amount of lung expansion space available is proportionately limited.

A baby born by cesarean birth does not have as much lung fluid expelled at birth as one born vaginally and so may have more difficulty establishing effective respirations, because excessive fluid blocks air exchange space. Newborns who are immature and whose alveoli collapse each time they exhale (because of the lack of pulmonary surfactant) have difficulty establishing effective residual capacity and respirations. If the alveoli do not open well, a newborn's cardiac system becomes compromised, because closure of the foramen ovale and ductus arteriosus depends on free blood flow through the pulmonary artery and good oxygenation of blood. Therefore, a newborn who has difficulty establishing respirations at birth should be examined closely in the postpartal period for a cardiac murmur or other indication that he or she still has patent fetal cardiac structures, especially a patent ductus arteriosus.

Gastrointestinal System

Although the gastrointestinal tract is usually sterile at birth, bacteria may be cultured from the intestinal tract in most babies within 5 hours after birth and from all babies at 24 hours of life. Most of these bacteria enter the tract through the newborn's mouth from airborne sources. Others may come from vaginal secretions at birth, from hospital bedding, and from contact at the breast. Accumulation of bacteria in the gastrointestinal tract is necessary for digestion and for the synthesis of vitamin K.

Although a newborn's stomach holds about 60 to 90 mL, a newborn has limited ability to digest fat and starch because the pancreatic enzymes, lipase and amylase, remain deficient for the first few months of life. A newborn regurgitates easily because of an immature cardiac sphincter between the stomach and esophagus. Immature liver functions may lead to lowered glucose and protein serum levels.

Stools. The first stool of a newborn is usually passed within 24 hours after birth. It consists of **meconium,** a sticky, tarlike, blackish-green, odorless material formed from mucus, vernix, lanugo, hormones, and carbohydrates that accumulated during intrauterine life. If a newborn does not pass a meconium stool by 24 to 48 hours after birth, the possibility of some factor such as meconium ileus, imperforate anus, or volvulus should be suspected.

About the second or third day of life, newborn stool changes in color and consistency, becoming green and loose. This is termed **transitional stool,** and it may resemble diarrhea to the untrained eye. By the fourth day of life, breastfed babies pass three or four light yellow stools per day. They are sweet-smelling, because breast milk is high in lactic acid, which reduces the amount of putrefactive organisms in the stool. A newborn who receives formula usually passes two or three bright yellow stools a day. These have a slightly more noticeable odor, compared with the stools of breastfed babies.

A newborn placed under phototherapy lights as a treatment for jaundice has bright green stools because of increased bilirubin excretion. Newborns with bile duct obstruction have clay-colored (gray) stools, because bile pigments are not entering the intestinal tract. Blood-flecked stools usually indicate an anal fissure. Occasionally, a newborn has swallowed some maternal blood during birth and either vomits fresh blood immediately after birth or passes a black tarry stool after 2 or more days. Maternal blood may be differentiated from fetal blood by a dipstick Apt test. If the stools remain black or tarry, intestinal bleeding should be suspected. If mucus is mixed with stool or the stool is watery and loose, a milk allergy, lactose intolerance, or some other condition interfering with digestion or absorption should be suspected.

Urinary System

The average newborn voids within 24 hours after birth. A newborn who does not take in much fluid for the first 24 hours may void later than this, but the 24-hour point is a good general rule. Newborns who do not void within this time should be examined for the possibility of urethral stenosis or absent kidneys or ureters.

The possibility of obstruction in the urinary tract can be assessed by observing the force of the urinary stream in both male and female infants. Males should void with enough force

to produce a small projected arc; females should produce a steady stream, not just continuous dribbling. Projecting urine farther than normal may signal urethral obstruction, because it indicates that urine is being forced through a narrow channel.

The kidneys of newborns do not concentrate urine well, making newborn urine usually light-colored and odorless. The infant is about 6 weeks of age before much control over reabsorption of fluid in tubules and concentration of urine becomes evident.

A single voiding in a newborn is only about 15 mL and may be easily missed in a thick diaper. Specific gravity ranges from 1.008 to 1.010. The daily urinary output for the first 1 or 2 days is about 30 to 60 mL total. By week 1, total daily volume rises to about 300 mL. The first voiding may be pink or dusky because of uric acid crystals that were formed in the bladder in utero; this is an innocent finding. A small amount of protein may be normally present in voidings for the first few days of life, until the kidney glomeruli are more fully mature. Diapers can be weighed to determine the amount of urine output.

Immune System

Because they have difficulty forming antibodies against invading antigens until about 2 months of age, newborns are prone to infection. This inability to form antibodies is the reason that most immunizations against childhood diseases are not given to infants younger than 2 months of age. Newborns do have some immunologic protection, because they are born with passive antibodies (immunoglobulin G) from their mother that crossed the placenta. In most instances, these include antibodies against poliomyelitis, measles, diphtheria, pertussis, chickenpox, rubella, and tetanus. Newborns are routinely administered hepatitis B vaccine during the first 12 hours after birth to protect against this disease (American Academy of Pediatrics [AAP], 2009). Little natural immunity is transmitted against herpes simplex. Any health care personnel with herpes simplex eruptions (cold sores) should not care for newborns until the lesions have crusted. Without antibody protection, herpes simplex infections can become systemic or create a rapidly fatal form of the disease in a newborn.

Neuromuscular System

Mature newborns demonstrate neuromuscular function by moving their extremities, attempting to control head movement, exhibiting a strong cry, and demonstrating newborn reflexes. Limpness or total absence of a muscular response to manipulation is never normal and suggests narcosis, shock, or cerebral injury. A newborn occasionally makes twitching or flailing movements of the extremities in the absence of a stimulus because of the immaturity of the nervous system. Newborn reflexes can be tested with consistency by using simple maneuvers.

Blink Reflex. A blink reflex in a newborn serves the same purpose as it does in an adult—to protect the eye from any object coming near it by rapid eyelid closure. It may be elicited by shining a strong light such as a flashlight or an otoscope light on an eye. A sudden movement toward the eye sometimes can elicit the blink reflex.

Rooting Reflex. If the cheek is brushed or stroked near the corner of the mouth, a newborn infant will turn the head in that direction. This reflex serves to help a newborn find food: when a mother holds the child and allows her breast to brush the newborn's cheek, the reflex makes the baby turn toward the breast. The reflex disappears at about the sixth week of life. At about this time, newborn eyes focus steadily, so a food source can be seen, and the reflex is no longer needed.

Sucking Reflex. When a newborn's lips are touched, the baby makes a sucking motion. The reflex helps a newborn find food: when the newborn's lips touch the mother's breast or a bottle, the baby sucks and so takes in food. The sucking reflex begins to diminish at about 6 months of age. It disappears immediately if it is never stimulated such as in a newborn with a tracheoesophageal fistula who cannot take in oral fluids. It can be maintained in such an infant by offering the child a non-nutritive sucking object such as a pacifier (after the fistula has been corrected by surgery and until oral feedings can be given).

Swallowing Reflex. The swallowing reflex in a newborn is the same as in the adult. Food that reaches the posterior portion of the tongue is automatically swallowed. Gag, cough, and sneeze reflexes also are present in newborns to maintain a clear airway in the event that normal swallowing does not keep the pharynx free of obstructing mucus.

Extrusion Reflex. A newborn extrudes any substance that is placed on the anterior portion of the tongue. This protective reflex prevents the swallowing of inedible substances. It disappears at about 4 months of age. Until then, the infant may seem to be spitting out or refusing solid food placed in the mouth.

Palmar Grasp Reflex. Newborns grasp an object placed in their palm by closing their fingers on it (Fig. 18.4). Mature

FIGURE 18.4 Palmar grasp reflex.

FIGURE 18.5 Step-in-place reflex.

FIGURE 18.6 Tonic neck reflex.

newborns grasp so strongly that they can be raised from a supine position and suspended momentarily from an examiner's fingers. This reflex disappears at about 6 weeks to 3 months of age. A baby begins to grasp meaningfully at about 3 months of age.

Step (Walk)-in-Place Reflex. Newborns who are held in a vertical position with their feet touching a hard surface will take a few quick, alternating steps (Fig. 18.5). This reflex disappears by 3 months of age. By 4 months, babies can bear a good portion of their weight unhindered by this reflex.

Placing Reflex. The placing reflex is similar to the step-in-place reflex, except that it is elicited by touching the anterior surface of the lower part of a newborn's leg against a hard surface such as the edge of a bassinet or table. The newborn makes a few quick lifting motions, as if to step onto the table, because of the reflex.

Plantar Grasp Reflex. When an object touches the sole of a newborn's foot at the base of the toes, the toes grasp in the same manner as do the fingers. This reflex disappears at about 8 to 9 months of age in preparation for walking. However, it may be present during sleep for a longer period.

Tonic Neck Reflex. When newborns lie on their backs, their heads usually turn to one side or the other. The arm and the leg on the side toward which the head turns extend, and the opposite arm and leg contract (Fig. 18.6). The movement is most evident in the arms but may also be observed in the legs. If you turn a newborn's head to the opposite side, he or she will often change the extension and contraction of legs and arms accordingly. This is also called a boxer or fencing reflex, because the position simulates that of someone preparing to box or fence. Unlike many other reflexes, the tonic neck reflex does not appear to have a function. It does stimulate eye coordination, because the extended arm moves in front of the face. It may signify handedness. The reflex disappears between the second and third months of life.

Moro Reflex. A Moro (startle) reflex (Fig. 18.7) can be initiated by startling a newborn with a loud noise or by jarring the bassinet. The most accurate method of eliciting the reflex is to hold newborns in a supine position and allow their heads to drop backward about 1 inch. In response to this sudden head movement, they abduct and extend their arms and legs. Their fingers assume a typical "C" position. Finally,

FIGURE 18.7 Moro reflex.

FIGURE 18.8 Babinski reflex. When the examiner moves her finger upward, the newborn's toes will fan outward.

they swing their arms into an embrace position and pull up their legs against their abdomen (adduction). The reflex simulates the action of someone trying to ward off an attacker, then covering up to protect himself. It is strong for the first 8 weeks of life and then fades by the end of the fourth or fifth month, at the same time an infant can roll away from danger.

Babinski Reflex. When the sole of the foot is stroked in an inverted "J" curve from the heel upward, a newborn fans the toes (positive Babinski sign) (Fig. 18.8). This is in contrast to the adult, who flexes the toes. This reaction occurs because nervous system development is immature. It remains positive (toes fan) until at least 3 months of age, when it is supplanted by the down-turning or adult flexion response.

Magnet Reflex. If pressure is applied to the soles of the feet of a newborn lying in a supine position, he or she pushes back against the pressure. This and the two following reflexes are tests of spinal cord integrity.

Crossed Extension Reflex. If one leg of a newborn lying supine is extended and the sole of that foot is irritated by being rubbed with a sharp object, such as a thumbnail, the infant raises the other leg and extends it, as if trying to push away the hand irritating the first leg.

Trunk Incurvation Reflex. When newborns lie in a prone position and are touched along the paravertebral area by a probing finger, they flex their trunk and swing their pelvis toward the touch (Fig. 18.9).

Landau Reflex. A newborn who is held in a prone position with a hand underneath, supporting the trunk, should demonstrate some muscle tone. Babies may not be able to

FIGURE 18.9 Trunk incurvation reflex. When the paravertebral area is stroked, the newborn flexes his or her trunk toward the direction of the stimulation.

lift their head or arch their back in this position (as they will at 3 months of age), but neither should they sag into an inverted "U" position. The latter response indicates extremely poor muscle tone, the cause of which should be investigated.

Deep Tendon Reflexes. A patellar reflex can be elicited in a newborn by tapping the patellar tendon with the tip of the finger. The lower leg moves perceptibly if the infant has an intact reflex. To elicit a biceps reflex, place the thumb of your left hand on the tendon of the biceps muscle on the inner surface of the elbow. Tap the thumb as it rests on the tendon. You are more likely to feel the tendon contract than to observe movement. A biceps reflex is a test for spinal nerves C5 and C6; a patellar reflex is a test for spinal nerves L2–L4.

✔ Checkpoint Question 18.2

A Moro reflex is the single best assessment of neurologic ability in a newborn. What is the best way to test this reflex?

a. Observe the infant while she is on her abdomen to see whether she can turn her head.
b. Lift the infant's head while she is supine and allow it to fall back 1 inch.
c. Shake the infant's crib until the infant responds by flailing her arms.
d. Make a sharp noise, such as clapping your hands, to wake the infant.

The Senses

The senses in newborns are already developed at birth.

Hearing. A fetus is able to hear in utero even before birth. As soon as amniotic fluid drains or is absorbed from the middle ear by way of the eustachian tube—within hours after birth—hearing becomes acute. Newborns appear to have difficulty locating sound, however, and so do not turn toward it consistently. Perhaps they must learn to interpret small differences among sounds arriving at their ears at different times. They respond with generalized activity to a sound such as a bell ringing a short distance from their ear. A newborn who is actively

crying when a bell is rung stops crying and seems to attend. Similarly, newborns calm in response to a soothing voice and startle at loud noises. They recognize their mother's voice almost immediately, as if they have heard it in utero.

Vision. Newborns see as soon as they are born and possibly have been "seeing" light and dark in utero for the last few months of pregnancy, as the uterus and the abdominal wall were stretched thin. Newborns demonstrate sight at birth by blinking at a strong light (blink reflex) or by following a bright light or toy a short distance with their eyes. Because they cannot follow past the midline of vision, they lose track of objects easily. This is why parents sometimes think and report that their newborn does not see. Newborns focus best on black and white objects at a distance of 9 to 12 in. A pupillary reflex or ability to contract the pupil is present from birth.

Touch. The sense of touch is also well developed at birth. Newborns demonstrate this by quieting at a soothing touch and by sucking and rooting reflexes, which are elicited by touch. They also react to painful stimuli.

Taste. A newborn has the ability to discriminate taste, because taste buds are developed and functioning even before birth. A fetus in utero, for example, will swallow amniotic fluid more rapidly than usual if glucose is added to sweeten its taste. The swallowing decreases if a bitter flavor is added. A newborn turns away from a bitter taste such as salt but readily accepts the sweet taste of milk or glucose water.

Smell. The sense of smell is present in newborns as soon as the nose is clear of lung and amniotic fluid. Newborns turn toward their mothers' breast partly out of recognition of the smell of breast milk and partly as a manifestation of the rooting reflex. Their ability to respond to odors can be used to document alertness.

Physiologic Adjustment to Extrauterine Life

All newborns seem to move through periods of irregular adjustment in the first 6 hours of life, before their body systems stabilize. These periods were first described by Desmond in 1963 and are termed periods of reactivity (Desmond, 1963). The first phase lasts about half an hour. During this time, the baby is alert and exhibits exploring, searching activity, often making sucking sounds. Heart beat and respiratory rate are rapid. This is called the *first period of reactivity.*

Next comes a quiet *resting period.* Heartbeat and respiratory rates slow, and the newborn typically sleeps for about 90 minutes. The *second period of reactivity,* between 2 and 6 hours of life, occurs when the baby wakes again, often gagging and choking on mucus that has accumulated in the mouth. He or she is again alert and responsive and interested in surroundings.

These three periods are summarized in Table 18.1. Newborns who are ill or who had difficulty at birth may not pass through these typical stages; they may never have periods of alertness or periods of quiet. Their vital signs may not fall and rise again but remain rapid; their temperature may remain subnormal. Demonstration of this typical reactivity pattern, therefore, is an indication that a newborn is healthy and adjusting well to extrauterine life. The ability to transition from one period to another is an important indicator of neurologic status.

TABLE 18.1 ✻ Periods of Reactivity: Normal Adjustment to Extrauterine Life

Assessment	First Period (First 15–30 min)	Resting Period (30–120 min)	Second Period (2–6 hr)
Color	Acrocyanosis	Color stabilizing	Quick color changes occur with movement or crying
Temperature	Temperature begins to fall from intrauterine temperature of about 100.6° F (38.1° C)	Temperature stabilizes at about 99° F (37.2° C)	Temperature increases to 99.8° F (37.6° C)
Heart rate	Rapid, as much as 180 bpm while crying	Slowing to 120–140 bpm	Wide swings in rate with activity
Respirations	Irregular; 30–90 breaths per min while crying; some nasal flaring, occasional retraction may be present	Slowing to 30–50 breaths per min; barreling of chest occurs	Becoming irregular again with activity
Activity	Alert; watching	Sleeping	Awakening
Ability to respond to stimulation	Vigorous reaction	Difficult to arouse	Becoming responsive again
Mucus	Visible in mouth	Small amount present while sleeping	Mouth full of mucus, causing gagging
Bowel sounds	Can be heard after first 15 min	Present	Often passage of first meconium stool

APPEARANCE OF A NEWBORN

Although all newborns have similar physical findings, there are individual differences.

Skin

General inspection of a newborn's skin reveals many characteristic findings.

Color

Most term newborns have a ruddy complexion because of the increased concentration of red blood cells in blood vessels and a decrease in the amount of subcutaneous fat, which makes the blood vessels more visible. This ruddiness fades slightly over the first month. Infants with poor central nervous system control may appear pale and cyanotic. A gray color in newborns generally indicates infection. Twins may be born with a twin transfusion phenomenon, in which one twin is larger and has good color and the smaller twin has pallor (Roberts, Neilson, & Weindling, 2009).

Cyanosis. Generalized mottling of the skin is common. A newborn's lips, hands, and feet are likely to appear blue from immature peripheral circulation. Acrocyanosis (blueness of hands and feet) is so prominent in some newborns that it appears as if some stricture were cutting off circulation, with usual skin color on one side and blue on the other. Acrocyanosis is a normal phenomenon in the first 24 to 48 hours after birth; however, **central cyanosis,** or cyanosis of the trunk, is always a cause for concern. Central cyanosis indicates decreased oxygenation. It may be the result of a temporary respiratory obstruction or an underlying disease state.

Mucus obstructing a newborn's respiratory tract causes sudden cyanosis and apnea. Suctioning of the mucus relieves this. Always suction the mouth of a newborn before the nose, because suctioning the nose first may trigger a reflex gasp, possibly leading to aspiration if there is mucus in the posterior throat. Follow mouth suctioning with suction to the nose, because the nose is the chief conduit for air in a newborn.

What if... Ms. Ruiz inspects her new baby and says to you, "Her hands are cold and blue. Is something wrong with her hands?" How should you answer?

Hyperbilirubinemia. Hyperbilirubinemia leads to **jaundice,** or yellowing of the skin (Beachy, 2007). This occurs on the second or third day of life in about 50% of all newborns, as a result of a breakdown of fetal red blood cells **(physiologic jaundice).** The infant's skin and the sclera of the eyes appear noticeably yellow. This happens because the high red blood cell count built up in utero is destroyed, and heme and globin are released. Globin is a protein component that is reused by the body and is not a factor in the developing jaundice. Heme is further broken down into iron (which is also reused and not involved in the jaundice) and protoporphyrin. Protoporphyrin is further broken down into indirect bilirubin. Indirect bilirubin is fat soluble and cannot be excreted by the kidneys in this state. For removal from the body, it is converted by the liver enzyme glucuronyl transferase into direct bilirubin, which is water soluble. This is incorporated into stool and then excreted in feces. Many newborns have such immature liver function that indirect bilirubin cannot be converted to the direct form; it therefore remains indirect. As long as the buildup of indirect bilirubin remains in the circulatory system, the red coloring of the blood cells covers the yellow tint of the bilirubin. After the level of this indirect bilirubin has risen to more than 7 mg/100 mL, however, bilirubin permeates the tissue outside the circulatory system and causes the infant to appear jaundiced.

Observe infants who are prone to extensive bruising (large, breech, or immature babies) carefully for jaundice, because bruising leads to hemorrhage of blood into the subcutaneous tissue or skin. A **cephalhematoma** is a collection of blood under the periosteum of the skull bone. As the bruising in these locations heals and the red blood cells are hemolyzed, additional indirect bilirubin is released and can be another cause of jaundice (Nicholson, 2007).

If intestinal obstruction is present and stool cannot be evacuated, intestinal flora may break down bile into its basic components, leading to the release of indirect bilirubin into the bloodstream again. Early feeding of newborns promotes intestinal movement and excretion of meconium and helps prevent indirect bilirubin buildup from this source.

The level of jaundice in newborns may be judged grossly by estimating the extent to which it has progressed on the surface of the infant's body, as it is noticed first in the head and then spreads to the rest of the body.

Various commercial devices (transcutaneous bilirubinometry devices) are available to measure skin tone for jaundice and help in estimating jaundice levels. Although use of these devices rarely replaces serum measurements, they can be used to identify infants who need serum bilirubin determinations. The technique for obtaining a serum bilirubin specimen by heel puncture is shown in Chapter 37.

Treatment for physiologic jaundice or the routine rise in bilirubin in newborns is rarely necessary, except for measures such as early feeding to speed passage of feces through the intestine and prevent reabsorption of bilirubin from the bowel.

Above-normal indirect bilirubin levels are potentially dangerous because, if enough indirect bilirubin (about 20 mg/100 mL) leaves the bloodstream, it can interfere with the chemical synthesis of brain cells, resulting in permanent cell damage, a condition termed **kernicterus.** If this occurs, permanent neurologic damage, including cognitive challenge, may result.

There is no set level at which indirect serum bilirubin requires treatment, because other factors, such as age, maturity, and breastfeeding status, affect this determination. If the level rises to more than 10 to 12 mg/100 mL, treatment is usually considered. Phototherapy (exposure of the infant to light to initiate maturation of liver enzymes) is a common therapy (see Chapter 26). If this is necessary, the incubator and light source can be moved to the mother's room so that the mother is not separated from her baby. Some infants need continued therapy after discharge and receive phototherapy at home (Mills & Tudehope, 2009).

Compared with formula-fed babies, a small proportion of breastfed babies may have more difficulty converting indirect bilirubin to direct bilirubin, because breast milk contains pregnanediol (a metabolite of progesterone), which depresses the action of glucuronyl transferase. However, breastfeeding alone rarely causes enough jaundice to warrant therapy (Thilo

& Rosenberg, 2008). The decision to stop nursing in the first 2 weeks of life must never be made lightly, because it could interfere with breast filling and a breast milk supply.

Pallor. Pallor in newborns is usually the result of anemia. This may be caused by (a) excessive blood loss when the cord was cut, (b) inadequate flow of blood from the cord into the infant at birth, (c) fetal–maternal transfusion, (d) low iron stores caused by poor maternal nutrition during pregnancy, or (e) blood incompatibility in which a large number of red blood cells were hemolyzed in utero. It also may be the result of internal bleeding. A baby who appears pale should be watched closely for signs of blood in stool or vomitus.

Harlequin Sign. Occasionally, because of immature circulation, a newborn who has been lying on his or her side appears red on the dependent side of the body and pale on the upper side, as if a line had been drawn down the center of the body. This is a transient phenomenon; although startling, it is of no clinical significance. The odd coloring fades immediately if the infant's position is changed or the baby kicks or cries vigorously.

Birthmarks

Several common types of birthmarks occur in newborns. Most will fade by school age, although an association between children with birthmarks and the development of childhood cancer exists (Johnson et al., 2007). It is important to be able to differentiate the various types of hemangiomas that occur, so that you neither give false reassurance to parents nor worry them unnecessarily about these lesions.

Hemangiomas. The **hemangiomas** are vascular tumors of the skin. Three types occur.

Nevus Flammeus. **Nevus flammeus** (Fig. 18.10A) is a macular purple or dark-red lesion (sometimes called a *port-wine stain* because of its deep color) that is present at birth. These lesions typically appear on the face, although they are often found on the thighs as well. Those above the bridge of

FIGURE 18.10 Types of hemangiomas found on a newborn. (**A**) Nevus flammeus (port-wine stain) formed of a plexus of newly formed capillaries in the papillary layer of the corium. It is deep red to purple, does not blanch on pressure, and does not fade with age. (**B**) A telangectasia or stork's beak mark, commonly occurring on the nape of the neck. It blanches on pressure; although it does not fade, it is not noticeable as it becomes covered by hair. (**C**) Strawberry hemangiomas consist of dilated capillaries in entire dermal and subdermal layers. They continue to enlarge after birth but usually disappear by age 10 years. (**D**) Cavernous hemangiomas consist of a communicating network of venules in subcutaneous tissue and do not fade with age.

the nose tend to fade; the others are less likely to fade. Because they are level with the skin surface (macular), they can be covered by a cosmetic preparation later in life or removed by laser therapy, although lesions may reappear after treatment (Berger, 2009).

Nevus flammeus lesions also occur as lighter, pink patches at the nape of the neck, known as *stork's beak marks* or telangiectasia (see Fig. 18.10B). These do not fade, but they are covered by the hairline and therefore are of no consequence. They occur more often in females than in males.

Strawberry Hemangioma. **Strawberry hemangioma** refers to elevated areas formed by immature capillaries and endothelial cells (see Fig. 18.10C). Most are present at birth in the term neonate, although they may appear up to 2 weeks after birth. Typically, they are not present in the preterm infant because of the immaturity of the epidermis. Formation is associated with the high estrogen levels of pregnancy. They may continue to enlarge from their original size up to 1 year of age. After the first year, they tend to be absorbed and shrink in size. By the time the child is 7 years old, 50% to 75% of these lesions have disappeared. A child may be 10 years old before the absorption is complete. Application of hydrocortisone ointment may speed the disappearance of these lesions by interfering with the binding of estrogen to its receptor sites.

Be certain parents understand that the mark may grow in their child's early years. Otherwise, they can confuse it with cancer (a skin lesion increasing in size is one of the seven danger signals of cancer). Be sure they also understand that the mark will eventually disappear, so that they do not think of their child as imperfect or disfigured or continue to ask if the baby should have surgery. Surgery to remove strawberry hemangiomas is rarely recommended because it can lead to secondary infection, resulting in scarring and permanent disfigurement. Large lesions that are disfiguring can be removed by laser therapy (Edmonds, 2008).

Cavernous Hemangioma. **Cavernous hemangiomas** (see Fig. 18.10D) are dilated vascular spaces. They are usually raised and resemble a strawberry hemangioma in appearance. However, they do not d isappear with time as do strawberry hemangiomas. Such lesions can be removed surgically. Steroids, interferon-alfa-2a, or vincristine can be used to reduce these lesions in size, although their use must be weighed in light of side effects (Edmonds, 2008). Children who have a skin lesion may have additional ones on internal organs. Blows to the abdomen, such as those from childhood games, can cause bleeding from an internal hemangioma. For this reason, children with cavernous hemangiomas usually have their hematocrit levels assessed at health maintenance visits, to evaluate for possible internal blood loss.

Mongolian Spots. **Mongolian spots** are collections of pigment cells (melanocytes) that appear as slate-gray patches across the sacrum or buttocks and possibly on the arms and legs. They tend to occur in children of Asian, southern European, or African ethnicity (Thilo & Rosenberg, 2008). They disappear by school age without treatment. Be sure to inform parents that these are not bruises; otherwise, they may worry their baby sustained a birth injury.

Vernix Caseosa

Vernix caseosa is a white, cream cheese–like substance that serves as a skin lubricant in utero. Usually, it is noticeable on a term newborn's skin, at least in the skin folds, at birth. Document the color of vernix, because it takes on the color of the amniotic fluid. For example, a yellow vernix implies that the amniotic fluid was yellow from bilirubin; green vernix indicates that meconium was present in the amniotic fluid.

Until the first bath, when vernix is washed away, handle newborns with gloves to protect yourself from exposure to this body fluid. Never use harsh rubbing to wash away vernix. A newborn's skin is tender, and breaks in the skin caused by too vigorous attempts at removal may open portals of entry for bacteria.

Lanugo

Lanugo is the fine, downy hair that covers a newborn's shoulders, back, and upper arms. It may be found also on the forehead and ears. A baby born between 37 to 39 weeks of gestation has more lanugo than a newborn of 40 weeks' gestational age. Postmature infants (more than 42 weeks of gestation) rarely have lanugo. Lanugo is rubbed away by the friction of bedding and clothes against the newborn's skin. By 2 weeks of age, it has disappeared.

Desquamation

Within 24 hours after birth, the skin of most newborns has become extremely dry. The dryness is particularly evident on the palms of the hands and soles of the feet. This results in areas of peeling similar to those caused by sunburn. This is normal, however, and needs no treatment. Parents may apply hand lotion to prevent excessive dryness if they wish.

Newborns who are postmature and have suffered intrauterine malnutrition may have extremely dry skin, with a leathery appearance and cracks in the skin folds. This should be differentiated from normal desquamation.

Milia

All newborn sebaceous glands are immature. At least one pinpoint white papule (a plugged or unopened sebaceous gland) can be found on the cheek or across the bridge of the nose of almost every newborn. Such lesions, termed **milia** (Fig. 18.11), disappear by 2 to 4 weeks of age, as the sebaceous glands mature and drain. Teach parents to avoid scratching or squeezing the papules, to prevent secondary infections.

Erythema Toxicum

In most normal mature infants, a newborn rash called **erythema toxicum** can be observed (Fig. 18.12). This usually appears in the first to fourth day of life but may appear up to 2 weeks of age. It begins with a papule, increases in severity to become erythema by the second day, and then disappears by the third day. It is sometimes called a *flea-bite rash* because the lesions are so minuscule. One of the chief characteristics of the rash is its lack of pattern. It occurs sporadically and unpredictably and may last hours rather than days. It is caused by a newborn's eosinophils reacting to the environment as the immune system matures. It requires no treatment.

Forceps Marks

Forceps are rarely used for birth today but if they are used, they may leave a circular or linear contusion matching the rim of

FIGURE 18.11 Milia are unopened sebaceous glands frequently found on the nose, chin, or cheeks of a newborn.

FIGURE 18.12 Erythema toxicum is found on almost all newborns. The reddish rash consists of sporadic pinpoint papules on an erythematous base. It fades spontaneously in a few days.

FIGURE 18.13 Forceps marks are commonly found in newborns born by forceps. Such marks are transient and disappear in a day or two.

the blade of the forceps on the infant's cheek (Fig. 18.13). This mark disappears in 1 to 2 days, along with the edema that accompanies it. The mark is the result of normal forceps use and does not denote unskilled or too vigorous application of forceps. Closely assess the facial nerve while a newborn is at rest and during crying episodes, to detect any potential facial nerve compression requiring further evaluation.

Skin Turgor

Newborn skin should feel resilient if the underlying tissue is well hydrated. If a fold of the skin is grasped between the thumb and fingers, it should feel elastic. When it is released, it should fall back to form a smooth surface. If severe dehydration is present, the skin will not smooth out again but will remain in an elevated ridge. Poor turgor is seen in newborns who suffered malnutrition in utero, who have difficulty sucking at birth, or who have certain metabolic disorders such as adrenocortical insufficiency.

✔ Checkpoint Question 18.3

Beth Ruiz has milia on her nose. What is the necessary therapy for this?

a. Ice packs to reduce inflammation.
b. Warm heat to increase circulation.
c. No therapy is necessary for milia.
d. Lancing the lesions so they drain.

Head

A newborn's head appears disproportionately large because it is about one fourth of the total body length; in an adult, a head is one eighth of total height. The forehead of a newborn is large and prominent. The chin appears to be receding, and it quivers easily if an infant is startled or cries. Well-nourished newborns have full-bodied hair; poorly nourished and preterm infants have thin, lifeless hair. If internal fetal monitoring was used during labor, a newborn may exhibit a pinpoint ulcer at the point where the monitor was attached.

Fontanelles

The fontanelles are the spaces or openings where the skull bones join. The anterior fontanelle is located at the junction

of the two parietal bones and the two fused frontal bones. It is diamond shaped and measures 2 to 3 cm (0.8 to 1.2 in) in width and 3 to 4 cm (1.2 to 1.6 in) in length. The posterior fontanelle is located at the junction of the parietal bones and the occipital bone. It is triangular and measures about 1 cm (0.4 in) in length.

The anterior fontanelle can be felt as a soft spot. It should not appear indented (a sign of dehydration) or bulging (a sign of increased intracranial pressure) when the infant is held upright. The fontanelle may bulge if the newborn strains to pass a stool or cries vigorously or is lying supine. With vigorous crying, a pulse may additionally be seen in the fontanelle. The anterior fontanelle normally closes at 12 to 18 months of age.

In some newborns, the posterior fontanelle is so small that it cannot be palpated readily. The posterior fontanelle closes by the end of the second month.

Sutures

The skull *sutures,* the separating lines of the skull, may override at birth because of the extreme pressure exerted on the head during passage through the birth canal. If the sagittal suture between the parietal bones overrides, the fontanelles are less perceptible than usual. The overriding subsides in 24 to 48 hours.

Suture lines should never appear widely separated in newborns. Wide separation suggests increased intracranial pressure

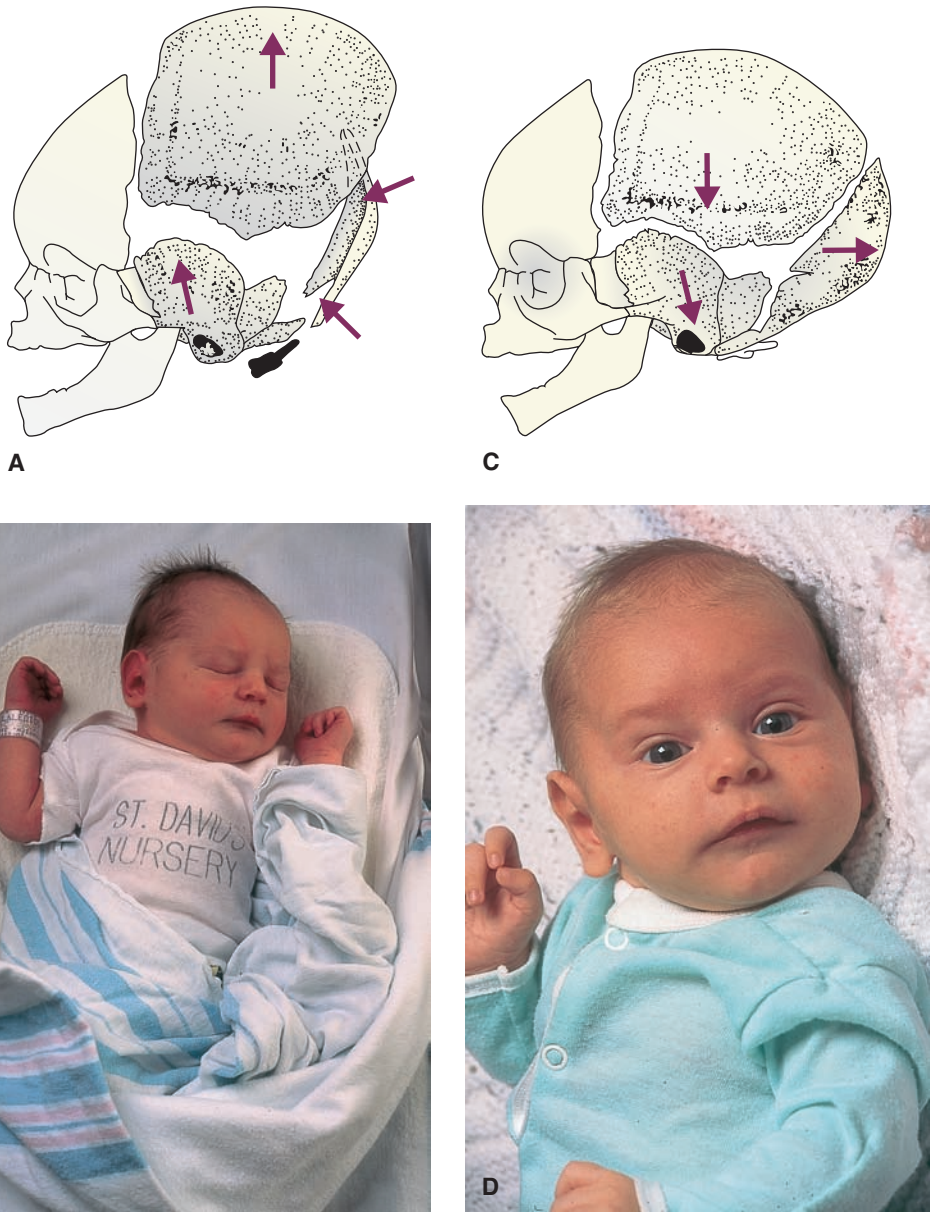

FIGURE 18.14 Molding. (**A, B**) The infant head molds to fit the birth canal more easily. On palpation, the skull sutures will be felt to be overriding. (**C, D**) The head shape returns to normal within 1 week.

because of abnormal brain formation, abnormal accumulation of cerebrospinal fluid in the cranium (hydrocephalus), or an accumulation of blood from a birth injury such as subdural hemorrhage. Fused suture lines also are abnormal; they require radiographic confirmation and further evaluation, because they will prevent the head from expanding with brain growth.

Molding

The part of the infant's head that engaged the cervix (usually the vertex) molds to fit the cervix contours during labor. After birth, this area appears prominent and asymmetric. Molding may be so extreme in the baby of a primiparous woman that the baby's head appears as a dunce cap (Fig. 18.14). The head will restore to its normal shape within a few days after birth.

Caput Succedaneum

Caput succedaneum (Fig. 18.15A) is edema of the scalp at the presenting part of the head. It may involve wide areas of the head, or it may resemble a large egg. The edema, which crosses the suture lines, is gradually absorbed and disappears at about the third day of life. It needs no treatment (Nicholson, 2007).

Cephalhematoma

A *cephalhematoma,* a collection of blood between the periosteum of a skull bone and the bone itself, is caused by rupture of a periosteal capillary because of the pressure of birth (see Fig. 18.15B). Swelling usually appears 24 hours after birth. Although the blood loss is negligible, the swelling is usually severe and is well outlined as an egg shape. It may be discolored (black and blue) because of the presence of coagulated blood. A cephalhematoma is confined to an individual bone, so the associated swelling stops at the bone's suture line.

It often takes weeks for a cephalhematoma to be absorbed. It might be supposed that the blood could be aspirated to relieve the condition. However, such a procedure would introduce the risk of infection and is unnecessary, because the condition will subside by itself. As the blood captured in the space is broken down, a great amount of indirect bilirubin may be released, leading to jaundice.

Craniotabes

Craniotabes is a localized softening of the cranial bones that is probably caused by pressure of the fetal skull against the mother's pelvic bone in utero. It is more common in firstborn infants than in infants born later, because of the lower position of the fetal head in the pelvis during the last 2 weeks of pregnancy in primiparous women. With craniotabes, the skull is so soft that the pressure of an examining finger can indent it. The bone returns to its normal contour after the pressure is removed. The condition corrects itself without treatment after a few months, as the infant takes in calcium in milk. It is an example of a condition that is normal in a newborn but would be pathologic in an older child or adult (in whom it probably would be the result of faulty metabolism or kidney dysfunction).

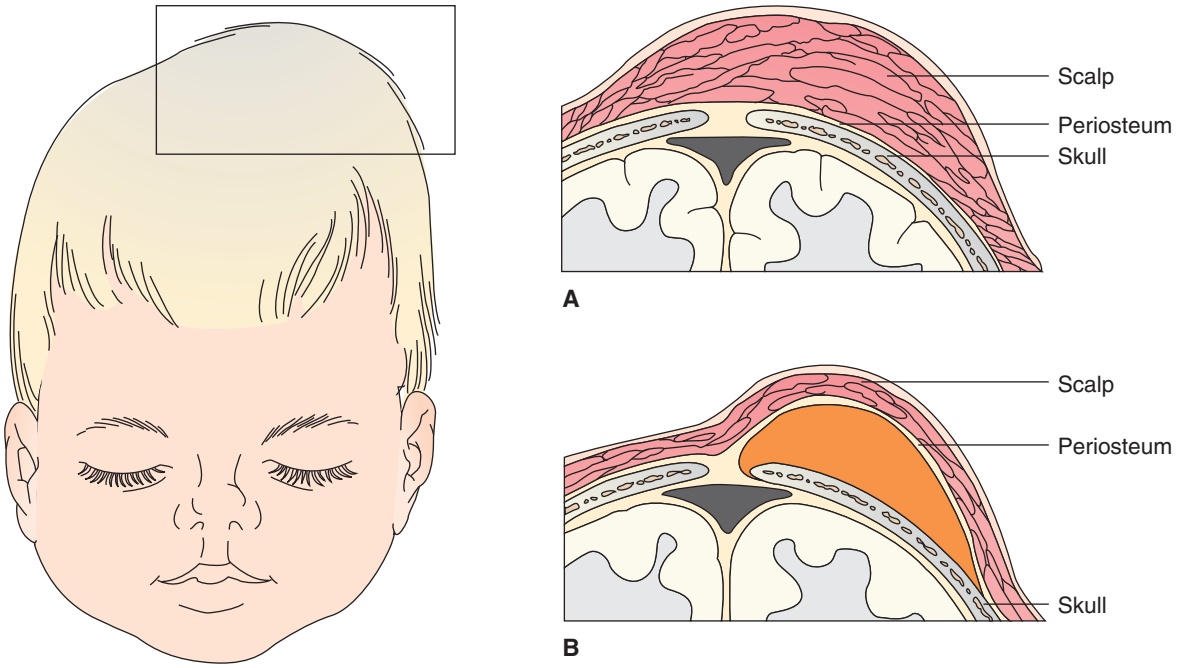

FIGURE 18.15 (**A**) Caput succedaneum. From pressure of the birth canal, an edematous area is present beneath the scalp. Note how it crosses the midline of the skull. (**B**) Cephalhematoma. A small capillary beneath the periosteum of the skull bone has ruptured, and blood has collected under the periosteum of the bone. Note how the swelling now stops at the midline. Because the blood is contained under the periosteum, it is necessarily stopped by a suture line.

Eyes

Newborns usually cry tearlessly, because their lacrimal ducts do not fully mature until about 3 months of age. Almost without exception, the irises of the eyes of newborns are gray or blue; the sclera may be blue because of its thinness. Infant eyes assume their permanent color between 3 and 12 months of age.

To inspect the eyes, lay the newborn in a supine position and lift the head. This maneuver causes the baby to open the eyes. A newborn's eyes should appear clear, without redness or purulent discharge. Occasionally, the administration of an antibiotic ointment such as erythromycin given at birth, to protect against *Chlamydia* infection and ophthalmia neonatorum (gonorrheal conjunctivitis), has caused a purulent discharge that lasts for the first 24 hours of life.

Pressure during birth sometimes ruptures a conjunctival capillary of the eye, resulting in a small **subconjunctival hemorrhage.** This appears as a red spot on the sclera, usually on the inner aspect of the eye, or as a red ring around the cornea. The bleeding is slight, requires no treatment, and is completely absorbed within 2 or 3 weeks. You can assure parents that these hemorrhages are normal variations. Otherwise, they may assume that their baby is bleeding from within the eye and that vision will be impaired.

Edema is often present around the orbit or on the eyelids. This remains for the first 2 or 3 days, until the newborn's kidneys are capable of evacuating fluid more efficiently.

The cornea of the eye should appear round and proportionate in size to that of an adult eye. A cornea that appears larger than usual may be the result of congenital glaucoma. An irregularly shaped pupil or discolored iris may denote disease such as a coloboma (see Chapter 50). The pupil should be dark. A white pupil suggests the presence of a congenital cataract.

Ears

A newborn's external ear is not as completely formed as it will be eventually, so the pinna tends to bend easily. In the term newborn, however, the pinna should be strong enough to recoil after bending.

The level of the top part of the external ear should be on a line drawn from the inner canthus to the outer canthus of the eye and back across the side of the head (see Chapter 34). Ears that are set lower than this are found in infants with certain chromosomal abnormalities, particularly trisomy 18 and 13, syndromes in which low-set ears and other physical defects are coupled with varying degrees of cognitive challenge (see Chapters 7 and 54).

A small tag of skin is sometimes found just in front of an ear. Although these tags may be associated with chromosomal abnormalities or kidney disease, they usually are isolated findings that are of no consequence. They can be removed by ligation immediately or when the child is 1 week old. A preauricular dermal sinus may be present directly in front of the ear as well. Always inspect in front of newborns' ears for pinpoint-size openings that reveal these sinuses. The sinus is usually small and can be removed surgically without consequence when the child is near school age.

Visualization of the tympanic membrane of the ear in a newborn is difficult and usually is not attempted, because amniotic fluid and flecks of vernix still fill the canal, obliterating the drum and its accompanying landmarks.

A good practice is to test a newborn's hearing by ringing a bell held about 6 inches from each ear. A hearing infant who is crying will stop momentarily at the sound. If quiet, a newborn who can hear will blink the eyes, appear to attend to the sound, and possibly startle. Although this method of testing is not highly accurate, a negative response (lack of response) is unusual. Infants with negative responses should be retested later. In many health care facilities, all newborns are tested by a commercial standardized response to sound before discharge (AAP, 2007; MacNeil et al., 2007).

Nose

A newborn's nose tends to appear large for the face. As the infant grows, the rest of the face grows more than the nose does, and this discrepancy disappears.

Test for choanal atresia (blockage at the rear of the nose) by closing the newborn's mouth and compressing one naris at a time with your fingers. Note any discomfort or distress while breathing this way. Nasal flaring upon inspiration is another indication of respiratory distress and should be further evaluated. Also record any evidence of milia on the nose.

Mouth

A newborn's mouth should open evenly when he or she cries. If one side of the mouth moves more than the other, cranial nerve injury is suggested. A newborn's tongue appears large and prominent in the mouth. Because the tongue is short, the frenulum membrane is attached close to the tip of the tongue, creating the impression that the infant is "tongue tied." At one time, it was almost routine to snip a newborn's frenulum membrane to lengthen it. Now this procedure is regarded as harmful, because it leaves a portal of entry for infection, risks hemorrhage because of the low level of vitamin K in most newborns, and causes feeding difficulties by making the tongue sore and irritated. This procedure is also unnecessary because, as the tongue grows, the frenulum recedes to its adult placement.

Inspect the palate of a newborn to be sure it is intact. Occasionally, one or two small, round, glistening, well-circumscribed cysts (Epstein's pearls) are present on the palate, a result of extra calcium that was deposited in utero. Be sure to inform parents that these pearl-like cysts are insignificant, require no treatment, and will disappear spontaneously within 1 week. Otherwise, a parent may mistake them for **thrush,** a *Candida* infection, which usually appears on the tongue and sides of the cheeks as white or gray patches and needs therapy with an antifungal drug (Subramanian et al., 2008).

All newborns have some mucus in their mouths. Newborns delivered by cesarean birth usually have an increased amount. If a newborn is placed on the side, the mucus drains from the mouth and results in no distress. If the mouth is filled with so much mucus that a neonate seems to be blowing bubbles, a tracheoesophageal fistula is suspected. This must be confirmed or ruled out before the newborn is fed; otherwise, formula can be aspirated into the lungs from the inadequately formed esophagus.

Small, white epithelial pearls (benign inclusion cysts) may be present on the gum margins. No therapy is necessary for these. It is unusual for a newborn to have teeth, but sometimes one or two (called **natal teeth)** will have erupted. Any teeth that are present must be evaluated for stability. If loose,

they should be extracted to prevent possible aspiration during feeding.

Neck

The neck of a newborn is short and often chubby, with creased skin folds. The head should rotate freely on it. If there is rigidity of the neck, congenital torticollis, caused by injury to the sternocleidomastoid muscle during birth, might be present (see Chapter 27). In newborns whose membranes were ruptured more than 24 hours before birth, nuchal rigidity suggests meningitis.

The neck of a newborn is not strong enough to support the total weight of the head but in a sitting position, a newborn should make a momentary effort at head control. When lying prone, newborns can raise the head slightly, usually enough to lift the nose out of mucus or spit-up formula. If they are pulled into a sitting position from a supine position, the head will lag behind considerably. Again, however, they should make some effort to control and steady the head as they reach a sitting position.

The trachea may be prominent on the front of the neck, and the thymus gland may be enlarged because of the rapid growth of glandular tissue (in comparison with other body tissues) early in life. The thymus gland will triple in size by 3 years of age; it remains at that size until the child is about 10 years old, and then shrinks. Although the thymus may appear to be bulging in a newborn, it is rarely a cause of respiratory difficulty, as was once believed.

Chest

The chest in some newborns looks small because the head is large in proportion. It is actually approximately 2 inches smaller in circumference and as wide in the anteroposterior diameter as it is across. Not until a child is 2 years of age does the chest measurement exceed that of the head. The clavicles should be straight. A crepitus or actual separation on one or the other clavicle may indicate that a fracture occurred during birth and calcium is now being deposited at that point. As the area heals, it may be possible to palpate a lump on the clavicle caused by temporary calcium overgrowth. Overall, a newborn's chest should appear symmetric side to side. Respirations are normally rapid (30 to 60 breaths per minute) but not distressed. A supernumerary nipple (usually found below and in line with the normal nipples) may be present. If so, it may be removed later for cosmetic purposes although this is not necessary.

In both female and male infants, the breasts may be engorged. Occasionally, the breasts of newborn babies secrete a thin, watery fluid popularly termed *witch's milk.* Engorgement develops in utero as a result of the influence of the mother's hormones. As soon as the hormones are cleared from the infant's system (about 1 week), the engorgement and any fluid that is present subside. Fluid should never be expressed from infants' breasts, because the manipulation could introduce bacteria and lead to mastitis.

Retraction (drawing in of the chest wall with inspiration) should not be present. An infant with retractions (Fig. 18.16) is using such strong force to pull air into the respiratory tract that he or she is pulling in the anterior chest muscle.

Because a newborn's lung alveoli open slowly over the first 24 to 48 hours and the baby invariably has mucus in the back of the throat, listening to lung sounds often reveals the sounds of rhonchi—the harsh, innocent sound of air passing over mucus. An abnormal sound, such as grunting, suggests respiratory distress syndrome; a high, crowing sound on inspiration suggests stridor or immature tracheal development.

FIGURE 18.16 Sternal retractions are a sign of respiratory distress requiring immediate intervention, such as mechanical ventilation or increased oxygen.

Abdomen

The contour of a newborn abdomen looks slightly protuberant. A scaphoid or sunken appearance may indicate missing abdominal contents or a diaphragmatic hernia (bowel positioned in the chest instead of the abdomen). Bowel sounds should be present within 1 hour after birth. The edge of the liver is usually palpable 1 to 2 cm below the right costal margin. The edge of the spleen may be palpable 1 to 2 cm below the left costal margin. Tenderness is difficult to determine in a newborn. If it is extreme, however, palpation will cause the infant to cry, thrash about, or tense the abdominal muscles to protect the abdomen.

For the first hour after birth, the stump of the umbilical cord appears as a white, gelatinous structure marked with the blue and red streaks of the umbilical vein and arteries. When the cord is first cut, the vessels are counted to be certain that one vein and two arteries are present. In 0.5% of births (3.5% of twin births), there is only a single umbilical artery, and in one-third of such infants, this single artery is associated with a congenital heart or renal abnormality. Because these heart and kidney anomalies may not be readily apparent, any child with a single umbilical artery needs close observation and assessment until anomalies are ruled out.

Inspect the cord clamp to be certain it is secure. After the first hour of life, the cord begins to dry and shrink, and it turns brown like the dead end of a vine. By the second or third day, it has turned black. It breaks free by day 6 to 10, leaving a granulating area a few centimeters wide that heals during the following week.

There should be no bleeding at the cord site. Bleeding suggests that the cord clamp has become loosened or the cord has been tugged loose by the friction of bedclothes. The base of the cord should appear dry. A moist or odorous cord suggests

infection. If present, infection should receive immediate treatment or it may enter a newborn's bloodstream and cause septicemia. Moistness at the base of the cord also may indicate a patent urachus (a canal that connects the bladder and the umbilicus), which will drain urine at the cord site until it is surgically repaired.

Inspect the base of the cord to be certain no abdominal wall defect such as an umbilical hernia is present. If there is a fascial (abdominal wall) defect smaller than 2 cm in diameter, it usually closes on its own by school age; a larger defect will probably require surgical correction. Taping or putting buttons or coins on the cord are home remedies that do not help defects to close. In fact, heavy taping may worsen the condition by preventing the development of good muscle tone in the abdominal wall. Tape also tends to keep the cord moist, making infection more likely than when it is dry.

Because a newborn's voiding only demonstrates there is at least one kidney functioning, but not two, attempt to verify the presence of kidneys by deep palpation of the right and left abdomen within the first few hours after birth. After this time, the intestines fill with air, making palpation more difficult. The right kidney (at least its lower pole) can usually be palpated readily, because it is located lower than the left; the left kidney is more difficult to locate, because the intestine is bulkier on the left side and the kidney is higher in the retroperitoneal space. Nonetheless, try to locate both of them. Placing one hand behind the infant while you palpate offers a firmer base and helps when evaluating kidney size (newborn kidneys are about the size of a walnut). An enlarged kidney suggests a polycystic kidney or pooling of urine from a urethral obstruction.

To finish the abdominal assessment, elicit an abdominal reflex. Stroking each quadrant of the abdomen will cause the umbilicus to move or "wink" in that direction. This superficial abdominal reflex is a test of spinal nerves T8–T10. The reflex may not be demonstrable in newborns until the 10th day of life.

Anogenital Area

Inspect the anus of a newborn to be certain it is present, patent, and not covered by a membrane (imperforate anus). Test for anal patency by gently inserting the tip of your gloved and lubricated little finger. Also note the time after birth at which the infant first passes meconium. If a newborn does not do so in the first 24 hours, suspect imperforate anus or meconium ileus.

Male Genitalia

The scrotum in most male newborns is edematous and has rugae (folds in the skin). It may be deeply pigmented in African American or dark-skinned newborns. Make a practice of pressing your nondominant hand against the inguinal ring before palpating for testes, so they do not slip upward and out of the scrotal sac as you palpate (Fig. 18.17).

Both testes should be present in the scrotum. If one or both testicles are not present (cryptorchidism), referral is needed to establish the extent of the problem. This condition could be caused by agenesis (absence of an organ), ectopic testes (the testes cannot enter the scrotum because the opening to the scrotal sac is closed), or undescended testes (the vas deferens or artery is too short to allow the testes to descend).

FIGURE 18.17 Press the nondominant hand against the inguinal ring when palpating testes.

Newborns with agenesis of the testes are usually referred for investigation of kidney anomalies, because the testes arise from the same germ tissue as the kidneys.

Elicit a cremasteric reflex by stroking the internal side of the thigh. As the skin is stroked, the testis on that side moves perceptibly upward. This is a test for the integrity of spinal nerves T8–T10. The response may be absent in newborns who are younger than 10 days.

The penis of newborns appears small, approximately 2 cm long. If it is less than this, the newborn should be referred for evaluation by an endocrinologist. Inspect the tip of the penis to see that the urethral opening is at the tip of the glans, not on the dorsal surface (epispadias) or on the ventral surface (hypospadias).

In most newborns, the prepuce (foreskin) slides back poorly from the meatal opening, so this should not be done. Although today most male newborns are circumcised, the necessity for this operation can be questioned unless it is for religious reasons, because it is rare to find an infant who physically requires it (i.e., has a foreskin so constricted that it interferes with voiding or circulation). In addition, surgery this early in life poses the risk of hemorrhage and infection. Circumcision should not be done if hypospadias or epispadias is present, because the surgeon may want to use the foreskin as tissue when repairing these conditions (see Chapter 46).

Female Genitalia

The vulva in female newborns may be swollen because of the effect of maternal hormones. Some female newborns have a mucus vaginal secretion, which is sometimes blood-tinged **(pseudomenstruation).** Again, this is caused by the action of maternal hormones. The discharge disappears as soon as the infant's system has cleared the hormones. The discharge should not be mistaken for an infection or taken as an indication that trauma has occurred.

Back

The spine of a newborn typically appears flat in the lumbar and sacral areas. The curves seen in an adult appear only after a child is able to sit and walk. Inspect the base of a newborn's spine carefully to be sure there is no pinpoint opening, dimpling, or sinus tract in the skin, which would

suggest a dermal sinus or spinal bifida occulta. True neural tube defects in newborns are greatly decreased in incidence because of the recognition that lack of folic acid during pregnancy leads to these (De Wals et al., 2007).

A newborn normally assumes the position maintained in utero, with the back rounded and the arms and legs flexed on the abdomen and chest. A child who was born in a frank breech position tends to straighten the legs at the knee and bring their feet up next to the face. The position of a baby with a face presentation sometimes simulates opisthotonos for the first week, because the curve of the back is deeply concave.

Extremities

The arms and legs of a newborn appear short. The hands are plump and clenched into fists. Newborn fingernails are soft and smooth, and usually long enough to extend over the fingertips. Test the upper extremities for muscle tone by unflexing the arms for approximately 5 seconds. If tone is good, an arm should return immediately to its flexed position after being released. Hold the arms down by the sides and note their length. The fingertips should reach the proximal thigh. Unusually short arms may signify achondroplastic dwarfism. Observe for unusual curvature of the little finger, and inspect the palm for a simian crease (a single palmar crease, in contrast to the three creases normally seen in a palm). Although curved fingers and simian creases can occur normally, they are commonly associated with Down syndrome (Elias, Chun-Hui, & Manchester, 2008).

A newborn's arms and legs should move symmetrically (unless the infant is demonstrating a tonic neck reflex). An arm that hangs limp and unmoving suggests possible birth injury, such as injury to a clavicle or to the brachial or cervical plexus or fracture of a long bone. Assess for webbing (syndactyly), extra toes or fingers (polydactyly), or unusual spacing of toes, particularly between the big toes and the others (this finding is present in certain chromosomal disorders, although it is also a normal finding in some families). Test to see whether the toenails fill immediately after blanching from pressure.

Normally, newborn legs are bowed as well as short. The sole of the foot appears flat because of an extra pad of fat in the longitudinal arch. The foot of a term newborn has many crisscrossed lines on the sole, covering approximately two-thirds of the foot. If these creases cover less than two-thirds of the foot or are absent, suspect immaturity.

Move the ankle through a range of motion to evaluate whether the heel cord is unusually tight. Check for ankle clonus by supporting the lower leg in one hand and dorsiflexing the foot sharply two or three times by pressure on the sole of the foot with the other hand. After the dorsiflexion, one or two continued movements are normal. Rapid alternating contraction and relaxation (clonus) is abnormal, suggesting neurologic involvement. The feet of many newborns turn in (varus deviation) because of their former intrauterine position. This simple deviation needs no correction if the feet can be brought into the midline position by easy manipulation. When the infant begins to bear weight, the feet will align themselves. If a foot does not align readily (will not turn to a definite midline position), a talipes deformity (clubfoot) may be present. This condition needs further investigation, because congenital problems of this kind are best treated in the immediate newborn period.

FIGURE 18.18 Hip abduction in a newborn—both hips should abduct so completely they lie almost flat against the mattress (180 degrees).

With a newborn in a supine position, both hips can be flexed and abducted to such an extent (180 degrees) that the knees touch or nearly touch the surface of the bed (Fig. 18.18). If the hip joint seems to lock short of this distance (160 to 170 degrees), hip subluxation (a shallow and poorly formed acetabulum) is suggested (McCarthy & MacEwen, 2007). A further test for subluxation can be elicited by holding the infant's leg with the fingers on the greater and lesser trochanter and then abducting the hip; if subluxation is present, a "clunk" of the femur head striking the shallow acetabulum can be heard (Ortolani's sign). If the hip can be felt to actually slip in the socket, this is Barlow's sign. Subluxated hip may be bilateral but is usually unilateral. It is important that hip subluxation be discovered as early as possible, because correction is most successful if it is initiated early.

When lying on the abdomen, newborns are capable of bringing their arms and legs underneath them and raising their stomach off the bed high enough for a hand to be slipped underneath. This ability helps to prevent pressure or rubbing at the cord site, because the cord does not actually touch the bedding when in this position. The preterm newborn does not have this ability, so it is an indication of maturity.

ASSESSMENT FOR WELL-BEING

There are several traditional standardized assessments to evaluate a newborn quickly at birth.

Apgar Scoring

At 1 minute and 5 minutes after birth, newborns are observed and rated according to an Apgar score, an assessment scale used as a standard since 1958 (Apgar et al., 1958). As shown in Table 18.2, heart rate, respiratory effort, muscle

TABLE 18.2 ✻ Apgar Scoring Chart

	Score		
Sign	***0***	***1***	***2***
Heart rate	Absent	Slow (<100)	>100
Respiratory effort	Absent	Slow, irregular; weak cry	Good; strong cry
Muscle tone	Flaccid	Some flexion of extremities	Well flexed
Reflex irritability:			
Response to catheter in nostril, *or*	No response	Grimace	Cough or sneeze
Slap to sole of foot	No response	Grimace	Cry and withdrawal of foot
Color	Blue, pale	Body normal pigment, extremities blue	Normal skin coloring

Source: Apgar, V., et al. (1958). Evaluation of the newborn infant: Second report. *JAMA: Journal of the American Medical Association, 16*(82), 1985–1988. Copyright 1958, American Medical Association.

tone, reflex irritability, and color of the infant are each rated 0, 1, or 2; the five scores are then added. A newborn whose total score is less than 4 is in serious danger of respiratory or cardiovascular failure and needs resuscitation. A score of 4 to 6 means that the infant's condition is guarded and the baby may need clearing of the airway and supplementary oxygen. A score of 7 to 10 indicates that the infant scored as high as 70% to 90% of all infants at 1 to 5 minutes after birth or is adjusting well to extrauterine life (10 is the highest score possible). The Apgar score is repeated every additional 5 minutes, until a minimum score of 7 is reached.

The Apgar score standardizes infant assessment at birth and serves as a baseline for future evaluations. There is a high correlation between low 5-minute Apgar scores and neurologic illness (Harrington et al., 2007). The following points should be considered in obtaining an Apgar rating.

Heart Rate

Auscultating a newborn heart with a stethoscope is the best way to determine heart rate; however, heart rate also may be obtained by observing and counting the pulsations of the cord at the abdomen if the cord is still uncut. Once the cord has been cut and clamped, a pulse may often be palpated by placing an index finger and thumb at the base of the cord.

Respiratory Effort

Respirations are counted by watching respiratory movements. A mature newborn usually cries and aerates the lungs spontaneously at about 30 seconds after birth. By 1 minute, he or she is maintaining regular, although rapid, respirations. A depressed respiratory effort might be anticipated in a newborn whose mother received large amounts of analgesia or a general anesthetic during labor or birth.

Muscle Tone

Mature newborns hold their extremities tightly flexed, simulating their intrauterine position. Muscle tone is tested by observing their resistance to any effort to extend their extremities. Poor muscle tone is observed when the infant shows no flexion of the arms and legs and extremities "flop" back to the mattress when manipulated or flexed.

Reflex Irritability

One of two possible cues is used to evaluate reflex irritability in a newborn: response to a suction catheter in the nostrils or response to having the soles of the feet slapped. A good response to these actions would be vigorous crying or a strong facial grimace. A baby whose mother was heavily sedated will probably demonstrate a low score in this category.

Color

All infants appear cyanotic at the moment of birth. They grow pink with or shortly after the first breath, which makes the color of newborns correspond to how well they are breathing. Acrocyanosis (cyanosis of the hands and feet) is so common in newborns that a score of 1 in this category can be thought of as normal.

Respiratory Evaluation

Good respiratory function obviously has the highest priority in newborn care, so assessment for it is ongoing at every newborn contact. The Silverman and Andersen index, originally devised in 1956 (Silverman & Andersen, 1956), can be used to estimate degrees of respiratory distress in newborns. For this assessment, a newborn is observed and then scored on each of five criteria (Fig. 18.19). Each item is given a value of 0, 1, or 2; the values are then added. A total score of 0 indicates no respiratory distress. Scores of 4 to 6 indicate moderate distress. Scores of 7 to 10 indicate severe distress. Notice that the scores of this index run opposite to those of the Apgar: an Apgar score of 7 to 10 would indicate a well infant.

✔ Checkpoint Question 18.4

Beth Ruiz had Apgar scores of 6 and 8. The five areas assessed with Apgar scoring are:

a. Heart rate, respiratory effort, muscle tone, reflex irritability, and color.
b. Respiratory rate, abdominal tone, reflex irritability, color, and head circumference.
c. Color, breathing rate, cry, amount of brown fat, and response to an adult voice.
d. Abdominal tone, persistence, gastric acidity, arterial pressure, and response to pain.

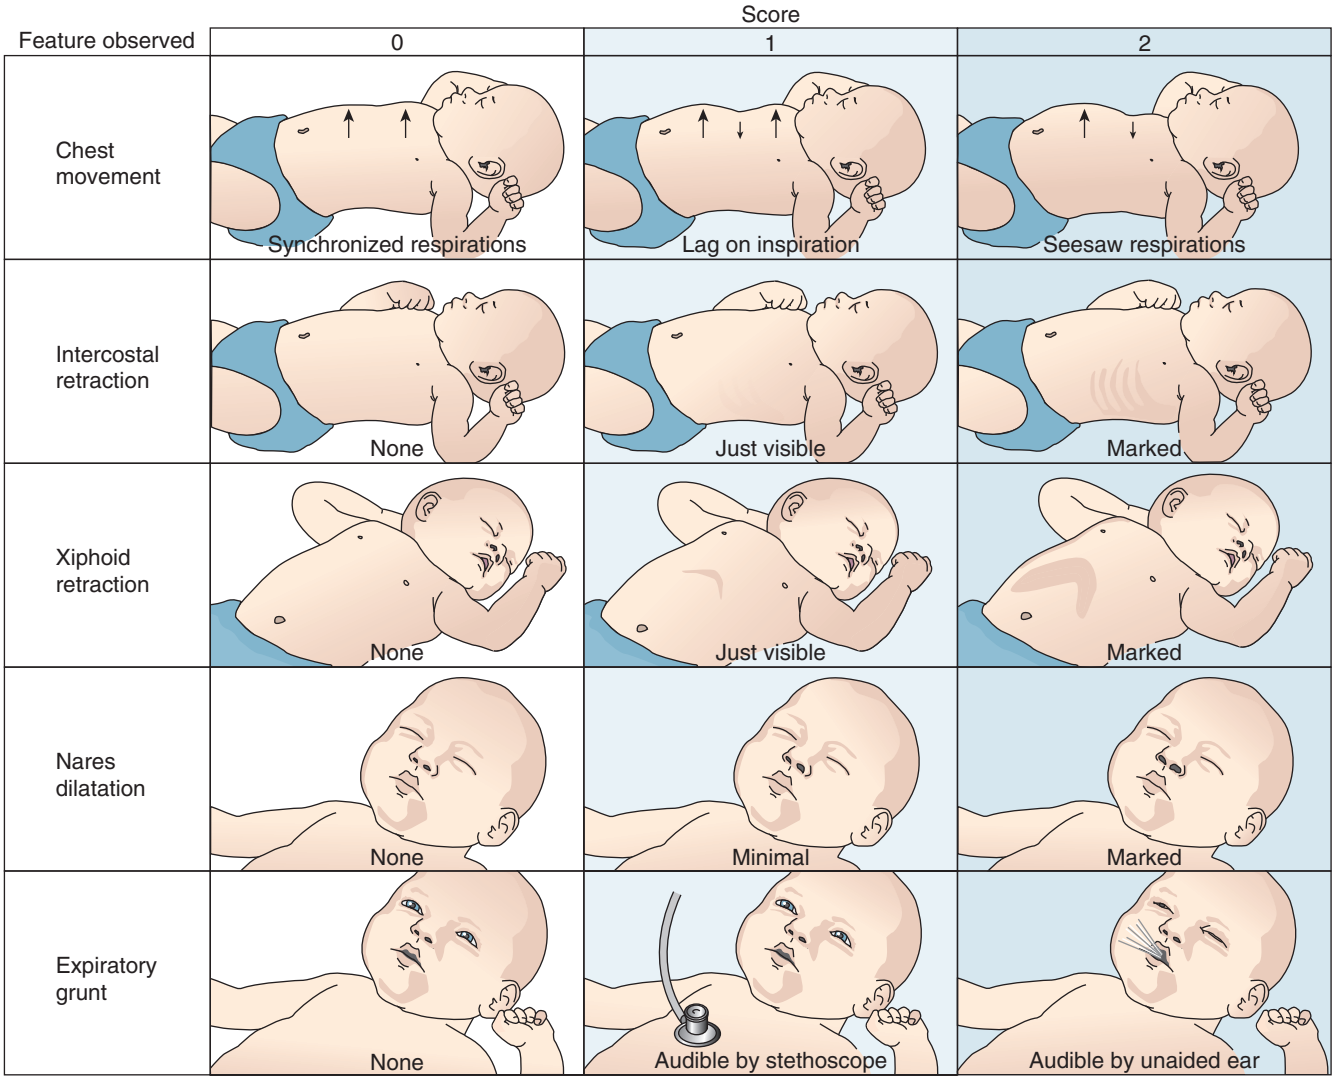

FIGURE 18.19 Grading of neonatal respiratory distress based on Silverman-Andersen index. (Silverman, W. A., & Andersen, D. H. [1956]. A controlled clinical trial of effects of water mist on obstructive respiratory signs, death rate and necroscopy findings among premature infants. *Pediatrics, 17*[4], 1–9.)

Physical Examination

A newborn is given a preliminary physical examination immediately after birth, to establish gestational age and to detect any observable condition such as difficulty breathing, a congenital heart anomaly, meningocele, cleft lip or palate, hydrocephalus, a birthmark, imperforate anus, tracheoesophageal atresia, or bowel obstruction (Table 18.3). This assessment may be the responsibility of the delivering physician, nurse practitioner, nurse-midwife, pediatrician, or nurse. This health assessment is done quickly, to prevent overexposing a newborn, yet not so swiftly that important findings are overlooked.

Height and Weight

Assuming newborns are breathing well, they are weighed nude and without a blanket soon after birth in the birthing room (Fig. 18.20). Measurements such as body length and head, chest, and abdominal circumferences can be obtained later. Performing these measurements while an infant is still damp only exposes the newborn unnecessarily to chilling.

A newborn's weight is important because it helps to determine maturity as well as establish a baseline against which all other weights can be compared. Following this initial weight, an infant is weighed nude once a day, at approximately the same time every day, during a hospital or birthing center stay. Compare the weight obtained each day with that of the preceding day to be certain an infant is not losing more than the normal physiologic amount (5% to 10% of birth weight). Abnormal loss of weight may be the first indication that a newborn has an inborn error of metabolism, such as adrenocortical insufficiency (salt-dumping type), or is becoming dehydrated.

Laboratory Studies

After the first hour of undisturbed rest, depending on health agency policy, newborns may have heel-stick tests for hematocrit, hemoglobin, and hypoglycemia determinations. Hematocrit and hemoglobin are assessed to detect newborn anemia that can be caused by hypovolemia because of bleeding

TABLE 18.3 ✻ Congenital Anomaly Appraisal

Procedure	Abnormalities Considered
Inquire for hydramnios or oligohydramnios	Presence of hydramnios suggests congenital gastrointestinal obstruction. Oligohydramnios suggests genitourinary obstruction or extreme prematurity.
Appearance of abdomen	Distended abdomen suggests ascites, possible bowel obstruction, or tumor. Empty abdomen suggests diaphragmatic hernia.
Passage of nasogastric tube (no. 8 feeding catheter) through nares into stomach	Failure to pass nasogastric tube through nares on either side establishes choanal atresia. Failure to pass it into the stomach confirms presence of esophageal atresia.
Aspiration of stomach with recording of color and amount of fluid obtained	With excess of 20 mL of fluid, or yellow fluid, duodenal or ileal atresia is suspected.
Insertion of rectal catheter	Failure to obtain meconium suggests imperforate anus or higher obstruction.
Counting of umbilical arteries	The presence of one artery suggests possible congenital urinary or cardiac anomalies or chromosomal trisomy (if other portions of examination are consistent).

Source: Van Leeuwen, G., & Glenn, L. (1968). Screening for hidden congenital anomalies. *Pediatrics, 41*(6), 147–152. Copyright American Academy of Pediatrics, 1968.

from placenta previa or premature separation of the placenta or by a cesarean birth that accidentally involved incision into the placenta. Another condition as dangerous as anemia is the presence of an excess of red blood cells (polycythemia), probably caused by excessive flow of blood into an infant from the umbilical cord. A heel-stick hematocrit reveals this also so treatment then can be instituted. A normal hematocrit at 1 hour of life is about 50% to 55%.

Hypoglycemia may produce few symptoms, so it is determined by a heel-stick glucose measurement. Infants of diabetic mothers and infants considered to be large for gestational age (LGA) are routinely tested for blood glucose levels soon after birth. If a blood glucose heel-stick reading is less than 45 mg/100 mL of blood, hypoglycemia is present. To correct this condition, the infant is prescribed oral glucose or infant formula to be given immediately. This elevates the infant's blood sugar to a safe level. It is important that hypoglycemia be treated quickly because, if brain cells become completely depleted of glucose, brain damage can result. If a newborn exhibits symptoms of hypoglycemia (jitteriness, lethargy, seizures) in addition to the low laboratory test results, intravenous glucose will be prescribed. A continuous intravenous infusion of glucose may be necessary if the newborn is unable to maintain glucose levels higher than 45 mg/100 mL. Heel-sticks require a minimum of blood, and, although not pain free, they cause minimal trauma to a baby. In some settings, these tests are not routine but are reserved only for newborns with symptoms of anemia, polycythemia, or hypoglycemia.

FIGURE 18.20 Weighing a newborn. Notice the protective hand held over the infant.

Assessment of Gestational Age

Specific findings on physical assessment provide clues to a newborn's gestational age. As early as 1966, Usher and colleagues (1966) proposed five criteria to evaluate gestational maturity (Table 18.4). These quick criteria can be used for assessment of all newborns.

Dubowitz Maturity Scale

Dubowitz and colleagues (1970) devised a gestational rating scale that uses more extensive criteria. All newborns appearing to be immature by Usher's criteria or who are light in weight at birth or early by dates should be assessed by means of these more definitive criteria. Although completing a Dubowitz assessment takes practice, it can yield important results; it can help determine whether a newborn needs immediate high-risk nursery intervention.

During the 1970s and again in the 1990s, Ballard modified the Dubowitz scale (Ballard et al., 1991) to an assessment scale that can be completed in 3 to 4 minutes. The assessment consists of two portions: physical maturity and neuromuscular maturity (Fig. 18.21). The first is a series of observations about skin texture, color, lanugo, foot creases, genitalia, ear, and breast maturity. Each designated body part is inspected and

TABLE 18.4 ✻ Clinical Criteria for Gestational Assessment

	Gestation Age (wk)

FIGURE 18.21 Ballard's assessment of gestational age criteria. (**A**) Physical maturity assessment criteria. (**B**) Neuromuscular maturity assessment criteria. *Posture:* With infant supine and quiet, score as follows: arms and legs extended = 0; slight or moderate flexion of hips and knees = 2; legs flexed and abducted, arms slightly flexed = 3; full flexion of arms and legs = 4. *Square Window:* Flex hand at the wrist. Exert pressure sufficient to get as much flexion as possible. The angle between hypothenar eminence and anterior aspect of forearm is measured and scored. Do not rotate wrist. *Arm Recoil:* With infant supine, fully flex forearm for 5 sec, then fully extend by pulling the hands and release. Score as follows: remain extended or random movements = 0; incomplete or partial flexion = 2; brisk return to full flexion = 4. *Popliteal Angle:* With infant supine and pelvis flat on examining surface, flex leg on thigh and fully flex thigh with one hand. With the other hand, extend leg and score the angle attained according to the chart. *Scarf Sign:* With infant supine, draw infant's hand across the neck and as far across the opposite shoulder as possible. Assistance to elbow is permissible by lifting it across the body. Score according to location of the elbow: elbow reaches opposite anterior axillary line = 0; elbow between opposite anterior axillary line and midline of the thorax = 1; elbow at midline of thorax = 2; elbow does not reach midline of thorax = 3; elbow at proximal axillary line = 4. *Heel to Ear:* With infant supine, hold infant's foot with one hand and move it as near to the head as possible without forcing it. Keep pelvis flat on examining surface. (**C**) Scoring for a Ballard assessment scale. The point total from assessment is compared to the left column. The matching number in the right column reveals the infant's age in gestation weeks. (From Ballard, J. L. [1991]. New Ballard score expanded to include extremely premature infants. *Journal of Pediatrics, 119*[3], 417–424.)

given a score of 0 to 5, as described in Figure 18.21A. This observational scoring should be done as soon as possible after birth, because skin assessment becomes much less reliable after 24 hours. Illustrations of mature and immature body features for Ballard scale use are shown in Chapter 26 as part of the discussion of the preterm infant.

To complete the second half of the gestational examination, observe or position a newborn as shown in Figure 18.21B. Again, score the child's response numerically from 0 to 5.

To establish a baby's gestational age, the total score obtained (on both sections) is compared with the rating scale in Figure 18.21C. An infant with a total score of 5 is at 26 weeks' gestational age; a total score of 10 reveals a gestational age of about 28 weeks; a total score of 40 points is found in infants at term or 40 weeks' gestation.

Using such a standard method to rate maturity is helpful in detecting infants who are small for gestational age (they are light in weight, but the neuromuscular and physical observation scales are adequate for their weeks in utero) and differentiating them from newborns who are immature because of a miscalculated due date. An infant who is found to be less than 35 weeks' gestation requires close observation, usually in a special care nursery.

Assessment of Behavioral Capacity

Term newborns are physically active and emotionally prepared to interact with the people around them. They are people oriented from the beginning—how much so can be demonstrated by the way they immediately attune to human voices or concentrate on their mother's face (Fig. 18.22).

Brazelton Neonatal Behavioral Assessment Scale

The *Brazelton Neonatal Behavioral Assessment Scale* is a rating scale devised by Brazelton in the early 1970s (Brazelton, 1973) to evaluate a newborn's behavioral capacity or ability to respond to set stimuli. Six major categories of behavior—habituation, orientation, motor maturity, variation, self-quieting ability, and social behavior—are assessed.

FIGURE 18.22 A newborn recognizes her parent's face.

To perform an assessment using the scale requires training to ensure that it is used consistently from one individual to another. Unlike many assessment scales, the infant is scored on best performance rather than on average performance. A total evaluation takes 20 to 30 minutes to complete. It is useful for comparing different groups of infants, such as those exposed or not exposed to cocaine in utero (Richardson, Goldschmidt, & Larkby, 2007).

The information supplied by this scale has provided concrete evidence that newborns are not passive, nonhearing, unseeing, unresponsive, or even all alike. An important finding from the scale is that newborns are able to quiet themselves after crying. Many of the items tested on the scale, such as how infants alert (eyes widen, head held as if listening) or orient to sound (turn toward the direction of the parent's voice or appear to listen to the sound of a voice) and how they naturally cuddle when held next to their parent, are excellent examples of newborn behavior to point out to parents. If parents perceive a newborn as passive and unresponsive, they are likely to talk to or look at their newborn very little. The more they know about their baby, the more they will be able to understand the baby's cues and determine and meet the baby's needs. Performing a Brazelton assessment and pointing out positive infant behavior can lead to improved parenting ability.

CARE OF A NEWBORN AT BIRTH

Birthing rooms provide an island for newborn care separate from the supplies needed for the mother's care. Necessary equipment includes a radiant heat table or warmed bassinet; a warm, soft blanket; and equipment for oxygen administration, resuscitation, suction, eye care, identification, and weighing of a newborn.

The philosophy of health care providers has always been that newborns should be handled as gently at birth as they are at any other time. The image of an obstetrician holding a newborn up by the heels and spanking to stimulate breathing has existed only in movies. It has long been accepted that holding a baby by the feet and letting the back extend fully is probably painful after the months spent in a flexed position in utero; in addition, a measure such as spanking is not as effective in helping a newborn breathe as is gentle stimulation, such as rubbing the back.

Newborn Identification and Registration

Infant identification is important, because there always exists the possibility that a newborn may be handed to the wrong parents or be switched or kidnapped from a health care facility, although these events are rare. The profile of a newborn kidnapper is a woman who has recently lost a pregnancy or had an infant stillborn and therefore desires an infant very much. She often is someone familiar with hospitals; she pretends to be a volunteer or an unlicensed health care worker and says she needs to take a baby out of the nursery or the mother's room for a procedure. Health care agency personnel need to be alert to the potential danger of kidnapping, and not only take measures to prevent this from happening but also alert parents to the danger (Box 18.3).

BOX 18.3 ✻ Focus on Family Teaching

Measures to Help Prevent Kidnapping From a Hospital Unit

Q. Beth's mother tells you, "I've heard babies are being kidnapped from hospitals. How can we make sure this doesn't happen to us?"

A. Although kidnapping is rare, it can happen. To minimize the risk, use the following guidelines:

- Review the hospital's newborn identification procedure with a nurse so you are familiar with it and can feel comfortable with the safeguards being taken.
- Check that identification bands are in place on your infant as you care for her. These can slide off easily over small newborn hands and feet. If a band or necklace is missing, ask a nurse to replace it immediately.
- Do not allow any person without proper hospital identification to remove your baby from your room.
- Do not leave your baby unattended in your room. Either return the baby to the nursery or take your baby with you if you are leaving your room to walk in the hall, for example.
- Report the presence of any suspicious person in the unit.
- Be aware that some hospitals use a microchip system embedded in identification bands, similar to the tag used to thwart shoplifting in department stores, that sounds an alarm if a baby is removed from the unit. If this type of band is used, be certain it is removed before hospital discharge, or it will set off the alarm.

FIGURE 18.23 This newborn is wearing a security band, which sets off an alarm and locks exits if an infant is taken off the unit.

Identification Band

One traditional form of identification used with newborns is a plastic bracelet with permanent locks that require cutting to be removed. A number that corresponds to the mother's hospital number, the mother's full name, and the sex, date, and time of the infant's birth are printed on the band. If an identification band is attached to a newborn's arm or leg, two bands should be used. This is because a newborn's wrist and hand, as well as the ankle and foot, are not very different in width, and bands can slide off easily. A newer form of identification band has a built-in sensor unit that sounds an alarm, similar to those attached to clothing in department stores to stop shoplifting, if a baby is transported beyond set hospital boundaries (Fig. 18.23).

After identification bands are attached, an infant's footprints may be taken (Fig. 18.24A) and thereafter kept with the baby's chart for permanent identification (see Fig. 18.24B). Babies who are born elsewhere and then admitted to the hospital should have their footprints taken and identification band secured on admission.

Birth Registration

The physician or nurse-midwife who supervised the birth of an infant has the responsibility to see that a birth registration is filed with the Bureau of Vital Statistics of the state in which the infant was born. The infant's name, the mother's name, the father's name (if the mother chooses to reveal

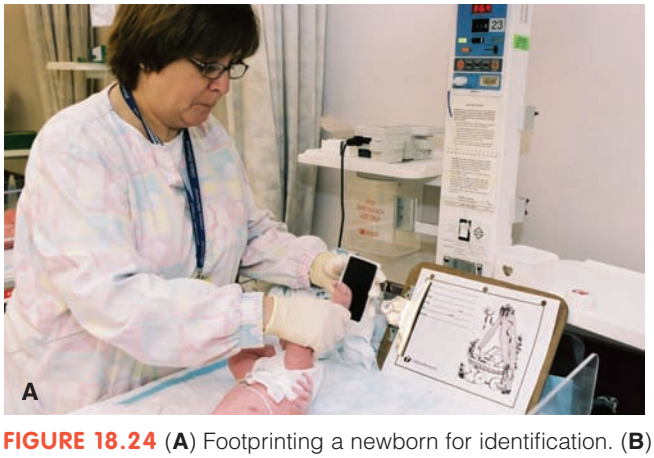

FIGURE 18.24 (**A**) Footprinting a newborn for identification. (**B**) Newborn footprints.

this), and the birth date and place are recorded. Official birth information is important in proving eligibility for school and, later, for voting, passports, and Social Security benefits.

Birth Record Documentation

The infant's chart is also a vital piece of documentation. It serves as a baseline indicating whether the infant was well at birth. Be certain a newborn chart contains the following information:

- Time of birth
- Time the infant breathed
- Whether respirations were spontaneous or aided
- Apgar score at 1 minute and at 5 minutes of life
- Whether eye prophylaxis was given
- Whether vitamin K was administered
- General condition of the infant
- Number of vessels in the umbilical cord
- Whether cultures were taken (they are taken if at some point sterile birth technique was broken or the mother has a history of vaginal or uterine infection)
- Whether the infant voided and whether he or she passed a stool (this information is helpful if, later on, the diagnosis of bowel obstruction or absence of a kidney is considered)

Many nurses indicate a three-vessel cord with the symbol shown in Figure 18.25. Do not mistake this drawing for a "smiling face" and assume that it is not important.

Nursing Diagnoses and Related Interventions

In most health care facilities, the physician or nurse-midwife hands the newborn to a nurse moments after birth to begin care. Be certain to adhere to standard infection precautions when caring for newborns. To avoid touching the vernix caseosa, wear gloves. Hold a warm, sterile blanket and grasp the infant through the blanket by placing one hand under the back and the other around a leg. Newborns are slippery because they are wet from amniotic fluid and the vernix.

Nursing Diagnosis: Risk for ineffective thermoregulation related to newborn's transition to extrauterine environment

Outcome Evaluation: Newborn maintains axillary temperature of 98.6° F (37° C) by 1 hour after birth.

Several time-honored procedures help a baby to conserve body heat at birth.

Keep Newborn Warm. Gently rub a newborn dry, remove the wet linen, then swaddle loosely with a clean, warm, and dry blanket. Be certain to place a cap on the infant's head (Fig. 18.26). These actions all help to prevent heat loss. Swaddling helps to mimic the tight confines of the uterus and appears to offer a sense of security as swaddled infants sleep for longer periods (Bregje et al., 2007).

Ask which parent wants to hold the child, and place the infant in the parent's arms as this not only helps conserve heat but also encourages bonding. The period immediately after birth is an important time for parents to begin interaction with their child. Newborns are alert (first period of activity) and respond well to the parents' first tentative touches or interactions with them. Although the temperature of newborns who are dried, wrapped, and then held by their parents immediately after birth apparently falls slightly lower than that of infants placed in heated cribs, their core temperature does not fall below safe limits. Any extensive procedures, such as resuscitation, should be done under a radiant heat source to reduce heat loss.

At the end of the first hour of life, reassess the newborn's temperature. Axillary rather than rectal temperatures are recommended for newborns, to prevent accidental bowel perforation. If the temperature is subnormal and the baby is in a bassinet, he or she should be placed in a heated bassinet or under a radiant warmer for additional heat. If the temperature is normal, a newborn can be bathed quickly to remove excess vernix caseosa and blood, then dressed in a shirt and diaper, reswaddled in a snug blanket (to give the baby a familiar feeling of the tight confines of the uterus), and placed in a bassinet or returned to the mother's side.

During the first day of life, a newborn's temperature is usually taken every 4 to 8 hours. Thereafter, unless the temperature is elevated or subnormal, or the infant appears to be in distress, measurement once a day while in the health care facility is enough.

Nursing Diagnosis: Risk for ineffective airway clearance related to presence of mucus in mouth and nose at birth

Outcome Evaluation: Neonate maintains a respiratory rate of 30 to 60 breaths per minute without evidence of retraction or grunting by 5 minutes after birth.

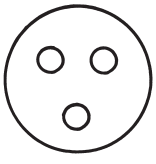

FIGURE 18.25 A chart abbreviation for a three-vessel cord.

FIGURE 18.26 A newborn wrapped and capped to conserve body heat.

Record the First Cry. A crying infant is a breathing infant, because the sound of crying is made by a current of air passing over the larynx. The more lusty the cry, the greater the assurance the newborn is breathing deeply and forcefully. Vigorous crying also helps blow off the extra carbon dioxide that makes all newborns slightly acidotic, so helps to correct this condition. Although gentleness is necessary to make an infant's transition from intrauterine life to extrauterine life as untraumatic as possible, there is no need to completely halt the initial crying of a newborn.

A newborn who does not breathe spontaneously or who takes a few quick, gasping breaths but is unable to maintain respirations needs resuscitation as an emergency measure. An infant with grunting respirations needs careful observation for respiratory distress syndrome (see Chapter 26).

Promote Adequate Breathing Pattern and Prevent Aspiration. Mucus is suctioned from a newborn's mouth by a bulb syringe as soon as the head is born. As soon as the body is born, the baby should be held for a few seconds with the head slightly dependent, for further drainage of secretions. It is important that mucus be removed from the mouth and pharynx before the first breath this way to prevent aspiration of the secretions. If the infant continues to have an accumulation of mucus in the mouth or nose after these first steps, you may need to suction further after the baby is placed under a warmer (Fig. 18.27). Use a bulb syringe or a soft, small (no. 10 or 12) catheter to suction. Never suction vigorously, because this irritates the mucous membrane and could leave a portal of entry for infection. Brisk suctioning also has been associated with bradycardia in newborns because of vagal nerve stimulation. If you use a bulb syringe, decompress the bulb before inserting it into the infant's mouth or nose; otherwise, the force of decompression will push secretions back into the pharynx or bronchi rather than remove them. Although the effectiveness of the procedure is not well documented, when an infant is born with meconium-stained amniotic fluid, intubation may be performed so that deep tracheal suction can be accomplished before the first breath, to help prevent meconium aspiration (Halliday & Sweet, 2009). Administration of surfactant may also be helpful to assist breathing (El Shahed et al., 2009).

FIGURE 18.27 A newborn is suctioned by means of a bulb syringe to remove mucus from the mouth and nose. The head-down-and-to-the-side position facilitates drainage. Care is given with the infant under a radiant heat source.

Nursing Diagnosis: Risk for infection related to newly clamped umbilical cord and exposure of eyes to vaginal secretions

Outcome Evaluation: Area around cord is dry and free of erythema. Eyes are free of inflammation and drainage. Axillary temperature is maintained between 97.6° and 98.6° F (36.5° and 37° C).

Inspect and Care for Umbilical Cord. The umbilical cord pulsates for a moment after an infant is born as a last flow of blood passes from the placenta into the infant. Two clamps are then applied to the cord about 8 inches from the infant's abdomen, and the cord is cut between the clamps. Some fathers choose to do this as their responsibility. The infant cord is then clamped again by a permanent cord clamp, such as a Hazeltine or a Kane clamp. The clamp on the maternal end of the cord should not be released after the cord is cut, to prevent blood still remaining in the placenta from leaking out. This loss is not important, because the mother's circulation does not connect to the placenta. It is messy, however, and that is why the clamp is left in place.

Every time you handle a newborn, inspect the cord to be certain it is clamped securely. If a clamp loosens before thrombosis obliterates the umbilical vessels, hemorrhage could result. As previously mentioned, the number of cord vessels should be counted and noted immediately after the cord is cut. Cords begin to dry almost immediately, and the vessels may be obscured by the time of the infant's first thorough physical examination in the nursery. Wiping the cord with alcohol at each diaper change helps to hurry drying and possibly reduce the development of infection.

Until the cord falls off, at about day 7 to 10 of life, a newborn should receive sponge baths rather than be immersed in a tub of water to keep the cord dry. Be certain that diapers are folded below the level of the umbilical cord, so that, when the diaper becomes wet, the cord does not become wet also.

Remind parents to continue to keep the cord dry until it falls off after they return home. The use of creams, lotions, and oils near the cord should be discouraged, because they tend to slow drying of the cord and invite infection. Some health care agencies recommend applying rubbing alcohol to the cord site once or twice a day to hasten drying. Others prefer the cord be left strictly alone, because manipulation could invite infection.

After the cord falls off, a small, pink, granulating area about a quarter of an inch in diameter may remain. This should also be left clean and dry until it has healed (about 24 to 48 additional hours). If the ulcerous area has remained as long as 1 week, it may require cautery with silver nitrate to speed healing.

Administer Eye Care. Although the practice may shortly become obsolete (as it is in Europe), every U.S. state still requires that newborns receive prophylactic eye treatment against gonorrheal conjunctivitis (Raab, 2007). Such infections are usually acquired from the mother as the infant passes through the birth canal. Formerly, eye prophylaxis was applied immediately after birth. Many parents today prefer to visit with their infant before the procedure, to be certain their newborn can focus on them without blurry vision caused by ointment or drops. Parents who know that they are free of a gonococcal or chlamydial infection can ask to have eye prophylaxis omitted entirely. Silver nitrate was exclusively used for prophylaxis in the past; today, erythromycin ointment is the drug of choice. Erythromycin ointment has the advantage of eliminating not only the organism of gonorrhea but that of *Chlamydia* as well (Box 18.4).

Always use a single-use tube or package of ointment, to avoid transmitting infection from one newborn to another. To instill the ointment, first dry the face of the newborn with a soft gauze square so that the skin is not slippery. The best procedure to open a newborn's eyes is to shade them from the overhead light and open one eye at a time by pressure on the lower and upper lids. Squeeze a line of ointment along the lower conjunctival sac, from the inner canthus outward, and then close the eye to allow the ointment to spread across the conjunctiva.

Credé, a German gynecologist, first proposed silver nitrate prophylaxis against gonorrheal conjunctivitis in 1884. For this reason, it is often referred to as the *Credé treatment* and may be listed that way on a health care agency form even though silver nitrate is no longer used. Babies born outside hospitals, in homes or in less orthodox settings such as a car or taxi, have the prophylactic treatment administered on admission to the hospital.

General Infection Precautions. Each newborn should have his or her own bassinet. Compartments in the bassinet should hold a supply of diapers, shirts, gowns, and individual equipment for bathing and temperature taking. Avoid sharing of these items, which could lead to the spread of infection.

Health care workers, parents, or siblings caring for newborns should wash their hands and arms to the elbows thoroughly with an antiseptic soap before handling an infant. Although not proved to reduce infections, agency personnel are usually required to wear cover gowns or nursery uniforms (Webster & Pritchard, 2009).

Staff members with infections (sore throats, upper respiratory tract infections, skin lesions, or gastrointestinal upsets) should be excluded from caring for mothers or infants until the condition is completely cleared. If a mother could have a contagious illness, her newborn should be excluded from her room until there is no longer a possibility of contagion. An instant photograph can be taken of the baby and shown to the mother so that she can follow the baby's progress. If the infant is breastfed, the mother could manually express milk during the time the infant is excluded, to maintain her milk supply. The mother can resume breastfeeding as soon as it is both possible and safe for her infant.

Any baby born outside a hospital or under circumstances conducive to infection such as rupture of membranes more than 24 hours before birth should be kept in a closed bassinet or in the mother's room until negative cultures show that the newborn is free of infection. Any newborn in whom symptoms of infection develop such as skin lesions or fever should be removed to an isolation nursery or housed in the mother's room to prevent the spread of infection to other babies. There is no reason for parents not to visit a baby housed in isolation care. In fact, they may have more need to hold a baby who is isolated than do average parents, because they have an extra reason to be worried that something is wrong with their child. To visit in isolation nurseries, teach parents to use the same infection control techniques that staff members use.

BOX 18.4 * Focus on Pharmacology

Erythromycin Ophthalmic Ointment

Classification: Erythromycin ointment is a topical antibiotic.

Action: Erythromycin is effective against gonorrhea and chlamydia organisms, making it the drug of choice for eye prophylaxis at birth (Karch, 2009).

Pregnancy Risk Category: B

Dosage: 0.5–1 cm each eye

Possible Adverse Effects: Mild irritation to conjunctiva; slight blurring of vision.

Nursing Implications

- Use a single-dose application tube.
- After gently pulling down on a newborn's lower eyelid, extrude a line of ointment the length of the lower eyelid from the inner canthus outward.
- Discard any remaining ointment to prevent its being used again.
- Close the child's eyes and count to about 5.
- Wipe away any excess ointment from the child's face.
- If desired, delay application for an hour after birth to allow the infant to view his or her parents clearly.

What if... Beth Ruiz had been born by cesarean birth? Would you still administer eye prophylaxis? Or do newborns acquire eye infections only during their transit through the birth canal?

NURSING CARE OF A NEWBORN AND FAMILY IN THE POSTPARTAL PERIOD

Newborns are usually kept in either a birthing room or a transitional nursery for optimal safety in the first few hours of life.

Newborn care is not universal but varies among cultures. For example, although it is usually a sound policy to point out the positive aspects of a child to parents to aid parent–child bonding, in some areas of the world, such as traditional Cambodia and Laos, newborns are not given compliments this way. It is believed that compliments will leave them vulnerable to evil spirits.

In the traditional Haitian culture, infants are not named immediately, but only after a full month. In some cultures, it is important for newborns to have an amulet (good-luck charm) tied around their neck or wrist. Respect these and leave them in place when bathing the infant. Oiling the infant's body and placing a belly band over the umbilical cord also are common care procedures. Being aware of cultural variations in newborn care such as these helps you plan care that is specific and meaningful to individual parents and can aid parent–child bonding. During this period of close observation, certain principles of care always apply.

Initial Feeding

A term newborn who is to be breastfed may be fed immediately after birth. A baby who is to be formula-fed may receive a first feeding at about 2 to 4 hours of age. Both formula-fed and breastfed infants do best on a demand schedule; many need to be fed as often as every 2 hours in the first few days of life. Chapter 19 covers the elements of breastfeeding and formula feeding in detail. Encouraging women to not only begin breastfeeding but also to continue for a minimum of 6 months is important (Box 18.5).

BOX 18.5 ✻ Focus on Evidence-Based Practice

Does self-efficacy influence whether women continue breastfeeding until 6 months' time?

Many women try breastfeeding in the hospital, then stop breastfeeding shortly after they return home; others continue for the minimum time recommended or until 6 months of age. To discover if a feeling of self-efficacy (the belief that one can bring about positive results) is important in determining whether women will continue breastfeeding, researchers assessed general self-efficacy in 27,753 pregnant women at 17 and 30 weeks during their pregnancy as well as by a questionnaire on infant feeding at 6 months postpartum. Analysis of the results of the study showed that high self-efficacy decreases the chance that mothers bottle feed. It helps them use predominantly breastfeeding. The researchers recommend that discussions of women about breastfeeding during pregnancy and the early postpartum period should include efforts to strengthen self-efficacy as this may be a prime reason why some women continue with breastfeeding.

Based on this study, would you include efforts to increase a mother's self-efficacy when helping her begin breastfeeding?

Source: Ystrom, E., et al. (2008). The impact of maternal negative affectivity and general self-efficacy on breastfeeding. *Journal of Pediatrics, 152*(1), 68–72.

Bathing

In most hospitals, newborns receive a complete bath to wash away vernix caseosa within an hour after birth. Thereafter, they are bathed once a day, although the procedure may be limited to washing only the baby's face, diaper area, and skin folds. Wear gloves when handling newborns until the first bath, to avoid exposing your hands to body secretions; babies of mothers with human immunodeficiency virus (HIV) infection should have a thorough bath immediately, to decrease the possibility of HIV transmission.

Bathing of an infant is best done by the parents under a nurse's supervision. Be sure the room is warm (about 75° F [24° C]), to prevent chilling. Bath water should be approximately 98° to 100° F (37° to 38° C), a temperature that feels pleasantly warm to the elbow or wrist. If soap is used, it should be mild and without a hexachlorophene base. Bathing should take place before, not after, a feeding, to prevent spitting up or vomiting and possible aspiration.

Equipment necessary for an infant's bath consists of a basin of water, soap, washcloth, towel, comb, and clean diaper and shirt. Assemble these items beforehand, so the baby is not left exposed or unattended while you go for more equipment.

Bathing should proceed from the cleanest to the most soiled areas of the body—that is, from the eyes and face to the trunk and extremities and, last, to the diaper area. Wipe a newborn's eyes with clear water from the inner canthus outward, using a clean portion of the washcloth for each eye to prevent spread of infection to the other eye. Wash the face with clear water only (no soap) to avoid skin irritation; soap may be used on the rest of the body.

Teach parents to wash the infant's hair with each bath. The easiest way to do this is to first soap the hair with the baby lying in the bassinet. Then, hold the infant in one arm over the basin of water, as you would a football (Fig. 18.28). Splash water from the basin against the head to rinse the hair. Dry the hair well to prevent chilling.

Wash each area of the baby's body, rinse so no soap is left on the skin (soap is drying and newborns are susceptible to desquamation), and then dry the body part. When you wash the skin around the cord, take care not to soak the cord. Give

FIGURE 18.28 A football hold. Such a position supports the infant's head and back and leaves the nurse's or mother's other hand free for assembling or using equipment.

particular care to the creases of skin, where milk tends to collect if the child spits up after feedings.

In male infants, the foreskin of the uncircumcised penis should not be forced back, or constriction of the penis may result. Wash the vulva of a female infant, wiping from front to back to prevent contamination of the vagina or urethra by rectal bacteria.

Most health care agencies do not apply powder or lotion to newborns, because some infants are allergic to these products. In addition, many adult talcum powders contain zinc stearate, which is irritating to the respiratory tract; such preparations should always be avoided. If a newborn's skin seems extremely dry and portals for infection are becoming apparent, a lubricant such as Nivea oil, added to the bath water or applied directly to the baby's skin, should relieve the condition.

Sleeping Position

Stress to parents that a newborn should be positioned on the back for sleep. Sudden infant death syndrome (SIDS) is the sudden, unexplained death of an infant younger than 1 year of age. Although the specific cause of SIDS cannot be explained, placing infants to sleep in a supine position with a pacifier has been shown to decrease the incidence of the syndrome (Damato, 2007). As one of the reasons that SIDS may occur is the infant rebreathing expired carbon dioxide–rich air, using a fan in the room during sleep or opening a window so there is a breeze in the room may be yet another way the incidence of SIDS can be reduced (Coleman-Phox, Odouli, & Li, 2008).

Diaper Area Care

Preventing diaper dermatitis is a practice that parents need to start from the very beginning with their newborns. With each diaper change, the area should be washed with clear water and dried well, to prevent the ammonia in urine from irritating the infant's skin and causing a diaper rash. After cleaning, a mild ointment such as petroleum jelly or A+D Ointment may be applied to the buttocks. The ointment keeps ammonia away from the skin and also facilitates the removal of meconium, which is sticky and tarry. Wear gloves for diaper care as part of standard precautions.

Metabolic Screening Tests

By state law, every infant must be screened for phenylketonuria (PKU; a disease of defective protein metabolism), hypothyroidism, and cystic fibrosis. Screening is done by means of a simple blood test in which three drops of blood from the heel are dropped onto a special filter paper. Ideally, the baby should have received formula or breast milk for 24 hours (providing an intake of phenylalanine, an essential amino acid found in milk) before the test for PKU will be accurate. If the infant has not received adequate milk before the blood sample is taken, the results may be falsely negative (a child with PKU will test as if normal). If an infant is discharged before this 24-hour period, a second screening test is necessary. Many states require other metabolic tests at birth, such as screening for galactosemia, cystic fibrosis, and maple syrup urine disease (Kayton, 2007). These also require filter paper blood tests.

If blood testing is not done before discharge, alert the parents that they must schedule the tests to be done at a home health visit or at an ambulatory visit in 2 to 3 days' time. Always assess at the first newborn health supervision visit whether these procedures were done. As with any heel-stick for blood, sampling of this nature is done best by a spring-activated lancet rather than a regular lancet, so that the skin incision is made as quickly and painlessly as possible. Allowing a newborn to suck on a pacifier during painful procedures may be helpful.

Hepatitis B Vaccination

All newborns receive a first vaccination against hepatitis B within 12 hours after birth; a second dose is administered at 1 month and a third at 6 months. Infants whose mothers are positive for the hepatitis B surface antigen (HBsAg) also receive hepatitis B immune globulin (HBIG) at birth (APA, 2009).

Vitamin K Administration

Newborns are at risk for bleeding disorders during the first week of life because their gastrointestinal tract is sterile at birth and unable to produce vitamin K, which is necessary for blood coagulation. A single dose of 0.5 to 1.0 mg of vitamin K is administered intramuscularly within the first hour of life to prevent such problems (Box 18.6). Infants

BOX 18.6 ✻ Focus on Pharmacology

Vitamin K (Phytonadione, AquaMEPHYTON)

Action: Vitamin K is used to prevent and treat hemorrhagic disease in newborns. It is a necessary component for the production of certain coagulation factors (II, VII, IX, and X) and is produced by microorganisms in the intestinal tract (Karch, 2009).

Pregnancy risk category: C

Dosage: Prophylaxis—0.5 to 1.0 mg IM one time immediately after birth; treatment of hemorrhagic disease—1 to 2 mg IM or SC daily.

Possible adverse reactions: Local irritation, such as pain and swelling at the site of injection.

Nursing Implications

- Anticipate the need for injection immediately after birth.
- Administer IM injection into large muscle, such as the anterolateral muscle of a newborn's thigh.
- If giving for treatment, obtain prothrombin time before administration (the single best indicator of vitamin K–dependent clotting factors).
- Assess for signs of bleeding, such as black, tarry stools (different from meconium stools, which have a greenish shade), hematuria, decreased hemoglobin and hematocrit levels, and bleeding from any open wounds or base of the cord. (These signs would indicate that more vitamin K is necessary, because bleeding control has not been achieved.)

born outside a hospital also should receive this important protection.

Circumcision

Circumcision is the surgical removal of the foreskin of the penis. In only a few babies, constriction (phimosis) of the foreskin is so severe that it obstructs the urinary meatal opening; otherwise, there are few medical indications for circumcision of a male newborn. Circumcision is performed on Jewish boys on the eighth day of life as part of a religious rite, in a ceremony called a *bris*. In the United States, from the 1920s to the 1960s, circumcision became so popular for aesthetic reasons that most male infants were routinely circumcised at birth. The reasons supporting circumcision include easier hygiene because the foreskin does not have to be retracted during bathing, and possibly fewer urinary tract infections develop. There also may be an increased incidence of penile cancer in uncircumcised men, as well as increased cervical cancer in their sexual partners. However, because the procedure is not essential and does carry some risk, parents need to be well informed about the procedure so they can evaluate carefully whether they wish to have it performed on their son.

Contraindications for circumcision include congenital abnormalities such as hypospadias or epispadias, because the prepuce skin may be needed when a plastic surgeon repairs these defects. Another contradiction is a history of a bleeding tendency in the family.

The procedure is not done immediately after birth, because at that time a newborn's level of vitamin K, which is necessary to prevent hemorrhage, is at a low point and the child would be exposed to unnecessary cold. It is best performed during the first or second day of life, after the baby has synthesized enough vitamin K to reduce the chance of faulty blood coagulation. If parents elect early discharge, they may be asked to return the infant to the hospital or to an ambulatory setting for the surgery. Parents should check that their health insurance plan will reimburse for the procedure if it is done on a return visit, after their newborn has been discharged from the hospital.

For the procedure, an infant is placed in a supine position and restrained either manually or with a commercial swaddling board. In the past the procedure was done without anesthesia, but today use of local or regional block anesthesia to reduce the pain as much as possible is used. Application of EMLA cream (a *e*utectic *m*ixture of *l*ocal *a*nesthetics) is a popular choice for local anesthesia (Taddio, Ohlsson, & Ohlsson, 2009).

For the procedure, a metal clamp (Gomco) or a specially designed plastic bell (Plastibell) is used. If the Gomco clamp is used, the infant's foreskin is stretched over the bell-shaped attachment of the clamp. The foreskin is then cut away with a scalpel. Petrolatum gauze is then wound around the penis to keep the surgical area from sticking to a diaper and to reduce bleeding and the threat of infection.

If a Plastibell is used, it is fitted over the end of the penis. A suture is then tied around the rim of the bell and a circle of the prepuce is cut away so that the foreskin can be easily retracted and the glans will be fully exposed (Fig. 18.29). The rim of the bell, which remains in place for about 1 week and then falls off by itself, protects the healing penis from sticking to a diaper, and helps protect against infection and bleeding. Although not necessary with the bell rim in place, petrolatum ointment may be applied if desired.

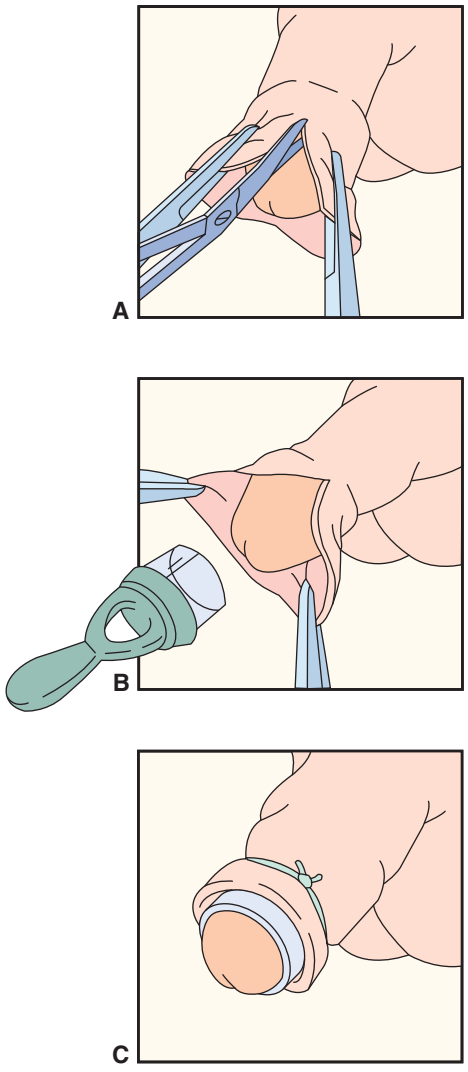

FIGURE 18.29 Technique for performing circumcision using a Plastibell. (**A**) An incision is made in the top of the foreskin. (**B**) The Plastibell is placed over the head of the penis, and the foreskin is pulled over the Plastibell. (**C**) A suture is tied around the foreskin over the tying groove in the Plastibell. Excess skin beyond the suture is trimmed away. The Plastibell falls off in 3 to 7 days. (Courtesy of Hollister Inc., Libertyville, IL.)

Complications that can occur from circumcision include hemorrhage, infection, and urethral fistula formation. To keep the risk of these complications to a minimum, observe infants closely for the first 2 hours after circumcision. Check the infant for bleeding every 15 minutes for the first hour. Also, document that the infant is voiding after the procedure.

Parents should keep the area clean and covered with petrolatum (if used) for about 24 hours. If they see any redness or tenderness, or if the baby cries as if in constant pain, they should report it by telephone. Circumcision sites appear red but should never have a strong odor or discharge. A film of yellowish mucus often covers the glans (similar to a scab) by the second day after surgery. This should not be washed away. The yellow color is from accumulated serum, an innocent finding, and should not be mistaken for the yellow of a purulent exudate.

ASSESSMENT OF FAMILY'S READINESS TO CARE FOR A NEWBORN AT HOME

It is important to assess how prepared each family is to care for their newborn at home, to be sure the newborn remains safe (Box 18.7). Parents may need to make changes in their routine, such as shifting their usual dinner time or work schedule. Sleep schedules are certain to be disrupted, because infants wake during the night for one or more feedings for about the first 4 months of life.

The physical environment of the home to which a newborn will be discharged is a good subject to explore with parents. Questions and areas to consider include:

- Is it an apartment or a house?
- How many flights of stairs will the mother have to climb when she takes the baby home or when she takes the baby out in a stroller?
- How many other people live in the home? (Infections spread more rapidly in crowded homes.)
- Are there any pets in the home? Will a large dog, for example, be a safe pet around the baby?
- Is there a bed for the baby?
- Will the baby be sleeping alone in a room or with older children? Will the baby share a bed with a parent?
- Who will be the primary caregiver?
- Will grandparents or other persons offer support by visiting or helping with care of the child?
- Do the parents have anyone to turn to if they have questions about the baby?
- Is there a refrigerator in which formula or breast milk can be stored?
- Is there adequate heat? An infant needs a temperature of 70° to 75° F during the day and 60° to 65° F at night.
- Are the windows draft free and screened to keep out insects?
- If housing is in poor condition, is there a danger that rodents might attack the baby?
- Is there a danger of lead poisoning?
- Does the mother or do the parents have a source of income? If not, what sort of referral should be made so that money can be provided to care for this child?

These are not prying questions but means of determining whether the home will be adequate and safe. Good prenatal and postnatal care is wasted if an infant contracts pneumonia during the first week at home because no one at a hospital or a birthing center took the time to ask the right questions about the home environment. If the home environment is found to be unsafe, a referral to social services may be necessary before the newborn is discharged.

BOX 18.7 ✻ Focus on Communication

When you enter Beth Ruiz's room, you notice her mother sitting on the side of the bed staring into Beth's face.

Less Effective Communication

Nurse: You seem concerned, Mrs. Ruiz. Is something wrong?
Mrs. Ruiz: Do you think she can tell how little I remember about babies?
Nurse: You're doing a great job. That's the important thing.
Mrs. Ruiz: How long will it take for me to feel like a great mother?
Nurse: You're worrying too much. Relax and enjoy your new baby.

More Effective Communication

Nurse: You seem concerned, Mrs. Ruiz. Is something wrong?
Mrs. Ruiz: Do you think she can tell how little I remember about babies?
Nurse: Is there something special you feel you don't know?
Mrs. Ruiz: My big problem is, I don't feel anything toward her yet. Why do I keep wondering if this whole thing is real?
Nurse: Let's talk about how maternal love develops. It isn't automatic.

Most new mothers have so many questions, it is easy to dismiss a very serious question as "just another question." Resist assuring women that they will be good mothers until you are certain their concern isn't something that could interfere with good mothering.

Nursing Diagnoses and Related Interventions ✻

Nursing Diagnosis: Health-seeking behaviors related to needs of a normal newborn after discharge from the health care facility

Outcome Evaluation: Parents state ways in which they have already altered their home and lifestyle to accommodate their newborn and indicate that they are prepared for other changes; parents voice relative confidence in their ability to care for the newborn and state names of individuals within their family or community who can be resources to them when needed.

Before discharge, the parents should think through how they are going to care for their child at home. Many parents have been mulling over these concerns throughout the pregnancy, whereas others may not yet have addressed some or any of these important issues (see Focus on Nursing Care Planning Box 18.8).

Young mothers without family support and mothers who did not seek regular prenatal care in particular may be unprepared for newborn care. With all parents, try to anticipate problems that may be relevant to them. If there are other children at home, discuss whether the parents are aware that sibling jealousy may occur. Pets in the home can cause similar problems with jealousy. Discuss with a mother who is not going to breastfeed what she will use to feed her baby until she has time to buy formula. Most hospitals sell a discharge formula kit to help parents through the first day at home. Be sure the parents have decided when and where they will take their newborn for health supervision. Check the child's identification band against the mother's one final

BOX 18.8 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Term Newborn

Carlotta Ruiz has just given birth to her second child, a 6-lb 5-oz baby girl. While Jose, Carlotta's husband, is in the room, Carlotta tells you she is a "veteran" at baby care. Jose adds, "Little Joe [their 3-year-old] will be so excited to see his new sister. That's all he's been talking about lately." When Carlotta is alone, you notice she seems a little apprehensive about caring for her new daughter. She tells you, "She's so much smaller than Joe was. And why does it sound like she has a cold? And what is this rash all over her? Isn't it bad enough she has a birthmark?"

Family Assessment ✻ Family is composed of two parents, a 3-year-old sibling, and newborn. They live in a three-bedroom flat over a dry cleaning store. Father clerks in a grocery store; mother works as a school bus driver. Finances rated as "hanging in there."

Client Assessment ✻ Apgar score: 6 at 1 minute; 8 at 5 minutes. Birth from LOA position. Breathed at 30 seconds after birth after administration of blow-by oxygen. Respiratory rate, 74 breaths per minute with mild substernal retractions; rhonchi in upper lobes bilaterally; no grunting or nasal flaring present. Vital signs: temperature (axillary), 98.2° F (36.8° C); heart rate, 136 bpm. Length, 18.5 in; head circumference, 34 cm; chest circumference, 32 cm. She has a 2 × 3 cm red pigmented area on outer right thigh. Mother attempted breastfeeding in birthing room, but newborn had difficulty sucking because of rapid respirations. Remainder of physical examination within acceptable parameters.

Nursing Diagnosis ✻ Risk for ineffective parenting related to infant's smaller than expected size, continuing rapid respirations, and birthmark.

Outcome Criteria ✻ Respiratory rate is decreased to 30 to 50 breaths per minute; retractions, nasal flaring, and grunting are absent; lungs are clear to auscultation. Infant sucks well at breast q2 to 3 hours; mother responds to infant's clues as if bonding with infant.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Assess respiratory rate every 15 min for 1 hr.	Report increase in rate, retractions, or development of nasal flaring or grunting.	Increases in respiratory rate and retractions, accompanied by nasal flaring and grunting, may indicate respiratory distress.	Infant gradually decreases respiratory rate to 30–50/min by 24 hr.
Nurse	Monitor newborn's temperature every hour.	Keep infant warm via radiant warmer or swaddled and held by parent; place a cap on her head.	Newborns have difficulty conserving body heat. Exposure to cold increases metabolic rate, increasing need for oxygen and a higher respiratory rate.	Infant's temperature remains at 98.2° F axillary.
		Consultations		
Nurse/ physician	Assess whether parents would like a dermatology consultation for child's birthmark.	Refer parents to dermatology consultant if desired.	A second opinion can help assure parents birthmark is no more than a birthmark.	Parents visit with consultant if desired; state they understand the prognosis for port-wine lesions.

(continued)

BOX 18.8 ✻ Focus on Nursing Care Planning (continued)

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Procedures/Medications		
Nurse	Assess whether infant's lung sounds reveal fluid.	Position newborn on her side with head slightly lower than body; suction mouth and then nose with bulb syringe as indicated.	Positioning facilitates drainage of secretions from airway. Gentle suctioning removes secretions. Suctioning mouth before nose prevents possible aspiration of oral secretions.	Infant appears comfortable in chosen position; need for suctioning becomes infrequent.
		Nutrition		
Nurse	Assess mother's knowledge of breastfeeding techniques.	Assist mother with breastfeeding as needed; remind her that rapid respirations make sucking difficult.	Breast milk is the preferred milk for human newborns; a mother may need assistance if an infant sucks poorly.	Infant and mother establish mutually enjoyable breastfeeding by hospital discharge.
		Patient/Family Education		
Nurse/ physician	Review with parents what were their expectations of new child (bigger? prettier? more relaxed?)	Inform parents that a rapid respiratory rate is common in newborns because of unabsorbed lung fluid. Help them mold expectations with reality.	Providing information helps to allay parents' anxieties and fears.	Parents state they understand their infant's condition.
		Psychosocial/Spiritual/Emotional Needs		
Nurse	Assess what is parents' greatest concern about taking newborn home.	Explain that the presence of a birthmark, rapid respirations, and smaller than expected size are normal variations of newborns.	Explanation of normal range of infant variation provides information to help allay parents' fears and concerns.	Parents state they were initially surprised by baby's appearance, but are adjusting to new image.
Nurse	Assess infant for general physical condition.	Point out positive attributes of newborn, such as pretty eyes, alert expression.	Pointing out positive areas helps parents focus attention on the unique and special qualities of their child.	Parents state they appreciate learning more about their newborn from health care professionals.
		Discharge Planning		
Nurse	Assess whether parents have made plans for hospital discharge.	Remind parents about importance of car seat, sleeping on back, and aspiration.	Safety awareness plays a big role in preventing early-age accidents.	Parents state they feel ready to begin parenting their new infant.

time before discharge, to help prevent the possibility of wrong identification of the infant.

Daily Home Care. Newborns thrive on a gentle rhythm of care, a sense of being able to anticipate what is to come next. Based on this, parents can decide what is the best daily at-home routine for them and their new child. There are no fixed rules. There is no set time at which an infant must be bathed, nor even a rule that requires a bath every day. All infants do not have to be in bed for the night by 8:00 PM. If the father works evenings, it may be important to have the baby awake at midnight so that he has time to spend with his child.

Your aim in helping parents plan their schedule of care is to arrive at one that:

- Offers a degree of consistency (a mother cannot expect an infant to stay awake until midnight 5 nights a week, then go to sleep at 7:00 PM on the sixth night)
- Appears to satisfy the infant
- Gives the parents a sense of well-being and contentment with their child

Sleep Patterns. A newborn sleeps an average of 16 of every 24 hours during the first week home, an average of 4 hours at a time. By 4 months of age, an infant sleeps an average of 15 hours of every 24 and through the night.

It is exhausting for a parent who is already tired from labor and birth to have to awaken during the night to feed a newborn. For this reason, parents may try various methods to induce a baby to sleep through the night much earlier than 4 months. One approach is to introduce solid food (particularly cereal) in the first weeks of life, on the theory that the bulk will fill the infant's stomach so that he or she will not wake up crying to be fed. In practice, there is no correlation between the age at which solid food is introduced and a baby's capability for sustained sleep. Also, a newborn is not developmentally ready to deal with nonliquid food until about the end of the third month. There are also other reasons not to introduce solid food early: large protein molecules from solid foods can pass through a newborn's immature gastrointestinal tract, becoming antigens that may sensitize the newborn for possible allergic reactions. In breastfed infants, too-early introduction of solid foods may interfere with the desire for breast milk, decrease the newborn's sucking, and subsequently decrease the mother's milk supply.

A baby probably wakes every 4, 5, 6, or 8 hours because of a physiologic need for fluid. Advise parents that, because of this fluid need, they should not try to eliminate night feedings. Knowing their baby is not sick, that you are concerned and willing to listen to their questions, and that every other parent of a newborn is also up at night does not solve the difficulty of interrupted sleep, but it is a help.

They should be certain their infant does not sleep on the stomach, because there is an association between this sleeping position and SIDS (Richardson, Walker, & Horne, 2008. They also need to use an approved crib with a firm mattress that is free of stuffed animals and toys. Placing a fan in the room and sucking on a pacifier may also reduce the possibility of SIDS as the infant stirs and sucks periodically and does not fall as deeply asleep.

Crying. Many new parents are not prepared for the amount of time a newborn spends crying. Infants, however, typically cry an average of 2 of every 24 hours during the first 7 weeks of life. The frequency seems to peak at age 6 or 7 weeks and then tapers off.

Almost all infants have a period during the day when they are wide awake and invariably fussy. New parents need to recognize this as normal and not worry that it means their child is ill. Parents might use this fussy time for bathing or playing with the infant, arranging their schedules accordingly. It is important to learn the infant's cues and to help the infant learn to self-quiet. The most typical time for wakefulness is between 6:00 and 11:00 PM, which, unfortunately, is when parents may be tired and least able to tolerate crying.

Whether to use pacifiers to reduce crying is a question parents must decide for themselves, depending on how they feel about them and their infant's needs. It is rare that infants have such a need for sucking they must have a pacifier in their mouth constantly. Discussing a few pros and cons with parents helps clarify the subject.

An infant who completes a feeding and still seems restless and discontented, who actively searches for something to put into the mouth, and who sucks on hands and clothes may need the increased sucking activity a pacifier provides. The major drawback of pacifiers is the problem of cleanliness. They tend to fall on the floor or sidewalk and are then put back into the infant's mouth. Clipping the pacifier onto the infant's shirt prevents this problem. If parents use pacifiers, be certain they are of one-piece construction, so that loose parts cannot be aspirated.

Parental Concerns Related to Breathing. Some parents report that their newborns have stuffy noses or make snoring noises in their sleep and that they sneeze frequently. This occurs because most newborns continue to have some mucus in the upper respiratory tract and posterior pharynx for up to 2 weeks after birth. The snoring noise is a result of this mucus, not a cold. In addition, infants continue to breathe irregularly for about the first month. A new parent may wake at night, notice this breathing pattern, and grow alarmed that the baby is in respiratory distress. If these are the only symptoms, this is a normal newborn respiratory pattern. If the child has rhinitis (nasal discharge) or a fever, he or she needs to be seen by a health care provider, because these symptoms suggest an upper respiratory tract infection.

Continued Health Maintenance for a Newborn. Parents do not need to continue to weigh a newborn or take the temperature at home. These practices only cause worry, because weight fluctuates day by day, and infant activity and clothing can influence temperature. Teach parents to judge their infant's state of health by overall appearance, eagerness to eat, general activity, and disposition, as well as weight gain (Box 18.9).

Make certain that parents make and keep a health care appointment for a first newborn assessment according to their primary care provider's schedule (2 to 6 weeks). The mother was conscientious throughout pregnancy to bring a well child into the world. Parents must now begin a health care program to keep the child well.

Car Safety. Automobile accidents are a safety problem all during childhood. For protection while in automobiles, newborns should always be transported in car seats (Decina & Lococo, 2007). Without this protection, if a car stops suddenly, an infant can be thrown onto the floor or, in a collision, thrown out of the car or through the windshield. In an accident, centrifugal force on an infant can be as much as 450 lb,

BOX 18.9 ✻ Focus on Family Teaching

Determining If a Newborn Is Well

Q. Ms. Ruiz asks you, "Could you review with me how to know if a newborn is well?"

A. The following items are helpful to determine your newborn is well:

- Sucks as if she is hungry
- Possibly spits up a slight amount after feeding, but has no vomiting
- Moves bowels approximately three to four times per day (may be more often if breastfed), with stools that are loose or semiformed but not runny and watery
- Appears happy overall (despite a fussy period during the day) and sleeps for 2 to 3 hours at a time
- Has a normal temperature
- Breathes more rapidly than an adult, but breathing is easy and not stressed
- Skin is neither yellow nor blue in tone.

making it impossible for a passenger to hold onto a child. At a speed of only 30 mph, an infant may hit the dashboard with a force equal to a fall from a three-story building. If an adult holding the infant is not wearing a seat belt, the adult can be thrown against the infant, killing the child.

When purchasing a car seat, parents should look at the label to be sure the seat meets federal guidelines. Local health departments or Red Cross chapters have lists of all the approved car seats available in a particular area as well as details of their comparable features and cost. The AAP web site (http://www.aap.org) lists these as well. Some hospitals and Red Cross chapters loan infant car seats for temporary use, such as when visiting out of state with grandparents or when first coming home from the hospital. New cars are mandated to be equipped with lower anchors and tethers for car seats.

The best location for a car seat is the back seat of the car; this is especially true if the car has a passenger seat air bag, because the force of an air bag expanding could kill an infant in the front seat. While the infant is less than 21 lb or 26 in long, the best type of car seat is an "infant-only" seat that, when properly positioned, faces the back of the car (Fig. 18.30). The ideal model has a five-point harness with broad straps, which help spread the force of a collision over the chest and hips, and a shield, which cushions the head. A mirror can be positioned in the back seat so the parent can observe the infant from the front seat or while driving.

Parents should dress an infant in clothing with pant legs if the infant is to be placed in a car seat, because the harness crotch strap must pass between the legs for a snug and correct fit. Advise parents not to use a sack sleeper or papoose bunting; nor should they wrap the baby in a bulky blanket so that the straps do not fit securely while the baby is in the seat. To support the baby's head, parents can use a rolled-up receiving blanket, towel, or diaper on each side of the head. The AAP recommends to only use a manufactured head rest if it comes packaged with the car seat. To provide extra warmth, they can cut holes in a blanket for the harness and crotch straps to pass through, place the baby in the seat, fasten the buckles, and then fold the blanket over the child for warmth. A second blanket can be draped over the seat if needed.

FIGURE 18.30 Newborns should ride in a supportive car seat. Be certain every parent planning to drive a child home from the health care facility is properly equipped.

Infants should sit in a backward-facing seat until they are able to sit up without support, usually when they weigh about 21 lb. At that point, they are old enough for a forward-facing toddler seat. Caution parents that plastic car seats grow extremely hot in the summer, so they need to test the temperature of the surface before placing an infant in one. Stress also that it is dangerous to use a car seat improperly, such as not fastening the harness or not securing the seat belt. To ensure proper car seat installation, an inspection may be performed by a certified CPS (Child Passenger Safety) technician at a local inspection station. These may be located at http://www.seatcheck.org.

✔ Checkpoint Question 18.5

Ms. Ruiz is preparing to take her new daughter home. On about what day of life can she expect her baby's umbilical cord to fall off?

a. Day 1.
b. Days 2 to 3.
c. Days 6 to 10.
d. Day 30.

Key Points for Review

- Converting from fetal to adult respiratory function is a major step in adaptation to extrauterine life. Newborns need particularly close observation during the first few hours of life to determine that this adaptation has been made.
- Maintaining body heat is a second major problem of newborns. The temperature of the term baby's environment

should be about 75° F (24° C). When procedures that require undressing an infant for an extended period are being carried out such as circumcision, a radiant heat source should be used.

- Newborns may suffer hypoglycemia in the first few hours of life because they use energy to establish respirations and maintain heat. Signs of jitteriness and a blood glucose level of less than 45 mg/100 mL by heel-stick help to identify hypoglycemia.
- Identification bands should be attached securely to newborns; assess these bands carefully before hospital discharge. To help prevent the possibility of kidnapping, be certain of the identification of anyone to whom you give a newborn.
- To feel confident with newborn care, parents need to hold and give care in the hospital. Encouraging them to spend as much time as possible with a newborn is a major nursing role. Be certain parents have a car seat to use at discharge and know to schedule a well child visit for their newborn at 2 to 6 weeks.

CRITICAL THINKING EXERCISES

1. Beth Ruiz is the newborn described at the beginning of the chapter. Her mother is concerned because Beth seems small, is covered by erythema toxicum, and has noisy respirations. You discover that the family has no car seat to transport the baby home. What would you teach the mother to make her feel more comfortable with her newborn? What would you do about the car seat—ask that they stay until they can arrange to rent or borrow one, or discharge them?
2. When you are assessing Beth in her mother's room, what newborn reflexes would you assess? Suppose it is cold in the room, so that you have time to test only one reflex. Which one would you test, and why?
3. Beth has a port-wine stain on her left thigh. Her father tells you he is not concerned about this because he knows that all birthmarks fade by school age. How would you respond to him?
4. Examine the National Health Goals related to newborn care. Most government-sponsored money for nursing research is allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to the Ruiz family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to nursing care of a newborn. Confirm your answers are correct by reading the rationales.

Chapter 19

Nutritional Needs of a Newborn

KEY TERMS

- areola
- bifidus factor
- colostrum
- engorgement
- fore milk
- hind milk
- interferon
- lactiferous sinuses
- lactoferrin
- let-down reflex
- lysozyme
- prolactin

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe nutritional requirements for a term newborn.
2. Identify National Health Goals related to newborn nutrition that nurses can help the nation achieve.
3. Use critical thinking to assist parents with nutritional problem solving and be sure newborn nutrition is family centered.
4. Assess nutritional intake and feeding method of a newborn to determine adequate nutritional status.
5. Formulate nursing diagnoses related to newborn nutrition.
6. Identify outcomes for a newborn and parents related to nutrition.
7. Plan nursing care such as helping a mother decide on a type of infant feeding that will be satisfying for both her and her infant.
8. Implement nursing care such as supporting a new mother while breastfeeding.
9. Evaluate expected outcomes for achievement and effectiveness of care.
10. Identify areas related to nutrition and newborns that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of normal newborn nutrition with nursing process to achieve quality maternal and child health nursing care.

Linda Satir is a new mother of a term baby girl. During the pregnancy, she and her husband, Paul, both agreed Linda would breastfeed. Linda will be returning to work as an executive assistant after her 6-week maternity leave. She attempted to breastfeed her newborn in the birthing room with minimal success. As you offer to help her feed her baby for the second time, she says, "Do you think I made the right choice? Maybe I should formula feed her. Paul could help that way and I won't have to worry about what to do when I go back to work."

Previous chapters described the care of a woman and family during the antepartal, intrapartal, postpartal, and newborn periods. This chapter adds information about the nutritional needs of a newborn. A newborn's nutritional needs are high during this time because of a rapid rate of growth and development. Knowing these needs fortifies you to play a key role in educating parents about how to provide adequate nutrition to meet both physiologic and psychological needs of their newborn.

How would you answer Linda?

Proper nutrition is essential for optimal growth and development, especially in the first few months of life, because brain growth proceeds at such a rapid rate during this time. Providing adequate nutrition for a newborn extends beyond physiologic need, however; it also fulfills important psychological needs. During feeding, a parent is close to the infant, and a baby is apt to be particularly sensitive to the parent's demonstration of affection or lack of warmth. An infant who does not experience a warm relationship with a mother or primary caregiver may fail to thrive as surely as one who is denied sufficient protein or calories (Britton et al., 2009). National Health Goals related to newborn nutrition are shown in Box 19.1.

BOX 19.1 * Focus on National Health Goals

The number of National Health Goals that address nutrition of a newborn was increased in the midcourse review to include two that speak to exclusive breastfeeding.

- Increase to at least 75% the proportion of mothers who breastfeed their babies in the early postpartum period from a baseline of 64%.
- Increase to at least 50% the proportion of mothers who continue breastfeeding until their babies are 5 to 6 months old from a baseline of 29%.
- Increase to 25% the proportion of mothers who continue breastfeeding until 1 year of age from a baseline of 16%.
- Increase to at least 60% the proportion of mothers who breastfeed exclusively through 3 months from a baseline of 43%.
- Increase to 25% the proportion of mothers who breastfeed exclusively through 6 months from a baseline of 13%.
- Decrease the proportion of children with untreated dental decay in primary or permanent teeth to 21% from a baseline of 29% (http://www.nih.gov).

Nurses can help the nation achieve these goals by educating women about breastfeeding during pregnancy and supporting a family during the postpartal period while a woman is breastfeeding. Home visits with postpartal families and well-child health assessments provide opportunities to advocate for continued and exclusive breastfeeding. For the woman who will formula feed her infant, education during pregnancy should include the fact that putting an infant to bed with a bottle of milk or juice is associated with tooth decay and should be avoided.

Areas that could benefit from additional nursing research include techniques parents could use to initiate sleep without using a bedtime bottle; reasons women discontinue breastfeeding early in the postpartal period; and legislation or education necessary in the workplace to encourage women to continue breastfeeding after they return to work.

Nursing Process Overview

For Promoting Nutritional Health in a Newborn

Assessment

Assessment of infant nutrition begins during pregnancy with assessment of the mother's and father's attitudes and choices about infant feeding. Breastfeeding is widely accepted as the preferred method of human newborn nutrition. However, if a mother chooses not to breastfeed because of her individual circumstances, it is important that she not be made to feel guilty for her choice, because formula feeding can be substituted. Most important, parents need to feel comfortable with and confident about the feeding method they choose.

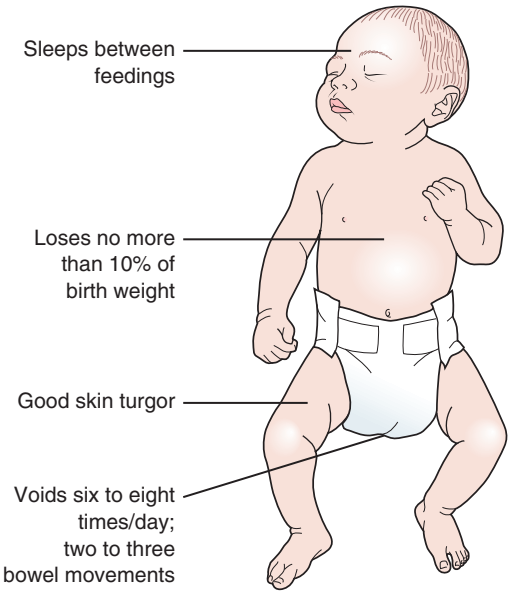
Teach parents how to recognize signs of hunger in a newborn such as restlessness, tense body posture, smacking lips, and tongue thrusting. Otherwise, they may wait for their infant to cry, and this is actually a late sign of newborn hunger. Once infant feeding begins, teach parents to assess whether the amount the infant is receiving is adequate—not by how long the newborn breastfeeds at a time or by how much formula is taken at a feeding, but by a larger measure, such as whether the newborn is voiding, growing, and alert (Box 19.2). A formula-fed newborn regains birth weight at about 10 days, a breastfed infant at about 14 days.

Nursing Diagnosis

Nursing diagnoses in relation to nutrition usually center on a woman's choice regarding method of feeding or a newborn's nutritional intake and feeding patterns. It may be difficult to establish diagnoses during the first part of the

Box 19.2 Assessment

Assessing the Newborn for Adequate Nutrition



newborn period, because the mother and infant are still getting used to each other. Examples of nursing diagnoses are:

- Effective breastfeeding related to well-prepared mother and healthy newborn
- Risk for ineffective breastfeeding related to nipple soreness
- Imbalanced nutrition, less than body requirements, related to poor newborn sucking response
- Risk for impaired parenting related to need to formula feed newborn

Outcome Identification and Planning

As breastfeeding is best for newborns, planning begins while a woman is still pregnant, focusing on providing her with the information necessary to allow her to become familiar and comfortable with breastfeeding. After birth, a teaching plan addressing the nutritional needs of both the woman and her newborn can be developed. Helpful Internet sites for referral are La Leche League International (http://www.llli.org) and the International Lactation Consultant Association (http://www.ilca.org). Despite the advantages of breastfeeding, some parents still choose formula feeding because of their individual preferences. Parents who choose formula feeding need to plan ways to make feeding time special for both themselves and the baby. An Internet site that discusses formula feeding is a pediatrician's site, http://www.askdrsears.com.

Implementation

A major intervention related to newborn nutrition is supporting a mother's choice of feeding method and helping her to trust her judgment as to whether her infant is full and content and the feeding method is as natural as possible. In addition to sponsoring classes on breastfeeding, a helpful service of La Leche League is its hotline, through which a breastfeeding woman who is discouraged or is having difficulty can contact a member and ask for advice. *The Womanly Art of Breastfeeding*, published by the League (2004), is a comprehensive and informative book to recommend for both new mothers and fathers.

When assisting a new mother with breastfeeding, remember that breast milk can carry the human immunodeficiency virus (HIV). Adhere to standard infection precautions, therefore, when helping with manual expression of milk or disposing of soiled breast pads.

Outcome Evaluation

Evaluation is an important final step to ensure that a newborn receives adequate nutrition, because unforeseen circumstances, such as an unsuspected milk allergy or mastitis (breast infection), may interfere and require drastic changes to reach desired outcomes. Help parents appreciate that newborns are very adaptive and can adjust to another feeding method if necessary. Examples suggesting successful expected outcomes related to newborn feeding are:

- Infant breastfeeds every 2 to 3 hours; is content and sleeps between feedings.
- Newborn ingests a total of 12 oz of formula with iron every 24 hours.
- Mother states she feels satisfied with chosen method of infant feeding.
- Infant voids six times daily as a measure of adequate hydration by 1 week.

NUTRITIONAL ALLOWANCES FOR A NEWBORN

Nutritional allowances for a newborn need to take into account total calories, protein, vitamins, minerals, and fluid. Dietary reference intake for calories, protein, vitamins, and minerals for newborns are shown in Table 19.1.

Calories

Growth in the neonatal period and early infancy is more rapid than at any other period of life (Raab, 2007). Therefore, the caloric requirements exceed those at any other age. An infant up to 2 months of age requires 110 to 120 calories per kilogram of body weight (50 to 55 kcal/lb) every 24 hours to provide an adequate amount for maintenance and growth. After 2 months of age, this amount gradually declines until the requirement at 1 year is 100 kcal/kg (45 kcal/lb) per day. In contrast, the adult requirement is 42 kcal/kg (20 kcal/lb) per day.

The actual caloric requirement, of course, depends on an infant's individual activity level and growth rate. For example, an active infant, one who cries frequently and squirms constantly, needs more calories than one who is more passive, content to spend long hours playing quietly or just studying the environment. During growth spurts, more calories are needed to supply additional energy.

TABLE 19.1 ✻ Dietary Reference Intakes For Newborns And Infants

Nutrient	Recommended Dietary Allowance	
	Birth to 6 Mo	*6 Mo to 1 Yr*
Calories	kg × 110	kg × 100

Commercial infant formulas simulate breast milk. They contain about 9% to 12% of their calories as protein and 45% to 55% of calories as lactose carbohydrate. The balance is fat, of which about 10% (4% of the calories) is linoleic acid.

Protein

Protein, necessary for the formation of new cells, has a high requirement during the newborn and infancy periods to provide for rapid growth of new cells as well as maintenance of existing cells. The nutritional allowance of protein for the first 2 months of life is 2.2 g per kilogram of body weight. Both human milk and commercial formulas provide all the essential amino acids necessary to form protein. Histidine, an amino acid that appears to be essential for infant growth but is not necessary for adult growth, is found in both milk forms.

Unaltered cow's milk is not recommended for newborns, because it contains about 16% of its calories as protein, whereas human milk contains about 8%. This means that cow's milk can create such a rich solute load (the amount of urea and electrolytes that must be excreted in the urine) that a newborn's kidneys could be overwhelmed. In addition, the protein in cow's milk, casein, differs from that in human milk, lactalbumin, both in composition and in amount. The amount of casein present in milk determines its curd tension. The curd in cow's milk is large, tough, and difficult to digest, whereas in human milk the curd is softer and easier to digest. This is the rationale for formula-fed infants to be given a commercial formula containing albumin rather than cow's milk. Cow's milk products, such as yogurt and cottage cheese, should not be introduced until 9 to 12 months of age for the same reason.

Fat

Linoleic acid, an essential fatty acid necessary for growth and skin integrity in infants, is found in both human milk and commercial formulas. Use of fat-free milk for long periods (when other sources of food are not being offered) can result in linoleic acid deficiency. Therefore, parents should not feed fat-free milk as a means of preventing obesity in a young infant. In addition, fat-free milk does not contain sufficient calories for a newborn; it has only about half as many calories as commercial formulas or breast milk.

Carbohydrate

Lactose, the disaccharide found in human milk and added to commercial formulas, appears to be the most easily digested of the carbohydrates. Lactose also improves calcium absorption and aids in nitrogen retention. It produces stools consisting predominantly of gram-positive rather than gram-negative bacteria and therefore decreases the possibility of gastrointestinal illness (which usually results from gram-negative organisms). Adequate lactose also allows protein to be used for building new cells rather than for calories, encouraging normal water balance and preventing abnormal metabolism of fat. Lactose intolerance, which can occur in older children, is rarely present in newborns; they typically use the calories provided by lactose well.

Fluid

It is important to maintain a sufficient fluid intake in newborns because their metabolic rate is so high (and metabolism requires water). In addition, a newborn's body surface area is large in relation to body mass. This means that a baby loses water by evaporation much more readily than does an adult. Because the kidneys of a newborn are not yet capable of fully concentrating urine, a newborn cannot conserve body water by this mechanism to prevent dehydration.

Another difference between newborns and adults is that body water is distributed differently. In a newborn, 30% to 35% of body weight is extracellular fluid; in an adult, this proportion is only 20%. Consequently, if a newborn's extracellular fluid store is depleted through loss of fluid or inadequate fluid intake, as much as 35% of a newborn's fluid component may be lost.

Because of all these factors, a newborn needs 150 to 200 mL/kg (2.5 to 3.0 oz/lb) of water intake every 24 hours (adults require 2400 mL/day or less than 1 oz/lb). This requirement can be supplied completely by breastfeeding or formula feeding. Fruit juice is not recommended as a supplemental fluid because it supplies no protein and, if not pasteurized, can carry infectious organisms (American Academy of Pediatrics [AAP] Committee on Nutrition, 2001).

Minerals

A number of minerals are particularly important to early growth.

Calcium

Calcium is an important mineral in the newborn period because a newborn's skeleton is growing so rapidly. Because milk is high in calcium, tetany resulting from a low calcium level seldom occurs in infants who suck well, regardless of whether they are fed human milk or commercial formula.

Iron

The term newborn of a mother who had an adequate iron intake during pregnancy will be born with iron stores that, theoretically, last for the first 3 months of life, until the newborn begins to produce adult hemoglobin. Because not all mothers eat an iron-rich diet during pregnancy (and socioeconomic level is not a good criterion for judging the quality of a diet), the AAP recommends that infants who are formula fed ingest an iron enriched formula for the entire first year of life (AAP Committee on Nutrition, 1999). It is unnecessary to provide iron supplementation for breastfed infants, because breast milk usually provides an adequate amount of iron.

Fluoride

Fluoride is essential for building sound teeth and for preventing tooth decay. Because teeth grow into their primary form during pregnancy, it is important for women to drink fluoridated water during pregnancy. A lactating mother should continue drinking fluoridated water (although only a small amount of fluoride passes into breast milk), and formulas should be prepared with fluoridated water. This is an essential point to remember, because a mother may think she is helping her child by using bottled, "natural" water in formula rather than chlorinated (and fluoridated) water from a tap.

If a mother is breastfeeding and a source of fluoridated water is not available (the family drinks well, spring, or bottled water, or the tap water is not fluoridated), a fluoride sup-

plement, 0.25 mg daily, may be given to the infant beginning at 6 months of age. Remind parents that too much fluoride can be detrimental or cause staining of the teeth, to prevent them from giving infants unnecessary fluoride supplements.

Vitamins

Vitamin additives are unnecessary for a formula-fed infant because vitamins A, C, and D are incorporated into commercial formula. Because vitamins are naturally included in breast milk, supplementation is not necessary for breastfed infants either. If a newborn will not be exposed to sunlight for some reason, 400 U of vitamin D daily may be prescribed for the breastfeeding mother, to increase the level of the vitamin in breast milk, or given to the formula-fed infant. Additional vitamins are not usually begun until the infant approaches 6 months of age.

BREASTFEEDING

It is universally agreed that breast milk is the preferred method of feeding a newborn, because it provides numerous health benefits to both a mother and an infant; it remains the ideal nutritional source for infants through the first year of life (American College of Obstetricians & Gynecologists [ACOG], 2007). Nurses are prime people to teach women about the benefits of breastfeeding and provide anticipatory guidance for problems that may occur (Li, Rock, & Grummer-Strawn, 2007). You can also help create an atmosphere conducive to breastfeeding success in health care facilities by implementing steps such as:

- Educating all pregnant women about the benefits and management of breastfeeding
- Helping women initiate breastfeeding within half an hour after birth
- Assisting mothers to breastfeed and maintain lactation even if they should be separated from their infant
- Not giving newborns food or drink other than breast milk unless medically indicated, so they are hungry to breastfeed
- Supporting rooming-in (such as allowing mothers and infants to remain together) 24 hours a day
- Encouraging breastfeeding on demand
- Fostering the establishment of breastfeeding support groups and referring mothers to them on discharge from the birthing center or hospital

Women are recognized as the "keepers of the culture," or the main people who transmit customs to the next generation. Chief among these customs is the method for feeding newborns. The rate of breastfeeding varies in communities from almost 70% to a low of 13% as this is culturally influenced (Singh, Kogan, & Dee, 2007). If a woman comes from a family where no one has ever breastfed, she may be very interested in being a "pioneer" in her family. On the other hand, she may be more interested in following her family's tradition of formula feeding.

How soon women want to begin breastfeeding after birth is also culturally determined. Although it is the usual practice in hospitals to begin immediately after birth, some cultures believe that colostrum is not appropriate for newborns and have a cultural preference not to begin breastfeeding until milk is present, at about 3 days of age. It is necessary to assess each family individually to recognize cultural preferences such as these.

Physiology of Breast Milk Production

Breast milk is formed in the acinar or alveolar cells of the mammary glands (Fig. 19.1). With the delivery of the placenta, the level of progesterone in a woman's body falls dramatically, stimulating the production of **prolactin,** an anterior pituitary hormone. Prolactin acts on the acinar cells of the mammary glands to stimulate the production of milk. In addition, when an infant sucks at a breast, nerve impulses travel from the nipple to the hypothalamus to stimulate the production of prolactin-releasing factor. This factor stimulates further active production of prolactin. Other anterior pituitary hormones, such as adrenocorticotropic hormone, thyroid-stimulating hormone, and growth hormone, probably also play a role in growth of the mammary glands and their ability to secrete milk.

Colostrum, a thin, watery, yellow fluid composed of protein, sugar, fat, water, minerals, vitamins, and maternal antibodies, is secreted by the acinar breast cells starting in the fourth month of pregnancy. For the first 3 or 4 days after birth, colostrum production continues. Because it is high in protein and fairly low in sugar and fat, colostrum is easy to digest and capable of providing adequate nutrition for a newborn until it is replaced by transitional breast milk on the second to fourth day. True or mature breast milk is produced by the 10th day.

Milk flows from the alveolar cells, where it is produced, through small tubules to reservoirs for milk, the **lactiferous sinuses,** located behind the nipple. This constantly forming milk is called **fore milk.** Its availability depends very little on the infant's sucking at the breast. As the infant sucks at the breast, oxytocin, released from the posterior pituitary, causes the collecting sinuses of the mammary glands to contract,

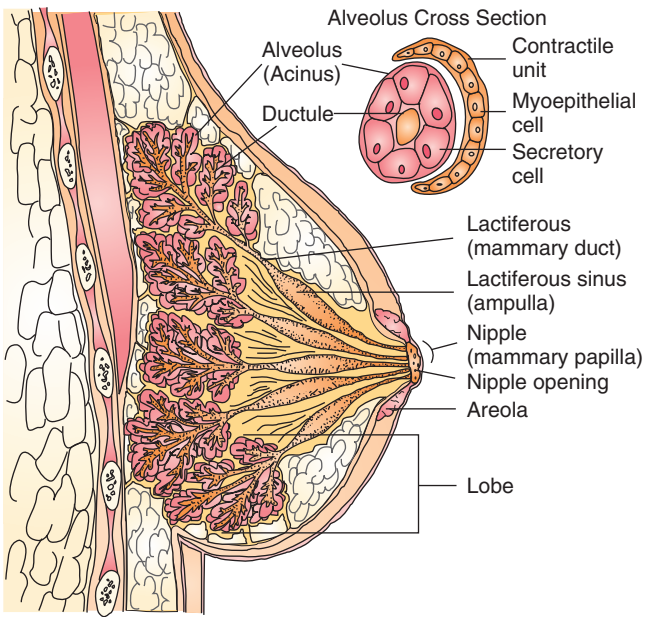

FIGURE 19.1 Anatomy of the breast.

forcing milk forward through the nipples, making it available for the baby. This action is called a **let-down reflex.** A let-down reflex may also be triggered by the sound of a baby crying or by thinking about the baby. New milk, called **hind milk,** is formed after the let-down reflex. Hind milk, higher in fat than fore milk, is the milk that makes a breastfed infant grow most rapidly. Release of oxytocin has a second advantage in that, by causing smooth muscle contraction, it helps contract the uterus. As a result, a woman may feel a small tugging or cramping in her lower pelvis during the first few days of breastfeeding (afterpains) (Pavone & Purinton, 2007).

Advantages of Breastfeeding

Little controversy exists about breastfeeding as the best nutrition for human infants, but the ultimate decision to breastfeed should depend on what would please a woman and her infant most. If she is pleased with what she is doing, her infant will be comfortable and pleased, will enjoy being fed, and will thrive.

Breastfeeding is contraindicated in only a few circumstances, such as:

- An infant with galactosemia (such infants cannot digest the lactose in milk)
- Herpes lesions on a mother's nipples
- Maternal diet is nutrient restricted, preventing quality milk production
- Maternal exposure to radioactive compounds (e.g., during thyroid testing)
- Breast cancer
- Maternal active, untreated tuberculosis, hepatitis B or C, cytomegalovirus, or human immunodeficiency syndrome
- Maternal active, untreated varicella. Once the infant has been given varicella zoster immunoglobulin, the infant can receive expressed breast milk if there are no lesions on the breast. Within 5 days of the appearance of the rash, maternal antibodies are produced, and thus breastfeeding could be beneficial in providing passive immunity against varicella (Sadeharju et al., 2007)
- Mothers receiving antimetabolites or chemotherapeutic agents
- Mothers receiving prescribed medications that would be harmful to an infant such as lithium or methotrexate
- A mother lives in an area where environmental contaminants can be carried via breast milk to the infant (AAP Committee on Drugs, 2002)

A number of situations call for individual planning such as a mother or an infant too ill for breastfeeding or a mother who has undergone breast-reduction surgery where the nipples were detached during surgery.

Advantages for a Mother

A woman gains several physiologic benefits from breastfeeding:

- Breastfeeding may serve a protective function in preventing breast cancer.
- The release of oxytocin from the posterior pituitary gland aids in uterine involution.
- Successful breastfeeding can have an empowering effect, because it is a skill only a woman can master.
- Breastfeeding reduces the cost of feeding and preparation time.
- Breastfeeding provides an excellent opportunity to enhance a true symbiotic bond between mother and child. Although this does occur readily with breastfeeding, a woman who holds her baby to formula feed can form this bond as well.

Common reasons that women give for not exclusive breastfeeding are (a) they want to provide the "best of both" or ensure that their babies get both the healthy aspects of breast milk and "vitamins" in formula, (b) breastfeeding can be embarrassing in public places, and (c) relatives give messages that supplementation is good for babies who are crying or not chubby (Deshpande, 2008).

Some women believe that breastfeeding, because it causes a delay in menstruation (lactational amenorrhea), is a foolproof contraceptive technique. It is not: 50% of women resume ovulating by the fourth week after delivery, even while breastfeeding (Van der Wijden, Kleijnen, & van den Berk, 2009).

Some women believe that breastfeeding will help them lose weight gained during pregnancy. This also is not true, and women who are breastfeeding need to concentrate on eating a well-balanced diet to ensure their milk will be rich in nutrients. Some women are reluctant to breastfeed because they fear that having to be available to feed the baby every 3 or 4 hours will tie them down. Like mothers who formula feed, however, they can leave a bottle (with expressed breast milk) with the baby's father or a caregiver if they need to be away from their baby at the time of a feeding.

Advantages for an Infant

Breastfeeding has major physiologic advantages for an infant as well. Breast milk contains secretory immunoglobulin A (IgA), which binds large molecules of foreign proteins, including viruses and bacteria, keeping them from being absorbed from the gastrointestinal tract into the infant. **Lactoferrin** is an iron-binding protein in breast milk that interferes with the growth of pathogenic bacteria. The enzyme **lysozyme** in breast milk apparently actively destroys bacteria by lysing (dissolving) their cell membranes, possibly increasing the effectiveness of antibodies. Leukocytes in breast milk provide protection against common respiratory infectious invaders. Macrophages, responsible for producing **interferon** (a protein that protects against viruses), help interfere with virus growth. The **bifidus factor** is a specific growth-promoting factor for the beneficial bacteria *Lactobacillus bifidus.* The presence of *L. bifidus* in breast milk interferes with the colonization of pathogenic bacteria in the gastrointestinal tract, reducing the incidence of diarrhea.

In addition to these anti-infective properties, breast milk contains the ideal electrolyte and mineral composition for human infant growth. It is high in lactose, an easily digested sugar that provides ready glucose for rapid brain growth. The protein in breast milk is easily digested, and the ratio of cysteine to methionine (two amino acids) in breast milk favors rapid brain growth in the early months. It contains nitrogen in compounds other than protein, so that an infant can receive cell-building materials from sources other than just protein.

Breast milk contains more linoleic acid, an essential fatty acid for skin integrity, and less sodium, potassium, calcium, and phosphorus than do many formulas. Breast milk also has a better balance of trace elements, such as zinc. These levels

of nutrients are enough to supply the infant's needs, yet they spare the infant's kidneys from having to process a high renal solute load of unused nutrients. Women who have a familial history of allergy are usually encouraged to breastfeed to try and eliminate the possibility of exposing their infant to cow's milk protein, which could be allergenic this early in life (Hampton, 2008).

Yet another advantage is that breastfed newborns appear to be able to regulate their calcium/phosphorus levels better than infants who are formula fed. Decreased calcium levels in a newborn can lead to tetany (muscle spasm). The increased concentration of fatty acid in commercial formulas may bind calcium in the gastrointestinal tract, increasing the danger of tetany. Breastfeeding may also help prevent excessive weight gain in infants (Box 19.3).

A great deal of discussion about the benefits of breastfeeding has centered on the effects of breastfeeding on the formation of the dental arch, because babies suck differently from a breast than from a bottle (Fig. 19.2). Babies pull their tongue backward as they suck from a breast. They thrust their tongue forward to suck from a rubber nipple. That may make breastfeeding the best preparation for forming common speech sounds (Ferguson & Molfese, 2007).

✔ Checkpoint Question 19.1

Newborns need more fluid than adults, because their extracellular fluid component differs from that of adults. How much of a newborn's body weight is extracellular fluid?

a. 20%, compared with 35% in an adult.
b. 35%, compared with 20% in an adult.
c. 50%, compared with 70% in an adult.
d. 70%, compared with 40% in an adult.

BOX 19.3 ✻ Focus on Evidence-Based Practice

Can breastfeeding help reduce the epidemic of obesity in children?

To answer this question, researchers studied the health records of 3692 children at 4 years of age to determine whether they were overweight and whether they had been breastfed.

Overweight was defined as body mass index for age at the 95th percentile and above. Results of the study showed that the longer the period of breastfeeding, the more apt a child was less likely to be overweight, or breastfeeding offered a significant protective association against childhood obesity for non-Hispanic children.

Would this study be helpful when discussing an advantage of breastfeeding?

Source: Procter, S. B., & Holcomb, C. A. (2008). Breastfeeding duration and childhood overweight among low-income children in Kansas, 1998–2002. *American Journal of Public Health, 98*(1), 106–110.

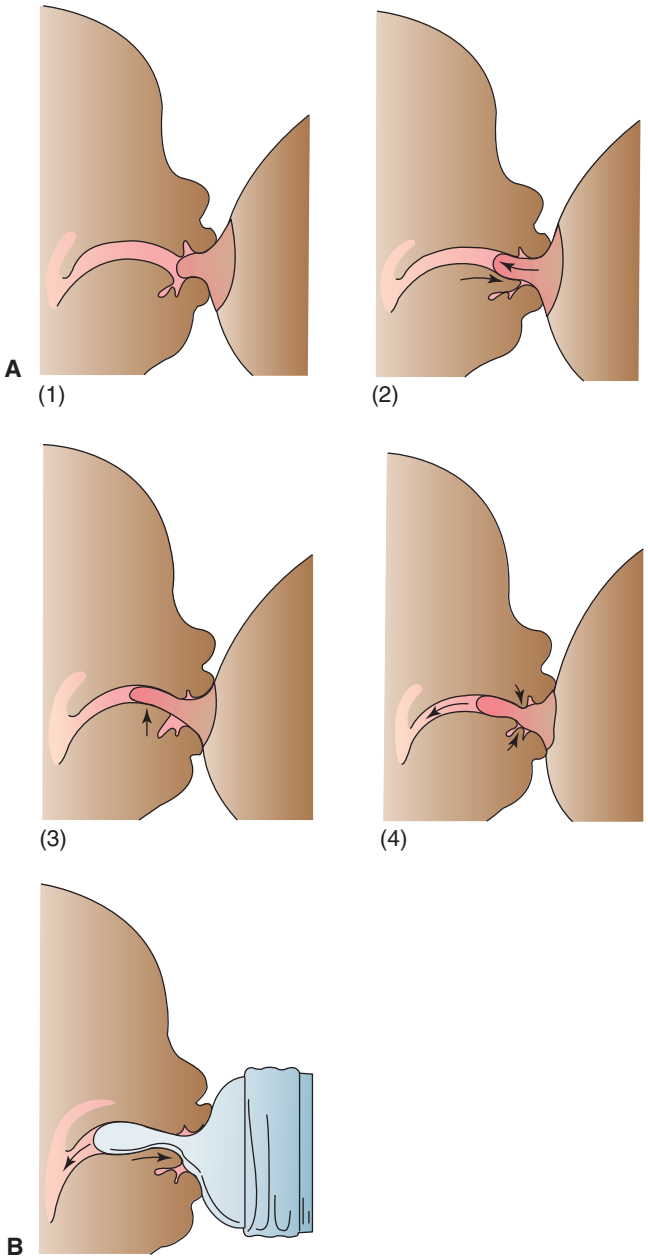

FIGURE 19.2 Differences in sucking mechanism. (**A**) The breast. (**1**) Lips of the infant clamp in a C-shape. The cheek muscles contract. (**2**) The tongue thrusts forward to grasp nipple and areola. (**3**) The nipple is brought against the hard palate as the tongue pulls backward, bringing the areola into the mouth. (**4**) The gums compress the areola, squeezing milk into the back of the throat. (**B**) Formula feeding. The large rubber nipple of a bottle strikes the soft palate and interferes with the action of the tongue. The tongue moves forward against the gums to control the overflow of milk into the esophagus.

Techniques of Breastfeeding

Ask all women during pregnancy whether they plan to breastfeed or formula feed their newborn as thinking about feeding in advance allows couples to make informed choices. Some fathers experience jealousy at the thought of breastfeeding. Early discussion can help them work through this

natural sensation, with the eventual realization that parenting will involve many other opportunities for interaction with their child.

Physical preparation such as nipple rolling, advised in the past as a way of making a woman's nipples more protuberant, is not necessary because few women have inverted or nonprotuberant nipples. In addition, oxytocin, which is released by this maneuver, could lead to preterm labor (nipple rolling is used to create uterine contractions for stress tests). The occasional woman who has inverted nipples may need to wear a nipple cup (a plastic shell) to help her nipples become more protuberant.

Practicing breast massage to move the milk forward in the milk ducts (manual expression of milk) may be helpful. This can help a woman who feels hesitant about handling her breasts grow accustomed to doing so, and allows her to assist with milk production in the first few days after birth. Manual expression consists of supporting the breast firmly, then placing the thumb and forefinger on the opposite sides of the breast, just behind the areolar margin, first pushing backward toward the chest wall and then downward until secretions begins to flow (Box 19.4). During the last months of pregnancy and immediately after birth, the fluid obtained will be colostrum. By the third day of infant life, milk will be obtained.

Teach women to wash their breasts with clear water because soap tends to dry and crack nipples.

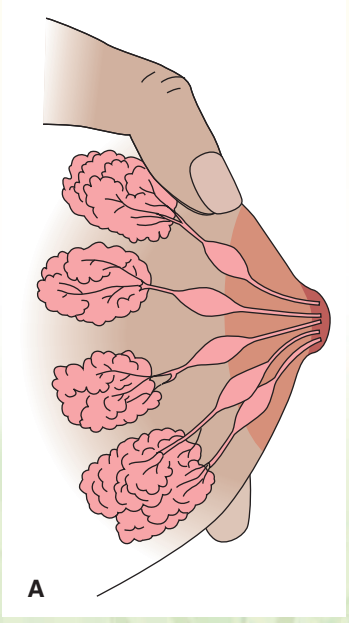
Beginning Breastfeeding

Breastfeeding should begin as soon after birth as possible, ideally while the woman is still in the birthing room and while the infant is in the first reactivity period (Forster & McLachlan,

Box 19.4 Nursing Procedure ✻ Manual Breast Milk Expression

Purpose: To assist the woman to manually express milk so she can strengthen her milk supply and supply milk for her newborn should she be separated from the newborn

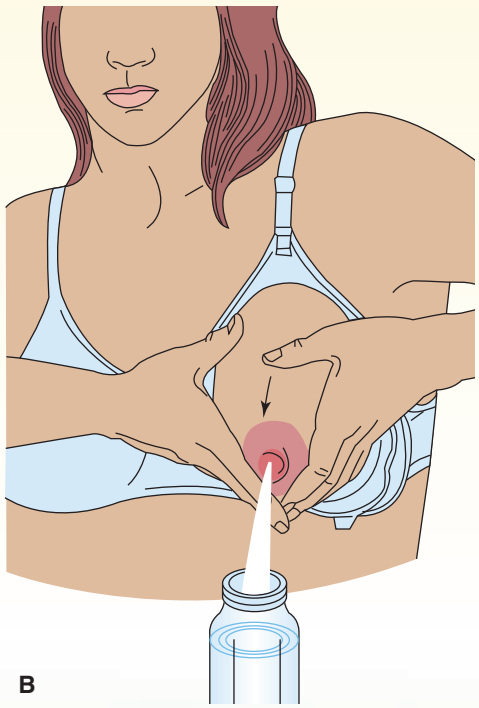
Procedure	Principle
1. Explain the procedure to the client.	**1.** Explanations help decrease anxiety and enhance learning; they also provide information for the client to carry out the procedure on her own.
2. Assemble equipment, including a clean towel and collection container.	**2.** Assembling equipment aids in organization and efficiency.
3. Wash your hands and put on clean gloves; have client wash her hands.	**3.** Handwashing prevents the transmission of infection; use of gloves protects self and client from possible infection.
4. Provide privacy and place the woman in a comfortable sitting position.	**4.** The let-down reflex may not occur readily if the woman is tense or nervous.
5. Instruct the woman to place her right hand on her right breast, with her right thumb on the top of the breast at the outer limit of the areola and her right fingers underneath the breast. Tell the woman to press inward toward the chest wall (Fig. A).	**5.** Milk is expressed by pressure on the collecting ducts, not the nipple.



A

Box 19.4 Nursing Procedure ✻ Manual Breast Milk Expression

6. Help the woman hold the collecting jar just under her nipple.	**6.** Collecting bottles should be made of plastic to preserve antibodies found in milk; having the container close by prevents waste of any breast milk that is expressed.
7. Have the woman slide her hand forward in a milking motion, causing the milk to be expressed from the nipple into the container (Fig. B).	**7.** Pressure on the lactiferous sinuses pushes milk forward.



B

8. Have the woman move her thumb and fingers around her breast, repeating the technique.	**8.** Repeating the technique ensures that all milk sinuses are emptied.
9. Caution the woman not to use excess force.	**9.** Excess force will damage sensitive breast tissue.
10. After collection, refrigerate milk if it will be used within 24 hours; freeze if this time is longer.	**10.** Breast milk spoils in the same manner as cow's milk if not protected.
11. Reinforce the woman's success with this maneuver, regardless of the amount of breast milk expressed.	**11.** Manual breast milk expression is an easy technique to carry out once it is learned, but it can be difficult to grasp at first. Positive reinforcement enhances progress and self-esteem.

2007). The release of oxytocin by breastfeeding at this time begins the let-down of milk and also stimulates uterine contraction. However, if the woman is overly fatigued or extremely modest, trying to learn this new skill at this time may only convince her that breastfeeding is not for her.

Most women enjoy having an experienced nurse with them for a first feeding to offer suggestions. It is important that infants open their mouths wide enough to grasp both the nipple and the **areola** (the pigmented circle surrounding the nipple) when sucking. This gives them effective sucking action and helps to empty the collecting sinuses completely.

Milk forms in response to being used. If breasts are completely emptied, they completely fill again. If half emptied, they only half fill, and, after a time, milk production will be insufficient for proper nourishment. A woman should always place her infant first at the breast at which the infant fed last in the previous feeding, to help ensure that each breast is completely emptied at every other feeding.

Because it takes less energy for an infant to suck at a bottle, urge parents not to offer bottles of breast milk until 4 to 6 weeks of age, after they are thoroughly accustomed to breastfeeding. The American Academy of Pediatrics (2008) recommends the use of pacifiers when placing infants to sleep for the first year of life to help prevent sudden infant death syndrome (SIDS) but delaying this practice until 1 month of age in breastfed infants. As one of the reasons that SIDS may occur is the infant rebreathing expired carbon dioxide–rich air, using a fan in the room during sleep or opening a window so there is a breeze in the room may be yet another way the incidence of SIDS can be reduced (Coleman-Phox, Odouli, & Li, 2008).

What if... Linda told you that she doesn't want to breastfeed but her husband is insisting that she do so? What would you do?

Prolonged Jaundice in Breastfed Infants

Jaundice occurs in as many as 15% of breastfed infants. This is because pregnanediol (a breakdown product of progesterone) in breast milk depresses the action of glucuronyl transferase, the enzyme that converts indirect bilirubin to the direct form, which is then readily excreted in bile (Huether, & McCance, 2008). To prevent hyperbilirubinemia in their infant, women should feed frequently in the immediate birth period, because colostrum is a natural laxative and helps promote passage of meconium and bile. Newborns who are discharged early need to be observed for jaundice while at home. However, breastfeeding rarely results in a serum bilirubin level high enough to warrant therapy or to require discontinuation of breastfeeding, because pregnanediol remains in breast milk for only 24 to 48 hours (Thilo & Rosenberg, 2008).

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Health-seeking behaviors related to lack of knowledge about lactation and breastfeeding techniques

Outcome Evaluation: Woman states correct information as to how lactation begins and is maintained in adequate supply; demonstrates effective positioning for baby and herself by 24 hours.

In cultures where breastfeeding is practiced by almost all mothers, the technique is learned early in life by observation. In the United States, women may have had few, if any, opportunities to observe breastfeeding. Lactation consultants are health care professionals especially educated to assist women with breastfeeding. Making a referral to such a person can be extremely helpful. With managed care, however, fewer such specialists may be available, so all nurses need to be well prepared to assist with breastfeeding.

When a woman first begins breastfeeding, help her learn to reserve a special part of her day for this so she can relax to do it. If she is tense and anxious, she may have difficulty achieving a let-down reflex, and her infant may have difficulty obtaining adequate milk. This can lead to increasing tension and anxiety because the infant does not seem content. As a result, the infant becomes hungrier and is left even more unsatisfied, creating a vicious circle of events. Support, adequate instruction, and reassurance from health care personnel are important in helping a woman feel secure enough to be able to relax (Furber & Thomson, 2007). Rooming-in is ideal for breastfeeding, because it allows a woman to sense when her infant is hungry and feed before the infant grows fatigued from crying or her breasts grow uncomfortable from filling.

FIGURE 19.3 Side-lying position for breastfeeding.

Many women who are breastfeeding sleep with their infant at night so they can easily breastfeed (bed sharing). As studies as to whether bed sharing increases the incidence of sudden infant death are contradictory, bed sharing should not be recommended, especially before 11 weeks of age (Ateah & Hamelin, 2008).

Provide Information Regarding Lactation and Proper Positioning Techniques. Breast milk looks like nonfat milk. It is thin and almost blue-tinged in appearance. Some women may need assurance that this color and consistency are normal; otherwise, they may think their milk is not nutritious enough.

Before breastfeeding, recommend that a woman wash her hands to be sure they are free of pathogens picked up from handling perineal pads or other sources. Washing her breasts is not necessary unless she notices caked colostrum on the nipples. When she is first attempting to breastfeed, lying on her side with a pillow under her head is a good position to use (Fig. 19.3). This relieves fatigue because it allows her infant to rest on the bed. Figure 19.4

FIGURE 19.4 Sitting position for breastfeeding.

shows a sitting position with a pillow under the baby. Using a football hold with the baby supported on a pillow also may be helpful, especially if a mother had a cesarean birth.

Brushing the infant's cheek with a breast nipple stimulates a newborn's rooting reflex. The baby then turns toward the breast. Do not try to initiate a rooting reflex by pressing a baby's face against the mother's breast; this will cause the child to turn away from the mother and toward your hand. Although not well documented as to efficiency or reliable results, an assessment tool such as the LATCH assessment (Table 19.2) can provide measures to help evaluate a newborn's breastfeeding effectiveness (Howe et al., 2008).

If a woman has large breasts, the infant may have trouble breathing while nursing because breast tissue presses against the nose. A woman can prevent this happening by grasping the areolar margin of her breast between her thumb and forefinger, holding the bulk of the breast supported while her infant feeds. This also makes the nipple more protuberant.

During the first few days of life, because they are receiving only colostrum and need the nutrients and fluid obtained by frequent sucking, babies should be fed as often as they seem hungry (every 2 to 3 hours). Frequent feeding also is advantageous to sustain a milk supply, because the more often breasts are emptied, the more efficiently they fill and continue to maintain a good supply of milk.

As important as making certain that infants grasp the breast areola is helping them to break away from the breast when they are through feeding. Teach a woman to insert a finger in the corner of the infant's mouth or pull down the infant's chin to release suction. Otherwise, the baby may pull too hard on the nipple, causing cracking or soreness.

Promote Adequate Sucking. Often, a newborn being breastfed drops off to sleep during the first few feedings. To both stimulate milk production effectively and ensure adequate fluid intake, a woman may need to keep the infant awake and urge him or her to suck. Advise mothers to be sure to awaken newborns fully before feeding by handling them, stroking their backs, changing their position, rubbing their arms and chest, or changing their diaper. Gently tickling the bottom of a baby's feet will also wake a baby effectively. Many women are unwilling to cause their newborns discomfort in these ways. This reaction is a positive one, because it may be one of the first signs that a woman is transferring the protectiveness toward her own body that she felt during pregnancy to her newborn.

If an infant is not sucking well, a woman can use breast massage after a feeding to empty her breasts manually. This helps ensure good milk production for the time when the infant is ready to suck.

Provide Immediate Support If Problems Arise. When handled intelligently by health care personnel, the common problems that arise with breastfeeding usually pass and seem unimportant to a woman. Handled otherwise, they can complicate breastfeeding and discourage a woman from continuing. It is unfortunate when complications deter a woman from using the most natural and least complicated of all infant feeding methods.

Provide Information Regarding Techniques for Burping the Breastfed Baby. Some infants seem to swallow little air when they breastfeed, whereas others swallow a great deal. As a rule, it is helpful to bubble (burp) newborns after they have emptied the first breast and again after the total feeding.

TABLE 19.2 ✻ Latch Breastfeeding Charting System

	0	1	2
L Latch	Too sleepy or reluctant; no latch achieved	Repeated attempts; hold nipple in mouth; stimulate to suck	Grasps breast; tongue down; lips flanged; rhythmic sucking
A Audible Swallowing	None	A few with stimulation	Spontaneous and intermittent under 24 hr old; spontaneous and frequent over 24 hr old
T Type of Nipple	Inverted	Flat	Everted (after stimulation)
C Comfort (Breast/Nipple)	Engorged; cracked, bleeding, large blisters or bruises; severe discomfort	Filling; reddened/small blisters or bruises; mild/moderate discomfort	Soft, nontender
H Hold (Positioning)	Full assist (staff holds infant at breast)	Minimal assist (i.e., place pillows for support, elevate head of bed); teach one side, mother does other; staff holds and then mother takes over	No assist from staff; mother able to position/hold baby by self

Source: Jensen, D., Wallace, S., & Kelsey, P. (1994). LATCH: a breastfeeding charting system and documentation tool. *Journal of Obstetric, Gynecologic, and Neonatal Nursing, 23*(1), 27–32.

FIGURE 19.5 A nurse burps a newborn using a sitting position. The infant's head is supported by the nurse's hand.

Placing the baby over one shoulder and gently patting or stroking the back is an acceptable position. However, this position is not always satisfactory for a small infant, who has poor head control. In addition, a parent may have difficulty supporting the baby's head and patting the back at the same time.

Holding the baby in a sitting position on the lap, then leaning the child forward against one hand, with the index finger and thumb supporting the head, is often the best position to use. This position provides head support but leaves the other hand free to pat the baby's back (Fig. 19.5). Parents usually need to be shown this method, because it does not seem as natural as placing a baby against the shoulder. Laying the baby prone across the lap is another alternative position.

Support for a Mother Who Is Breastfeeding Multiple Infants. Because of in vitro fertilization, many more women today than previously give birth to twins or multiple infants. You can assure women that the average woman can easily produce enough milk to feed multiple infants. Because of the time involved, however, many fewer women with multiple infants choose to breastfeed than do mothers of single infants (Moore, 2007). Support those who want to breastfeed multiple infants by being sure they drink adequate fluid and help them to organize their time.

Nursing Diagnosis: Pain related to breast engorgement or sore nipples

Outcome Evaluation: Client states she is experiencing little or no discomfort; can breastfeed without undue discomfort; infant grasps nipple firmly.

On the third or fourth day after birth, when breast milk forms, some women may notice breast distention, accompanied by hardness, tenderness, and perhaps heat in their breasts. The skin appears red, tense, and shiny. This is primary **engorgement,** caused by vascular and lymphatic congestion arising from an increase in the blood and lymph supply to the breasts. Infants have difficulty sucking on engorged breasts, because the areola is too hard to grasp (Fig. 19.6). A woman also may have difficulty breastfeeding her infant, because her breasts feel so tender.

Prevent or Relieve Engorgement. The primary method for relieving engorgement is emptying the breasts of milk by having the infant suck more often, or at least continue to suck as much as before. Unfortunately, a woman's breasts are sometimes so painful that it is difficult for her to continue to breastfeed unless she is given something for pain relief. Good breast support from a firm-fitting bra helps prevent a pulling, heavy feeling.

If an infant cannot grasp a nipple to suck strongly because of engorgement, warm packs applied to both breasts or standing under a warm shower for a few minutes before feeding, combined with massage to begin milk flow, often promotes breast softness so an infant can suck. Manual expression or the use of a breast pump to complete emptying of the breasts after the baby has nursed can help maintain or promote a good milk supply during a period of engorgement (Fig. 19.7).

Fortunately, engorgement is a transient problem. Unfortunately, it occurs just as women are beginning to feel skilled at breastfeeding. Suddenly their breasts are swollen, hot, and tender. They may worry that an infection has developed or their baby will not get enough milk. Assure a mother that symptoms of engorgement are healthy; it is an announcement her breasts are producing milk. Assure her that engorgement is only temporary and should begin to subside 24 hours after it first becomes apparent.

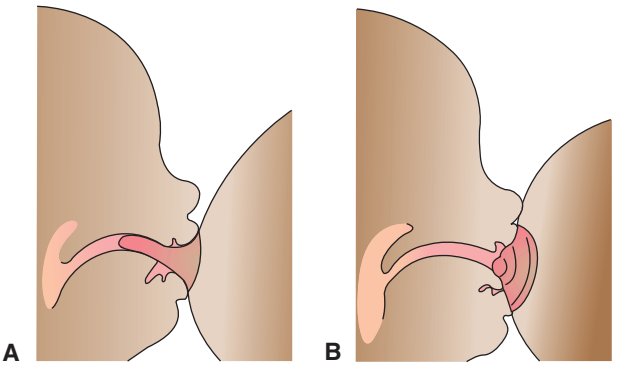


FIGURE 19.6 The problem that breast engorgement causes to breastfeeding. (**A**) When sucking at a normal breast, the infant's lips compress the areola and fit neatly against the sides of the nipple. The infant also has adequate room to breathe. (**B**) When a breast is engorged, the infant has difficulty grasping the nipple. Breathing ability is compromised.

FIGURE 19.7 A nurse and mother discuss the advantages and disadvantages of an electric breast pump (shown on the table) and a manual pump (shown in the mother's hands).

Promote Healing of Sore Nipples. Painful nipples result from the strong sucking action of a newborn. This may be worsened by:

- Improper positioning of an infant (failure to grasp the areola as well as the nipple)
- Forcefully pulling an infant from a breast
- Allowing an infant to suck too long at a breast after the breast is emptied
- Permitting a nipple to remain wet from leaking milk

Normally, nipples are kept supple from the secretions of the Montgomery tubercles in the areola. They can become sore when they are excessively dry or wet, which makes them crack or fissure. To help prevent soreness, encourage a mother to position her baby slightly differently for each feeding. This helps prevent the same area of the nipple from receiving the majority of pressure. Advise her to expose her nipples to air by leaving her bra unsnapped for 10 to 15 minutes after feeding. Some mothers use a hair dryer set on low to aid drying. Discourage the use of plastic liners that come with nursing bras; it is preferable to have air always circulating around the breasts. Applying vitamin E lotion after air exposure may toughen the nipples and prevent further irritation. Applying a few drops of breast milk to the nipples after feeding and gently massaging it into the areola is also recommended.

Advise women not to use a hand pump with sore nipples, because the pressure may cause fissures to worsen. An electric or battery-operated pump (standard equipment in most maternity or pediatric hospitals) usually can be used; these devices exert less pressure on the nipples.

Sore nipples, like engorgement, are not a contraindication to breastfeeding. If steps to prevent sore nipples are followed, the problem is unlikely to become acute again.

Nursing Diagnosis: Anxiety related to inability to measure amount of milk taken by the baby

Outcome Evaluation: Client states the baby seems satisfied after feeding and voices confidence that the baby is getting enough milk; baby voids six to eight times per day after the first week.

Some breastfeeding mothers wonder whether their infant is getting enough to eat. They watch a woman formula feed and listen to her report, "He took 3 ounces this feeding," and wish they could tell as surely whether their infant's intake is adequate. Assure them that the ultimate test with either breastfeeding or formula feeding is not how much an infant swallows at one time but whether the infant seems content between feedings. Acceptable criteria during the first week of life are wetting six to eight diapers within 24 hours or losing no more than 10% of birth weight. After the first week, weight gain and voiding six to eight times each 24 hours are good criteria. Although the formula-feeding mother measures the amount of formula as a way of determining adequate feeding in the early weeks, soon she, too, begins to use the alternative criteria: her baby is happy, voids an adequate number of times, and is gaining weight. Helping a woman use these criteria allows her to develop confidence in her judgment to evaluate her child's health, a role that will be hers for the next 18 or more years.

Nursing Diagnosis: Deficient knowledge related to potential harm to baby from drugs taken by breastfeeding mother

Outcome Evaluation: Client states she is aware almost all drugs taken may be excreted in her breast milk; voices importance of consulting physician or nurse practitioner before taking any medication.

For years, it was believed that a placental barrier protected a fetus from exposure to drugs taken by a woman during pregnancy; a similar protection was postulated for breast milk. However, it is clear a fetus is extremely susceptible to drugs ingested by a woman, and the same is true of breastfed infants. Almost any drug may cross into the acinar cells and be secreted in breast milk. Drugs that should be avoided by breastfeeding mothers because of their documented harmful effects on infants are shown in Appendix C. The rule a woman followed all during pregnancy, that she should take no drug unless prescribed or approved by her primary care provider, continues to apply during lactation.

Nursing Diagnosis: Effective breastfeeding related to mother's desire to provide the best nutrition for her child

Outcome Evaluation: Client states she intends to continue breastfeeding at home; voices confidence in her ability to provide adequate milk for infant; names resources for help if needed; infant exhibits adequate weight gain and elimination pattern for age.

Anticipate Potential Problems and Suggest Methods for Resolving Them. Common problems that can arise with breastfeeding once a mother returns home are summarized in Table 19.3. Women who do not remember to begin nursing the baby at the breast the infant finished on the last time may find their milk supply decreasing in one breast. Although changing breasts may be easy to remember in the hospital,

TABLE 19.3 ✻ Common Concerns of Breastfeeding Mothers

Concern	Cause	Nursing Interventions
Mother worries about amount of milk being taken	Mother cannot see the amount taken	Assure mother that the best way to judge amount taken is to note whether infant appears content between feedings and is wetting diapers.
Infant does not suck well	Possible effect of analgesia from labor Infant brought to mother when not hungry Infant exhausted by crying from hunger	Adjust feeding pattern to child's needs; assure mother that effect of analgesia is temporary. Encourage rooming-in. Encourage feeding on cue, not on demand.
Mother reports infant's stools are loose and thin	Stools normally looser and lighter in color than in formula-fed babies	Examine stools; explain normal stool pattern and transitions.
Father feels shut out of parent–child relationship	Father does not participate in infant feeding	Show other ways of interacting with infant than through feeding.
Sore nipples	Infant not gripping entire areola Nipple kept wet	Help infant to grasp nipple correctly; expose nipple to air between feedings; aloe vera or vitamin E applied to nipples helps heal tissue.
Engorgement	Lymphatic filling as milk production begins	Encourage infant to suck (engorgement subsides best if infant can be encouraged to suck); apply warm packs to breasts or have mother take a warm shower before feeding to help soften breast tissue.
Breastfeeding in public	Some people make a woman feel uncomfortable breastfeeding at work or other public places.	Encourage a woman to use discretion to avoid confrontation (unless she wants to make a point that breastfeeding is a natural action) and to speak to work site administrator about comfortable arrangements.

distractions at home can make the sequence difficult to remember. Pinning a safety pin to the bra strap on the side to start with at the next feeding is a useful way to help remember this.

Fatigue can be another problem on returning home if a woman does not take adequate measures to conserve her energy. Sitting relaxed in a comfortable chair with her feet elevated, feeding her baby, and enjoying this time is an excellent way to rest.

Remind women that adequate maternal fluid intake is necessary to maintain an adequate milk supply. Women who are breastfeeding should drink at least four 8-oz glasses of fluid a day, and many need to drink six glasses. They need to increase their calorie intake by about 500 calories a day (Table 19.4). A daily diet plan for a lactating woman is given in Table 19.5.

At one time, women were given a list of foods not to eat while they were breastfeeding because it was thought they caused diarrhea, constipation, or colic in infants. Today, there are no rules other than to use common sense. A woman can eat anything that agrees with her, is taken in moderation, and to which she is not allergic.

Some women stop breastfeeding because they have no one to talk to about a problem or to give them support. A nurse working as a hospital community liaison person, community health nurse, or lactation consultant can be a valuable resource to provide answers and support while a woman is at home (see Focus on Nursing Care Planning Box 19.5).

TABLE 19.4 ✻ Daily Reference Intakes for Women During Lactation

Nutrient	During Lactation
Calories (kcal)	+500
Protein (g)	71
Vitamin A	1300
Vitamin D (μg)	5.0
Vitamin E (mg)	19
Vitamin K (μg)	75–90
Vitamin C (mg)	120
Folate (μg)	500
Niacin (mg)	17
Riboflavin (mg)	1.6
Thiamine (mg)	1.4
Vitamin B_6 (mg)	2.0
Calcium (mg)	1000–1300
Vitamin B_{12} (μg)	2.8
Phosphorus (mg)	700–1250
Iodine (μg)	290
Iron (mg)	9–10
Magnesium (mg)	320–360
Zinc (mg)	12–13

TABLE 19.5 ✻ Daily Quantities of Food Necessary for a Woman During Lactation

Food Group	Quantities for Active Nonpregnant Woman	Quantities for Lactating Woman
Meat, fowl, or fish	2 servings daily	2–3 servings daily
Vegetables	3–5 servings daily	4 servings daily
Fruits	2–4 servings daily	4 servings daily
Breads, cereals, rice, pasta	6–11 servings daily	6–12 servings daily
Milk	2 glasses (8-oz) daily	4–6 glasses (8-oz) daily
Fats, oils, sweets	Use sparingly	1 serving daily
Additional fluid	As desired	4–6 glasses daily

BOX 19.5 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Woman Who Is Breastfeeding for the First Time

Linda Satir is a new mother of a term baby girl. During the pregnancy, she and her husband, Paul, both agreed Linda would breastfeed. She attempted to breastfeed her newborn in the birthing room, with minimal success. As you offer to help her feed her baby for the second time, she says, "Do you think I made the right choice? Maybe I should formula-feed her. Paul could help that way and I won't have to worry about what to do when I go back to work."

Family Assessment ✻ Client lives with husband in two-bedroom trailer in suburban trailer park. Husband works as an interpreter for local Chamber of Commerce. Linda will be returning to work as an executive assistant at an advertising agency after her 6-week maternity leave.

Client Assessment ✻ Mother is 2 hours postpartum. Newborn had difficulty latching onto breasts immediately after birth. Nipples without signs of redness or irritation. Breasts slightly firm. Colostrum present. Client discouraged with first breastfeeding attempt.

Nursing Diagnosis ✻ Risk for ineffective breastfeeding related to anxiety and inexperience

Outcome Criteria ✻ Client describes ways to properly position a newborn at the breast; states that newborn is latching on and sucking; verbalizes satisfaction and confidence with each feeding session.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Assess client's usual daily activity pattern.	Review with client how she intends to adjust activities to accommodate breastfeeding.	Preplanning can help to avoid problems with breastfeeding.	Client describes her daily routines and identifies adjustments she can predict will need to be made for breastfeeding.
		Consultations		
Nurse	Investigate whether client would like consultation from a lactation consultant; determine which lactation consultant is available.	If client agrees, initiate a referral to a lactation consultant.	Lactation consultants can provide an additional source of support, encouragement, and information.	Client meets with consultant if desired.

(continued)

BOX 19.5 ✻ Focus on Nursing Care Planning (continued)

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Procedures/Medications		
Nurse	Observe client breastfeeding to determine techniques she uses.	Make suggestions as necessary regarding breastfeeding techniques such as how to break suction, remove newborn from breast, or begin next feeding on breast newborn used most recently.	Additional suggestions can help make breastfeeding successful by encouraging client to relax during feedings.	Client states she is willing to try additional suggestions to help improve breastfeeding success.
		Nutrition		
Nurse	Assess client's present daily fluid intake.	Advise client to drink at least four to six 8-oz glasses of fluid per day.	Adequate fluid intake is essential to maintain an adequate milk supply.	Client confirms she drinks suggested fluid every day and will continue to do this at home.
		Patient/Family Education		
Nurse/ lactation consultant	Assess client's knowledge about breastfeeding. Allow time for questions.	Educate client regarding any gaps in knowledge.	The better informed women are about breastfeeding, the more apt they are to feel comfortable with the process.	Client asks questions regarding areas of breastfeeding of which she is unsure.
		Psychosocial/Spiritual/Emotional Needs		
Nurse/ lactation consultant	Assess what client thought breastfeeding would be like.	Acknowledge that breastfeeding involves newly learned skills and is not as easy as it looks.	Assurance can increase self-esteem when a person is learning a new skill.	Client states she is willing to try for a longer time than a few feedings to see if she can be successful at breastfeeding.
		Discharge Planning		
Nurse	Assess steps client intends to take to ensure breastfeeding success after return home or returning to work.	Provide feedback and suggestions, reinforcing accomplishments and assisting with any difficulties.	Feedback and positive reinforcement promote self-confidence and learning, enhancing the success of teaching and effectiveness of breastfeeding.	Client describes well-thought-out plans for continuing breastfeeding and integrating it into her lifestyle.
Nurse	Assess if local support organization is available for referral.	Suggest client keep telephone numbers of support group and lactation consultant available if she needs additional help while at home or work.	Support can go a long way toward preventing a client from becoming discouraged once she returns home.	Client states she will contact support people as necessary if she has questions after discharge.

Provide Information on Supplemental Feedings. A breastfeeding woman may leave her child during the day or evening in the care of a babysitter or another care provider, just as a formula-feeding woman may. She can express breast milk manually and leave it in a bottle in the refrigerator or prepare a single bottle of formula for the time she is away.

Bottles used for storage should be washed using normal dishwashing practice. Breast milk then may be refrigerated for 24 hours, frozen for 30 days, or placed in a deep freezer for 6 months. Use of commercially prepared formula or powder formula is appropriate and convenient to replace a single feeding because one bottle at a time can be prepared. The bottle used should be glass or opaque, nonshiny plastic as shiny types may contain polycarbonate, a compound that can leech into stored milk and is associated with chromosomal aberrations (Raloff, 2007).

Once breastfeeding has been established (after about 6 weeks), missing one feeding will not affect milk production enough to make a difference at the next feeding. There is no need for a mother to express milk manually to safeguard a supply while the infant takes a supplemental feeding, although she may prefer to do so to reduce tension and discomfort.

Provide Information for a Mother Who Works Outside the Home. Many women return to work while continuing to breastfeed by bringing their infant with them to their workplace. Others express breast milk for a caregiver to give by bottle while they work. As there are many considerations to think about, women should review with an employer the best way for them to continue breastfeeding at their worksite (Abdulwadud & Snow, 2009) (Box 19.6).

Provide Information on Weaning. It is best for infants if they are exclusively breastfed for at least 6 months (Kramer & Kakuma, 2009). Women breastfeed for varying lengths of time, however. Some do it for 1, 2, or 3 months and then wean their children from breast to formula. Others continue until their children are 6 to 12 months of age and then wean directly to a small cup or glass. Some continue to breastfeed until the child is of toddler or preschool age (Fig. 19.8). The AAP recommends that infants be breastfed for a full year; the World Health Organization (2002) recommends exclusive breastfeeding for 6 months and continuation for 2 years. Discontinuing breastfeeding may make infants more susceptible to infection as infants are no longer receiving immune protection (Akus & Bartick, 2007). Too lengthy a time of breastfeeding, however, may lead to nutritional deficiencies if the child is taking in a large quantity of milk at the expense of other foods (Ambruso, Hays, & Goldenberg, 2008).

At any age, breastfeeding should be discontinued gradually to prevent engorgement and pain in a mother's breasts while still providing satisfaction for the infant. To do this, a woman could first omit one breastfeeding a day, substituting a formula feeding or milk from a glass or cup. Then she could omit two breastfeedings, then three, and so on, until her infant is feeding entirely from a bottle, glass, or cup. If breasts are not emptied by regular feedings, the resulting pressure leads to milk suppression and natural, gradual discontinuance of milk secretion. If weaned before 12 months, infants should be weaned to formula, not whole milk, so that they continue to receive the added vitamins and the low solute load of commercial formulas.

Urge women who have discontinued breastfeeding to explore whether there is a breast milk bank in their community that would appreciate breast milk donors. Such milk is used to feed hospitalized infants, especially preterm infants. Being fed breast milk can help prevent necrotizing enterocolitis, a possibly fatal bowel infection (see Chapter 45) (Boyd, Quigley, & Brocklehurst, 2007).

BOX 19.6 ✻ Focus on Family Teaching

Suggestions for Returning to Work While Breastfeeding

Q. Linda Satir tells you, "I'm going to be returning to work in 6 weeks. How can I continue to breastfeed my baby?"

A. Here are some suggestions for returning to work while breastfeeding:

- Some women are able to arrange for child care near or at their worksite so they can breastfeed at lunch or during a morning or afternoon break. Discuss with your employer or your immediate work supervisor whether this would be a possibility for you.
- Breastfeeding can be done in a public place, such as a lounge area, without undue exposure if you wear a smock-type or buttoned blouse that you lift or unfasten only as far as necessary; covering any bared breast with a shawl or towel ensures modesty.
- If you are not able to breastfeed during work hours, you will need to express milk manually at least once during the day to maintain a milk supply. You might want to rent an electric pump to keep at work. Expressed breast milk can be safely stored in the refrigerator or in an iced container for 24 to 48 hours and used by your caregiver to feed the infant the next day.
- Plastic is the best type of storage container for breast milk, because antibodies apparently cling to glass and may therefore be lost to the milk.
- Any reminder of a baby may cause leaking of milk from breasts. Wear gauze pads inside your bra to prevent stains on your clothing, and keep an extra change of clothing at work. Pressing against your breasts with the heel of your hands may be helpful in halting leakage.
- Drink four to six 8-oz glasses of fluid during the day to ensure a high fluid intake.
- Try to arrive early at your day care center or sitter so you can breastfeed just before leaving the baby.
- Fatigue can interfere with breastfeeding. Relax and enjoy your baby during the time you are home.

FIGURE 19.8 Some women choose to breastfeed their child beyond 1 year. Accepting various preferences is important in care planning.

✔ Checkpoint Question 19.2

How does breast milk help prevent infection in a newborn?

a. It is rich in fatty acid, so bacteria are destroyed by it.
b. It is always flowing forward in the breast, so it is not static.
c. It contains maternal antibodies and viral binding factors.
d. It is low in lactose, so it becomes a poor culture medium.

BOX 19.7 ❊ Focus On Communication

Mrs. Morgan, Linda 's roommate in the hospital, is a new mother who has chosen to formula feed her newborn. You notice on the second day after birth that she is studying her baby closely.

Less Effective Communication

Nurse: Is everything all right? You look worried.
Mrs. Morgan: I feel guilty I'm not breastfeeding.
Nurse: Breastfeeding would be better for your baby.
Mrs. Morgan: I can't. I'm going back to work next week.
Nurse: You really should breastfeed. It's so much better for the baby.
Mrs. Morgan: I guess I'm not going to be a very good mother.

More Effective Communication

Nurse: Is everything all right? You look worried.
Mrs. Morgan: I feel guilty I'm not breastfeeding.
Nurse: What made you decide not to do that?
Mrs. Morgan: I work as an electrician at a construction site. I can't breastfeed on a scaffold a hundred feet in the air in freezing weather.
Nurse: Your work situation definitely sounds like an exception to the rule. Infant formula may be the best option for you.
Mrs. Morgan: I'm trying to be a good mother. Thanks for the support.

Imposing your opinions on someone is not therapeutic. Allowing a woman to explain her individual situation permits a nurse to understand the woman's decision and support her in it.

FORMULA FEEDING

There is little opposition to the concept that breastfeeding is the best method for feeding human infants unless it is contraindicated. Women who develop a breast abscess may be advised not to breastfeed. Some women who are uncomfortable with the thought of exposing their breasts may not be able to hold a baby warmly and enjoy breastfeeding. Others who plan to return to work outside their home or who have older children to care for may choose not to breastfeed (Box 19.7). Fortunately, formulas that closely resemble human milk are available for infants who will be formula fed, and formula feeding still allows women to establish a close bond with their infant. Support a woman's choice by helping her adjust to formula feeding (Gomella & Haist, 2007).

Preparing for Formula Feeding

Women should use commercial formulas for formula feeding because they so closely mimic human milk. Occasionally, an infant is allergic to the protein in infant formulas. This can lead to such severe intestinal inflammation, diarrhea, and vomiting that the infant becomes anemic and dehydrated from loss of blood and inability to absorb nutrients. In these instances, the infant needs to be switched to a specially designed prescription formula.

Commercial Formulas

The contents of commercial formulas are supervised by the U.S. Food and Drug Administration. Formulas are available in three types: milk based, soy based, and elemental (fat, protein, and carbohydrate content is modified, such as in lactose-free formula). Milk-based formulas are used for the average newborn; lactose-free formulas are used for infants with lactose intolerance or galactosemia (inability to use sugar). Soy formulas were devised for infants who are allergic to cow's milk protein. Today, such infants may be given casein hydrolysate formulas, which have protein particles too small to be recognized by the immune system, rather than soy formulas. Elemental formulas are used for infants with protein allergies or fat malnutrition. Milk-based, soy-based, and lactose-free formulas are all designed to simulate the nutritional content of breast milk. They all contain supplemental vitamins. Parents should be advised to purchase types with added iron to ensure that their newborn receives enough of this element to prevent iron-deficiency anemia (Marotz,

2009). Formulas for term newborns contain 20 cal/oz when diluted according to directions (the same number of calories as breast milk). Common brands are shown in Appendix B. Parents should plan on using formula for the first full year of their infant's life. Participation in a supplemental food program such as the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC) can help low-income parents afford formula.

Four separate forms of commercial formulas are available:

- Powder that is combined with water
- Condensed liquid that is diluted with an equal amount of water
- Ready-to-pour type, which requires no dilution
- Individually prepackaged and prepared bottles of formula

The powder is the least expensive. A single bottle at a time is easy to prepare by vigorous shaking. The prepackaged type does not need refrigeration or preparation (simply remove the bottle cap and it is ready), but it is the most expensive type. Cost should not be the only basis for a parent's choice, however. Tolerance of the formula by the infant and convenience for the parents also are important.

Calculating a Formula's Adequacy

To calculate the adequacy of a formula, remember these two rules of thumb:

1. The total fluid ingested for 24 hours must be sufficient to meet the infant's fluid needs: 75 to 90 mL (2.5 to 3 oz) of fluid per pound of body weight (150 to 200 mL/kg) per day.
2. The number of calories required per day is 50 to 55 per pound of body weight (100 to 120 kcal/kg).

If an infant is taking a commercial formula, only total fluid needs to be calculated. For example, a 7-lb infant needs 17.5 to 21 oz (7 lb × 2.5 to 3 oz) per day. Commercial formula contains 20 cal/oz, so this amount supplies 350 to 420 cal/day. The total volume can be divided into six feedings of 3 to 3.5 oz each. A 9-lb infant would need 22.5 to 27 oz of fluid per day, supplying 450 to 540 cal/day as well as adequate protein, minerals, and vitamins.

A quick rule of thumb to estimate how much an infant will drink at a feeding is to add 2 or 3 to the infant's age in months. After initially taking 0.5 to 1 oz for the first 2 days, a newborn (0 age) will take 2 to 3 oz each feeding; a 3-month-old child, 5 to 6 oz; and a 6-month-old child, 8 oz. As infants change from six to five feedings a day (at about 4 months of age, when they begin to sleep through the night), they begin to take more at each feeding, keeping their total intake the same. Knowing the minimum requirements for fluid and calories per day, being able to calculate whether formula is adequate, and remembering to assess an infant's intake over 24 hours allow evaluation of the adequacy of an infant's intake.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Health-seeking behaviors related to techniques of formula feeding

Outcome Identification: Client verbalizes knowledge of techniques of formula feeding by hospital discharge.

Provide Information Regarding Supplies Needed. Most parents today do not prepare a full day's supply of formula at once but prepare it bottle by bottle, as needed. Caution parents to keep opened cans of liquid formula covered and refrigerated, discarding any unused formula within 24 hours. They should use glass or nonshiny plastic bottles as these do not contain polycarbonate, a chemical that is capable of leeching into stored milk and possibly causing chromosomal aberrations (Raloff, 2007). A baby who develops colic (abdominal pain after feeding) may be pulling in too much air and would benefit from an angled or disposable liner bottle.

Nipples for bottles should be firm enough so an infant sucks vigorously. A soft, flabby nipple allows a baby to suck in milk so rapidly that the need for sucking may not be satisfied. A way to judge a nipple's adequacy is to hold a bottle of milk with nipple attached upside down. The milk should drip from it at a rate of about one drop a second. Bottle caps to cover nipples are helpful to keep nipples clean when outdoors or during transport.

Provide Information Regarding Formula Preparation. Infant formula of any type must be prepared with careful attention to cleanliness to prevent pathogenic microorganisms from growing in it.

When using presterilized formula, the parent need only do the following to prepare a full day's supply of formula:

- Wash off the top of the can with warm, soapy water and rinse.
- Open the can and pour the desired amount of formula and water into each previously cleaned bottle (cleaning in a dishwasher is best).
- Put on the nipples, taking care not to handle the nipple projection.
- Place the bottle caps over the nipples and refrigerate.

To prepare a single bottle, the parent simply combines clean water and liquid or powdered formula in a previously cleaned bottle, caps the bottle, and shakes it to mix the ingredients.

Provide Information Regarding Feeding Techniques. Whether to warm formula or not is a parental decision: infants who are fed cooled formula directly from the refrigerator thrive as well as those who are fed warmed formula. The best method to warm formula is to stand the bottle in a bowl of warm water or hold it under a faucet of running hot water for a few minutes. Caution parents not to use a pan on the stove to warm formula because if the pan boils dry, the bottle of milk will burst. Disposable bottles with plastic liners should definitely not be heated on the stove; the liner tends to melt and then leak during feeding.

It also is not recommended to warm bottles in a microwave oven, because the milk in the center of the bottle can become hotter than that near the sides. If

FIGURE 19.9 A newborn receives a bottle feeding from her father. Notice the en face position.

parents do not follow this recommendation, caution them to heat no longer than 30 seconds for a 4-oz bottle and 45 seconds for an 8-oz bottle (Goldenring, 2007). After warming, they should add the nipple and shake the bottle well to mix the cool and warm portions. Finally, with all warming methods. parents should test the temperature of the formula by allowing a drop or two to fall onto the inside of a wrist, to make sure it is not hot enough to burn the baby's mouth.

With any type of bottle, any contents remaining after a feeding should be thrown away, not stored and reused. When sucking, an infant exchanges a small amount of saliva for milk. Because milk is a good growth medium for bacteria and the baby's mouth harbors many bacteria, the bacterial content in reused formula is likely to be high.

Like breastfeeding, formula feeding an infant is a skill that must be learned. A parent needs a comfortable chair (as does a nurse who feeds babies) and adequate time (at least half an hour) to enjoy the process and not rush the baby (Fig. 19.9). Holding the baby with the head slightly elevated reduces the danger of aspiration and retention of air bubbles. A parent should be sure the nipple is kept filled so that the baby is sucking milk, not air. He or she can be assured a baby is sucking effectively if small bubbles rise in the bottle. Babies in the early weeks should be bubbled (burped) after every ounce of milk taken. The technique is the same as that used for breastfed infants.

Remind parents not to prop up bottles, because babies are in danger of aspiration if a bottle is propped. In addition, an increased incidence of otitis media has been associated with bottle-propping, because the infant's head is not upright and formula may enter the eustachian tube. Propping also can limit the amount of parent–child interaction. Also remind parents not to put a baby to bed with a bottle of formula, because this can lead to "baby-bottle syndrome," or cavities of the lower teeth (see Chapter 29). Some common problems that can arise with formula feeding are summarized in Table 19.6.

What if... Linda tells you she is going to give her baby one supplemental bottle of formula daily in addition to breastfeeding while she works? She does not plan to refrigerate this bottle during the day. What questions would you want to ask her to be certain this approach is safe for her baby?

DISCHARGE PLANNING

Mothers only remain in a hospital or birthing center a short time so teaching a mother and her family about either breastfeeding or formula feeding is crucial. Be certain to review a

TABLE 19.6 ✻ Common Concerns of Formula-Feeding Mothers

Concern	Possible Causes	Nursing Interventions
Infant sucks for a few minutes, then stops and cries	Either nipple is blocked and infant is unable to get milk or flow is too fast and baby has choking sensation.	Show parent how to test flow of milk from the nipple (hold bottle upside down); milk should flow from nipple at rate of about 1 drop/sec.
Infant does not burp well after feeding	Some infants swallow little air with feeding. Parent may be handling infant too tentatively or not burping effectively.	Observe baby feeding and parent's technique of handling; rubbing newborn's back may be more effective than patting it.
Parent reports constipation	Bowel movements from formula-fed infants are not as loose as those from breastfed infants, so parents may be concerned.	Examine stools; assure parent and explain normal stool pattern and that straining to pass stool is normal.

mother's plans for feeding her baby just before discharge, so there is time to answer any remaining questions. If needed, check to see that a home care referral or visit has been scheduled and that the new mother has a telephone number she can call if she has a question before the home visit occurs.

Review with a mother the criteria for adequate nutrition (wetting a diaper six to eight times a day, sleeping between feedings, no excessive crying). Supply the telephone number of the local La Leche League or Association of Lactation Consultants or another local support group as needed.

Be certain a woman has an appointment with a primary care provider for her infant or the telephone number of this person to call for an appointment. Remind her that infant nutrition is an important topic and one she should always feel free to discuss at health care visits. Babies experience growth spurts during the first year at about 3 months, 6 months, and 9 months; during these times, they need to be fed more frequently to meet their nutritional needs. No one can anticipate all of the questions or problems regarding feeding that will arise in the next few months. Empowering women to learn to make decisions regarding feeding and not be reluctant to ask for help when they need it will go a long way toward solving these problems.

✔ Checkpoint Question 19.3

Linda 's husband will offer their baby bottled breast milk once a day when Linda returns to work. Which of the following would you teach him?

a. He should stop feeding bottled milk if the baby has loose yellow stools.
b. He should microwave the milk for a full minute to be certain it is sterile.
c. He should prop the bottle so the baby continues to enjoy breastfeeding.
d. After the baby drinks from a bottle, discard any milk still in the bottle.

Key Points for Review

- Breastfeeding is the preferred feeding method for newborns, because it supplies antibodies as well as nutrients. Urge all women at least to try breastfeeding unless they are taking a drug that would be a contraindication or there is a potential for spreading a microorganism through the breast milk.
- Linoleic acid is an essential fatty acid that is necessary for growth and skin integrity and cannot be manufactured by the body. It is supplied by both infant formula and human milk but not by nonfat milk.
- Both breast milk and commercial formulas contain 20 kcal/oz. A term newborn requires 120 kcal/kg/day and 150 to 200 mL/kg of fluid.
- Encourage mothers who are breastfeeding to drink fluoridated water and formula-feeding mothers to prepare formula using fluoridated water to help build strong teeth in the infant. If a newborn will not have exposure to sunlight, the breastfeeding mother may need to take a supplement of vitamin D; formula-fed infants may need supplemental oral vitamin D.
- Almost all drugs pass into breast milk. A breastfeeding mother must be certain not to take any medication without contacting her primary care provider to be certain it is compatible with breastfeeding.
- If a baby will be formula fed, be certain the parents understand the potential danger of warming bottles in a microwave oven (the inner core of milk may grow very hot).
- Caution parents not to prop bottles, because it increases the risk for aspiration and otitis media. It also deprives infants of the pleasure of being held for feedings.
- To avoid nursing bottle syndrome (cavities of the lower teeth), infants should not be put to bed with a bottle.

CRITICAL THINKING EXERCISES

1. Linda Satir is the new mother you met at the beginning of the chapter. She is unsure whether she wants to breastfeed, especially because she does not know how she will manage breastfeeding when she returns to work. How would you advise her?
2. Linda worries that her 1-day-old newborn is not receiving enough milk. How could you assure her that her baby is receiving enough?
3. Linda's grandmother tells you that she always changed her babies to fat-free milk at 3 months to keep them from gaining too much weight. Would you support this practice?
4. Examine the National Health Goals related to newborn nutrition. Most government-sponsored money for nursing research is allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to the Satir family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to nutritional needs of newborns. Confirm your answers are correct by reading the rationales.

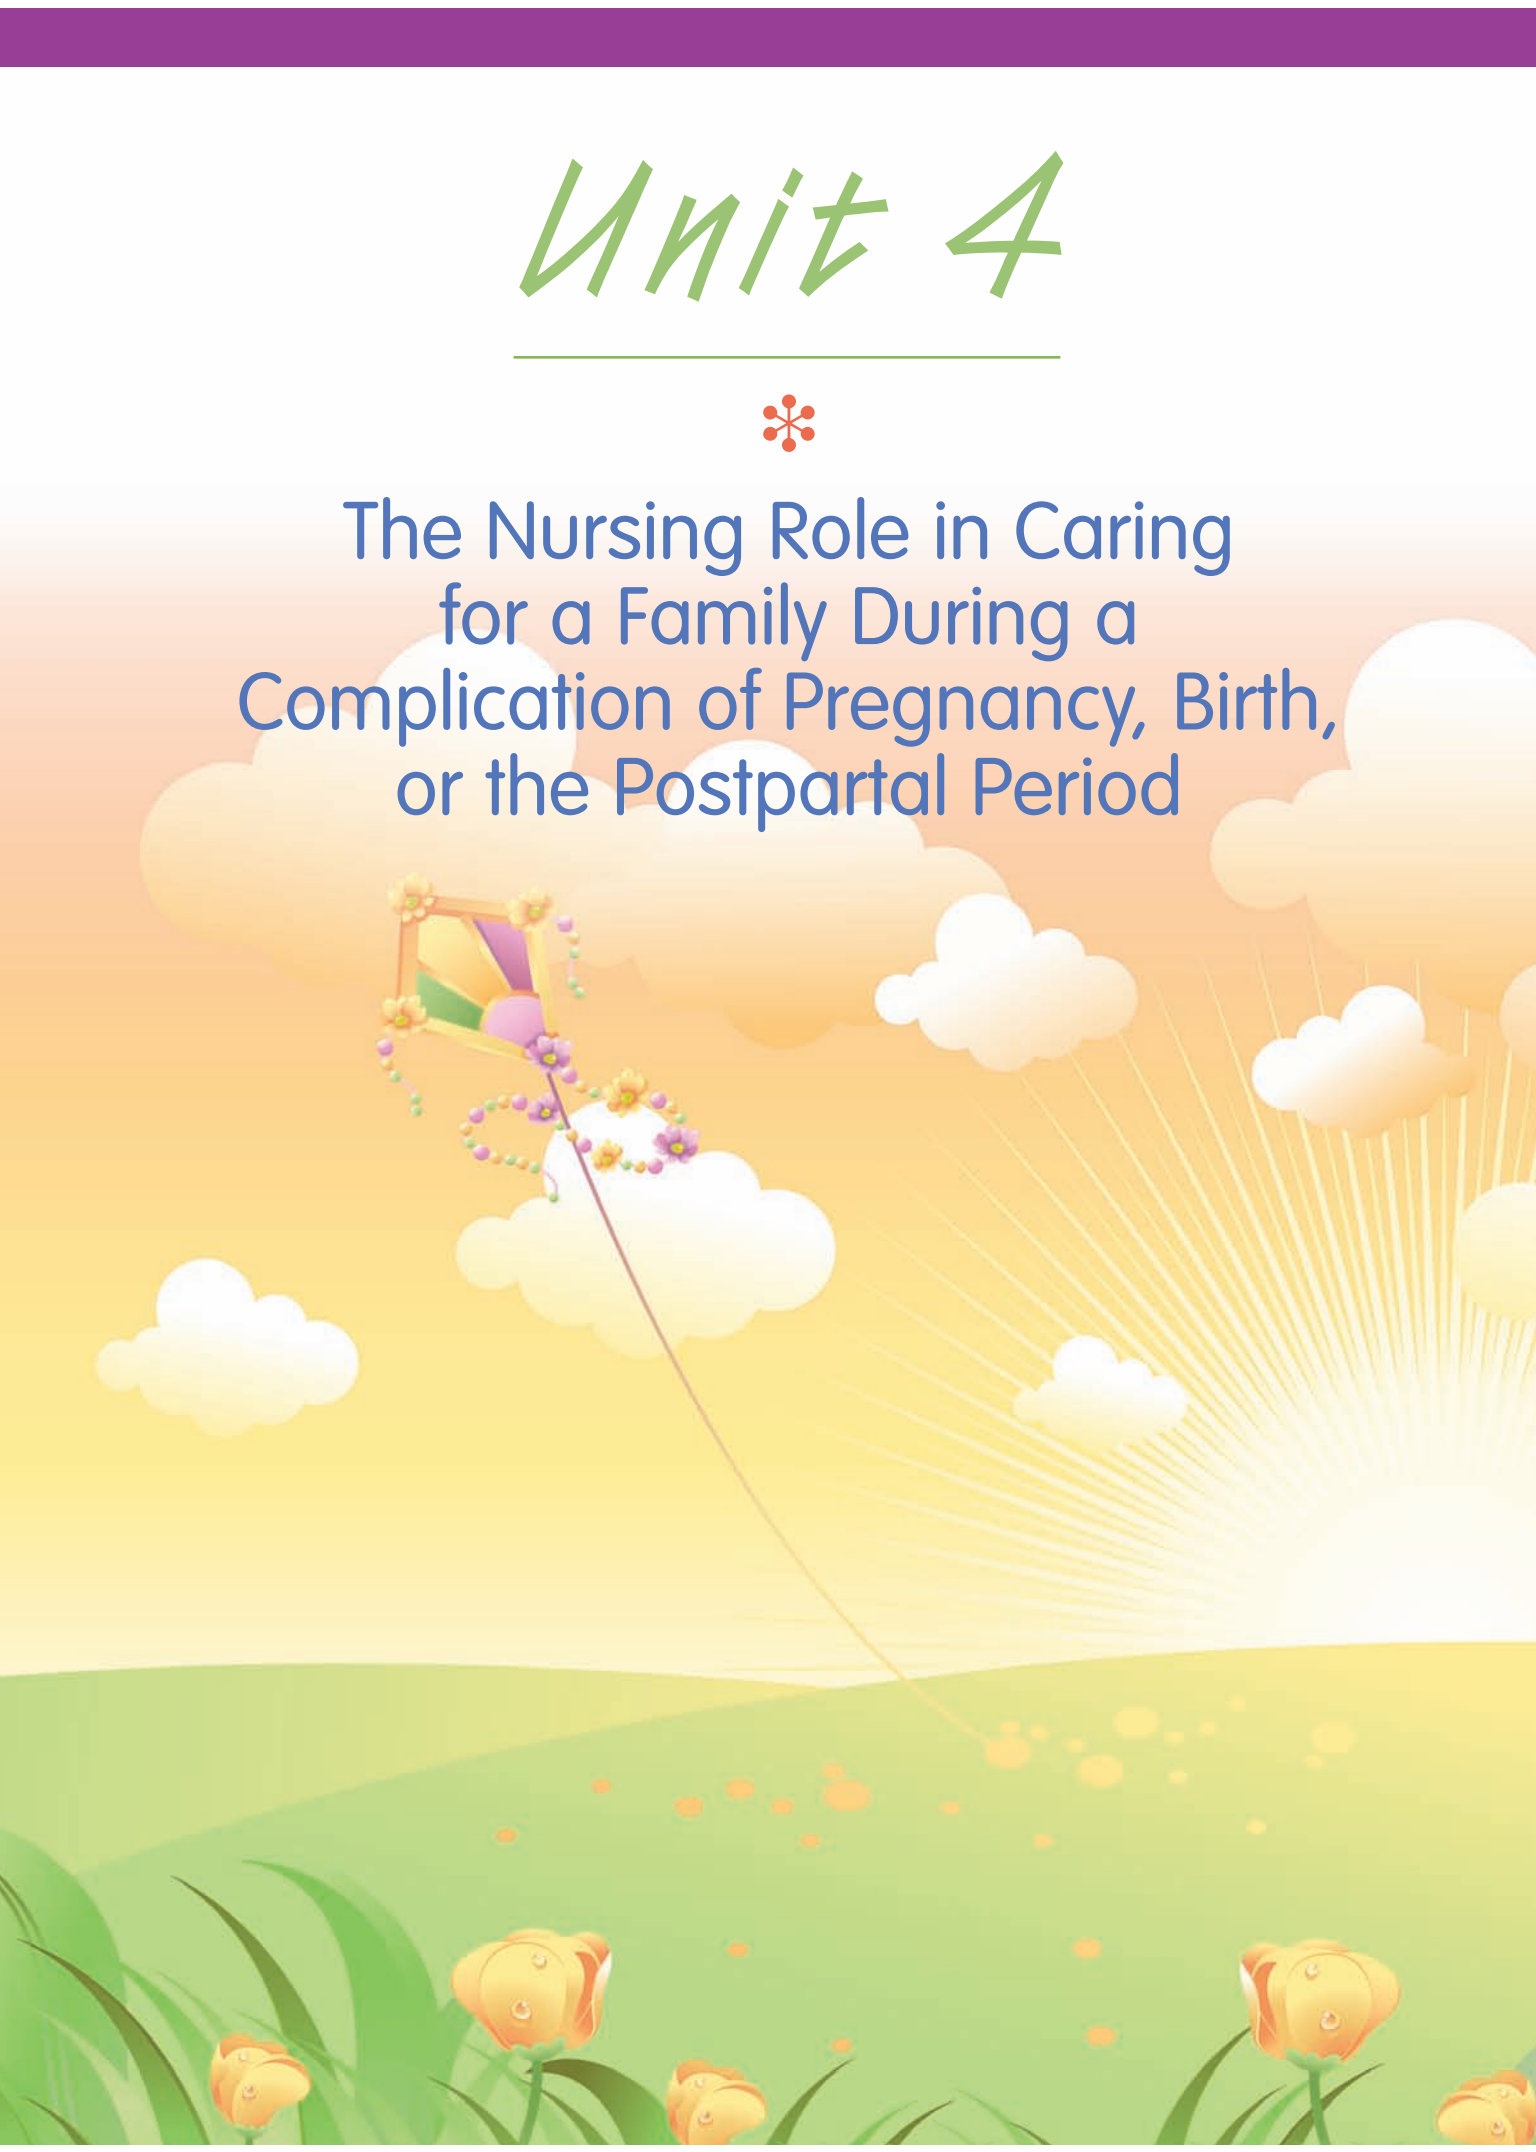
Unit 4

The Nursing Role in Caring for a Family During a Complication of Pregnancy, Birth, or the Postpartal Period



This page intentionally left blank.

Chapter

20 Nursing Care of a Family Experiencing a Pregnancy Complication From a Pre-existing or Newly Acquired Illness

KEY TERMS

- deep vein thrombosis
- glucose tolerance test
- glycosuria
- glycosylated hemoglobin
- high-risk pregnancy
- hyperglycemia
- hypoglycemia
- megaloblastic anemia
- orthopnea
- paroxysmal nocturnal dyspnea
- peripartal cardiomyopathy
- proteinuria

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Define *high-risk pregnancy,* including pre-existing factors that contribute to its development.
2. Describe common illnesses such as cardiovascular disease, diabetes mellitus, or renal and blood disorders that can result in complications when they exist with pregnancy.
3. Identify National Health Goals related to complications of pregnancy that nurses can help the nation achieve.
4. Use critical thinking to analyze ways that nursing care can remain family centered when a pre-existing or newly acquired illness develops during pregnancy.
5. Assess a woman with an illness during pregnancy for changes occurring in the illness because of the pregnancy or the pregnancy because of the illness.
6. Formulate nursing diagnoses related to the effect of a pre-existing or newly acquired illness on pregnancy.
7. Identify expected outcomes that will contribute to a safe pregnancy outcome when illness occurs with pregnancy.
8. Plan nursing care for a woman with an illness during pregnancy such as how a woman with heart disease could manage to get more rest.
9. Implement nursing care for a woman when illness complicates pregnancy such as teaching how to measure blood glucose.
10. Evaluate expected outcomes for achievement and effectiveness of care.
11. Identify areas related to illness and pregnancy that could benefit from additional nursing research or application of evidence-based practice.
12. Integrate knowledge of high-risk pregnancy and nursing process to achieve quality maternal and child health nursing care.

Angelina Gomez, 22, is pregnant with her first child. She had rheumatic fever with mitral stenosis as a child. She developed gestational diabetes early in her pregnancy. By the 34th week, she has already been hospitalized twice for hyperglycemia. She fainted this afternoon while participating in her weekly hour-long aerobic class. When seen in the emergency department, her serum glucose is 207 mg/dL. Her blood pressure is 90/40 mm Hg; her pulse is 130/min; the fetal heart rate is 180/min. An abdominal monitor shows moderate-strength uterine contractions 7 minutes apart. The emergency physician asks for an echocardiogram to see if her mitral stenosis is contributing to her low blood pressure. Angelina says to you, "If exercise is supposed to be good for you, why did this happen?"

Previous chapters discussed normal pregnancy and the minor discomforts that may occur. This chapter adds information about illnesses and other events that can complicate pregnancy when they occur prior to or during pregnancy. As more women wait until they are over 30 to have their first child, more and more women enter pregnancy with a pre-existing disorder such as cardiac or respiratory illness that can complicate pregnancy.

How would you answer Angelina? Do you think she realizes that pregnancy often becomes high risk not because of any one factor, but an accumulation of them?

When a woman enters pregnancy with a chronic condition such as cardiovascular or kidney disease, both she and the fetus can be at risk for complications because either the pregnancy can complicate the disease or the disease can complicate the pregnancy, affecting the baby or leaving a woman less equipped to function in the future or undergo a future pregnancy. Nursing care for a woman with a pre-existing illness focuses on close observation of maternal health and fetal well-being, education of a woman and her family about special danger signs to watch for during pregnancy, and actions to minimize complications whenever possible.

In addition to pre-existing illnesses, the pregnant woman, like any person, may develop a new illness during a pregnancy. When this occurs, the illness can adversely affect not only the woman but also her unborn child. Nursing care for the well, pregnant woman focuses on preventing illness by promoting an especially healthy lifestyle. When accidents and illness occurs despite these safeguards, nursing care focuses on:

- Preventing such disorders from affecting the health of the fetus
- Helping a woman regain her health as quickly as possible so she can continue a healthy pregnancy and prepare herself psychologically and physically for labor and birth and the arrival of her newborn
- Helping a woman learn more about her chronic illness so she can continue to safeguard her health during her childrearing years

Conditions that cause severe symptoms such as a marked change in fluid and electrolyte balance, altered cardiovascular or respiratory function, or severe blood loss are especially dangerous to a fetus. Because of this danger, National Health Goals related to complications of pregnancy have been established (Box 20.1).

Although pregnancy can be a stressful time, generally women experience overall good health during their pregnancies, perhaps in part because of their extra care and concern in keeping healthy for two. This extra motivation also encourages a woman with a high-risk pregnancy to carefully follow a therapeutic regimen established for her to keep her and her fetus safe.

BOX 20.1 * Focus on National Health Goals

Several National Health Goals are aimed at reducing complications of pregnancy that arise from existing or newly acquired disorders. These goals are:

- Reduce the rate of fetal deaths to 4.1 per 1000 live births from a baseline of 6.8 per 1000.
- Reduce the rate of maternal deaths to 3.3 per 100,000 live births from a baseline of 7.1 per 100,000.
- Reduce the rate of maternal illness and complications during pregnancy to 24 per 100 births from a baseline of 31.2 per 100 (http://www.nih.gov).

Nurses can help the nation reach these goals by educating women about the importance of entering pregnancy in the best state of health possible. Helping women who have diabetes mellitus understand the importance of prepregnancy care so they enter pregnancy without hyperglycemia is an important step toward reducing congenital anomalies in newborns. Supporting women with kidney, heart, or respiratory disease during pregnancy to continue to follow their medical regimen is yet another way.

Evidence-based practice and nursing research in specific effects of illnesses on pregnancy or the fetus and how women can best deal with these are needed.

Nursing Process Overview

For Care of a Woman With a Pre-existing or Newly Acquired Illness

Assessment

Accurate prenatal assessment of a woman with a pre-existing or newly acquired illness requires a thorough understanding of the signs and symptoms of illnesses, such as cardiovascular disease or diabetes mellitus, in addition to an understanding of the course of a normal pregnancy. Assessment techniques include objective measures such as establishing baseline vital signs as well as subjective factors such as the extent of edema or level of exhaustion a woman is experiencing (Fig. 20.1). Such assessment is best made by health care personnel who care for a woman consistently throughout the pregnancy so that subtle changes in data can be recognized. In the absence of a consistent care provider, teach a woman to assess her own health in relation to objective parameters. She could report exhaustion, for example, in relation to daily activity such as, "Two weeks ago I could walk a block without being short of breath. Today I could walk only half a block"; "The last time I was in for a checkup, edema didn't occur until bedtime. Now I notice it every afternoon by the time my son comes home from school."

Nursing Diagnosis

Nursing diagnoses developed for a woman with a high-risk pregnancy address her specific, disease-related condition as

FIGURE 20.1 It is important to establish baseline vital signs to later identify a complication related to a pre-existing condition. (© Bob Kramer.)

well as any therapeutic restrictions her condition might require. Examples of possible nursing diagnoses are:

- Ineffective tissue perfusion (cardiopulmonary) related to poor heart function secondary to mitral valve prolapse during pregnancy
- Pain related to pyelonephritis secondary to pressure on ureters
- Social isolation related to prescribed bed rest during pregnancy secondary to concurrent illness
- Ineffective role performance related to increasing level of daily restrictions secondary to chronic illness and pregnancy
- Knowledge deficit related to normal changes of pregnancy versus illness complications
- Fear regarding pregnancy outcome related to chronic illness
- Health-seeking behaviors related to the effects of illness on pregnancy
- Situational low self-esteem related to illness during pregnancy

Outcome Identification and Planning

Be certain that expected outcomes established are realistic in light of a woman's pregnancy and the restrictions placed on her by her health. One family member with illness affects all family members; therefore, outcomes should relate to the entire family's health.

Try to make plans with a woman who has a preexisting medical condition based on the pattern of her life before the pregnancy. For example, to ensure that a pregnant woman receives adequate rest during pregnancy, planning for an afternoon rest period a day is usually adequate. However, for a woman with cardiac disease who took two rest periods a day before pregnancy, this would be ineffective because now she probably needs four rest periods. Remember that the additional health supervision needed during pregnancy may involve increased expenses for a family, so a family may need to develop new ways to meet these expenses. A primary goal for a woman with a severe chronic condition might be to maintain her health during pregnancy, so she can remain at home as long as possible, thereby minimizing hospitalization and family disruptions.

Planning for a new illness may be difficult for a woman because of the shock of the diagnosis. Be careful, however, not to make plans for her such as, "Your best plan would be to begin strict bedrest." Instead, give a woman the available alternatives such as, "As the doctor explained, there are two separate therapies possible; let me review with you the advantages and disadvantages of each therapy." Allowing a woman to choose among alternatives this way helps her to participate in her own care and also maintain self-esteem, helping her move a step toward parenthood and assuming care for her family. Web sties that can be helpful to recommend to families are those of The American Heart Association (http://www.americanheart.org), The National Kidney Foundation (http://www.kidney.org), The American Diabetes Association (http://www.diabetes.org), and The Sickle Cell Association of America (http://www.sickle celldiseaseorg).

Implementation

Nursing interventions for the pregnant woman with a chronic illness may focus on teaching her new or additional measures to maintain health because of the pregnancy. Imaginative solutions to problems may need to be created because a woman may be unable to adjust to the extent of changes she must make.

An illness during pregnancy can complicate not only a pregnancy but also a woman's entire lifestyle and that of her family. Women who think of pregnancy as a time of wellness may have a great deal of difficulty accepting a medical regimen such as daily blood glucose monitoring because this is contradictory to their primary belief about pregnancy. Women in extended families may have an easier time accepting hospitalization during pregnancy than those living in nuclear families, because more people are available to take over their role at home. Conversely, women in extended families may have more difficulty with hospitalization because more people are depending on them to be at home.

Provide a pregnant woman who develops a new illness with an opportunity to talk about the event after her initial care is complete. She may feel guilty that she was not more careful to avoid infection or failed to recognize beginning signs of the illness. Her partner may feel equally guilty that he or she wasn't more alert to what was happening.

A woman and her partner can usually work through these emotions if the pregnancy progresses normally after this point and the fetus is uninjured. If the fetus is injured or the pregnancy disrupted, the event may cause a great deal of stress, and a woman and her partner may need counseling to overcome feelings of guilt and anger. Assessing all families individually and asking about the effect on the entire family of an illness during pregnancy helps to identify concerns and can lead to timely timely solving.

Outcome Evaluation

If evaluation of outcomes at health care visits reveals that an expected outcome is not being met, new assessment, analysis, and planning need to be done. In some instances, an outcome is not met because a woman did not understand the need for an additional pregnancy measure. In another instance, a woman may need better psychological support to continue to follow a health care routine consistently. Nine months is a long time to adhere to restrictions. Make evaluation ongoing to ensure that you know throughout the pregnancy whether interventions are successful. Some examples of outcomes that might be established are:

- Client states she rests for 2 hours morning and afternoon; dependent edema remains at 1+ or less at next prenatal visit.
- Family members state they are all participating in an exercise program since mother developed gestational diabetes.
- Client reports no burning on urination or flank pain at next prenatal visit.
- Client states she understands the importance of taking daily thyroid medicine for total length of pregnancy.

IDENTIFYING A HIGH-RISK PREGNANCY

A **high-risk pregnancy** is one in which a concurrent disorder, pregnancy-related complication, or external factor jeopardizes the health of the woman, the fetus, or both.

Some women enter pregnancy with a chronic illness that, when superimposed on the pregnancy, makes it high risk. Other women enter pregnancy in good health but then develop a complication of pregnancy that causes it to become high risk. In some instances, a combination of particular circumstances—poverty, lack of support people, poor coping mechanisms, genetic inheritance, or past history of pregnancy complications—can cause a pregnancy to be categorized as high risk.

In most instances, more than one factor contributes to the classification of a pregnancy this way. The pregnancy of a woman who is diabetic, for example, is automatically termed one with greater than normal risk because it forces a fetus to grow in an environment in which **hyperglycemia** (increased serum glucose levels) becomes the rule. During such a pregnancy, a woman, worrying that something will happen to her baby, may fail to begin the "pregnancy work" that she must do so bonding can take place. At birth, her child is in double jeopardy: not only is the baby born with altered glucose metabolism, but he or she also is at high risk for poor maternal–child attachment.

A preterm infant born to a teenage girl, likewise, could have this double problem. Not only is the infant immature (and at risk for all the complications that accompany immaturity), but also he or she may have a mother who is immature as well (see Chapter 22 for discussion of the special needs of the pregnant adolescent).

Table 20.1 lists psychological, social, and physical factors that commonly cause a pregnancy to be categorized as high risk. Categorizing risks as minimal, moderate, or extensive differs with each woman because of her individual coping mechanisms and level of support. A woman living in extreme poverty who does not have access to community support, for example, would be at high risk for poor nutritional intake during pregnancy, whereas a woman with a similar income who could depend on a nutritional assistance program such as WIC and counseling from a community health nurse might be only at minimal risk.

Remembering that the term "high risk" rarely refers to just one causative factor helps in the planning of holistic and ultimately effective nursing care. Pre-existing or newly acquired maternal illnesses that can make a pregnancy high risk are discussed in this chapter. Chapter 21 discusses conditions specific to pregnancy that can make a pregnancy high risk. Chapter 22 covers populations that are at high risk because of age (younger than 18 years or older than 40 years), the presence of a disability or trauma, or drug abuse.

CARDIOVASCULAR DISORDERS AND PREGNANCY

The number of women of childbearing age who have heart disease is diminishing as more and more congenital heart anomalies (discussed in Chapter 41) are corrected in early infancy. Also, rheumatic fever is being more actively prevented and treated so that cardiac damage from this disorder is also reduced. For these reasons, even with hypertension included, once a major threat to pregnancy, cardiovascular disease now complicates only approximately 1% of all pregnancies (Cunningham et al., 2008). Cardiovascular disease is still a concern in pregnancy, however, because it can lead to serious complications: it is responsible for 5% of maternal deaths during pregnancy (Crombleholme, 2009). Because of improved management of women with cardiac disorders, women who might never have risked pregnancy in the past are able to complete pregnancies successfully today.

The cardiovascular disorders that most commonly cause difficulty during pregnancy are valve damage caused by rheumatic fever or Kawasaki disease and congenital anomalies such as atrial septal defect or uncorrected coarctation of the aorta. Aortic dilatation may occur from Marfan's syndrome and also be a concern (Chaffins, 2007). As the number of women delaying their first pregnancy until later in life is increasing, there is a corresponding increase in the incidence of coronary artery disease and varicosities during pregnancy. In contrast, heart disease that occurs specifically with pregnancy (peripartum heart disease) still only rarely occurs as it is apparently unrelated to age.

A woman with cardiovascular disease needs a team approach to care during pregnancy, combining the talents of an internist, obstetrician, and nurse. Ideally, a woman should visit her obstetrician or family physician before conception so the health care team can become familiar with her state of health when she is not pregnant and establish baseline evaluations of her heart function, such as with an echocardiogram (Hameed & Akhter, 2007). A woman should begin prenatal care as soon as she suspects she is pregnant (1 week after the first missed menstrual period) so that her general condition and circulatory system can be monitored (Mooney, 2007).

Pregnancy taxes the circulatory system of every woman, even without cardiac disease, because both the blood volume and cardiac output increase approximately 30% (perhaps as much as 50%). Half of this increase occurs by 8 weeks; it is maximized by mid pregnancy.

Because of the increased blood flow past valves, functional (innocent) or transient murmurs can be heard in many women during a usual pregnancy. Heart palpitations on sudden exertion are also normal in pregnancy. Neither of these symptoms is a sign of cardiovascular disease, but merely an indication of the normal physiologic adjustment to pregnancy. These symptoms disappear after pregnancy. Women who had Kawasaki disease or rheumatic fever as a child may have both valvular and aortic artery constrictions that lead to true valve dysfunction and organic murmurs (Hibbard, Fajardo, & Briller, 2007).

The danger of pregnancy in a woman with cardiac disease occurs primarily because of the increase in circulatory volume. The most dangerous time for a woman is in weeks 28 to 32, just after the blood volume peaks. However, if heart disease is severe, symptoms can occur as early as the beginning of pregnancy. A woman's heart may become so overwhelmed by the increase in blood volume toward the end of pregnancy that her cardiac output falls to the point that vital organs (including the placenta) are no longer perfused adequately. When this happens, neither the oxygen nor nutritional requirements of her cells or those of the fetus can be met.

The estimation of whether a woman with cardiovascular disease can complete a pregnancy successfully or not depends

TABLE 20.1 ✻ Factors That Categorize a Pregnancy as High Risk

Psychological	Social	Physical
Prepregnancy		
History of drug dependence (including alcohol)	Occupation involving handling of toxic substances (including radiation and anesthesia gases)	Visual or hearing challenges
History of intimate partner abuse	Environmental contaminants at home	Pelvic inadequacy or misshape
History of mental illness	Isolated	Uterine incompetency, position, or structure
History of poor coping mechanisms	Lower economic level	Secondary major illness (heart disease, diabetes mellitus, kidney disease, hypertension, chronic infection such as tuberculosis, hemopoietic or blood disorder, malignancy)
Cognitively challenged	Poor access to transportation for care	Poor gynecologic or obstetric history
Survivor of childhood sexual abuse	High altitude	History of previous poor pregnancy outcome (miscarriage, stillbirth, intrauterine fetal death)
	Highly mobile lifestyle	History of child with congenital anomalies
	Poor housing	Obesity (BMI >30)
	Lack of support people	Underweight (BMI <18.5)
		Pelvic inflammatory disease
		History of inherited disorder
		Small stature
		Potential of blood incompatibility
		Younger than age 18 years or older than 35 years
		Cigarette smoker
		Substance abuser
Pregnancy		
Loss of support person	Refusal of or neglected prenatal care	Subject to trauma
Illness of a family member	Exposure to environmental teratogens	Fluid or electrolyte imbalance
Decrease in self-esteem	Disruptive family incident	Intake of teratogen such as a drug
Drug abuse (including alcohol and cigarette smoking)	Decreased economic support	Multiple gestation
Poor acceptance of pregnancy	Conception less than 1 year after last pregnancy	A bleeding disruption
		Poor placental formation or position
		Gestational diabetes
		Nutritional deficiency of iron, folic acid, or protein
		Poor weight gain
		Pregnancy-induced hypertension
		Infection
		Amniotic fluid abnormality
		Postmaturity
Labor and Birth		
Severely frightened by labor and birth experience	Lack of support person	Hemorrhage
Inability to participate because of anesthesia	Inadequate home for infant care	Infection
Separation of infant at birth	Unplanned cesarean birth	Fluid and electrolyte imbalance
Lack of preparation for labor	Lack of access to continued health care	Dystocia
Birth of infant who is disappointing in some way (such as sex, appearance, or congenital anomalies)	Lack of access to emergency personnel or equipment	Precipitous birth
		Lacerations of cervix or vagina
		Cephalopelvic disproportion
		Internal fetal monitoring
		Retained placenta
Illness in newborn		

on the type and extent of her disease. As a rule, a woman with artificial but well-functioning heart valves can be expected to complete a pregnancy without difficulty as long as she has consistent prenatal and postpartum care. A woman with a pacemaker implant can also expect to complete pregnancy successfully. Even women who have had heart transplants can be expected to have successful pregnancies (Sibanda et al., 2007).

To predict pregnancy outcome, heart disease is divided into four categories based on criteria established by the New York State Heart Association (Table 20.2). A woman with class I or II heart disease can expect to experience a normal pregnancy and birth. Women with class III can complete a pregnancy by maintaining almost complete bed rest. Women with class IV heart disease are poor candidates for pregnancy because they are in cardiac failure even at rest and when they are not pregnant. They are usually advised to avoid pregnancy.

A Woman With Cardiac Disease

Cardiac disease affects either the left or right side of the heart.

TABLE 20.2 ✻ Classification of Heart Disease

Class	Description
I	Uncompromised. Ordinary physical activity causes no discomfort. No symptoms of cardiac insufficiency and no anginal pain.
II	Slightly compromised. Ordinary physical activity causes excessive fatigue, palpitation, and dyspnea or anginal pain.
III	Markedly compromised. During less than ordinary activity, woman experiences excessive fatigue, palpitations, dyspnea, or anginal pain.
IV	Severely compromised. Woman is unable to carry out any physical activity without experiencing discomfort. Even at rest symptoms of cardiac insufficiency or anginal pain are present.

Source: Criteria Committee of the New York Heart Association. (1994). *Nomenclature and criteria for diagnosis of diseases of the heart and great vessels* (9th ed.). Boston: Little, Brown & Co.

A Woman With Left-Sided Heart Failure

Left-sided heart failure occurs in conditions such as mitral stenosis, mitral insufficiency, and aortic coarctation. In these instances, the left ventricle cannot move the volume of blood forward that it has received by the left atrium from the pulmonary circulation. The heart becomes so overwhelmed it fails to function. The reason for the failure is most often at the level of the mitral valve. The normal physiologic tachycardia of pregnancy shortens diastole (atrial contraction) and decreases the time available for blood to flow across this valve. The inability of the mitral valve to push blood forward causes back-pressure on the pulmonary circulation, causing it to become distended; systemic blood pressure decreases in the face of lowered cardiac output, and pulmonary hypertension occurs. When pressure in the pulmonary vein reaches a point of about 25 mm Hg, fluid begins to pass from the pulmonary capillary membranes into the interstitial spaces surrounding the alveoli and then into the alveoli themselves (pulmonary edema). Pulmonary edema produces profound dyspnea as it interferes with oxygen–carbon dioxide exchange as the fluid coats the alveolar exchange space (Bashore & Granger, 2009). If pulmonary capillaries rupture under the pressure, small amounts of blood leak into the alveoli and a productive cough of blood-speckled sputum develops. Because of the limited oxygen exchange, women with pulmonary hypertension are at extremely high risk for spontaneous miscarriage, preterm labor, or maternal death.

As the oxygen saturation of the blood decreases from dysfunction of the alveoli, chemoreceptors stimulate the respiratory center to increase respiratory rate. At first this is noticeable only on exertion, then finally with rest also. A woman experiences increased fatigue, weakness, and dizziness (specifically from lack of oxygen in brain cells). As the systemic decrease in blood pressure registers on the pressoreceptors in the aorta, the heart rate increases and peripheral vasoconstriction occurs in an attempt to increase the systemic blood pressure. As the fall in blood pressure is registered with the renal-angiotensin system, retention of both sodium and water occurs. The placenta may not receive adequate blood because of the decreased peripheral circulation.

As pulmonary edema becomes severe, a woman cannot sleep in any position except with her chest and head elevated **(orthopnea)**. Elevating her chest allows fluid to settle to the bottom of her lungs and frees space for gas exchange. She may also notice **paroxysmal nocturnal dyspnea**—suddenly waking at night short of breath. This occurs because heart action is more effective when she is at rest. With the more effective heart action, interstitial fluid returns to the circulation. This overburdens the circulation, causing increased left-side failure and increased pulmonary edema.

If mitral stenosis is present, it is so difficult for blood to leave the left atrium that a secondary problem of thrombus formation can occur from noncirculating blood. A woman may need to be prescribed an anticoagulant to prevent this. If coarctation of the aorta is causing the difficulty, dissection of the aorta from high blood pressure from trying to push blood past the constriction can occur. In this instance, a woman may be prescribed antihypertensives to control blood pressure, diuretics to reduce blood volume, and beta-blockers to improve ventricular filling (Hameed & Akhter, 2007). If these complications result in impaired blood flow to the uterus, poor placental perfusion, intrauterine growth restriction, and fetal mortality can occur. A woman needs serial ultrasound and nonstress tests done after weeks 30 to 32 of pregnancy to monitor fetal health. Balloon valve angioplasty to loosen mitral valve adhesions can be performed safely during pregnancy (Davidson & Graham, 2007).

If an anticoagulant is required, heparin is the drug of choice for early pregnancy because it does not have teratogenic effects, as does sodium warfarin (Coumadin). Warfarin can be used after week 12 but a woman will then be returned to heparin therapy during the last month of pregnancy so the fetus will not develop a coagulation disorder at birth (heparin does not cross the placenta and enter the fetus).

A Woman With Right-Sided Heart Failure

Congenital heart defects such as pulmonary valve stenosis and atrial and ventricular septal defects can result in right-sided heart failure. Right-sided failure occurs when the output of the right ventricle is less than the blood volume received by the right atrium from the vena cava. Back-pressure from this results in congestion of the systemic venous circulation and decreased cardiac output to the lungs. Blood pressure decreases in the aorta because less blood is reaching it; pressure is high in the vena cava from back-pressure of blood; both jugular venous distention and increased portal circulation occur. The liver and spleen become distended. Liver enlargement can cause extreme dyspnea and pain in a pregnant woman because the enlarged liver, as it is pressed upward by the enlarged uterus, puts extreme pressure on the diaphragm. Distention of abdominal vessels can lead to exudate of fluid from the vessels into the peritoneal cavity (ascites). Fluid also moves from the systemic circulation into lower extremity interstitial spaces (peripheral edema).

The congenital anomaly most apt to cause right-sided heart failure in women of reproductive age is Eisenmenger

syndrome, a right-to-left atrial or ventricular septal defect with an accompanying pulmonary stenosis (Davidson & Graham, 2007).

Women who have an uncorrected anomaly of this type may be advised not to become pregnant. If they do become pregnant, they can expect to be hospitalized for the last part of pregnancy. They need oxygen administration and frequent arterial blood gas assessments to ensure fetal growth. During labor, they may need a pulmonary artery catheter inserted to monitor pulmonary pressure. They need extremely close monitoring after epidural anesthesia to minimize the risk of hypotension.

✔ Checkpoint Question 20.1

Angelina Gomez is the 22-year-old woman you met at the beginning of the chapter. Suppose she develops a deep vein thrombosis while in the hospital on bed rest and is prescribed low-molecular-weight heparin subcutaneous. What education will she need in relation to this?

a. Her infant will be born with scattered petechiae on his trunk.
b. Heparin can cause darkened or nonflexible skin in newborns.
c. Heparin does not cross the placenta and so does not affect a fetus.
d. Some infants will be born with allergic symptoms to heparin.

A Woman With Peripartum Heart Disease

An extremely rare condition, **peripartal cardiomyopathy** can originate in pregnancy in women with no previous history of heart disease (American College of Obstetrics and Gynecology [ACOG], 2007). Although the cause is unknown, it is apparently because of the effect of the pregnancy on the circulatory system. The mortality rate can be as high as 50%. In many instances, it occurs from previously undetected heart disease, although it occurs most often in African American multiparas in conjunction with hypertension of pregnancy. A woman develops signs of myocardial failure such as shortness of breath, chest pain, and edema. Her heart begins to increase in size (cardiomegaly). If cardiomegaly occurs, she must sharply reduce her physical activity. Many women need a diuretic, an arrhythmia agent, and digitalis therapy to maintain heart action. Low-molecular-weight heparin may be administered to decrease the risk of thromboembolism. Immunosuppressive therapy may improve the symptoms.

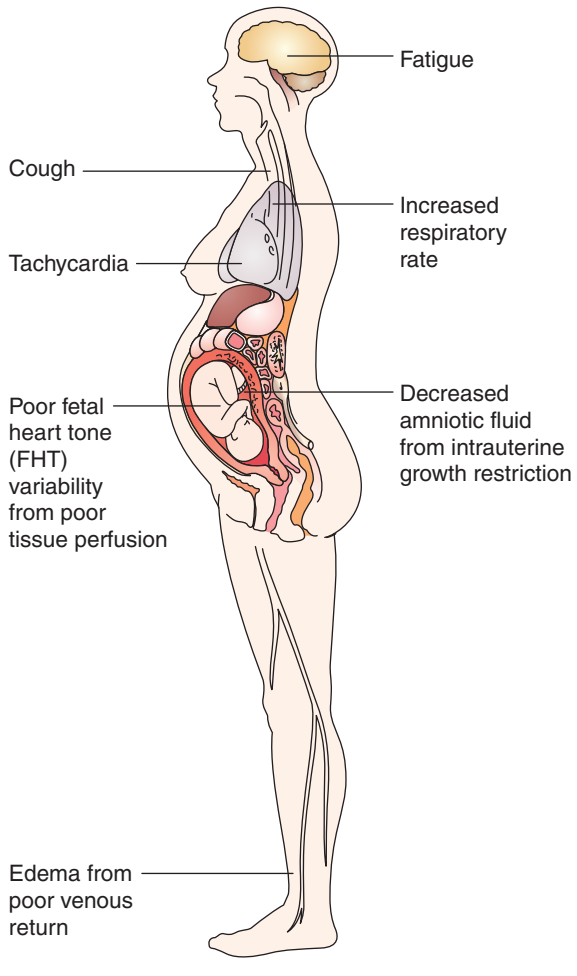
If the cardiomegaly persists past the postpartum period, it is generally suggested that a woman not attempt any further pregnancies because the condition tends to recur in additional pregnancies. Oral contraceptives are contraindicated because of the danger of thromboembolism they could create. The disease may progress to the point that following pregnancy, a woman may need a heart transplant (McAnulty, Metcalfe, & Ueland, 2008).

Assessment of a Woman With Cardiac Disease

Nurses play a major role in the care of a pregnant woman with cardiovascular disease because continuous assessment of a woman's health status, health education, and health-promotion activities are so essential. Assessment of a woman with cardiac disease begins with a thorough health history to document her prepregnancy cardiac status (Box 20.2). Ask about her level of exercise performance (what level she can do before growing short of breath and what physical symptoms she experiences, such as cyanosis of the lips or nail beds). Ask if she normally has a cough or edema. Instruct women with cardiac disease always to report coughing during pregnancy, because pulmonary edema from heart failure may first manifest itself as a simple cough.

Never assess edema in women with heart disease lightly as the normal edema of pregnancy (innocent) must be distinguished from the beginning of pregnancy-induced hypertension (serious) or the edema of heart failure (also serious). The normal edema of pregnancy involves only the feet and ankles, but edema of either pregnancy-induced hypertension or heart failure also begins this way. Edema of pregnancy-induced hypertension usually begins after week 20. If the edema is a sign of heart failure, it can begin at any time and other symptoms will probably also be present: irregular pulse, rapid or difficult respirations, and perhaps chest pain on exertion. Record a baseline blood pressure, pulse rate, and

Box 20.2 Assessment
Assessing a Pregnant Woman With Cardiac Disease



respiratory rate in either a sitting or lying position at the first prenatal visit; then, at future health visits, always take these in the same position for the most accurate comparison. Making comparison assessments for nail bed filling (should be <5 seconds) and jugular venous distention is also helpful throughout pregnancy. If a woman's heart disease involves right-sided heart failure, assessment of liver size is helpful. Keep in mind that liver assessment becomes difficult and probably inaccurate late in pregnancy because the enlarged uterus presses the liver upward under the ribs and makes it difficult to palpate.

For additional cardiac status assessment, a woman may need an electrocardiogram (ECG), chest radiograph, or echocardiogram done at periodic points in pregnancy. Assure her that an ECG merely measures cardiac electrical discharge and so cannot harm her fetus in any way. Echocardiography uses ultrasound and so will also not harm her fetus. Chest radiography is considered safe as long as a woman's abdomen is covered by a lead apron during the exposure. An ECG may become less accurate late in pregnancy (demonstrates left axis deviation) because the enlarged uterus presses upward on the diaphragm and displaces the heart laterally.

Fetal Assessment

Cardiac failure can affect fetal growth at the point at which maternal blood pressure becomes insufficient to provide an adequate supply of blood and nutrients to the placenta. For this reason, the infants of women with severe heart disease tend to have low birth weights because not enough nutrients can be furnished to them. A poor perfusion level may also lead to an acidotic fetal environment if the blood flow becomes inadequate for carbon dioxide exchange. Preterm labor also may occur. This exposes an infant to the hazards of immaturity as well as low birth weight. An infant may not respond well to labor (evidenced by late deceleration patterns on a fetal heart monitor) if cardiac decompensation has reached a point of placental incompetency.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Deficient knowledge regarding steps to take to reduce the effects of maternal cardiovascular disease on the pregnancy and fetus

Outcome Evaluation: Client identifies danger signs and steps to take when they occur; maternal blood pressure is maintained above 100/60 mm Hg and fetal heart rate at 120 to 160 beats per minute.

Be certain that goals and outcomes established with a woman with heart disease are realistic. Not all women with heart disease will be able to complete a pregnancy successfully; some infants of women with severe involvement will be born with the effects of placental insufficiency, such as neurologic involvement or cognitive challenge. However, there are positive actions a woman with heart disease can take to reduce or eliminate complications during pregnancy. These include measures to rest and strengthen heart action.

Promote Rest. As a rule, women with cardiac disease need two rest periods a day (fully resting, not getting up frequently to answer the door or telephone) and a full night's sleep (not tossing and turning because of excess noise or heat in the room) to obtain adequate rest. Rest should be in the left lateral recumbent position to prevent supine hypotension syndrome and increased heart effort.

Remember that when cardiac output is not enough to meet systemic body demands, peripheral vasoconstriction occurs. Because the uterus is a peripheral organ, this causes uterine/placental constriction. Therefore, a rest program must be carefully designed so a woman stops exercising before this point is reached. Exactly how much rest she is to have should be carefully detailed for her. She may need to discontinue employment early in pregnancy rather than work until the end of pregnancy, as the average woman usually plans to do. Exactly how much work she will be allowed to do at home should be detailed as well. Allowing "normally heavy" housework may mean nothing more strenuous than dusting to some women. To others, it may mean washing windows, turning mattresses, and shoveling snow. Make certain a woman's definition of "heavy work" is the same as yours and her physician's or nurse-midwife's.

Promote Healthy Nutrition. A woman with cardiac disease may need closer supervision of nutrition during pregnancy than the average woman because she must gain enough weight to ensure a healthy pregnancy and a healthy baby, but she must not gain so much weight that she has to supply additional cells with nutrients. This could overburden her heart and circulatory system.

Be certain she is taking her prenatal vitamins. These contain an iron supplement to help prevent anemia. Anemia places an extra burden on the heart because it requires the body to circulate blood more vigorously to distribute oxygen to all body cells. If a woman was following a sodium-restricted diet before pregnancy, this may be continued during pregnancy, although typically a woman's sodium intake is only limited, not severely restricted, during pregnancy. Sodium is necessary for maintaining fluid volume and balance and thus is necessary to allow a woman's body to retain enough blood volume to supply blood to the placenta.

Educate Regarding Medication. Women taking cardiac medication before pregnancy may need to increase their maintenance dose because of their expanded blood volume during pregnancy. A woman who needed digoxin before pregnancy for heart action will continue to require it (and can take it safely) during pregnancy. A woman who was not digoxin dependent before pregnancy may need such therapy prescribed as pregnancy advances and her cardiac output has to be increased or strengthened. To aid a woman in continuing to think of herself as basically a well person, help her to understand that this does not mean her heart function is weakening, but rather that it is only being stressed further by the

increased circulatory load of pregnancy. Digoxin is sometimes administered to a woman during pregnancy to slow the fetal heart if fetal tachycardia is present. An arrhythmia agent such as adenosine, beta-blockers, and angiotensin-converting enzyme (ACE) inhibitors to reduce hypertension are safe to use during pregnancy. Nitroglycerin, a compound often prescribed for angina, is not well studied during pregnancy (a category C drug) but is apparently safe (Karch, 2009).

A woman who was taking penicillin prophylactically because she had rheumatic fever as a child to prevent a recurrence (often taken for 10 years after the occurrence of rheumatic fever, or at least until age 18 years) should continue to take this drug during pregnancy because penicillin is not known to be a fetal teratogen (a category B drug). Close to the anticipated day of birth, some physicians begin a course of an antibiotic for women with heart disease such as penicillin. This is because the postpartum period always involves some mild invasion of bacteria from the denuded placental site on the uterus into the bloodstream. Since this invading bacteria may be streptococci, the bacteria often responsible for subacute bacterial endocarditis, a course of ampicillin, amoxicillin (Amoxil), or clindamycin (Cleocin) at this time offers women needed protection against bacterial endocarditis developing (Chambers, 2009).

It is often difficult to keep healthy women from taking over-the-counter medicines during pregnancy; conversely, it can be just as difficult to encourage women to take the medicine they need to take during pregnancy. Help women with heart disease to understand that there are valid exceptions to the rule of "no medicine during pregnancy."

Educate Regarding Avoidance of Infection. A systemic infection almost automatically increases body temperature, causing a woman to have to expend more energy and increase her cardiac output as her metabolism increases, an insult that could be too extreme for a woman with heart disease to withstand. Caution a woman with heart disease, therefore, to avoid visiting or being visited by people with infections. She should alert health care personnel at the first indication of an upper respiratory tract infection or urinary tract infection so that, if warranted, antibiotic therapy can be begun early in the course of the infection. Monthly screening for bacteriuria with a clean-catch urine test may be recommended.

Be Prepared for Emergency Actions. Women with heart disease may need supplemental oxygen if they overexert as could happen during a prenatal visit. Cardiac resuscitation in women who are pregnant does not differ from usual instructions (Box 20.3).

BOX 20.3 Nursing Procedure ✻ CPR During Pregnancy

Purpose: To restore respiratory and cardiac function.

Plan	Principle
1. Shake the woman's shoulders and shout.	**1.** Shaking the shoulders and shouting are an attempt to determine unconsciousness and to rouse a woman who may have fainted or be asleep.
2. Phone or call for help.	**2.** The woman may need more than simple resuscitation.
3. Place a rolled or folded towel under the woman's right hip.	**3.** A towel placed under one hip helps to prevent uterine compression on the vena cava or helps prevent supine hypotension syndrome.
4. Lift the chin to position the airway.	**4.** Lifting the chin aids in straightening the airway to ensure that it is patent.
5. Establish lack of respirations by listening and feeling for air movement.	**5.** Listening and feeling for air movement provides evidence of breathing.
6. Begin rescue breathing with administration of two quick breathing-bag breaths.	**6.** Rescue breathing introduces oxygen for gas exchange.
7. Assess carotid pulse.	**7.** Presence of carotid pulse indicates cardiac function.
8. Begin chest compressions if there is no carotid pulse. Place both hands on the lower sternum just above xiphoid process and deliver 15 chest compressions followed by 2 rescue breaths (1 second each) until cardiopulmonary function returns.	**8.** External chest compressions stimulate the action of the heart to maintain tissue perfusion. They should be at a rate of 100 bpm and allow the chest to rise in between compressions.
9. If an automated external defibrillator (AED) is necessary, remove any fetal or uterine monitors if these are in place. Follow standard application and procedure according to agency protocol.	**9.** AED is effective in stimulating heart action and is not detrimental to pregnancy or a fetus.

What if... Angelina tells you she has abruptly discontinued the daily penicillin she has been taking for her heart disease since childhood? As it has been a long time since she had rheumatic fever, what would you recommend she do?

Nursing Interventions During Labor and Birth

Monitor fetal heart rate and uterine contractions during labor in all women with heart disease. Assess a woman's blood pressure, pulse, and respirations frequently. A rapidly increasing pulse rate (>100 beats per minute) is an indication that a heart is pumping ineffectively and has increased its rate in an effort to compensate. Advise a woman to assume a side-lying position to reduce the possibility of supine hypotension syndrome. If she has some pulmonary edema, it may be necessary for her to have her chest and head elevated (semi-Fowler's position) to ease the work of breathing. Remember, fatigue is a symptom of heart decompensation. If this occurs in labor, evaluate a woman carefully to determine whether the fatigue is heart or labor related.

Women with extreme heart disease need oxygen administered during labor to compensate for the added oxygen required because of the increased exertion needed for labor as well as continuous hemodynamic monitoring such as by a Swan-Ganz catheter to monitor heart function. The anesthetic of choice during labor for women with heart disease is an epidural, because this can make both labor and birth less taxing. Many women with heart disease should not push with contractions; pushing requires more effort than they should expend. If an epidural anesthetic is used, low forceps or a vacuum extractor can be used for birth. A woman may be disappointed that her birth is not more "natural." Stress that these measures can help her achieve her ultimate goals, which are a healthy newborn and a mother able to care for her new baby.

Postpartum Nursing Interventions

The period immediately after birth may be a critical time for a woman with heart disease. With delivery of the placenta, the blood that supplied the placenta is now released into her general circulation, subsequently increasing her blood volume 20% to 40%. During pregnancy, the increase in blood volume occurred over a 6-month period, so the heart had time to adjust to this change gradually. After birth, the increase in pressure takes place within 5 minutes, so the heart must make a rapid and major adjustment (Davidson & Graham, 2007).

If a woman is in severe congestive heart failure after birth, she needs a program of decreased activity and possibly anticoagulant and digoxin therapy until her circulation stabilizes. Antiembolic stockings and ambulation may be needed to increase venous return from the legs. If prophylactic antibiotics had not been started prior to birth, they will be started immediately after birth to discourage subacute bacterial endocarditis caused by introduction of microorganisms through the placental site.

A woman with heart disease is often interested in close inspection of her baby immediately after birth because she wants to know her infant does not have a heart defect or was not harmed by any medication she took. Be sure to point out that acrocyanosis is normal in newborns, so she does not interpret her baby's severe peripheral cyanosis as cardiac inadequacy.

In the postpartum period, agents to encourage uterine involution such as oxytocin (Pitocin) must be used with caution because they tend to increase blood pressure, and this necessitates increased heart action. As a rule, a woman with heart disease can breastfeed without difficulty. Kegel exercises are acceptable for perineal strengthening immediately, but the woman should not begin postpartum exercises to improve abdominal tone until her physician or nurse-midwife approves them. A stool softener can be prescribed to prevent straining with bowel movements.

Before discharge, be certain a woman has thought through what help she will need at home so she can continue getting periods of rest. Also ensure that she schedules a return appointment for a postpartum checkup for both her gynecologic health and her cardiac status.

What if... Angelina tells you she tries to eat absolutely no salt in an attempt to limit ankle edema and to keep her heart symptoms to a minimum? What would you do?

A Woman With an Artificial Valve Prosthesis

Once, women with heart valve prostheses were advised not to become pregnant for fear the increased blood volume gained during pregnancy would overwhelm the artificial valve. Today, women with a valve prosthesis complete pregnancy safely (Davidson & Graham, 2007). One potential problem involves the use of oral anticoagulants that a woman takes to prevent the formation of clots at the valve site. Because sodium warfarin (Coumadin) may increase the risk of congenital anomalies in infants (pregnancy risk category D), women are usually placed on low-molecular-weight heparin therapy before becoming pregnant to reduce this risk. Heparin does not cross the placenta and so does not interfere with fetal development or fetal coagulation (category C). Subclinical bleeding from the anticoagulant in the mother can cause placental dislodgement. Observe a woman who is taking an anticoagulant for signs of petechiae and signs of premature separation of the placenta during pregnancy and labor.

A Woman With Chronic Hypertensive Vascular Disease

Women with chronic hypertensive disease come into pregnancy with an elevated blood pressure (140/90 mm Hg or above). Hypertension of this kind is usually associated with arteriosclerosis or renal disease, making it a problem of the older pregnant woman. Chronic hypertension places both the woman and fetus at high risk because fetal well-being can be compromised by poor placental perfusion during the pregnancy (Schulenburg, 2007). Management is prescription of beta-blockers and ACE inhibitors to reduce blood pressure by peripheral dilation to a safe level but not reduce it below the threshold that allows for good placenta circulation. Methyldopa (Aldomet) is a typical drug that is prescribed.

A Woman With Venous Thromboembolic Disease

The incidence of venous thromboembolic disease increases during pregnancy because of a combination of stasis of blood in the lower extremities from uterine pressure and hypercoagulability (the effect of elevated estrogen; Box 20.4). When the pressure of the fetal head at birth puts additional pressure on lower extremity veins, damage can occur to the walls of the veins. When this triad of effects is in place (stasis, vessel damage, and hypercoagulation), the stage is set for thrombus formation in the lower extremities. The likelihood of **deep vein thrombosis (DVT)** leading to pulmonary emboli increases for women 30 years of age or older because increased age is yet another risk factor for thrombosis formation (Segal et al., 2007).

A woman notices pain and redness usually in the calf of a leg. The risk of thrombus formation can be reduced through common-sense measures such as avoiding the use of constrictive knee-high stockings, not sitting with legs crossed at the knee, and avoiding standing in one position for a long period. If a thrombus does occur during pregnancy, it is diagnosed by a woman's history and Doppler ultrasonography. A woman will be treated with bed rest and intravenous heparin for 24 to 48 hours. After this, she may be prescribed subcutaneous heparin every 12 or 24 hours for the duration of the pregnancy. It is generally recommended that the lower abdomen be used for rotating sites for subcutaneous heparin administration. With pregnancy, however, this site is usually avoided and the injection sites are limited to the arms and thighs. Heparin dosage is regulated by frequent partial thromboplastin time (PTT) determinations. Additional measures of care for a woman with DVT, such as heat, elevation, and bed rest, are discussed in Chapter 25, because 50% of thromboses that occur with pregnancy occur in the postpartum period.

Women taking heparin during pregnancy should not take any additional injections once labor begins to help reduce the possibility of hemorrhage at birth; they are not candidates for routine episiotomy or epidural anesthesia for this same reason unless at least 4 hours has passed since the last heparin dose was given. PTT determinations should be continued during labor. Either heparin or sodium warfarin (Coumadin) can be prescribed after birth if a woman is not breastfeeding; Coumadin should be used cautiously wih breastfeeding.

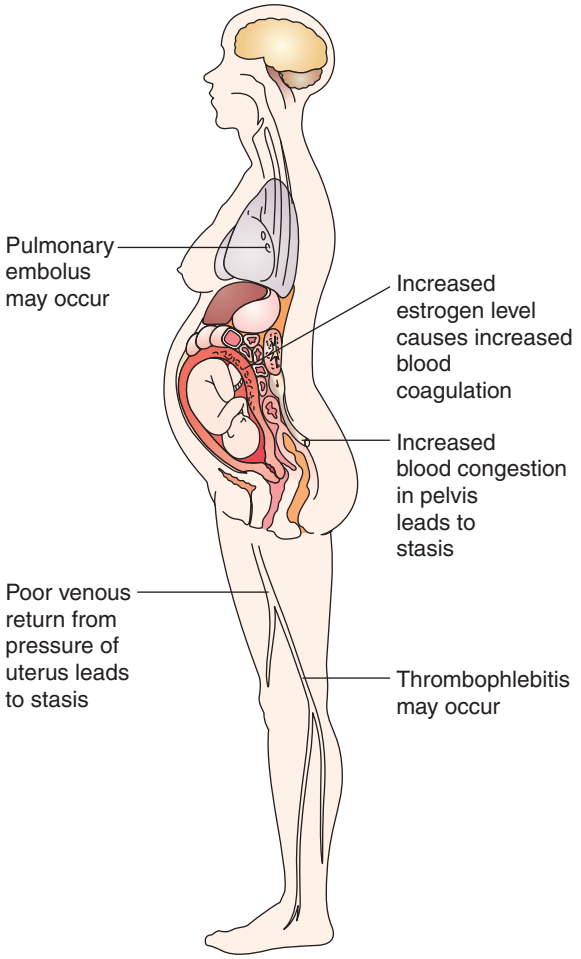
A particular group of women has been identified as being more susceptible to thrombi formation, spontaneous miscarriage, fetal death, and hypertension of pregnancy: women with antiphospholipid antibodies (aPLA) (Mavragani et al., 2007). It is not known why aPLA occur in some women and not in others, but these antibodies probably represent an autoimmune process. Women who are identified as aPLA positive may be started on a prophylactic program of aspirin or subcutaneous heparin during pregnancy that is continued postpartum to reduce the possibility of DVT. Administration of a corticosteroid may help to reduce the formation of additional antibodies and so may also be prescribed. After pregnancy, such women should not begin an oral contraceptive because it can increase blood coagulation and the possibility of thrombi formation.

The chief danger of thrombophlebitis is pulmonary embolism or a clot lodging in the pulmonary artery and blocking circulation to the lungs and heart. Symptoms of pulmonary embolism include:

- Chest pain
- Sudden onset of dyspnea
- Cough with hemoptysis
- Tachycardia or missed beats
- Severe dizziness or fainting from lowered blood pressure

Pulmonary embolism needs to be recognized as it is an immediate emergency (Cansino & Lipsett, 2007). Care measures for this are discussed in Chapter 25.

Box 20.4 Assessment
Assessing a Pregnant Woman With Venous Thromboembolic Disease



HEMATOLOGIC DISORDERS AND PREGNANCY

Hematologic disorders during pregnancy involve either blood formation or coagulation disorders.

Anemia and Pregnancy

Because the blood volume expands during pregnancy slightly ahead of the red cell count, most women have a pseudo-anemia

of early pregnancy. This condition is normal and should not be confused with true types of anemia that can occur as complications of pregnancy. True anemia is present when a woman's hemoglobin concentration is less than 11 g/dL (hematocrit <33%) in the first or third trimester of pregnancy or hemoglobin concentration is less than 10.5 g/dL (hematocrit <32%) in the second trimester (Arnett & Greenspoon, 2007).

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for ineffective tissue perfusion related to maternal anemia during pregnancy.

Outcome Evaluation: Client's hemoglobin is above 11 mg/dL; fetal heart rate is 120 to 160 beats per minute; client takes prenatal supplement daily.

A Woman With Iron-Deficiency Anemia

Iron-deficiency anemia is the most common anemia of pregnancy, complicating as many as 15% to 25% of all pregnancies (Reveiz, Gyte, & Cuervo, 2009). Many women enter pregnancy with a deficiency of iron stores resulting from a diet low in iron, heavy menstrual periods, or unwise weight-reducing programs. Iron stores are apt to be low in women who were pregnant less than 2 years before the current pregnancy or those from low socioeconomic levels who have not had iron-rich diets. When the hemoglobin level is below 12 mg/dL (hematocrit <33%), iron deficiency is suspected. It is confirmed by a corresponding low serum iron level and an increased iron-binding capacity.

Iron is made available to the body by absorption from the duodenum into the bloodstream after it is ingested. In the bloodstream, it is bound to transferrin for transport to the liver, spleen, and bone marrow. At these sites, it is incorporated into hemoglobin or stored as ferritin.

Iron-deficiency anemia is characteristically a microcytic (small red blood cell), hypochromic (less hemoglobin than the average red cell) anemia because when an inadequate supply of iron is ingested, iron is unavailable for incorporation into red blood cells. Both hematocrit and hemoglobin will be reduced (<33% and <12 mg/dL, respectively). The serum transferrin level will be under 100 mg/dL, the transferrin saturation level will be under 5%, the serum iron level will be under 30 μg/dL, and the mean corpuscular hemoglobin concentration will be under 30; iron-binding capacity, in contrast, will be increased (>400 μg/dL). Iron-deficiency anemia is mildly associated with low birth weight and preterm birth. Because the body recognizes that it needs increased nutrients, some women with this develop pica, or the craving and eating of substances such as ice or starch (Mills, 2007). A woman experiences extreme fatigue and poor exercise tolerance because she cannot transport oxygen effectively.

To prevent this common anemia, women should take prenatal vitamins containing an iron supplement of 60 mg elemental iron as prophylactic therapy during pregnancy. In addition, they need to eat a diet high in iron and vitamins (green leafy vegetables, meat, legumes, fruit). Women who develop iron-deficiency anemia will be prescribed therapeutic levels of medication (120 to 200 mg elemental iron/day), usually in the form of ferrous sulfate or ferrous gluconate.

Iron is best absorbed from an acid medium. Therefore, advise women to take iron supplements with orange juice or a vitamin C supplement, which supplies ascorbic acid. If they are not already enrolled in the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC) but are eligible, making a referral could help ensure a better diet. When women begin to take a prescribed iron supplement, new red blood cells should begin to increase, or their reticulocyte counts should rise from a normal range (0.5% to 1.5%) to 3% to 4% by 2 weeks' time. Some women report constipation or gastric irritation when taking oral iron supplements. Increasing roughage in the diet and always taking the pills with food help reduce these symptoms. Ferrous sulfate turns stools black so caution women about this to prevent them worrying that they are bleeding internally. If iron-deficiency anemia is severe and a woman has difficulty with oral iron therapy, intramuscular or intravenous iron dextran can be prescribed.

A Woman With Folic Acid–Deficiency Anemia

Folic acid, or folacin, one of the B vitamins, is necessary for the normal formation of red blood cells in the mother as well as being associated with preventing neural tube defects in the fetus. Folic acid–deficiency anemia is seen in 1% to 5% of pregnancies. It occurs most often in multiple pregnancies because of the increased fetal demand; in women with a secondary hemolytic illness in which there is rapid destruction and production of new red blood cells; in women who are taking hydantoin, an anticonvulsant agent that interferes with folate absorption; in women who have been taking oral contraceptives; and in women who have had a gastric bypass for morbid obesity (Arnett & Greenspoon, 2007). The anemia that develops is a **megaloblastic anemia** (enlarged red blood cells). The mean corpuscular volume will be elevated, in contrast to the lowered level seen with iron-deficiency anemia. The deficiency may take several weeks to develop, so it often becomes most apparent during the second trimester of pregnancy. It may be a contributory factor in early miscarriage or premature separation of the placenta.

Because the fetal effects of deficiency occur in the first few weeks of fetal development, women expecting to become pregnant are advised to begin a supplement of 400 μg folic acid daily (Bernstein & Weinstein, 2007) in addition to eating folacin-rich foods (green leafy vegetables, oranges, dried beans). During pregnancy, the folic acid requirement increases to 600 μg/day. Over-the-counter multivitamin preparations generally do not contain adequate folic acid for pregnancy, whereas vitamins specifically designed for pregnancy do. Women who develop folic acid–deficiency anemia are prescribed even higher or therapeutic levels of folic acid (Novak, 2007).

At prenatal visits, ask whether a woman is taking her prescribed vitamin. To save money, women may not have a prescription filled and may be using over-the-counter, less expensive types, not being aware of the difference.

A Woman With Sickle Cell Anemia

Sickle cell anemia is a recessively inherited hemolytic anemia caused by an abnormal amino acid in the beta chain of hemoglobin. If the abnormal amino acid replaces the amino acid valine, sickle hemoglobin (HbS) results; if it is substituted for

the amino acid lysine, nonsickling hemoglobin (HbC) results. An individual who is heterozygous (has only one gene in which the abnormal substitution has occurred) has the sickle cell trait (HbAS). If the person is homozygous (has two genes in which the substitution has occurred), sickle cell disease (HbSS) results.

With the disease, the majority of red blood cells are irregular or sickle shaped so they cannot carry as much hemoglobin as can normally shaped red blood cells. When oxygen tension becomes reduced, as occurs at high altitudes, or blood becomes more viscid than usual (dehydration), the cells tend to clump because of the irregular shape. This clumping can result in vessel blockage with reduced blood flow to organs. The cells then will hemolyse, reducing the number available and causing a severe anemia.

Approximately 1 in every 10 African Americans has the sickle cell trait (i.e., carries a recessive gene for S hemoglobin but is asymptomatic); theoretically, 1 in every 400 African Americans has the disease, although with interracial marriages increasing, the disease is no longer confined to one ethnic group (Zack-Williams, 2007).

Although the sickle cell trait does not appear to influence the course of pregnancy, prematurity, miscarriage, or perinatal mortality rates of these may be higher for women with the homozygous disease. Women with the trait seem to have an increased incidence of asymptomatic bacteriuria, resulting in an increased incidence of pyelonephritis.

At any time in life, sickle cell anemia is a threat to life if vital blood vessels such as those to the liver, kidneys, heart, lungs, or brain become blocked. In pregnancy, blockage to the placental circulation can directly compromise the fetus, causing low birth weight and possibly fetal death.

Assessment. All African American women who have not been previously tested should be screened for sickle cell anemia at a first prenatal visit. Hemoglobin levels for all women with sickle cell disease should be obtained throughout pregnancy. A woman with sickle cell disease may normally have a hemoglobin level of 6 to 8 mg/100 mL. Unless she receives active interventions to raise this level, she will maintain it during pregnancy, reducing oxygen to the fetus. Hemolysis in a sickle cell crisis may occur so rapidly that a woman's hemoglobin level can fall to 5 or 6 mg/100 mL in a few hours. There is an accompanying rise in her indirect bilirubin level because she cannot conjugate the bilirubin released from so many red blood cells so quickly destroyed.

Because a pregnant woman with sickle cell anemia is more susceptible to bacteriuria than other women, a clean-catch urine sample is collected periodically during pregnancy to detect developing bacteriuria while a woman is still asymptomatic.

Throughout pregnancy, monitor a woman's diet to be certain she is consuming sufficient amounts of folic acid and possibly an additional folic acid supplement, which may be necessary to build new red blood cells. Her fluid intake should also be carefully monitored. She should consume at least eight glasses of fluids daily. Early in pregnancy, when she may be nauseated, her fluid intake can easily decrease, and dehydration and a subsequent sickle cell crisis may occur.

Assess a woman's lower extremities at prenatal visits for varicosities or pooling of blood in leg veins, which are apt to occur from uterine pressure as pregnancy advances. Such pooling and pressure can lead to red cell destruction. Standing for long periods during the day increases this pressure, whereas sitting on a chair with the legs elevated or lying on the side in a modified Sims' position encourages venous return from the lower extremities. Help a woman plan her day so she has limited long periods of standing and adequate rest periods.

Fetal health is usually monitored during pregnancy by an ultrasound examination at 16 to 24 weeks to assess for intrauterine growth restriction and by weekly nonstress or ultrasound examinations beginning at about 30 weeks. Blood flow through the uterus and placenta may be measured by blood flow velocity. If blood flow velocity is reduced, the chance of intrauterine growth restriction is increased.

Therapeutic Management. Interventions to prevent sickle cell crisis can include periodic exchange transfusions throughout pregnancy to replace sickled cells with non-sickled cells. An exchange transfusion serves a secondary purpose of removing a quantity of the increased bilirubin resulting from the breakdown of red blood cells as well as restoring the hemoglobin level (Linker, 2009). If a crisis occurs, controlling pain, administering oxygen as needed, and increasing the fluid volume of the circulatory system to lower viscosity are important interventions (see Chapter 44 for a discussion of therapy of sickle cell anemia in children). The fluid administered is often hypotonic (0.45 saline) to keep plasma tension low because of the difficulty a woman has concentrating urine to remove large amounts of fluid. As a rule, women with sickle cell disease are not given an iron supplement during pregnancy. Sickled cells cannot incorporate iron in the same manner as non-sickled cells can, so excessive iron buildup may result. Women do need a folic acid supplement to keep the new cells produced from being megaloblastic.

If a woman develops an infection that raises her temperature and causes her to perspire more than normally (creates dehydration) or contracts a respiratory infection that compromises air exchange so that her Po_2 is lowered, hospitalization for observation may be necessary to rule out the development of a sickle cell crisis and subsequent hemolysis of crowded cells (Szymanski & Aina-Mumuney, 2007).

When the fetus is mature, the time and method of birth are individualized. Keep a woman well hydrated in labor. If an operative birth is necessary, she generally receives epidural anesthesia as general anesthesia poses a possible risk of hypoxia. In the postpartal period, early ambulation and wearing pressure stockings can help reduce the risk of thromboembolism from stasis in lower extremities.

Women generally are interested in determining at birth whether their child has inherited the disease. Because the disorder is recessively inherited, if one of the parents has the disease and the other is free of the disease and trait, the chances that the child will inherit the disease are zero. If a woman has the disease and her partner has the trait, the chances that the child will be born with the disease are 50% (see Chapter 7). If both parents have the disease, all their children will also have the disease.

Symptoms of sickle cell disease do not become clinically apparent until an infant's fetal hemoglobin converts to a largely adult pattern (in 3 to 6 months). Fetal hemoglobin is composed of two alpha and two gamma chains; adult hemoglobin is composed of two alpha and two beta chains. Because the sickle cell trait is carried on the beta chain,

symptoms will not be manifested clinically until this chain appears. Electrophoresis of red blood cells obtained during fetal life by percutaneous umbilical blood sampling or amniocentesis, however, can reveal the presence of the disease on the few beta chains already present in utero. Newborns have approximately 15% adult hemoglobin at birth, so electrophoresis testing at birth can also reveal if the disease is present. Screening is routine in some settings. Nursing care of the child with sickle cell disease is discussed in Chapter 44.

The Woman with Thalassemia

The thalassemias are a group of autosomal recessively inherited blood disorders that lead to poor hemoglobin formation and severe anemia. They occur most frequently in Mediterranean, African, and Asian populations (Waterbury, 2007). Symptoms first appear in childhood. Treatment focuses on combating anemia through such measures as folic acid supplementation and perhaps blood transfusion to infuse hemoglobin rich red blood cells. Women do not usually take an iron supplement during pregnancy or they could receive an iron overload because of the iron also infused by blood transfusions. Care of a child with both forms of thalassemia, alpha and beta, is discussed in Chapter 44.

The Woman with Malaria

Malaria is a protozoan infection that is transmitted to people by *Anopheles* mosquitoes (Garner & Gulmezoglu, 2009). The infection causes red blood cells to stick to the surface of capillaries causing obstruction of these vessels. This can result in end organ anoxia when blood can not reach organs effectively.

Although the disorder does not have a high incidence in the United States, newly immigrated women may be infected with it. It is important to consider during pregnancy as it can be transmitted to a fetus by mother-to-fetus transmission.

The incubation period for the most frequently occurring type is 12 to 14 days. The most noticeable symptoms are elevated liver function tests accompanying fever, malaise, and headache. If not treated, thrombocytopenia, anemia, and renal failure can develop.

Malaria can be prevented by wearing clothing that covers most of the body and using an insect repellent when in an area infested with mosquitoes, sleeping at night with mosquito nets, or keeping windows closed to prevent mosquitoes from entering. As further prevention, urge women to delay travel to endemic areas until after pregnancy if possible.

Treatment is with several antimalaria drugs. Chloroquine is safe to administer during all trimesters of pregnancy so it is the drug of choice (Wiltz et al., 2008). Sulfadoxine-pyrimethamine may be administered during the last trimester. Quinine, malarone, or tetracyclines should not be used at any point in pregnancy or with women who are breastfeeding. Antimalarial therapy may also reduce the incidence of low birth weight and preterm birth.

Coagulation Disorders and Pregnancy

Most coagulation disorders are sex linked or occur only in males and so have little effect on pregnancies. However, von Willebrand disease is a coagulation disorder inherited as an autosomal dominant trait that does occur in women (Linker, 2009). From the time she was a child, a woman would have noticed menorrhagia or frequent episodes of epistaxis. If these symptoms were not severe, though, the condition may go undiagnosed until pregnancy, when a woman experiences a spontaneous miscarriage or postpartum hemorrhage.

Women with the disorder have normal platelet counts, but bleeding time is prolonged. Levels of factor VIII–related antigen (VIII-R) and factor VIII coagulation activity (VIII-C) are both reduced. Replacement of these factors by infusion of cryoprecipitate or fresh-frozen plasma may be necessary before labor to prevent excessive bleeding.

Hemophilia B (Christmas disease, factor IX deficiency) is a sex-linked disorder, so the actual disease occurs only in males. However, female carriers may have such a reduced level of factor IX (only 33% of normal) that hemorrhage with labor or a spontaneous miscarriage can be a serious complication in these women. Carriers of the disorder need to be identified before pregnancy. Restoration of factor IX levels can be done by infusion of factor IX concentrate or fresh-frozen plasma.

Percutaneous umbilical blood sampling can be used to detect whether a male fetus has hemophilia. If there is a family history of hemophilia, before an internal fetal heart rate monitor is attached or fetal scalp blood sampling is done during labor, the fetal status needs to be determined. If the fetus has a coagulation disorder, these procedures would be contraindicated because they could result in extensive fetal blood loss.

Idiopathic thrombocytopenic purpura (ITP), a decreased number of platelets, can occur at any time in life and so occasionally occurs during pregnancy. The cause of the condition is unknown, but it is assumed to be an autoimmune illness (an antiplatelet antibody that destroys platelets is apparently released). Symptoms of the illness usually occur shortly after a viral invasion such as an upper respiratory infection (McMillan, 2007).

Without an adequate level of platelets, minute petechiae or large ecchymoses appear on a woman's body. Frequent nosebleeds may occur. Laboratory studies reveal a marked thrombocytopenia (platelet count may be as low as 20,000/mm^3 from a usual count of 150,000 mm^3).

The illness typically runs a 1- to 3-month limited course, but because the symptoms are similar to pregnancy-induced hypertension with HELLP syndrome, a serious complication of pregnancy (see Chapter 21), they are frightening when they occur during pregnancy. A platelet transfusion or plasmapheresis may be administered to temporarily increase the platelet count. Oral prednisone is also effective. Women with the phenomenon need to be identified during pregnancy because the decreased platelet count can lead to increased bleeding at birth. In addition, the antiplatelet factor can cross the placenta and cause accompanying platelet destruction in the newborn, or allow a newborn to be born with the illness (see Chapter 44 for care of the child with ITP).

✔ Checkpoint Question 20.2

Which statement by a woman with sickle cell anemia would alert you she may need further instruction on prenatal care?

a. "I understand why folic acid is important for red cell formation."

b. "I'm careful to drink at least eight glasses of fluid every day."
c. "I take an iron pill every day to help grow new red blood cells."
d. "I've stopped jogging so I don't risk becoming dehydrated."

RENAL AND URINARY DISORDERS AND PREGNANCY

Adequate kidney function is important to a successful pregnancy outcome because a woman is excreting waste products not only for herself but also for the fetus. This dual function makes any condition that interferes with kidney or urinary function potentially serious.

A Woman With a Urinary Tract Infection

As many as 4% to 10% of nonpregnant women have asymptomatic bacteriuria (organisms are present in the urine without symptoms of infection). In a pregnant woman, because the ureters dilate from the effect of progesterone, stasis of urine occurs. The minimal glucosuria that occurs with pregnancy allows more than the usual number of organisms to grow. This causes asymptomatic urinary tract infections (UTIs) in as many as 10% to 15% of pregnant women (Vazquez & Villar, 2009). Asymptomatic infections are potentially dangerous because they can progress to pyelonephritis (infection of the pelvis of the kidney) and are associated with preterm labor and premature rupture of membranes. Women with known vesicoureteral reflux (backflow of urine into the ureters) tend to develop UTIs or pyelonephritis more often than others. The organism most commonly responsible for UTI is *Escherichia coli* from an ascending infection. A UTI can also occur as a descending infection, or begin in the kidneys from the filtration of organisms present from other body infections. If the infectious organism is determined to be *Streptococcus* B, vaginal cultures should be obtained because streptococcal B infection of the genital tract is associated with pneumonia in newborns.

Assessment

A UTI typically is manifested by frequency and pain on urination. With pyelonephritis, a woman develops pain in the lumbar region (usually on the right side) that radiates downward. The area feels tender to palpation. She may have accompanying nausea and vomiting, malaise, pain, and frequency of urination. Her temperature may be elevated only slightly or may be as high as 103° to 104° F (39° to 40° C). The infection usually occurs on the right side because there is greater compression and urinary stasis on the right ureter from the uterus being pushed that way by the large bulk of the intestine on the left side. A urine culture will reveal over 100,000 organisms per milliliter of urine, a level diagnostic of infection.

Therapeutic Management

Obtain a clean-catch urine sample for culture and sensitivity from women with possible symptoms of UTI (see Chapter 11). Many health care agencies ask women for clean-catch urine specimens at intervals during pregnancy (tested by a rapid dipstick method) to detect infection before it becomes symptomatic. A sensitivity test after a culture will determine which antibiotic will best combat the infection. Amoxicillin, ampicillin, and cephalosporins are effective against most organisms causing UTIs and are safe antibiotics during pregnancy. The sulfonamides can be used early in pregnancy but not near term because they can interfere with protein binding of bilirubin, which then leads to hyperbilirubinemia in the newborn. Tetracyclines are contraindicated in pregnancy as they cause retardation of bone growth and staining of the fetal teeth (Subramanian et al., 2008).

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for infection related to stasis of urine with pregnancy

Outcome Evaluation: Oral temperature is below 100.4° F (38° C), and a clean-catch urine specimen has a bacteria count below 100,000 colonies per milliliter.

All women during pregnancy can be reminded of common measures to prevent UTIs, such as:

- Voiding frequently (at least every 2 hours)
- Wiping front to back after voiding and bowel movements
- Wearing cotton, not synthetic fiber, underwear
- Voiding immediately after sexual intercourse

The pregnant woman with a UTI needs to take the additional measure of drinking an increased amount of fluid to flush out the infection from the urinary tract. Do not merely tell her to "push fluids" or "drink lots of water." Give her a specific amount to drink every day (up to 3 to 4 L per 24 hours) to make certain she does increase her fluid intake sufficiently.

A woman can promote urine drainage by assuming a knee–chest position for 15 minutes morning and evening. In this position, the weight of the uterus is shifted forward, releasing the pressure on the ureters and allowing urine to drain more freely.

If a woman has one UTI during pregnancy, the chances are high that she will develop another late in pregnancy, when urinary stasis tends to be even greater. She may, therefore, be kept on prophylactic antibiotics throughout the remainder of the pregnancy. Ask at prenatal visits whether she is continuing to take this type of prophylactic medicine. When women have pain and symptoms of urinary frequency, they take medication well. When they no longer have any clinical evidence that they are sick, their compliance rate, like any other adult's, begins to fall dramatically. A woman may need to post a chart on her refrigerator door or in her bathroom to remind herself to take the medication. Leaving the medicine on a counter to remind herself to take it is not a good habit to develop because soon she will have a new baby in the house; encourage her to keep medicine out of sight and reach to get into the habit of "childproofing" even at this early stage.

Pyelonephritis occurs as an extension of a urinary tract infection or infection that originated in or spread to the kidney (Nguyen & Witter, 2007). If this develops, a

woman may be hospitalized for 24 to 48 hours while she is treated with intravenous antibiotics. After this acute episode, she will be maintained on a drug such as oral nitrofurantoin (Macrodantin) for the remainder of the pregnancy. Acidifying urine by the use of ascorbic acid (vitamin C), which is often recommended in nonpregnant women, is not usually recommended during pregnancy because a newborn can develop scurvy in the immediate neonatal period from withdrawal.

After birth, a woman who developed more than one UTI may have an intravenous pyelogram or ultrasound scheduled to help detect any urinary tract abnormality that might be present, such as vesicoureteral reflux, to help prevent future infections.

A Woman With Chronic Renal Disease

In the past, females with chronic renal disease did not reach childbearing age or were advised not to have children because of their high risk status during pregnancy. Today, women with chronic renal disease can have children because pregnancy does not appear to cause progressive deterioration of kidney lesions. With conscientious prenatal care, even women who have had renal transplants can expect to have healthy pregnancies and healthy children (Fischer, 2007).

Women with chronic renal disease may develop severe anemia during pregnancy because their diseased kidneys do not produce erythropoietin, which is necessary for red cell formation. Fortunately, synthetic erythropoietin is now available and is safe to take during pregnancy (Masters, 2007).

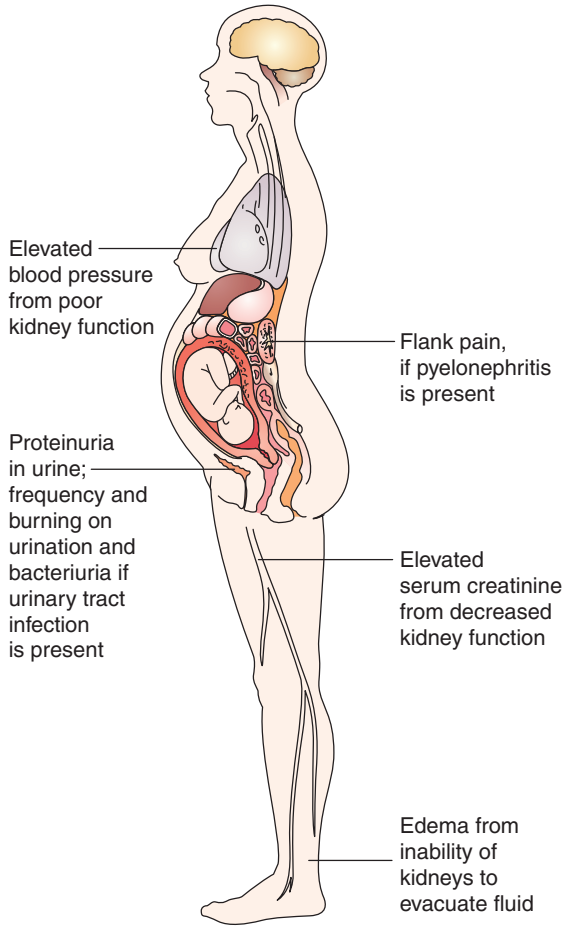
Because the glomerular filtration rate normally increases during pregnancy, a woman's serum creatinine level (a measure of kidney function that elevates when kidneys are under stress) may be actually slightly below normal during pregnancy. A usual serum creatinine level is 0.7 mg/100 mL; during pregnancy, it falls to about 0.5 mg/100 mL. Women with kidney disease who normally have a serum creatinine level of more than 2.0 mg/dL may be advised not to undertake a pregnancy in case the increased strain on already damaged kidneys leads to kidney failure.

In many women, it is difficult to interpret kidney function during pregnancy based on nonpregnant values (Box 20.5). Trace amounts of glucose and protein in the urine are common during pregnancy because of increased glomerular permeability, so **proteinuria** (protein in urine) must be compared to a woman's individualized prepregnancy level to be meaningful. If a woman is told proteinuria may occur during pregnancy, she will understand it is an expected change of pregnancy, not a forecast of changing kidney function. Many women with renal disease have elevated blood pressure. To be meaningful, their blood pressure levels during pregnancy must also be compared with prepregnancy levels (Williams & Davison, 2008).

Many women with renal disease routinely take a corticosteroid such as oral prednisone at a maintenance level. This drug therapy typically is continued throughout pregnancy. Although animal studies have shown an increased incidence of cleft palate from corticosteroid use during pregnancy, this does not appear to be true in humans. The infant may be hyperglycemic at birth because of the suppression of insulin activity by the corticosteroid.

Box 20.5 Assessment

Assessing a Pregnant Woman With Renal Disease



Although successful pregnancy in women with kidney transplants is to be expected, women should be considered individually to determine whether they will be able to carry a pregnancy to term before a pregnancy is initiated (del Mar Colon & Hibbard, 2007). Criteria to be evaluated include:

- A woman's general health and the time since the transplant (preferably >2 years)
- Serum creatinine level
- The presence of proteinuria or hypertension or signs of graft rejection
- Medications taken to reduce graft rejection

It is helpful if the drugs a woman is taking are limited to prednisone and azathioprine (an antimetabolite [Imuran], but with no reports of fetal compromise from its use). Women with severe renal disease may require dialysis to aid kidney function during pregnancy (Gomez et al., 2007). With dialysis, there is a risk of preterm labor, perhaps because progesterone is removed with the dialysis. To prevent this complication, progesterone may be administered intramuscularly before the procedure. If hemodialysis is used, it should be

scheduled frequently and for short durations to avoid acute fluid shifts. The heparin administered in connection with hemodialysis is safe during pregnancy because it does not cross the placenta. Even in light of the expanding uterine size, peritoneal dialysis is actually preferred over hemodialysis because it normally causes less drastic fluid shifts. This can be accomplished on an ambulatory basis (continuous ambulatory peritoneal dialysis) throughout pregnancy.

Women with renal disease may need a nutrition consultation during pregnancy if they are on a low potassium diet to avoid a buildup of potassium that accumulates because their diseased kidneys do not evacuate this well (Stover, 2007). They also may need a great deal of emotional support during pregnancy. They are aware that kidneys are vital for life and that the stress of pregnancy on damaged kidneys may cause them to fail. They are aware that by being pregnant they are risking not only the life of the child growing inside them but also their own life. They may need extra support and information to know how their fetus is doing. They may need extra time with their infant at birth for bonding because they may have been too concerned during pregnancy to begin this process.

RESPIRATORY DISORDERS AND PREGNANCY

Respiratory diseases range from mild (the common cold) to severe (pneumonia) to chronic (tuberculosis or chronic obstructive pulmonary disease [COPD]). Any respiratory condition can worsen in pregnancy because the rising uterus compresses the diaphragm, reducing the size of the thoracic cavity and available lung space. Any respiratory disorder can pose serious hazards to the fetus if allowed to progress to the point where the mother's oxygen–carbon dioxide exchange is altered or the mother or fetus cannot receive enough oxygen.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for ineffective breathing pattern related to respiratory changes during pregnancy

Outcome Evaluation: Respiratory rate is 16 to 20 per minute, P_{O_2} is above 80 mm Hg, P_{CO_2} is below 40 mm Hg, and fetal heart rate is 120 to 160 beats per minute with good variability.

A Woman With Acute Nasopharyngitis

Acute nasopharyngitis (common cold) tends to be more severe during pregnancy than at other times because during pregnancy, estrogen stimulation normally causes some degree of nasal congestion. This means that even with a minor cold, a woman can find it difficult to breathe. Aspirin should be avoided as a cold remedy during pregnancy because of possible interference with blood clotting in both mother and fetus and the possibility of prolonged pregnancy at term (Karch, 2009). Because common colds are invariably caused by a virus, antibiotic therapy is unnecessary except to prevent a secondary infection. Although most simple cough syrups contain no ingredients that would make them unsafe for use during pregnancy, women should check with their health care provider before taking any over-the-counter medication for a cold (Box 20.6).

BOX 20.6 ✻ Focus on Family Teaching

Relieving Upper Respiratory Symptoms During Pregnancy

Q. Angelina tells you, "I get a lot of colds. What should I do to keep symptoms under control during pregnancy?"

A. Use the following guidelines to help combat common cold symptoms during pregnancy:

- Be sure to get extra rest and sleep and eat a diet high in vitamin C (orange juice and fruit) to help boost the immune system.
- If you experience any aches and pains, take acetaminophen (Tylenol) every 4 hours. Do not take acetosalicylic acid (aspirin) during pregnancy.
- Use a room humidifier, especially at night, to moisten nasal secretions and help mucus drain.
- Use only over-the-counter cough drops or syrups that contain natural ingredients such as honey and lemon to help reduce coughing.
- Apply a medicated vapor rub to your chest if you prefer to help relieve nasal congestion.
- Use cool or warm compresses to relieve sinus headaches. Check with your health care provider regarding the use of over-the-counter cough drops, syrups, or decongestants to be certain that any drug you take is safe during pregnancy.

A Woman With Influenza

Influenza is caused by a virus, identified as type A, B, or C. The disease spreads in epidemic form and is accompanied by high fever, extreme prostration, aching pains in the back and extremities, and generally a sore, raw throat. Contrary to early reports, influenza infection has not been clearly correlated with congenital anomalies in children although it can be a cause of preterm labor. For unknown reasons, some studies have shown a link between influenza during pregnancy and schizophrenia in children born of that pregnancy (Venables et al., 2007). Treatment includes an antipyretic such as acetaminophen (Tylenol) to control fever. Oseltamivir (TamiFlu), an oral antiviral drug that is category C, should be used cautiously until its long-term effects are known (Subramanian et al., 2008). Because influenza vaccines are made from killed virus, women may be immunized safely against influenza during pregnancy (Fiore et al., 2007).

A Woman With Pneumonia

Pneumonia is the bacterial or viral invasion of lung tissue by pathogens such as *S. pneumoniae, Haemophilus influenzae,* and *Mycoplasma pneumoniae.* After the invasion, an acute inflammatory response occurs in the lung alveoli with exudate

of red blood cells, fibrin, and polymorphonuclear leukocytes into the alveoli. This process confines the bacteria or virus within segments of the lobes of the lungs but also fills alveoli with fluid, blocking off breathing space. If the collection of fluid is extreme, it can limit the oxygen available to the fetus. Therapy involves the use of an appropriate antibiotic and perhaps oxygen administration (Cansino & Lipsett, 2007). With severe disease, ventilation support may be necessary. There is a tendency for women with pneumonia late in pregnancy to begin preterm labor because of the oxygen deficit. If pneumonia is present during labor, oxygen should be administered so the fetus has adequate oxygen resources during contractions.

A Woman With Severe Acute Respiratory Syndrome

Severe acute respiratory syndrome (SARS) is a newly emerged infectious disease with the clinical symptoms of persistent fever, chills, muscle aches, malaise, dry cough, headache, and dyspnea. Common laboratory findings are decreased lymphocyte and platelet counts. A coronavirus has been identified as the pathogen responsible for the illness, which appears to have originated in southern China and has spread to become a potentially worldwide pandemic (Longman & Johnson, 2007). SARS spreads by close person-to-person contact via droplet transmission. The incubation period is 2 to 10 days. Therapy is vigorous, with intravenous antibiotics. Many women need respiratory support to survive. SARS during pregnancy creates such an acute illness that it is associated with high incidences of spontaneous miscarriage, preterm birth, and intrauterine growth restriction. There is no evidence of perinatal SARS infection among infants born to these mothers.

A Woman With Asthma

Asthma is a disorder marked by reversible airflow obstruction, airway hyperreactivity, and airway inflammation. It complicates about 5% to 9% of pregnancies and is potentially associated with an increased risk of perinatal complications. Women who have had asthma since childhood so know how to manage their asthma well are most apt to have successful pregnancies (Tata et al., 2007). Symptoms are often triggered by an inhaled allergen such as pollen or cigarette smoke. With inhalation of the allergen, there is an immediate release of bioactive mediators such as histamine and leukotrienes from an IgE/immunoglobulin interaction. This results in constriction of the bronchial smooth muscle, marked mucosal inflammation and swelling, and the production of thick bronchial secretions. These three processes cause a marked reduction in the size of the lumen of air passages. This causes a woman to have difficulty pulling in air; on exhalation, she has so much difficulty releasing air that she makes a high-pitched whistling sound (bronchial wheezing) from air being pushed past the bronchial narrowing. Asthma has the potential of reducing the oxygen supply to a fetus leading to preterm birth or fetal growth restriction if a major attack should occur during pregnancy, although this is not likely with well-managed asthma. Many women find that their asthma improves during pregnancy because of the high circulating levels of corticosteroids that are present. A woman should check with her physician or nurse-midwife about the safety of the medications she routinely takes for this disorder before pregnancy to be certain it will be safe to continue using them during pregnancy and breastfeeding.

The inhaled corticosteroids beclomethasone (Beclovent, Vancenase) and budesonide (Pulmicort, Rhinocort) are commonly used by women with persistent asthma and are also good choices for pregnant women and those who might become pregnant. Women who have been taking a corticosteroid during pregnancy may need parenteral administration of hydrocortisone during labor because of the added stress during this time. Beta-adrenergic agonists such as terbutaline and albuterol may be taken safely during pregnancy, but because they have the potential to reduce labor contractions the dosage is tapered close to term if possible (Boushey, 2007).

Many women use cromolyn sodium (Intal), a mast cell stabilizer, to help prevent symptoms. Many adolescents with asthma are prescribed leukotriene receptor antagonists such as montelukast sodium (Singulair) or zafirlukast (Accolate). All of these are pregnancy category B drugs and so may be continued during pregnancy (Montoro, 2007).

A Woman With Tuberculosis

Tuberculosis is a disease that should have been eradicated in view of the effective treatment available. However, in highly populated areas, the incidence has actually increased and in some areas is at epidemic proportions. Worldwide, it is still one of the leading causes of death.

With tuberculosis, lung tissue is invaded by *Mycobacterium tuberculosis,* an acid-fast bacillus. Macrophages and T lymphocytes surround the invading bacillus, but rather than actually killing it they merely surround and confine it. Fibrosis, calcification, and a final ring of collagenous scar tissue develop, effectively sealing off the organisms from the body and any further invasion or spread. The antibodies produced will thereafter cause a woman to have a positive response to a Mantoux (purified protein derivative [PPD]) test.

Assessment

In high-risk areas, women should undergo skin testing (a PPD test) at their first prenatal visit. Women need to be cautioned that a positive reaction does not necessarily mean they have the disease; it can mean they have at some time been exposed to tuberculosis and so have antibodies in their system. If a woman has a positive reaction, a chest radiograph to confirm the diagnosis will be scheduled. This can be done safely during pregnancy if the woman's abdomen is shielded. Symptoms of tuberculosis include:

- Chronic cough
- Weight loss
- Hemoptysis (coughing blood)
- Night sweats
- Low-grade fever
- Chronic fatigue

Therapeutic Management

Women with active tuberculosis need treatment during pregnancy (Cox, 2007). Isoniazid (INH) and ethambutol hydrochloride (Myambutol), the drugs of choice for tuberculosis, may be given without apparent teratogenic effects during

pregnancy. INH may result in a peripheral neuritis if a woman does not take supplemental pyridoxine (vitamin B_6) as well. Ethambutol may cause optic nerve involvement (optic atrophy and loss of green color recognition) in the mother. To detect this, test a woman monthly using the color section of a Snellen (eye test) chart. If symptoms develop, advise her to check with her health provider about discontinuing the drug.

A woman who had tuberculosis earlier in life must be especially careful to maintain an adequate level of calcium during pregnancy to ensure that tuberculosis pockets are not broken down. With tuberculosis, a woman is usually advised to wait 1 to 2 years after the infection becomes inactive before attempting to conceive. This is because recent inactive tuberculosis is more apt to become active during pregnancy than well-calcified lesions. Pressure on the diaphragm from below changes the shape of the lung, and an incompletely sealed pocket could be broken in this process. Pushing during labor may increase intrapulmonary pressure and cause the same phenomenon. Recent inactive tuberculosis may also become active during the postpartum period as the lung suddenly returns to its more vertical prepregnant position following birth, allowing calcium deposits to break open.

Although tuberculosis can be spread by the placenta to the fetus, it usually is spread to the infant after birth. A woman with a recent history of tuberculosis should have three negative sputum cultures before she holds or cares for her infant. If these are negative, there is no need to isolate the infant from the mother; she can even breastfeed. If active tuberculosis is in the home, the infant is generally discharged on prophylactic INH to prevent infection, with follow-up skin testing at 3-month intervals. If the infant is to be placed on INH, a mother also taking INH should not breastfeed (or the infant's dosage should be reduced). Otherwise, the combined dosage the infant receives (INH is found in breast milk) could be toxic to the infant.

A Woman with Chronic Obstructive Pulmonary Disease

COPD is constriction of the airway associated most often with long-term cigarette smoking. When women had their children between 20 and 30 years of age, COPD was rarely associated with pregnancy. Now that more and more women are waiting until age 35 to 40 to have children, the condition can be seen with pregnancy. Constrictive air disease limits the amount of oxygen that can reach the lungs so women may need additional rest because of fatigue and continuous supplemental oxygen for oxygen want. Some women have such severe symptoms while nonpregnant that they will be advised to avoid pregnancy (Wexler et al., 2007).

A Woman With Cystic Fibrosis

Cystic fibrosis is a recessively inherited disease in which there is generalized dysfunction of the exocrine glands (Uppalapati & Landry, 2007). This dysfunction leads to mucous secretions, particularly in the pancreas and lungs, becoming so viscid or thick that normal lung and pancreatic function is compromised.

Many men with cystic fibrosis are sterile because their semen is so thick that sperm cannot be motile. Fertility may be lessened in women with the disorder because sperm cannot migrate through viscid cervical mucus. This can make conception a concern. Reproductive technologies such as artificial insemination or in vitro fertilization may be necessary for conception so sperm are not obstructed by cervical mucus or fallopian tubal transport is not impaired.

Persons with the disease typically develop symptoms of chronic respiratory infection and overinflation of their lungs from the thickened mucus as well as an inability to digest fat and protein because the pancreas cannot release amylase. Because of poor pulmonary function that results in inadequate oxygen supply to the fetus, there is an increased risk for preterm labor and perinatal death during pregnancy. The presence of cystic fibrosis in the fetus may be identified by chorionic villi sampling or amniocentesis and identification of the abnormal gene on chromosome 7 during pregnancy or immediately after birth. Screening for the disorder is included in routine neonatal screening programs after birth.

Therapy for the illness consists of pancrelipase (Pancrease) to supplement pancreatic enzymes. Caution women to continue to take this even with nausea of early pregnancy. Although pancrelipase is a pregnancy risk category C drug (teratogenic effects are unknown), it does not appear to affect the fetus. Women are often also prescribed a bronchodilator or antibiotic to reduce pulmonary symptoms. In addition to pharmacologic measures, women with cystic fibrosis must perform chest physiotherapy daily to reduce the buildup of lung secretions. As women with the disorder excrete a higher level of sodium in persperation than others, they need to be carefully monitored during labor to be certain that they do not become dehydrated. Although pregnancy is a strain on an already stressed respiratory system, pregnancy does not appear to shorten the life span of women with the disorder.

Modifications for Pregnancy

Because pancrelipase may interfere with iron absorption, a woman is at greater risk for iron-deficiency anemia during pregnancy than other women. Therefore, an iron supplement usually is prescribed. Persons with cystic fibrosis have a higher-than-usual incidence of developing diabetes mellitus because of pancreas involvement; therefore, women need close monitoring of serum glucose levels at prenatal visits to detect the development of gestational diabetes.

Chest physiotherapy becomes difficult late in pregnancy because the process is exhausting. Moving to new positions is difficult, and lying prone, a position used frequently in postural drainage, is contraindicated in late pregnancy. A woman may need to plan more frequent and shorter sessions in modified positions (other than prone) to prevent exhaustion (Fig. 20.2). Fetal health will be monitored by ultrasound and nonstress tests to identify intrauterine growth restriction.

Modifications for the Postpartum Period

Help a woman plan how to conserve her energy for infant care in the immediate postpartum period so she does not become exhausted and can enjoy her newborn. The milk of a nursing mother with cystic fibrosis is high in sodium, and potentially places the infant at risk for hypernatremia, so

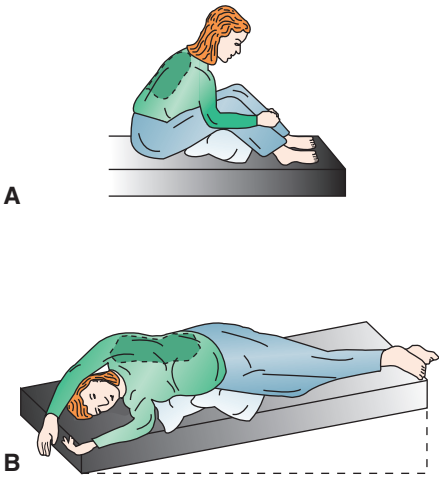


FIGURE 20.2 Modified positions for chest physiotherapy during pregnancy: (**A**) chest physiotherapy for the upper lobes; (**B**) chest physiotherapy for the lower lobes.

women with cystic fibrosis are usually advised not to breastfeed (Lipscomb & Novy, 2007). Breastfeeding could also be more tiring for the mother.

✔ Checkpoint Question 20.3

Suppose Angelina Gomez had tuberculosis as a teenager. What is a danger of this during pregnancy?

a. Calcium deposits that wall off old tuberculosis lesions can break down.
b. Tuberculosis can turn to pneumonia if a woman has a folic acid deficit.
c. PPD tests are always negative during pregnancy so TB goes undetected.
d. If tuberculosis spreads to the stomach, it can cause serious stomach ulcers.

RHEUMATIC DISORDERS AND PREGNANCY

Several rheumatic disorders occur in young adult women and so are seen during pregnancy. Because most of these illnesses result in discomfort, potential or actual pain related to disease pathology is the primary nursing diagnosis used. Women may not achieve a pain-free outcome during pregnancy because of the nature of these illnesses, but outcomes should center on a woman stating that her pain level is tolerable.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Pain related to rheumatic disorder during pregnancy

Outcome Evaluation: Client states she is moderately comfortable and able to maintain her usual level of daily activity.

A Woman With Rheumatoid Arthritis

Juvenile rheumatoid arthritis (sometimes referred to as chronic rheumatoid arthritis), a disease of connective tissue with joint inflammation and contracture, is most likely the result of an autoimmune response (Golding, Haque, & Giles, 2007). The disease pathology involves synovial membrane destruction. Inflammation with effusion, swelling, erythema, and painful motion of the joints occurs. Over time, formation of granulation tissue can fill the joint space, resulting in permanent disfigurement and loss of joint motion.

Women with juvenile rheumatoid arthritis frequently take corticosteroids and nonsteroidal anti-inflammatory drugs (NSAIDs) to prevent joint pain and loss of mobility. Some women may be taking oral aspirin therapy. Although they should continue to take these medications during pregnancy to prevent joint damage, large amounts of salicylates may lead to increased bleeding at birth or prolonged pregnancy (salicylate interferes with prostaglandin synthesis, so labor contractions are not initiated) (Karch, 2009). The infant may be born with a bleeding defect and may also experience premature closure of the ductus arteriosus because of the drug's effects. For this reason, a woman is asked to decrease her intake of salicylates approximately 2 weeks before term. A few women may be taking low-dose methotrexate, a carcinogen (pregnancy risk category X). They should consult their health care practitioner before becoming pregnant about the advisability of continuing this drug during pregnancy.

Symptoms of the disease may improve during pregnancy because of the naturally increased circulating level of corticosteroids in the maternal bloodstream during pregnancy. During the postpartum period, when a woman's corticosteroid levels fall to prepregnancy levels again, arthritis symptoms will probably recur.

In the postpartum period, the determination as to the safety of breastfeeding must be individualized based on the medication that each woman is taking. Those taking an NSAID such as ibuprofen can breastfeed. Those taking large doses of aspirin may be advised not to breastfeed because of the danger of increased bleeding in the infant.

A Woman With Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a multisystem chronic disease of connective tissue that can occur in women of childbearing age: its highest incidence is in women aged 20 to 40 years (Petri, 2007). It affects about 1 in every 2000 to 3000 pregnancies. Widespread degeneration of connective tissue (especially of the heart, kidneys, blood vessels, spleen, skin, and retroperitoneal tissue) occurs with onset of the illness. The most marked skin change is a characteristic erythematous butterfly-shaped rash on the face. In the kidneys, fibrin deposits develop, plugging and blocking the glomeruli and leading to necrosis and scarring. The thickening of collagen tissue in the blood vessels causes vessel obstruction. This can be life-threatening to a woman if blood flow to vital organs becomes compromised and life-threatening to a fetus if blood

flow to the placenta is obstructed. Many women with SLE have antiphospholipid antibodies, which increase the tendency for thrombi to form (Mavragani et al., 2007). In contrast, marked thrombocytopenia (decreased platelet count) is present, so clotting may be deficient. A woman may be taking a corticosteroid, NSAIDs, heparin, and salicylates to reduce disease symptoms.

The naturally increased circulation of corticosteroids during pregnancy may lessen symptoms in some women. In others, the chief complication of the disorder—acute nephritis with glomerular destruction—may occur for the first time during pregnancy.

With associated nephritis, a woman's blood pressure will rise. She will develop hematuria and decreased urine output. Proteinuria and edema may begin. It is difficult to differentiate these symptoms from the symptoms of pregnancy-induced hypertension, except that with pregnancy-induced hypertension there is no hematuria. Frequent monitoring of serum creatinine levels is necessary to assess kidney function. If this value is over 1.5 mg/dL and proteinuria and a decreased creatinine clearance value are also present, the fetus is seriously threatened. Dialysis to remove excess creatinine or plasmapheresis to replace platelets may be necessary to guard against hemorrhage at birth.

Women are asked to decrease salicylate use about 2 weeks prior to their anticipated birth to reduce the possibility of bleeding in the newborn. Intravenous hydrocortisone may be administered during labor to help a woman adjust to the stress at this time. During the postpartum period, there may be an acute exacerbation of symptoms in a woman as corticosteroid levels again fall to normal. Infants of women with SLE tend to be small for gestational age because of a decreased blood flow to the placenta. There is a greater-than-usual incidence of spontaneous miscarriage and preterm birth (Witter, 2007). Infants may be born with a lupus-like rash, anemia, thrombocytopenia (low platelet count), and neonatal heart block. Newborn symptoms last about 6 months and then fade. If congenital heart block occurs, a newborn pacemaker may be necessary. Screening for the exact type of autoantibodies present may be helpful in predicting which newborns are susceptible to this.

✔ Checkpoint Question 20.4

Suppose Angelina Gomez routinely takes acetylsalicylic acid (aspirin) for sinus headaches. Why should she limit or discontinue this toward the end of pregnancy?

a. Salicylates can lead to increased maternal bleeding at childbirth.
b. Newborns develop withdrawal headaches from salicylates.
c. Aspirin can lead to deep vein thrombosis following birth.
d. Newborns develop a red rash from salicylate toxicity.

GASTROINTESTINAL DISORDERS AND PREGNANCY

Although minor gastrointestinal discomforts (such as nausea, heartburn, constipation) are common during pregnancy, acute abdominal pain and protracted vomiting are causes for concern. Pregnancy complications such as premature separation of the placenta or ectopic pregnancy often manifest with acute abdominal pain, so differentiating the cause of abdominal pain is important. In other instances, abdominal pain is associated with a condition completely unrelated to the pregnancy such as ulcerative colitis, hepatitis, hiatal hernia, or cholecystitis. These conditions may be known to a woman before she becomes pregnant, or they may develop or be discovered during her pregnancy. Women who have colostomies can complete pregnancy without difficulty. Even a previous liver transplant is not a contraindication to pregnancy (Pan et al., 2007).

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Imbalanced nutrition, less than body requirements, related to a gastrointestinal disorder during pregnancy

Outcome Evaluation: Client's weight gain amounts to 25 to 30 lb during pregnancy; hemoglobin is above 11 mg/dL; specific gravity of urine is below 1.030.

A Woman With Appendicitis

Appendicitis is inflammation of the appendix. Its incidence is high in young adults so occurs as frequently as 1 in 1500 to 2000 pregnancies (Parangi et al., 2007).

Assessment

History taking is important. Appendicitis usually begins with a few hours of nausea, and then an hour or two of generalized abdominal discomfort. A woman may have vomiting during this time. Then comes the typical sharp, peristaltic, lower right quadrant pain of acute appendicitis.

The pain associated with appendicitis is different from the pain that occurs suddenly from an overstretched round ligament during pregnancy. Pain from an overstretched ligament may cause sharp lower quadrant pain if a woman stands up suddenly, but the pain fades again almost instantly. Appendicitis pain not only continues but grows more intense. Appendicitis pain is also different from that of ectopic pregnancy. With ectopic pregnancy, a woman may have morning sickness because she is pregnant; the nausea and vomiting of appendicitis is much more intense. The pain of ectopic pregnancy may be either diffuse or sharp. In the nonpregnant woman, the pain of appendicitis becomes sharp and localized at McBurney's point (a point halfway between the umbilicus and the iliac crest on the lower right abdomen). In the pregnant woman, the appendix is often displaced so far up in the abdomen that the localized pain may resemble the pain of gallbladder disease (Fig. 20.3). A complete blood count will reveal leukocytosis. However, because pregnant women have an elevated white blood cell count anyway, this finding is not as helpful in pregnancy as it might be otherwise. A woman's temperature may be elevated. There are typically ketones in the urine. An ultrasound will reveal the inflamed appendix.

Advise a woman not to take food, liquid, or laxatives while she is waiting to be evaluated for possible appendicitis, because increasing peristalsis could cause an inflamed appendix to rupture.

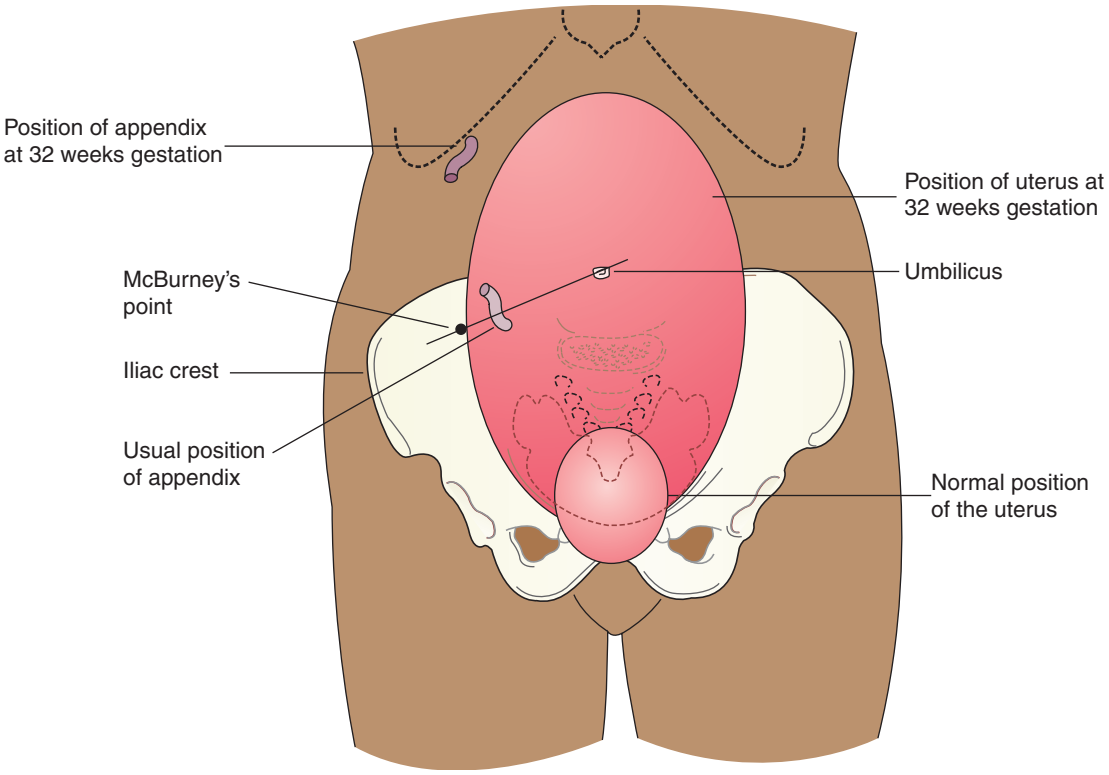

FIGURE 20.3 Change in position of appendix during pregnancy.

Therapeutic Management

If a woman is near term (past 36 weeks) and the fetus is believed to be mature, a cesarean birth may be done to birth the baby and then remove the inflamed appendix at the same time. If appendicitis occurs early in pregnancy, the inflamed appendix is removed by laparoscopy. As long as the anesthesiologist is aware that a woman is pregnant and carefully controls oxygen levels during anesthesia administration, the outcome of both the surgery and the pregnancy will be good.

If the appendix ruptures before surgery, the risk to both mother and fetus increases dramatically. This is because with rupture, infected fecal material escapes into the peritoneum and could spread by the fallopian tubes to the fetus. Also generalized peritonitis is such an overwhelming infection that it is difficult for a woman's body to combat it effectively and also maintain the pregnancy. As a third concern, peritoneal adhesions may develop after an appendix ruptures, resulting in future subfertility because of changes in the placement of fallopian tubes.

A Woman With Gastroesophageal Reflux Disease or Hiatal Hernia

Gastroesophageal reflux disease (GERD) refers to the reflux of acid stomach secretions into the esophagus. Hiatal hernia is a condition in which a portion of the stomach extends and protrudes up through the diaphragm into the chest cavity, trapping stomach acid and causing it to reflux into the esophagus. Although these conditions can be present constantly, symptoms most often occur only sporadically after increased peristaltic action. Both conditions may generate symptoms for the first time during pregnancy as the uterus pushes the stomach up against the esophageal valve and increases the reflux of acid or the extent of the hernia. Symptoms include:

- Heartburn, which is particularly extreme when lying supine after a full meal
- Gastric regurgitation
- Dysphagia (difficulty swallowing)
- Possible weight loss because of the inability to eat
- Hematemesis (vomiting of blood) if extreme esophageal irritation occurs from the reflux of hydrochloric acid from the stomach

During pregnancy, these conditions are usually diagnosed by direct endoscopy or ultrasound to avoid exposing a woman to barium x-rays. In most women, antacids will relieve pain. A histamine receptor antagonist, such as ranitidine, can be prescribed to inhibit gastric acid production and help minimize pain. Proton pump inhibitors such as esomeprazole magnesium (Nexium) are also safe during pregnancy (pregnancy category B) (Subramanian et al., 2008). Advise a woman to wear loose clothing and sleep with her head elevated to help confine stomach secretions. After pregnancy, as the uterine pressure is decreased, the symptoms generally become less noticeable or disappear. Some women may need to continue to take esomeprazole magnesium for several months until their esophagus is completely healed.

A Woman With Cholecystitis and Cholelithiasis

Cholecystitis (gallbladder inflammation) and cholelithiasis (gallstone formation) are most frequently associated with women older than 40 years, obesity, multiparity, and ingestion of a high-fat diet. Symptoms (constant aching and pressure in the right epigastrium, perhaps accompanied by jaundice), therefore, are more apt to occur in the older pregnant woman. Gallstones are formed from cholesterol. It is debated whether the hypercholesterolemia that naturally occurs during pregnancy leads to an increased incidence of cholecystitis or cholelithiasis, but both these conditions are seen with pregnancy.

Medical therapy for both conditions is to lower fat intake. A woman should eat a low-fat but not a fat-free diet during pregnancy because of the importance of linoleic acid for fetal growth. Cholecystitis can be diagnosed by ultrasound. If an acute episode occurs during pregnancy, it can generally be managed by halting oral intake to rest the gastrointestinal tract, administering intravenous fluids to provide fluid and nutrients as well as analgesics for pain. Surgery for gallbladder removal by laparoscopic technique may be done during pregnancy if a woman's symptoms cannot be controlled by conservative management (Augustin & Majerovic, 2007).

A Woman With Pancreatitis

Pancreatitis, inflammation of the pancreas, tends to occur in young adults and so is also seen during pregnancy (Parangi et al., 2007). Diagnosis may be difficult as serum amylase, which rises with pancreatitis, is also normally elevated during pregnancy. Only if this is greater than 2 times above normal is pancreatitis suspected. Pancreatitis is treated the same in pregnancy as in nonpregnant women: nasogastric suction, bowel rest, analgesia (pancreatic pain is sharp), and intravenous hydration through parenteral nutritional supplementation. Pancreatic inflammation usually subsides within a week. Pregnancy loss can occur from acidosis, hypovolemia, and fetal hypoxia.

A Woman With Hepatitis

Hepatitis is a liver disease that may occur from invasion of the A, B, C, D, or E virus. Hepatitis A is spread mainly by fecal–oral contact (children in day-care settings have a high incidence) or by ingestion of fecally contaminated water or shellfish. It has an incubation period of 2 to 6 weeks. Pregnant women exposed to hepatitis A may be given prophylactic gamma globulin to try to prevent the disease after exposure. This form follows a rather benign course and is not known to be transmitted to the fetus.

Hepatitis B and C are spread by exposure to contaminated blood or blood products. These two types also can be spread by contact with contaminated semen or vaginal secretions and so are considered STIs. Maternal/fetal transmission is now one of the most important modes of transmission. Hepatitis D and E are apparently spread by the same methods as hepatitis B but are rarely seen in pregnant women.

Hepatitis C demonstrates few symptoms, and these may not be present for 12 months after exposure. It is, however, the most common cause of chronic liver disease and liver transplantation in the United States (Jain et al., 2007).

Hepatitis B occurs about 1 in every 2000 pregnancies (Johnson & Ross, 2007). It has an incubation period of 6 weeks to 6 months. It occurs in both an acute and chronic form, leading to liver cell necrosis with scarring and inability to convert indirect to direct bilirubin or excrete direct bilirubin. Women exposed to the virus receive immune globulin for prophylaxis; hepatitis B vaccine may be administered to those who are at high risk, such as women who handle blood products to prevent the illness.

Assessment

With all forms of hepatitis, a woman experiences nausea and vomiting. Her liver area may feel tender to palpation. Urine will be dark yellow from excretion of bilirubin; stools will be light-colored from lack of bilirubin. Jaundice occurs as a late symptom. On physical examination, hepatomegaly (enlargement of the liver) is noted. The bilirubin level is elevated. Levels of liver enzymes such as transaminase are increased. Specific antibodies against the virus can be detected in the blood serum, so women at high risk may be routinely screened for this during pregnancy. If a liver biopsy is necessary for diagnosis, this can be performed safely during pregnancy.

Therapeutic Management

A woman is usually prescribed bed rest and encouraged to eat a high-calorie diet because her liver has difficulty converting stored glycogen into glucose in its diseased state so hypoglycemia could result. Cesarean birth may be planned to reduce the possibility of blood exchange between mother and fetus. Follow standard infection precautions when you give care to avoid contact with body fluids.

Hepatitis during pregnancy may lead to spontaneous miscarriage or preterm labor. Unlike other diseases, the later in pregnancy the mother contracts hepatitis B infection, the greater the risk the infant will be affected or develop hepatitis B. When this occurs, it is a serious consequence because a proportion of HB Ag-positive infants will develop liver cirrhosis or carcinoma later in life (Johnson & Ross, 2007). If the mother has anti-HB antibodies present (antibodies toward a virus subgroup), the incidence of this appears to be less. After birth, the infant should be washed well to remove any maternal blood, and hepatitis B immune globulin (HBIG) and immunization against hepatitis B should be administered (see Chapter 18 for additional newborn care). A mother may breastfeed. The infant needs to be observed carefully for symptoms of infection during the first few months of life and chronic liver disease as he or she grows older.

A Woman With Inflammatory Bowel Disease

Crohn's disease (inflammation of the terminal ileus) and ulcerative colitis (inflammation of the distal colon) occur most often in young adults between ages 12 and 30 years (childbearing years) and so are seen in pregnancy. The cause of these diseases is unknown, but an autoimmune process is thought to be responsible. They are associated with passive and active smoking (Mahid et al., 2007). In both diseases, the bowel develops shallow ulcers. A woman experiences chronic diarrhea, weight loss, occult blood in stool, and nausea and vomiting. If extreme, obstruction and fistula formation with peritonitis can occur. With Crohn's disease, malabsorption, particularly of vitamin B (a substance whose absorption occurs almost entirely in the ileum), occurs. Because of the potential difficulty with absorbing nutrients,

women with both disorders need careful monitoring for weight gain during pregnancy (Bortoli et al., 2007).

These diseases obviously have the potential for interfering with fetal growth if extreme malabsorption occurs. Therapy for the disorders is total rest for the gastrointestinal tract by administration of total parenteral nutrition. Although it is possible to sustain a pregnancy by this route, it is obviously not a desirable nutrition pattern. Sulfasalazine (Azulfidine), an anti-inflammatory and a mainstay of therapy, may be continued during pregnancy without fetal injury. Close to birth, the dosage of sulfasalazine, because of its sulfa base, is reduced because it may interfere with bilirubin binding sites and cause neonatal jaundice (Karch, 2009).

NEUROLOGIC DISORDERS AND PREGNANCY

Neurologic illness, as a whole, does not occur at a high incidence in women of childbearing age. However, any neurologic disease with symptoms of seizures must be carefully managed during pregnancy because the anoxia that could be caused by severe seizures could deprive a fetus of oxygen.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for injury (maternal) related to recurrent seizures

Outcome Evaluation: Client states she is seizure free, with no signs and symptoms of injury; no automobile or other accidents are documented.

A Woman With a Seizure Disorder

Recurrent seizures have several causes, such as head trauma or meningitis. The causes of most recurrent seizures, however, are unknown (idiopathic).

Recurrent seizures were at one time so incapacitating and it was believed that seizure control medications caused such a high risk of congenital anomaly that women with seizures were advised not to have children. Today, however, no contraindication to pregnancy exists for women with seizures as long as the medication they take is at the lowest dose possible and serum levels are carefully monitored.

Therapeutic Management

Because seizure medications as a group are mildly teratogenic, women with recurrent seizures need to meet with their obstetrician and primary care provider before pregnancy to be certain the medications they are taking are the least teratogenic ones possible and the dosage they are taking is the lowest possible to control seizures (Adab et al., 2009). In the early months of pregnancy, you may need to remind women to continue to take their antiseizure medications despite the nausea or vomiting of early pregnancy. Be certain they understand that the rule "Do not take medication during pregnancy" does not apply to their antiseizure medications. Recurrent seizures put a woman into the difficult position of having to take a drug to safeguard her own health, but by taking them may not be safeguarding the health of her fetus. The risk of adverse maternal or fetal outcome from seizures during pregnancy, however, is greater than the risk of teratogenicity from taking anticonvulsant drugs (Karch, 2009).

All women should have an evaluation of serum drug levels before pregnancy or early in pregnancy to establish that their medication is being prescribed at a therapeutic level (Adab et al., 2009). As blood volume increases with pregnancy, some women may need their dosage increased or their serum level will be diluted. Common drugs prescribed to control seizures are:

- Trimethadione (Tridione) (pregnancy risk category D)
- Valproic acid (sodium valproate and divalproex sodium) (pregnancy risk category D)
- Carbamazepine (Tegretol) (pregnancy risk category C)
- Ethosuximide (Zarontin), a drug often used to control absence seizures (pregnancy risk category C)
- Phenytoin sodium (Dilantin) (pregnancy risk category D). Dilantin can cause a syndrome involving fetal cognitive impairment and a peculiar facial proportion not unlike that of fetal alcohol syndrome. This may occur because of competition for folic acid binding sites. Some infants have an increased danger of neural tube disorders as a result of this folic acid displacement. An ultrasound can rule out the possibility of this.

Infants are also prone to hemorrhagic disease of the newborn because of decreased levels of vitamin K coagulation factors at birth from phenytoin. To counteract this, women may be prescribed vitamin K during labor or the last 4 weeks of gestation. Women who have been taking phenytoin (Dilantin) may have developed chronic hypertension. For these women, a baseline blood pressure should be established early in pregnancy so that changes can be interpreted correctly.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for ineffective tissue (placental) perfusion related to hypoxia resulting from maternal seizure

Outcome Evaluation: Client informs health care personnel about history of seizures; states importance of immediate care and oxygen therapy should she begin a seizure. Apgar score of infant is 7 to 10, with no apparent birth anomalies.

Absence seizures (often just a rapid fluttering of the eyelids or a moment's staring into space) should have no effect on a woman or fetus. Tonic-clonic seizures (sustained, full-body involvement) could affect a fetus because spasm of the chest muscles could lead to hypoxia. If a seizure should occur, a woman must be evaluated to ascertain that the cause of the seizure was the underlying disease, not beginning hypertension of pregnancy. Nonpregnant women experiencing tonic-clonic seizures do not need oxygen during a seizure, but in pregnancy, administering oxygen by mask is good prophylaxis to ensure adequate fetal oxygenation.

Urge a woman to alert hospital personnel at the time of labor that she has recurrent seizures and to report the type of medication she is taking. She should continue to take the medication during labor. If a general anesthetic should be necessary, the anesthesiologist needs to know about her condition before administering anesthesia; otherwise, during the excitement phase of anesthesia induction, a seizure could occur.

Nursing Diagnosis: Risk for impaired parenting related to maternal low self-esteem

Outcome Evaluation: Client accurately states the nature of her disorder (acquired or idiopathic) and the statistical chances of her child inheriting the disorder. After her child is born, client identifies sudden jerking movements in her newborn (such as Moro reflex) as healthy newborn characteristics.

A woman who has recurrent seizures may worry that her child will develop seizures as the child grows older. If a woman's seizures are the result of an acquired disorder such as meningitis or head trauma, a woman can be assured that her child's risk for seizures is no greater than that for any other child. If the etiology of her seizures is unknown, the chance that her child also will have them is slightly higher than in the normal population. This prediction is only theoretical, however, and cannot be made without a thorough review of the onset and nature of a woman's disorder. Be certain a woman has her newborn with her for long periods so she can become acquainted with the sudden jerking motions that occur such as when a newborn is startled (Moro reflex) or quivering of the jaw with prolonged crying. Otherwise she could interpret these normal movements as seizure activity.

A Woman With Myasthenia Gravis

Myasthenia gravis is an autoimmune disorder characterized by the presence of an IgG antibody against acetylcholine receptors in striated muscle. This causes failure of the striated muscles to contract, particularly those of the oropharyngeal, facial, and extraocular groups (Kalidindi et al., 2007).

Myasthenia gravis is treated with anticholinesterase drugs such as pyridostigmine (Mestinon) or neostigmine (Prostigmin) and possibly a corticosteroid such as prednisone. These medications may be continued during pregnancy, as the fetus will experience no effects from these drugs. Plasmapheresis (removal of and replacement of plasma) to remove immune complexes from the bloodstream may be prescribed to reduce symptoms. Plasmapheresis must be carried out gradually during pregnancy to reduce the risk of fluid overload or hypotension. Because smooth muscle is not affected by the disease, labor should occur normally. Magnesium sulfate should be avoided because it can diminish the acetylcholine effect and therefore increase disease symptoms.

An infant born to a woman with myasthenia gravis may demonstrate disease symptoms at birth because of the transfer of antibodies. This is further discussed in Chapter 51.

A Woman With Multiple Sclerosis

Multiple sclerosis (MS) occurs predominantly in women of childbearing age, usually between 20 and 40 years of age (Saraste et al., 2007). With MS, nerve fibers become demyelinated and therefore lose function. Women develop symptoms of fatigue, numbness, blurred vision, and loss of coordination. ACTH or a corticosteroid is commonly given to strengthen nerve conduction. These both can be administered safely during pregnancy. In contrast, cyclosporine (Sandimmune), azathioprine (Imuran), and cyclophosphamide (Cytoxan), drugs also frequently administered, are not safe for use during pregnancy. The pregnancy safety of interferon has not been tested; as such, it is classified as a pregnancy category C drug. Women may continue with plasmapheresis (withdrawal and replacement of plasma), another treatment regimen, during pregnancy as long as the volume of exchange is well controlled. Although women with the disorder may grow increasingly fatigued as pregnancy progresses, pregnancy does not affect the long-term course of MS. MS may actually improve with pregnancy because of the increased circulating corticosteroid levels. UTIs tend to occur as a poorly defined consequence of the illness.

MUSCULOSKELETAL DISORDERS AND PREGNANCY

Women of childbearing age have falls or other accidents that lead to bone fractures or muscle sprains. These are discussed in Chapter 22. A chronic musculoskeletal disorder that may be seen with pregnancy is scoliosis.

A Woman With Scoliosis

Scoliosis (lateral curvature of the spine) begins to be noticed first in girls between 12 and 14 years of age. If it is uncorrected at this time, the curvature progresses until it causes deformity, interfering with respiration and heart action because of chest compression. Pelvic distortion can interfere with childbirth, especially at the pelvic inlet. If a woman's spine is extremely curved, spinal or epidural anesthesia may be difficult to administer for pain management in labor.

Girls with scoliosis may wear a body brace during their adolescent years to maintain an erect posture. Although these braces are not as bulky as they once were, unless they are modified, they cannot be worn during the last half of pregnancy. Other girls have stainless-steel rods surgically implanted on both sides of their vertebrae to strengthen and straighten their spine. Such rod implantations do not interfere with pregnancy; a woman will notice some back pain from tension on the back muscles similar to that experienced by the average pregnant woman. If a woman's pelvis is distorted, a cesarean birth may be necessary to ensure a safe birth. Vaginal birth, if permitted, requires the same management as for any woman. Plot the course of labor on a labor graph so an unusually long first stage, suggesting cephalopelvic disproportion, can be recognized. Chapter 51 discusses in detail the nursing care of adolescents with scoliosis.

ENDOCRINE DISORDERS AND PREGNANCY

Endocrine disorders have the potential to be serious complications of pregnancy because enzymes or hormones control so many specific body functions.

A Woman With a Thyroid Dysfunction

As a normal effect of pregnancy, the thyroid gland enlarges (hypertrophies) slightly because of increased vascularity and blood flow. A woman with pre-existing thyroid problems may have difficulty making this pregnancy transition.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for maternal and fetal injury related to pre-existing thyroid disorder during pregnancy

Outcome Evaluation: No congenital anomalies are present in infant at birth; Apgar score is 7 to 10. Mother can continue prepregnancy level of activities.

A Woman With Hypothyroidism

Hypothyroidism is a rare condition in young adults and especially in pregnancy, because women with symptoms of untreated hypothyroidism are often anovulatory and unable to conceive. A woman who does conceive can have difficulty increasing thyroid functioning to a necessary pregnancy level. This can lead to early spontaneous miscarriage. Women with hypothyroidism fatigue easily and tend to be obese; their skin is dry (myxedema), and they have little tolerance for cold. It may be associated with an increased incidence of extreme nausea and vomiting (hyperemesis gravidarum).

Most women with hypothyroidism take levothyroxine (Synthroid) to supplement their lack of thyroid hormone. A woman who is taking levothyroxine needs to consult with her obstetrician and internist when she is planning on becoming pregnant. She needs to come for early diagnosis and close follow-up as soon as she suspects she is pregnant (1 week past her missed menstrual period). As a rule, her dose of levothyroxine will need to be increased as much as 20% to 30% for the duration of the pregnancy to simulate the increase that would normally occur in pregnancy (Neto et al., 2007). Be certain that a woman realizes the importance of taking this increased dose. Women should separate thyroxine ingestion from any medication containing iron, calcium, or soy products by about 4 hours to be sure that there is no problem with the absorption of thyroxine (Kyriazopoulou et al., 2008).

After the pregnancy, the dose of levothyroxine prescribed for pregnancy must be gradually tapered back to the prepregnancy level. Be certain a woman does not continue to take her pregnancy dose (trying to be economical and use up her higher-dose pills), or she could pass beyond normal thyroid function and develop hyperthyroidism.

A Woman With Hyperthyroidism

Hyperthyroidism, or overproduction of thyroid hormone, causes symptoms such as:

- Rapid heart rate
- Exophthalmos (protruding eyeballs)
- Heat intolerance
- Nervousness
- Heart palpitations
- Weight loss

Hyperthyroidism (Graves' disease) is more apt to be seen in pregnancy than hypothyroidism. If undiagnosed, a woman may develop heart failure during pregnancy because her heart rate, already high at the beginning of pregnancy, cannot increase enough to handle the increasing blood volume that occurs with pregnancy. She is more prone to symptoms of hypertension of pregnancy, fetal growth restriction, and preterm labor than the average woman.

Hyperthyroidism is normally diagnosed by a nuclear medicine imaging study involving the radioactive uptake of ^{131}I subtype. This diagnostic procedure should not be used during pregnancy because the fetal thyroid will also incorporate this drug, possibly resulting in destruction of the fetal thyroid.

Treatment for hyperthyroidism is with thioamides (methimazole [Tapazole] or propylthiouracil [PTU]), which reduce thyroid activity. These drugs are, unfortunately, teratogens. They cross the placenta and can lead to congenital hypothyroidism and consequently an enlarged thyroid gland (a goiter) in the fetus. If this abnormal neck growth enlarges enough, it can obstruct the airway and make resuscitation difficult for the infant at birth. Methimazole is the preferred drug for pregnant women as it appears to cross the placenta less easily (Chattaway & Klepser, 2007).

If hyperthyroidism is not regulated during pregnancy, an infant may be born with symptoms of hyperthyroidism because of the excess stimulation he or she receives in utero. The infant may appear jittery, and tachypnea and tachycardia may be present. An assay of fetal cord blood will reveal the level of T_4 and thyroid-stimulating hormone and the need for therapy in the infant. Women receiving smaller or minimal doses of antithyroid drugs may breastfeed, although women receiving large doses of these drugs may be advised not to breastfeed because these drugs are excreted in breast milk (Greenspan & Dong, 2007).

A woman should be regulated on the lowest possible dose of drug and cautioned to keep a careful record of doses taken so she does not forget or accidentally duplicate a dose. Surgical treatment to reduce the functioning of the maternal thyroid gland can be accomplished, but this is generally not the treatment of choice during pregnancy because of the need for general anesthesia. After a pregnancy, if a woman desires other children, the procedure might be suggested as an interpregnancy procedure so she does not enter a second pregnancy hyperthyroid.

A Woman With Diabetes Mellitus

Diabetes mellitus is an endocrine disorder in which the pancreas cannot produce adequate insulin to regulate body glucose levels. The disorder affects 3% to 5% of all pregnancies and is the most frequently seen medical condition in pregnancy (Strehlow et al., 2007). Before insulin was produced synthetically in 1921, women with type 1 diabetes, or diabetes acquired in childhood, died before reaching childbearing age, were infertile, or had spontaneous miscarriages early in pregnancy. Now that diabetes can be well managed and type 2 diabetes is occurring more frequently in young adults, four new problems have developed:

- How to care for women with both type 1 and type 2 diabetes during pregnancy

- How to bring a woman with type 1, type 2, and gestational diabetes through a pregnancy with good glucose and insulin control
- How to protect an infant in utero from the adverse effects of the increased glucose levels
- How to care for the infant in the first 24 hours after birth until the infant's insulin-glucose regulatory mechanism stabilizes

Reproductive planning may be a fifth concern as women with diabetes may not be good candidates for oral contraceptives because progesterone interferes with insulin activity and therefore increases blood glucose levels. The estrogen in contraceptives also has the potential for increasing lipid and cholesterol levels and blood coagulation. Intrauterine devices have been associated with higher-than-usual rates of pelvic inflammatory disease; because women with diabetes have difficulty fighting infections, these are not usually advised either. Subcutaneous implanted or intramuscular injections of progestin may be good choices (see Chapter 6).

Pathophysiology and Clinical Manifestations

The possible etiology and pathology of diabetes mellitus are discussed in detail in Chapter 48. The primary problem of any woman with this disorder is controlling the balance between insulin and blood glucose levels to prevent hyperglycemia or hypoglycemia. Both of these conditions are dangerous during pregnancy because they can become threats to normal fetal growth. Infants of diabetic women are five times more apt to be born with heart anomalies than others because of this threat (Strehlow et al., 2007).

If a woman's insulin level is insufficient, glucose cannot be used by body cells. The cells register their glucose want, and the liver quickly converts stored glycogen to glucose to increase the serum glucose level. Because of the insulin insufficiency, however, the body cells still cannot use the glucose, so the serum glucose levels continue to rise (hyperglycemia). When the level of blood sugar rises to 150 mg/100 mL (normal is 80 to 120 mg/dL), the kidneys begin to excrete quantities of glucose in the urine **(glycosuria)** in an attempt to lower the level. During pregnancy, the point at which this happens may be even lower than 150 mg/100 mL. Because of osmotic action, the increased amount of glucose in the urine reduces fluid absorption in the kidney, and large quantities of fluid are lost in urine (polyuria).

Dehydration begins to occur; the blood serum becomes concentrated and the blood volume may fall. With the reduced blood flow, cells do not receive adequate oxygen, and anaerobic metabolic reactions cause large stores of lactic acid to pour out of muscles into the bloodstream. Fat is mobilized from fat stores and metabolized for energy, pouring large amounts of ketone bodies into the bloodstream. Ketone bodies are acidic (the best example is acetone). These two acid sources lower the pH of the blood, and a metabolic acidosis develops.

Next, protein stores are tapped by the body as it attempts to find a source of energy. Protein breakdown reduces the supply of protein to body cells. As cells die, they release potassium and sodium, and this is lost from the body in the extensive polyuria. Long-term effects of diabetes mellitus are vascular narrowing that leads to kidney, heart, and retinal dysfunction.

Diabetes During Pregnancy

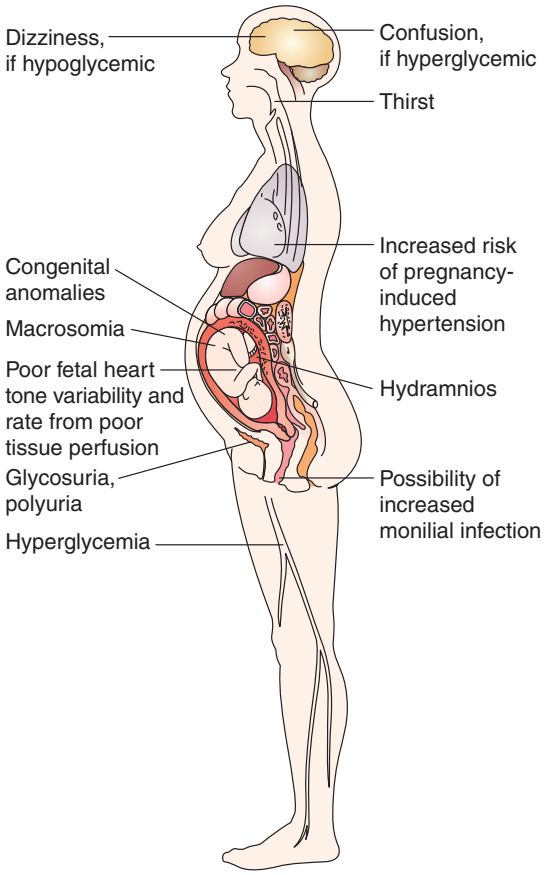
Diabetes often occurs as type 1 or diabetes which occurs in childhood and represents failure of the pancreas to produce adequate insulin for body requirements. Although not proved, it probably represents an autoimmune disorder as marker antibodies are present (Masharani, 2009). Type 2 diabetes traditionally has occurred in older adults and represents gradual failure of insulin production that occurs with aging. The incidence of type 2 diabetes in adolescents has increased dramatically in the last decade related to obesity in adolescents, so now, both type 1 and type 2 diabetes are seen during pregnancy.

Even a woman with type 1 or type 2 diabetes who has successful regulation of glucose and insulin metabolism before pregnancy is apt to develop less-than-optimal control during pregnancy, because all women experience several changes in the glucose-insulin regulatory system as pregnancy progresses. Glomerular filtration of glucose is increased (the glomerular excretion threshold is lowered), causing slight glycosuria. The rate of insulin secretion is increased, and the fasting blood sugar level is lowered. All women appear to develop an insulin resistance as pregnancy progresses or insulin does not seem as effective during pregnancy, a phenomenon that is probably caused by the presence of the hormone human placental lactogen (chorionic somatomammotropin) and high levels of cortisol, estrogen, progesterone, and catecholamines. Placental insulinase may cause increased breakdown or degradation of insulin. This resistance to or destruction of insulin is helpful in a usual pregnancy because it prevents the blood glucose from falling to dangerous limits, despite the increased insulin secretion that occurs. It causes difficulty for a pregnant woman with diabetes in that she must increase her insulin dosage beginning at about week 24 of pregnancy to prevent hyperglycemia.

At the same time, the continued use of glucose by the fetus may lead to **hypoglycemia** (lowered serum glucose levels) for the mother between meals; this is most apt to occur overnight. A low maternal level of glucogenic amino acids (used by the liver to produce glucose) compounds this. A woman may become ketoacidotic from the breakdown of stored fat between meals, most likely during the second and third trimesters. An increase in the amount of amniotic fluid occurs in at least 25% of diabetic women, probably because of hyperglycemia in the fetus that causes increased urine production. If this becomes extreme, amniocentesis may need to be done to decrease the level of amniotic fluid. Unfortunately, this exposes a woman to infection and possible preterm labor and is only a temporary measure because amniotic fluid is continually produced. If a woman has preexisting kidney disease (revealed by proteinuria, decreased creatinine clearance, and hypertension), the risk of fetal growth restriction, asphyxia, stillbirth, and maternal pregnancy-induced hypertension rises markedly (Masharani, 2009).

When glucose regulation is poor, a woman is at greater risk for pregnancy-induced hypertension and infection (particularly monilial infection) than other women. Infants of women with poorly controlled diabetes tend to be large (>10 lb) because the increased insulin the fetus must produce to counteract the overload of glucose he or she receives acts as a growth stimulant (Campaigne & Conway, 2007). The increased glucose adds subcutaneous fat deposits.

Box 20.7 Assessment
Assessing a Pregnant Woman With Diabetes Mellitus



A macrosomic infant may create birth problems at the end of the pregnancy because of cephalopelvic disproportion. This, combined with an increased risk for shoulder dystocia, may make it necessary for infants of women with diabetes to be born by cesarean birth.

There is a high incidence of congenital anomaly, especially caudal regression syndrome (failure of the lower extremities to develop), spontaneous miscarriage, and stillbirth in infants of women with uncontrolled diabetes. At birth, the neonates are more prone to hypoglycemia, respiratory distress syndrome, hypocalcemia, and hyperbilirubinemia. The first trimester of pregnancy is the most important time for fetal development; if a woman can be kept from becoming hyperglycemic during this time, the chances of a congenital anomaly are greatly lessened (Box 20.7) (Barnes-Powell, 2007).

Classification of Diabetes Mellitus

Diabetes is divided into various categories that can be used to predict pregnancy outcome (Table 20.3).

Approximately 2% to 3% of all women who do not begin a pregnancy with diabetes become diabetic during pregnancy, usually at the midpoint of pregnancy when insulin resistance becomes most noticeable. This is termed gestational diabetes mellitus (Ferrara, 2007). The symptoms fade again at the completion of pregnancy, but the risk of developing type 2 diabetes later in life may be as high as 50% to 60% (Box 20.8). It is unknown whether gestational diabetes results from inadequate insulin response to carbohydrate or from excessive resistance to insulin; a combination of both may occur. Risk factors for gestational diabetes include:

- Obesity
- Age over 25 years
- History of large babies (10 lb or more)
- History of unexplained fetal or perinatal loss
- History of congenital anomalies in previous pregnancies
- History of polycystic ovary syndrome
- Family history of diabetes (one close relative or two distant ones)
- Member of a population with a high risk for diabetes (Native American, Hispanic, Asian)

Assessment

Because diabetes is such a serious complication in pregnancy, all women should be screened during pregnancy for gestational diabetes. A fasting plasma glucose of 126 mg/dl or above or a nonfasting plasma glucose of 200 mg/dl or above meets the threshold for the diagnosis of diabetes and needs to be confirmed on a subsequent day as soon as possible. This is usually done using a 50-g oral glucose challenge test.

After the oral 50-g glucose load is ingested, a venous blood sample is taken for glucose determination 60 minutes later. If the serum glucose level at 1 hour is more than 140 mg/dL, the woman is scheduled for a 100-g, 3-hour fasting **glucose tolerance test.** If two of the four blood samples collected for this test are abnormal or the fasting value is above 95 mg/dL, a diagnosis of diabetes is made. The values that confirm diabetes are shown in Table 20.4.

Monitoring a Woman With Diabetes

A woman who is diabetic (type 1 or type 2) should meet with her obstetrician before she becomes pregnant; during this period, her condition can be well regulated so that hyperglycemia does not develop during the early weeks of pregnancy, when the tendency for congenital anomalies in the fetus is highest. A woman should use a home test kit to determine she is pregnant so she knows this at the earliest possible time. The best insulin control program for her during pregnancy can then be determined. The measurement of **glycosylated hemoglobin** is used to detect the degree of hyperglycemia present. This is a measure of the amount of glucose attached to hemoglobin. As glucose circulates in the bloodstream, it binds to a portion of the total hemoglobin in the blood. The amount of glucose that attaches to hemoglobin in this way will be high if the hemoglobin has been exposed to a greater level of glucose than normally present. Measuring glycosylated hemoglobin is advantageous because it reflects the average blood glucose level over the past 4 to 6 weeks (the time the red blood cells were picking up the glucose) not just the level on the day of testing. The upper normal level of HbA is 6% of total hemoglobin.

Ophthalmic examination should be done once during pregnancy for a woman with gestational diabetes and at each trimester for women with known diabetes. Background retinal

BOX 20.8 ✻ Focus on Communication

Angelina Gomez has developed gestational diabetes. You notice in her history she moved from Guadalajara, Mexico, only 2 years ago.

Less Effective Communication

Nurse: Buenos dias, Ms. Gomez. *Como esta usted?*
Ms. Gomez: Bien, gracias.
Nurse: Oh, that was fun. I love practicing Spanish with patients. I don't understand much, though. If you'd said anything other than a one-word answer, I wouldn't have known what you meant. How's your diet going? Are you having any trouble following the diet the nutritionist gave you?
Ms. Gomez: No.
Nurse: Do you get out for a walk every day?
Ms. Gomez: Si.
Nurse: Any trouble doing your blood sugar? Your *azucar de sangre?*
Ms. Gomez: No.
Nurse: Good. Glad you're doing well. It was fun talking to you.

More Effective Communication

Nurse: Buenos dias, Ms. Gomez. *Como esta usted?*
Ms. Gomez: Bien, gracias.
Nurse: Oh, that was fun. I love practicing Spanish with patients. I've noticed that sometimes when people answer that question with "Bien, gracias," though, they're only being polite. Do you really feel well?
Ms. Gomez: I'm tired all the time.
Nurse: Tell me more about that.
Ms. Gomez: I'm so tired by evening, I can't cook. So I haven't been eating much.

Women who develop a complication of pregnancy have an added stress to their life. In the example above, the nurse made an admirable attempt to communicate with a patient in the patient's primary language. She forgot, however, that people under stress do not necessarily process new information well, and if she was having trouble interpreting Spanish, a patient might have equal trouble interpreting her English. This patient interpreted the instruction that she could not understand more than a one-word answer to mean she shouldn't answer with more than one word. Learning a second language can be important in inner-city communities. This nurse would have communicated better, however, if she had remembered that the purpose of a nurse–patient exchange was not for her to have fun but for effective assessment.

TABLE 20.3 ✻ Classification of Diabetes Mellitus

Class	Description
Type 1	Formerly known as insulin-dependent diabetes mellitus. A state characterized by the destruction of the beta cells in the pancreas that usually leads to absolute insulin deficiency. a. Immune-mediated diabetes mellitus results from autoimmune destruction of the beta cells. b. Idiopathic type 1 refers to forms that have no known cause.
Type 2	Formerly known as non-insulin-dependent diabetes mellitus. A state that usually arises because of insulin resistance combined with a relative deficiency in the production of insulin.
Gestational diabetes	A condition of abnormal glucose metabolism that arises during pregnancy. Possible signal of an increased risk for type 2 diabetes later in life.
Impaired glucose homeostasis	A state between "normal" and "diabetes" in which the body is no longer using and/or secreting insulin properly. a. Impaired fasting glucose: A state when fasting plasma glucose is at least 110 but under 126 mg/dL. b. Impaired glucose tolerance: A state when results of the oral glucose tolerance test are at least 140 but under 200 mg/dL in the 2-hour sample.

TABLE 20.4 ✻ Oral Glucose Challenge Test Values (Fasting Plasma Glucose Values) for Pregnancy

Test Type	Pregnant Glucose Level (mg/dL)*
Fasting	95
1 hour	180
2 hours	155
3 hours	140

*Following a 100-g glucose load. Rate is abnormal if two values are exceeded.

changes, such as increased exudate (Fig. 20.4), dot hemorrhage, and macular edema, can progress or originate during pregnancy. If proliferation retinopathy was present before pregnancy, this also progresses and can lead to blindness. Laser therapy to halt these changes can be done during pregnancy without risk to the fetus. A urine culture may be done each trimester to detect asymptomatic UTI as the increased glucose concentration in urine leads to increased infection.

Nursing Diagnoses and Related Interventions ✻

Because diabetes is such a complex disorder, associated nursing diagnoses are many and varied. They include:

- Risk for ineffective tissue perfusion related to reduced vascular flow
- Imbalanced nutrition, less than body requirements, related to inability to use glucose
- Risk for ineffective coping related to required change in lifestyle
- Risk for infection related to impaired healing accompanying condition
- Deficient fluid volume related to polyuria accompanying disorder
- Deficient knowledge related to complex health problem
- Health-seeking behaviors related to voiced need to learn home glucose monitoring

FIGURE 20.4 Increased exudate in the retina can occur with progressing diabetes during pregnancy. It appears as a "cloud-like" finding obscuring a retinal vessel.

The following nursing diagnosis and related interventions illustrate one of the most important facets of the nurse's role in caring for the pregnant woman with diabetes: health teaching.

Nurses can be instrumental in teaching women with diabetes how to change their therapeutic regimen during pregnancy (or begin one if newly diagnosed). Important topics include nutrition, exercise, insulin administration, blood glucose monitoring, and explanations of the various fetal assessment tests that will be done (see Focus on Nursing Care Planning Box 20.9).

Nursing Diagnosis: Deficient knowledge related to therapeutic regimen necessary during pregnancy

Outcome Evaluation: Client states importance of careful attention to nutrition, exercise, and home monitoring of glucose levels during pregnancy; describes nutrition and exercise program; states intention to keep nutrition and exercise constant.

Education Regarding Nutrition During Pregnancy. Many women of childbearing age who have had diabetes since early childhood do not follow a strict diabetic diet but eat sensibly, covering any excess food eaten with the administration of additional insulin. This type of regimen is apt to require excessive insulin administration during pregnancy as a woman begins to "eat for two." Therefore, a woman is well advised to begin a stricter diabetic diet before she becomes pregnant. Women who develop gestational diabetes are advised to begin a diabetic diet complemented by an exercise program as soon as they are diagnosed (Box 20.10).

Dietary control, or maintaining an adequate glucose intake so hypoglycemia does not occur, may be extremely difficult early in pregnancy because of nausea and vomiting. A 1800- to 2400-calorie diet (or one calculated at 30 Kcal per kg of ideal weight), divided into three meals and three snacks, is a usual regimen for a woman with diabetes during pregnancy. Keeping calories evenly distributed this way helps to keep the serum glucose level constant.

In addition, her diet should include a reduced amount of saturated fats and cholesterol and an increased amount of dietary fiber. Increasing fiber decreases postprandial hyperglycemia and so lowers insulin requirements. Of dietary calories, 20% should be from protein, 40% to 50% from carbohydrate, and up to 30% from fat (Strehlow et al., 2007).

If a woman cannot eat because of vomiting or nausea early in pregnancy or heartburn in later pregnancy, she should notify her health care provider. She may need temporary intravenous fluid supplementation. Women are extremely vulnerable to hypoglycemia at night during pregnancy because of the continuous fetal use of glucose during the time they sleep. Urge a woman to make her final snack of the day one of protein and complex carbohydrate to allow slow digestion during the night.

No woman should reduce her intake to below 1800 calories during pregnancy. A diet this low in carbohydrates causes fat breakdown, which produces acidosis. In a woman with

BOX 20.9 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Woman With Multiple Threats to Pregnancy

Angelina Gomez, 22, is pregnant with her first child. She fainted this afternoon while participating in an aerobic class.

Family Assessment ✻ Client lives with 30-year-old Josh, the father of her child. Angelina works as a fundraiser for a movie producer. Josh works as an animation artist. Finances are rated as "workable." She fainted this afternoon while participating in her weekly hour-long aerobic class.

Client Assessment ✻ Client had rheumatic fever with mitral stenosis as a child. She developed gestational diabetes early in this pregnancy. By the 34th week, she has already been hospitalized twice for hyperglycemia. In the emergency department, her serum glucose level is 207 mg/dL. Her blood pressure is 90/40 mm Hg; her pulse is 130/min; the fetal heart rate is 180/min. An abdominal monitor shows moderate-strength uterine contractions 7 minutes apart. The emergency physician asks for an echocardiogram to see if mitral stenosis is contributing to low blood pressure. Angelina says to you, "If exercise is supposed to be good for you, why did this happen?"

Nursing Diagnosis ✻ Risk for ineffective tissue perfusion (peripheral) related to lowered blood pressure secondary to mitral stenosis and gestational diabetes.

Outcome Criteria ✻ Blood pressure returns to 100/70; pulse rate at 70–90; fetal heart rate at 120–160 bpm. Serum glucose is less than 126 mg/dl; labor is halted.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse/ physician	Assess whether client understands need for consistent exercise in light of cardiac and diabetes restrictions.	Review with client the need to regulate glucose during pregnancy by consistent diet and exercise.	Exercise increases energy expenditure, metabolic rate, and cardiac output, placing additional workload on the heart and reducing plasma glucose.	Client describes a more consistent exercise program to use during pregnancy rather than an aerobic class once a week.
		Consultations		
Physician/ nurse	Telephone pregnancy and cardiac care providers and alert them to client's admission.	Coordinate care with pregnancy and cardiac health care providers who know her best.	Collaboration with pregnancy and cardiac health care providers helps to ensure a healthy outcome for the woman and fetus.	Both pregnancy and cardiac care providers contact emergency staff to coordinate care.
		Procedures/Medications		
Physician/ nurse-midwife	Monitor client BP, pulse, fetal heart rate, and uterine contractions by continuous monitors.	Determine client progress by monitor and physical exam reports. Inform client of potential fetal distress and possibility of beginning labor	Increased fetal heart rate (tachycardia) is a sign of possible fetal distress. Uterine contractions could mark the beginning of preterm labor.	Client voices an understanding that excessive exercise could have compromised her infant's health.
Cardiac ultrasound technician/ physician	Record an echocardiogram to document mitral valve function.	Determine if heart disorder is complicating condition; assure client that procedure is safe during pregnancy.	Mitral stenosis can lower blood pressure by not allowing adequate blood flow to aorta.	Echocardiogram is recorded in an expedient manner.

(continued)

BOX 20.9 ✻ Focus on Nursing Care Planning (continued)

		Nutrition		
Nurse	Assess serum glucose q 15 minutes by finger stick.	Keep client NPO. Document pattern of blood glucose. Administer IV fluid, insulin additive as prescribed.	Client's serum glucose was above normal on admission. Correcting this is vital to both maternal and fetal well-being. NPO is necessary in light of possible cesarean birth.	Client's serum glucose is within normal level within 45 minutes.
		Patient/Family Education		
Nurse	Assess client's understanding that her complex situation (both cardiac and diabetes disorders) could be compromising her pregnancy.	Educate client about need for rest until condition is stabilized. Encourage client to rest in lateral recumbent position.	Activity restriction can help prevent uteroplacental insufficiency. Lateral recumbent position prevents supine hypotension syndrome.	Client voices she understands need for continuous monitoring and rest. Complies with position for rest.
		Psychosocial/Spiritual/Emotional Needs		
Nurse	Assess who is client's main support person and ask if she would like him notified.	Locate support person and invite him to join client in emergency department.	Anxiety and stressors can increase the workload of the heart. Support person can be instrumental in reducing stress.	Support person arrives and works with staff to alleviate anxiety.
		Discharge Planning		
Nurse/ physician	Assess if client is aware of need to admit to hospital for continuing monitoring and possible problems related to incident.	Assist client in transfer to hospital unit.	Continuous monitoring is necessary to detect if uterine contractions and preterm birth were halted.	Client is transferred to hospital unit for further monitoring and care.

BOX 20.10 ✻ Focus on Evidence-Based Practice

Should women who develop gestational diabetes limit any further pregnancies to reduce their risk of developing diabetes mellitus type 2 later in life?

The occurrence of gestational diabetes makes it more likely that a woman will develop diabetes mellitus type 2 later in life. If the chance of developing diabetes mellitus type 2 increases in women who have more than one pregnancy in which gestational diabetes occurred compared to women who have only one pregnancy marked by gestational diabetes, women might be well advised to limit their number of future pregnancies after one marked by gestational diabetes.

To investigate what are the risk factors for developing diabetes mellitus type 2, researchers followed the health course of 1401 nulliparous women with gestational diabetes for 13 years. Of the 1401 women, 251 (17.9%) developed diabetes during this follow-up period. Factors significantly associated with an increased risk of developing diabetes mellitus included a prepregnancy weight over 86 kg, the need for insulin therapy during the index pregnancy, hypoglycemia in their newborn, and a subsequent pregnancy when gestational diabetes again developed. A subsequent pregnancy where gestational diabetes did not develop did not increase the risk of developing diabetes mellitus type 2.

Would the above study be helpful when discussing the future risk of developing diabetes mellitus type 2 following a pregnancy with gestational diabetes?

Source: Russell, C., et al. (2008). Diabetes mellitus following gestational diabetes: role of subsequent pregnancy. *BJOG: An International Journal of Obstetrics and Gynaecology, 115*(2), 253–259.

diabetes, the weight of the infant is directly correlated with how much she gains during pregnancy (which directly correlates with her disease control). She must be extremely nutrition-conscious to maintain good control and keep her weight gain to a suitable amount (approximately 25 to 30 lb) in the hope of limiting the size of her infant and making a vaginal birth possible.

Education Regarding Exercise During Pregnancy. Exercise is another mechanism that lowers the serum glucose level and thereby the need for insulin. If a woman begins an exercise program for the first time during pregnancy, she may notice excessive glucose fluctuations at first. Therefore, she should begin her exercise program before pregnancy, when glucose fluctuation can be evaluated and food and snacks adjusted accordingly before a fetus is involved.

With exercise, the blood glucose level decreases because the muscles increase their need for glucose. This effect lasts for at least 12 hours after exercise. If the arm in which a woman injected insulin is actively exercised, the insulin is released so quickly that it can cause hypoglycemia. To avoid this phenomenon, a woman should eat a snack consisting of protein or complex carbohydrate before exercise and should maintain a consistent exercise program (she should not do aerobic exercises one day and then none the next, but rather 30 minutes of walking every day). In a woman with poor blood glucose control, extreme exercise will cause hyperglycemia and ketoacidosis as the liver both releases glucose and breaks down fatty acids in an attempt to supply enough energy for the exercise (yet the body cannot use them because of inadequate insulin) so exercise should be consistent day to day.

Therapeutic Management

As keeping blood glucose levels near normal helps minimize the risk of maternal and fetal complications, both women with gestational diabetes and those with overt diabetes need more frequent prenatal visits than usual to ensure close monitoring of their condition and that of the fetus.

Insulin. Early in pregnancy, a woman with diabetes may need less insulin than before pregnancy because the fetus is using so much glucose for rapid cell growth. Later in pregnancy, she will need an increased amount because her metabolic rate and need increase. If she has been taking one particular kind of insulin and a specified dosage for a long time before the pregnancy, changing the type and dosage may be unnerving for her. Be certain she understands that re-regulation is a necessity because of the changes in her metabolism. Women with gestational diabetes will be started on insulin therapy if diet alone is unsuccessful in regulating glucose values.

The type of insulin chosen is usually a short-acting insulin (regular) combined with an intermediate type. Two thirds of the total amount of the day's insulin is given in the morning; the other third is given in the evening. This is self-administered 30 minutes before breakfast in a ratio of 2:1 (intermediate to regular) and again just before dinner in a ratio of 1:1. Human insulin is recommended because it has the potential for provoking a lesser antibody response than beef or pork insulins. Use of a very-short-acting insulin such as Lispro or insulin aspart, which have a 1-hour peak time, can lead to more fluctuations in blood glucose levels than regular insulin but are ideal for some women. Women should eat almost immediately after injecting these short-acting insulins to prevent hypoglycemia before mealtimes. Oral hypoglycemia agents are not used for regulation during pregnancy because, unlike insulin, they cross the placenta and are potentially teratogenic to a fetus.

Help a woman plan her day based on the time interval her insulin takes to reach its peak. For example, an intermediate insulin given before breakfast reaches its peak after lunch or late in the afternoon just before dinner. Regular insulin given before breakfast reaches its peak just after breakfast. An intermediate insulin given in the evening reaches its peak into the next day before breakfast; the evening regular insulin injection peaks after dinner or at bedtime. Knowing when insulin reaches its peak level makes serum glucose monitoring meaningful and alerts women to the time of the day when they are most apt to be hypoglycemic (see Chapter 48).

Be certain a woman is using an injection technique for insulin of stretching the skin taut and injecting at a 90-degree angle. Although this is normally intramuscular injection technique, insulin syringes have such short needles (5/8 in) that this places the insulin in the subcutaneous tissue. Most women prefer not to use abdominal sites during pregnancy. Because insulin is absorbed more slowly from the thigh than the upper arm, a woman should maintain a consistent rotating injection routine (such as using all sites in one limb before using another or rotating limbs) to maintain as consistent a level of absorption as possible. Insulin is adjusted to keep a fasting blood glucose level below 95 to 100 mg/dL and a 2-hour postprandial level below 120 mg/dL.

Blood Glucose Monitoring. All women with diabetes need to do blood glucose monitoring to determine whether hyperglycemia or hypoglycemia exists. For this, a woman typically uses a fingerstick technique, using one of her fingertips as the site of lancet puncture. She places a drop of blood on a test strip. The strip is then inserted into a glucose meter that determines the glucose level. A fasting blood glucose level below 95 to 100 mg/dL and a 2-hour postprandial level below 120 mg/dL are well-adjusted values.

When a woman discovers that hypoglycemia is present, she should ingest some form of sustained carbohydrate such as a glass of milk and some crackers. Taking a less-concentrated fluid such as milk rather than orange juice and including a complex carbohydrate helps prevent a rebound phenomenon in which a high glucose level is created that produces even more pronounced hypoglycemia.

If a woman discovers an elevated blood glucose level, she should assess her urine for ketones. She should inform her health care provider if she finds ketones in two separate specimens. Acidosis during pregnancy must be prevented because maternal acidosis leads to fetal anoxia because of fetal inability to use oxygen when body cells are acidotic. The most common time during pregnancy for hypoglycemia is the second and third months, before insulin resistance peaks; for hyperglycemia, it is the 6th month, or the time insulin resistance is becoming most pronounced.

Insulin Pump Therapy (Continuous Subcutaneous Insulin Infusion). Because a woman will have some periods of relative hyperglycemia and hypoglycemia no matter how

carefully she maintains her diet and balances her exercise level, an effective method to keep serum glucose constant is to administer insulin by a continuous pump during pregnancy (Strehlow et al., 2007). An insulin pump is an automatic pump about the size of an mp3 player. A syringe of regular insulin is placed in the pump chamber and a small-gauge needle is attached to a length of thin polyethylene tubing and implanted into the subcutaneous tissue of a woman's abdomen or thigh (Fig. 20.5). Day and night, at a continuous rate of about 1 U per hour, the pump edges the syringe barrel forward, infusing insulin continually into the subcutaneous tissue. Depending on the individual prescription, before a snack and before a meal, a woman can dial or press a button on the pump; the pump then pushes the syringe barrel forward to administer the bolus. The site of the pump insertion is cleaned daily and covered with sterile gauze; the site is changed every 24 to 48 hours to ensure that absorption remains optimal.

Several restrictions are necessary when using an insulin pump. The pump must not be allowed to become wet; therefore, a woman should remove the pump (not the syringe and tubing) when showering and remove the complete apparatus (pump, syringe, and tubing) to bathe or swim (caution her not to leave it disconnected for more than 1 hour). A woman might prefer to wear clothing that hides the pump's outline (it can either be held against her abdomen by an over-the-shoulder sling or hung from a belt around her waist). To assess whether the pump is delivering insulin at the designated rate, a woman must do blood glucose determinations about four times throughout the day (fasting and 1 hour after each meal). When pump therapy first begins, she must wake at night and do a 2:00 AM blood glucose determination because this is a time when she is most vulnerable for hypoglycemia.

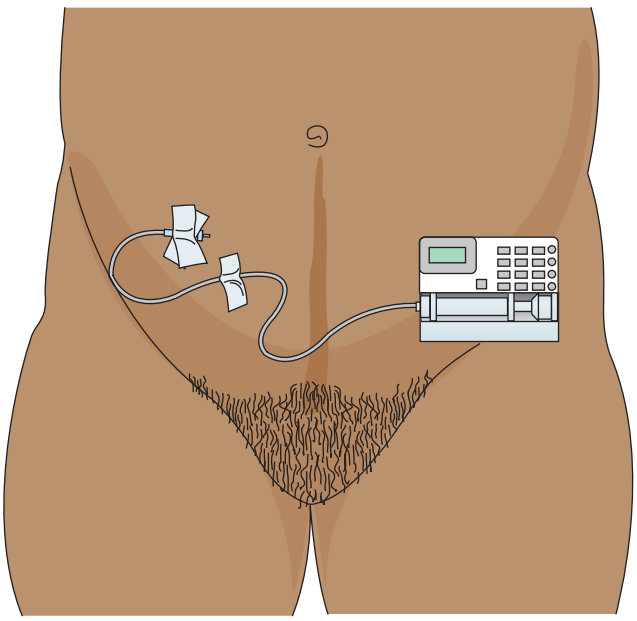

FIGURE 20.5 Using an insulin pump during pregnancy is the best assurance that insulin levels will remain constant.

Tests for Placental Function and Fetal Well-Being. Monitoring of fetal well-being is individualized depending on the woman's overall health. Because women with diabetes tend to have infants with a higher-than-normal incidence of birth anomalies, a woman will have a serum alpha-fetoprotein level obtained at 15 to 17 weeks to assess for a neural tube defect and an ultrasound examination performed at approximately 18 to 20 weeks to detect gross abnormalities. A creatinine clearance test may be ordered each trimester. A normal creatinine clearance rate suggests that a woman's vascular system is intact because kidney function is normal. This implies that uterine perfusion is also adequate. Placental functioning may also be assessed by a weekly nonstress test or biophysical profile during the last trimester (see Chapter 9) if a woman is in good control, or a daily nonstress test if her regulation is poor.

A woman may be asked to self-monitor fetal well-being by recording how many movements occur an hour. Be certain she knows that fetal activity varies depending on her activity and meal patterns to prevent her from becoming frightened by normal variations. The healthy fetus makes approximately 10 movements per hour (see Chapter 9). Ultrasounds may be taken at week 28 and then again at week 36 to 38 to determine fetal growth, amniotic fluid volume, placental location, and biparietal diameter. Oligohydramnios (a small amount of amniotic fluid) may indicate fetal growth restriction or fetal renal abnormality, whereas hydramnios (an excessive amount of amniotic fluid) may indicate gastrointestinal malformation or poorly controlled disease. The lecithin–sphingomyelin ratio by amniocentesis is performed by week 36 of pregnancy to assess fetal maturity. In pregnancies complicated by diabetes, this ratio tends not to show maturity as early as in other pregnancies because the synthesis of phosphatidylglycerol, the compound that stabilizes surfactant, is delayed in a diabetes-complicated pregnancy.

Because lung surfactant does not appear to form as early in these fetuses as others (because of the decreased level of cortisone present because of high serum glucose levels), the presence of phosphatidylglycerol at amniocentesis is used to indicate lung maturity. Although it is known that administering corticosteroids to the mother during the last week of pregnancy can hasten lung maturity, corticosteroids may also impair fetal insulin release and perhaps fetal pancreatic islet development. Therefore, with a fetus who already has a risk at birth from poor glucose control, corticosteroid use to improve lung maturity is not usually recommended.

Fetal surveillance is difficult for a woman. Having to wait during each weekly test to hear how her fetus is doing is emotionally draining especially for a woman who believes it is somehow her fault (it is, after all, her diabetes) this has happened and if the monitoring equipment shows fetal distress. She needs health care personnel with her who support her to minimize the feeling that she is alone.

Timing for Birth. Before women with diabetes were managed with maximum control during pregnancy, the timing of birth was a chief concern. Among the most hazardous times for a fetus are weeks 36 to 40 of pregnancy (when the fetus is drawing large stores of maternal nutrients because of its large size). In the past, many pregnancies were terminated early enough to prevent fetal loss from placental

insufficiency because of poor perfusion during these weeks; it was hoped that this was not so early that immaturity posed further complications.

To accomplish these early births, cesarean birth was routinely performed in pregnant diabetic women at 37 weeks' gestation. Cesarean birth had to be chosen as it is difficult to induce labor this early in pregnancy because the cervix is not yet ripe or responsive to labor contractions. Further, babies of diabetic women were large, making vaginal birth difficult. Moreover, a fetus suffering placental dysfunction or insufficiency did not do well in labor. Early cesarean births, however, often resulted in immature infants who died in the neonatal period because of respiratory distress syndrome (infants of diabetic women may be more prone to this than usual because surfactant is not mature).

Today, when accurate assessment of fetal age is available and the pregnancy can be maintained within safe limits by the use of nonstress testing for a longer period, the last weeks of pregnancy are not as hazardous as before, and the timing and type of birth is much more individualized.

Vaginal birth is preferred if at all possible. Cesarean birth always presents a higher risk than vaginal birth for a fetus, and because of the difficulty of glucose regulation, the fetus of a diabetic mother is already under stress. Labor may be induced by rupture of the membranes or an oxytocin infusion after measures to induce cervical ripening (see Chapter 23). Both labor contractions and fetal heart sounds should be monitored continuously during labor to ensure early detection of placental dysfunction. An internal fetal monitor may be used with pH monitoring. A woman's glucose level is regulated during labor by an intravenous infusion of regular insulin, with a blood glucose assay every hour. Regulating the glucose level carefully during labor reduces the possibility of rebound hypoglycemia in the newborn (see Chapter 26 for care of the infant of a diabetic woman at birth).

If a woman will be given an epidural anesthetic, use of an intravenous glucose solution as a plasma volume expander should be avoided to prevent hyperglycemia from developing; Ringer's lactate is infused instead.

Postpartum Adjustment. During the postpartum period, a woman who came into pregnancy with diabetes must undergo yet another readjustment to insulin regulation. With insulin resistance gone, often she needs no insulin during the immediate postpartum period; in another few days, however, she will return to her prepregnant insulin diabetic requirements. One- or 2-hour postprandial blood glucose determinations help to regulate how much insulin she needs. A woman with gestational diabetes usually demonstrates normal glucose values by 24 hours after birth and needs no further diet or insulin therapy. She requires careful observation, however, during the immediate postpartum period because if hydramnios was present during pregnancy, she is at risk of hemorrhage from poor uterine contraction. Women with diabetes may breastfeed because insulin is one of the few substances that does not pass into breast milk from the bloodstream (Koren, 2007).

Because a woman who has had gestational diabetes is at risk for developing type 2 diabetes later in life, she should have glucose testing done during health maintenance visits throughout life. Be certain women receive contraceptive information as appropriate. Remind women with diabetes that before they plan a second pregnancy, they will need to be certain their disease is stabilized and in good control.

CANCER AND PREGNANCY

Cancer occurs in about 1 in 1000 pregnancies (Cunningham, 2008b). The malignancies most commonly seen with pregnancy are those that occur most frequently in women during childbearing years:

- Cervical
- Breast
- Ovarian
- Thyroid
- Leukemia
- Melanoma
- Lymphomas

As so many women delay having their first child until they are past 30, the incidence of malignancy during pregnancy, especially breast cancer, which tends to occur in women over 40, is increasing. Although immunologic mechanisms are altered during pregnancy, there is no proof that pregnant women are more prone to cancer than other women or that pregnancy changes the course of existing disease.

If a woman is in the first trimester of pregnancy when a malignancy is diagnosed, she and her partner are asked to make a difficult decision: to delay treatment to avoid teratogenic risks to a fetus from treatment (possibly increasing a woman's risk); to end the pregnancy to allow chemotherapy or radiation treatment to be initiated; or to choose chemotherapy or radiation treatment with the knowledge that they may cause birth anomalies in the fetus (Latimer, 2007).

As a rule, women can receive chemotherapy in the second and third trimesters without adverse fetal effects. Radiation therapy, in contrast, another modality that is a mainstay of cancer therapy, puts the fetus at risk throughout pregnancy if the fetus is directly exposed.

Surgery to remove a tumor can be completed during pregnancy with the understanding that the fetus is at risk for anoxia during anesthesia. A woman is at more than the usual risk of thrombus formation postoperatively because of the increased coagulation process accompanying pregnancy. Cervical conization for cervical cancer has a particularly high fetal risk because the surgery may directly disrupt the pregnancy. With a vaccine against HPV now available, cervical cancer incidence should be seen much less in the future (Wysocki, Reiter, & Berman, 2007).

Cancer in a woman does not appear to metastasize to the fetus. This is because the placenta serves as a barrier against this spread and also because the fetus may be capable of resisting the invasion of the foreign cells. Melanoma is the only type of cancer that seems capable of spreading to the fetus (Leachman et al., 2007).

MENTAL ILLNESS AND PREGNANCY

Mental illness may precede or occur with pregnancy. Schizophrenia tends to have its highest incidence in adolescents and young adults and so occurs in young pregnant women. Depression occurs almost four times more commonly

in women than in men, and often in young adults. It is the most common mental illness seen in pregnant women.

Even normal levels of stress make it difficult to use effective coping mechanisms so pregnancy or childbirth may be the additional stress that reveals mental illness for the first time. A woman with a psychiatric disorder should be cared for by both a psychiatric care team and a prenatal care group to ensure that the stress of pregnancy is not exacerbating the mental illness, and distorted perceptions or depression do not complicate the pregnancy. Any psychotropic medication taken by a pregnant woman should be evaluated for possible fetal harm (Louik et al., 2007). For example, lithium, a mainstay of therapy for mood disorders such as bipolar disorder (manic depression), and serotonin-reuptake inhibitors used to counteract depression, are potentially teratogenic (Karch, 2009).

Mental illness may also occur in the postpartum period (postpartum depression or psychosis; see Chapter 25).

✔ Checkpoint Question 20.5

Angelina uses an insulin pump to administer insulin for gestational diabetes. Why is nighttime a particularly hazardous time for her fetus with pump therapy?

a. The fetus can develop hyperglycemia from excessive insulin administration.
b. Continuous insulin administration with no food can lead to hypoglycemia.
c. The mother's lack of exercise at night tends to lead to hypercalcemia.
d. The pump's needle can migrate inward and possibly pierce the fetus.

Key Points for Review

- A high-risk pregnancy is one in which a concurrent disorder, pregnancy-related complication, or external factor jeopardizes the health of the mother, the fetus, or both.
- Pregnancy is a stress to any family because it involves financial expenses plus changes in family roles. If a complication of pregnancy develops, this stress is almost automatically intensified. Families need support to be able to cope with the increased burden.
- When women with a pre-existing disease become pregnant, a thorough history and physical examination are crucial to obtain at the first prenatal visit to establish a baseline of information on the condition. Documentation of any medication being taken for a secondary condition is important to protect against adverse drug interactions and the possibility of teratogenic action on the fetus.
- Teaching is an important nursing intervention because a woman with a pre-existing illness must make modifications in her usual therapy to adjust to pregnancy. Pregnancy often stimulates women to learn more about their primary disease as well.
- Women who have a complication early in pregnancy may continue to worry about the health of their fetus all during pregnancy. They need to be assured (appropriately) that the episode was temporary and that, with continued monitoring, their fetus should not suffer harm. After giving birth, women may need to spend additional time with their newborns to convince themselves that their infants are healthy so bonding can begin.
- Because blood volume increases by as much as 50% during pregnancy, cardiac function may become inadequate if cardiovascular disease is present. Illnesses that cause difficulty can be either acquired disorders such as Kawasaki disease and rheumatic fever or congenital disorders such as mitral valve stenosis and coarctation of the aorta.
- Various forms of anemia can cause complications of pregnancy; iron-deficiency anemia, sickle cell anemia, and folic acid–deficiency anemia are examples. All these anemias can result in fetal distress because of inadequate oxygen transport.
- Urinary tract disorders can lead to pregnancy complications because pregnancy increases the workload of the kidneys. UTIs and chronic renal disease are two disorders that may lead to early pregnancy loss.
- Acute nasopharyngitis, asthma, pneumonia, influenza, and tuberculosis are common respiratory disorders seen in pregnancy. The incidence of tuberculosis is on the increase and these patients need special assessment and care.
- Juvenile rheumatoid arthritis and systemic lupus erythematosus are examples of rheumatic disorders seen in pregnancy. These disorders generally require large doses of NSAIDs for therapy. Women taking salicylates are advised to decrease use 2 weeks before birth to avoid bleeding disorders in the newborn.
- Some gastrointestinal illnesses that occur with pregnancy are hiatal hernia, cholecystitis, viral hepatitis, inflammatory bowel disease, and appendicitis. If surgery is necessary for conditions such as cholecystitis or appendicitis, it can be performed by laparoscopic technique during pregnancy, but this may result in preterm labor.
- Recurrent seizures are the most frequently seen neurologic condition during pregnancy. Many drugs used to control seizures are teratogenic; women need to have their medical regimen evaluated before pregnancy to be certain they are regulated on the fewest medications and the lowest dosages possible.
- The major endocrine disorder seen during pregnancy is diabetes mellitus. Gestational diabetes is diabetes that occurs during pregnancy and fades after it.

CRITICAL THINKING EXERCISES

1. Angelina Gomez, the woman you met at the beginning of the chapter, has developed congestive heart failure. She works at a job where she is on her feet almost all day. What suggestions could you make to her to help her incorporate some rest periods into her day?
2. Angelina has also developed gestational diabetes. She's resistant to learning about her condition, though, because she knows her symptoms are only temporary and

will fade at the end of pregnancy. What type of teaching plan would you devise to help her learn in the face of this attitude?

3. Angelina is prone to urinary tract infections during pregnancy because of her gestational diabetes. What are common measures you can suggest to women to help avoid UTIs during pregnancy?
4. Examine the National Health Goals related to complications of pregnancy. Most government-sponsored money for nursing research is allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to the Gomez family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to nursing care of families during a high-risk pregnancy. Confirm your answers are correct by reading the rationales.

Chapter 21

Nursing Care of a Family Experiencing a Sudden Pregnancy Complication

KEY TERMS

- abortion
- ankle clonus
- cervical cerclage
- chorioamnionitis
- Couvelaire uterus
- early pregnancy failure
- eclampsia
- ectopic pregnancy
- erythroblastosis fetalis
- gestational trophoblastic disease
- HELLP syndrome
- hemolytic disease of the newborn
- hydramnios
- isoimmunization
- miscarriage
- oligohydramnios
- placenta previa
- post term pregnancy
- pre-eclampsia
- premature cervical dilatation
- premature separation of the placenta
- preterm labor
- preterm rupture of membranes
- pseudocyesis
- recurrent pregnancy loss
- Rh incompatibility
- tocolytic agent

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe complications of pregnancy that place a pregnant woman and her fetus at high risk.
2. Identify National Health Goals related to complications of pregnancy and specific measures nurses can take to help the nation achieve these goals.
3. Use critical thinking to analyze ways that nurses can help prevent complications of pregnancy while keeping care family centered.
4. Assess a woman who is experiencing a complication of pregnancy.
5. Formulate nursing diagnoses that address the needs of a woman and her family experiencing a complication of pregnancy.
6. Identify expected outcomes to minimize the risks to a pregnant woman and her fetus when a complication of pregnancy occurs.
7. Plan nursing interventions to meet the needs and promote optimal outcomes for a woman and her family during a complication of pregnancy.
8. Implement nursing care specific to a woman who has developed a complication of pregnancy such as teaching her how to recognize the symptoms of preterm labor.
9. Evaluate expected outcomes for effectiveness and achievement of care.
10. Identify areas of nursing care related to high-risk pregnancy that could benefit from additional nursing research or the application of evidence-based practice.
11. Integrate knowledge of complications of pregnancy with nursing process to achieve quality maternal and child health nursing care.

Beverly Muzuki is a 20-year-old gravida 2, para 0, 30 weeks pregnant, whom you see in a prenatal clinic. She has had symptoms of a urinary tract infection for the past few days but did not call the clinic because she knew she had an appointment today and thought getting some help for it could wait until she came in. Yesterday she noticed some mild abdominal pain but thought it was irritation from the bladder infection. During the night, she woke twice because of a nagging backache. This morning, she has intermittent sharp uterine contractions. "Why am I starting labor so early?" she asks you. "I didn't do anything wrong."

Previous chapters described normal pregnancy and pre-existing and newly acquired conditions that can complicate pregnancy. This chapter adds knowledge about complications directly related to the pregnancy. Such complications can cause as much concern and worry for women as illnesses brought into a pregnancy.

Were Beverly's actions as informed as they could have been?

What additional health teaching might have prevented her from starting labor so early?

The majority of women who enter pregnancy in good health expect to complete a pregnancy and birth without complications. In a few women, however, for reasons that usually are unclear, unexpected deviations or complications from the course of normal pregnancy occur. When this happens, it places a severe burden on a woman and her family as well as her health care providers. All families benefit from the support and skill of a professional nurse who helps them work through the stages of pregnancy and prepare them to become new parents. The support and skills of a professional nurse are essential to a family who, in addition to the usual tasks of pregnancy, must take special care to ensure the continuation of the pregnancy. A woman becomes concerned that her baby cannot be carried to term. Hospitalization may be necessary. Once stabilized, a woman has to be monitored carefully until the pregnancy reaches term. As this is done on an ambulatory basis, nurses continue to be instrumental in care (Skouteris et al., 2009).

The leading complications related directly to the pregnancy are thromboembolism, hemorrhage, infection, pregnancy-induced hypertension, and ectopic pregnancy (Fortner, Althaus, & Gurewitsch, 2007). All of these have the potential to threaten the life of the mother and the fetus. National Health Goals established to help reduce complications of pregnancy such as these are shown in Box 21.1.

BOX 21.1 ✻Focus on National Health Goals

Preventing complications of pregnancy is viewed as so important by most people that this issue is included in the National Health Goals. Four of these goals are:

- Reduce the rate of maternal deaths from pregnancy-related causes to 3.3 per 100,000 live births from a baseline of 7.1 per 100,000.
- Reduce the rate of maternal illness and complications because of pregnancy to 24 per 100 births from a baseline of 31 per 100 births.
- Reduce the proportion of preterm births to 7.6% from a baseline of 11.6%.
- Reduce the incidence of low birthweight to no more than 5% of live births from a baseline of 7.6%, and of very low birth weight to no more than 0.9% of live births from a baseline of 1.4% (http://www.nih.gov).

Nurses working in prenatal settings can help to ensure that women are well informed about the normal course of pregnancy so they can recognize and alert health care providers when a complication is occurring. They can actively participate in risk assessment at prenatal visits. Nursing research is needed in areas such as what is the best way to determine each woman's individual needs so prenatal instructions can be specifically planned, and whether increasing the number of prenatal visits for high-risk women could reduce complications during pregnancy.

Nursing Process Overview

For a Woman Who Develops a Complication of Pregnancy

Assessment

Nurses often are the first health care providers to discover that a complication of pregnancy is beginning because they are the people who talk to clients first at prenatal visits. Always ask women at such visits about any symptoms that might indicate a complication such as pain or bleeding. Provide enough time for a thorough health history so more subtle problems such as headache, blurred vision, or vaginal spotting can be discovered and investigated thoroughly.

In addition, at the close of a visit, review the danger signs of pregnancy with a woman so she can recognize potential problems and contact the health care center if a problem should occur. Assure women that they are free to call whenever they are concerned. Otherwise, they may wait until a symptom is acute rather than call when they first notice it.

Nursing Diagnosis

Nursing diagnoses pertaining to a woman with a pregnancy complication should reflect both the physical problem and the family's concern. Some examples are:

- Anxiety related to guarded pregnancy outcome
- Deficient fluid volume related to third-trimester bleeding
- Risk for infection related to incomplete miscarriage
- Risk for ineffective tissue perfusion related to pregnancy-induced hypertension
- Deficient knowledge related to signs and symptoms of possible complications
- Fear of preterm labor ending the pregnancy

Outcome Identification and Planning

Complications of pregnancy produce emergency situations, so outcomes usually focus on a short timeframe. Be sure that outcomes address both fetal and maternal welfare and often total family welfare. Treatment protocols, such as those related to bleeding, preterm labor, and pregnancy-induced hypertension, should be regularly updated and maintained so they remain current. Be certain that they reflect a current nursing management level so nurses can act swiftly and independently as needed with life-saving measures. Once a woman's condition stabilizes, outcome identification can then focus on long-term objectives.

Many women who develop a pregnancy complication spend a few days in the hospital for therapy and monitoring followed by discharge to their homes. Waiting for a pregnancy that has been threatened this way to come to term can be difficult and anxious. Readmission to the health care facility, especially when a new complication occurs, compounds these feelings. Be certain that planning considers the many feelings this experience can cause. Offer referrals for counseling and/or community support groups. An Internet site that discusses complications of pregnancy that can be helpful to women is The American Pregnancy Association (http://www.americanpregnancy.org).

Implementation

Interventions for a woman experiencing a complication of pregnancy include measures to maintain several different areas:

- Continued healthy fetal growth
- Continued maternal physical health
- A woman's and family's psychological health
- Continuation of the pregnancy as long as possible

Maintaining an optimistic attitude of fetal progress is important so a woman does not begin anticipatory grieving for her fetus and halt the growth of bonding. If the complication can be contained and the pregnancy continues uninterrupted, this will help protect the mental health of the whole family. If the pregnancy cannot be continued, be available to offer support to a family who grieves for the loss of an unborn child and, in rare instances, loss of future childbearing potential or the woman herself.

After a pregnancy with complications, a woman has reason to be especially worried about her infant's health at the time of birth. The infant may be hospitalized in a special care nursery. Help her spend enough time with her child to see that although, perhaps born before term, her infant is well and healthy. This may be difficult because she still may be ill herself. It is helpful to assess the infant for such things as ability to follow a light and respond to a voice while the woman is present. This helps to demonstrate that the infant is well.

Outcome Evaluation

Although the success or failure of some nursing interventions cannot be fully evaluated until a child is born or even into the postnatal period, outcomes should be evaluated throughout the pregnancy if possible. Be aware that after a complication of early pregnancy, a woman cannot help but worry for the remainder of the pregnancy that the complication will recur or that the original insult to the fetus was severe enough to cause long-term effects. Evaluate a woman's attitude and physical status at each health care visit to be certain she is coping with the situation and the fear and strain she lives under until the child is born.

Unfortunately, even with sustained care, not all fetal outcomes will be optimal. Evaluation will then include the ability of the family to care for an ill infant or grieve because a newborn dies. Examples of expected outcomes are:

- Client's blood pressure is maintained within acceptable parameters.
- Couple state they feel able to cope with anxiety associated with the pregnancy complication.
- Client's signs and symptoms of pregnancy-induced hypertension do not progress to eclampsia.
- Client accurately verbalizes crucial signs and symptoms she should immediately report to her primary health care provider.
- Couple expresses feelings of sadness over pregnancy loss

BLEEDING DURING PREGNANCY

Vaginal bleeding during pregnancy is always a deviation from the normal, may occur at any point during pregnancy, and is always frightening. It must always be carefully investigated because if it occurs in sufficient amount or for sufficient cause, it can impair both the outcome of the pregnancy and a woman's life or health. The primary causes of bleeding during pregnancy are summarized in Table 21.1.

TABLE 21.1 ✻ Summary of Primary Causes of Bleeding During Pregnancy

Time	Type	Cause	Assessment	Cautions
First trimester	Threatened miscarriage (early—under 16 weeks; late—16 to 24 weeks)	Unknown; possibly chromosomal, uterine abnormalities	Vaginal spotting, perhaps slight cramping	
	Imminent (inevitable) miscarriage		Vaginal spotting, cramping, cervical dilatation	
	Missed miscarriage		Vaginal spotting, perhaps slight cramping; no apparent loss of pregnancy	Disseminated intravascular coagulation associated with missed miscarriage
	Incomplete miscarriage		Vaginal spotting, cramping, cervical dilatation, but incomplete expulsion of uterine contents	
	Complete miscarriage		Vaginal spotting, cramping, cervical dilatation, and complete expulsion of uterine contents	

(continued)

TABLE 21.1 ✻ Summary of Primary Causes of Bleeding During Pregnancy (continued)

Time	Type	Cause	Assessment	Cautions
	Ectopic (tubal) pregnancy	Implantation of zygote at site other than in uterus; tubal constricture, adhesions associated	Sudden unilateral lower abdominal quadrant pain; minimal vaginal bleeding, possible signs of shock or hemorrhage	May have repeat ectopic pregnancy in future if tubal scarring is bilateral
Second trimester	Hydatidiform mole (gestational trophoblastic disease)	Abnormal proliferation of trophoblast cells; fertilization or division defect	Overgrowth of uterus; highly positive human chorionic gonadotropin (hCG) test; no fetus present on ultrasound; bleeding from vagina of old or fresh blood accompanied by cyst formation	Retained trophoblast tissue may become malignant (choriocarcinoma); follow for 6 months to 1 year with hCG testing
	Premature cervical dilatation	Cervix begins to dilate and pregnancy is lost at about 20 weeks; unknown cause, but cervical trauma from dilatation and curettage (D&C) may be associated	Painless bleeding leading to expulsion of fetus	Can have cervical sutures placed to ensure a second pregnancy
Third trimester	Placenta previa	Low implantation of placenta possibly because of uterine abnormality	Painless bleeding at beginning of cervical dilatation	No vaginal examinations to minimize placental trauma
	Premature separation of the placenta (abruptio placentae)	Unknown cause; associated with hypertension; placenta separates from uterus	Sharp abdominal pain followed by uterine tenderness; vaginal bleeding; signs of maternal shock, fetal distress	Disseminated intravascular coagulation associated with condition
	Preterm labor	Many possible etiologic factors such as trauma, substance abuse, pregnancy-induced hypertension or cervicitis; increased chance in multiple gestation, maternal illness	Show (pink-stained vaginal discharge) accompanied by uterine contractions becoming regular and effective	Preterm labor may be halted if the cervix is less than 4 cm dilated and the membranes are intact. Corticosteroids are administered to aid fetal lung maturity.

Although vaginal bleeding may be innocent, any degree of this during pregnancy is potentially serious because it may mean that the placenta has loosened, cutting off nourishment to the fetus. Also, the amount visualized may be only a fraction of the blood actually being lost. This happens because an undilated cervix and intact membranes can contain blood within the uterus. A woman with any degree of bleeding, therefore, needs to be evaluated for the possibility that she is experiencing a significant blood loss or is developing hypovolemic shock.

The process of shock because of blood loss is shown in Figure 21.1. Because the uterus is a nonessential body organ, danger to the fetal blood supply occurs when a woman's body begins to decrease blood flow to peripheral organs (although the increased blood volume of pregnancy allows more than normal blood loss before

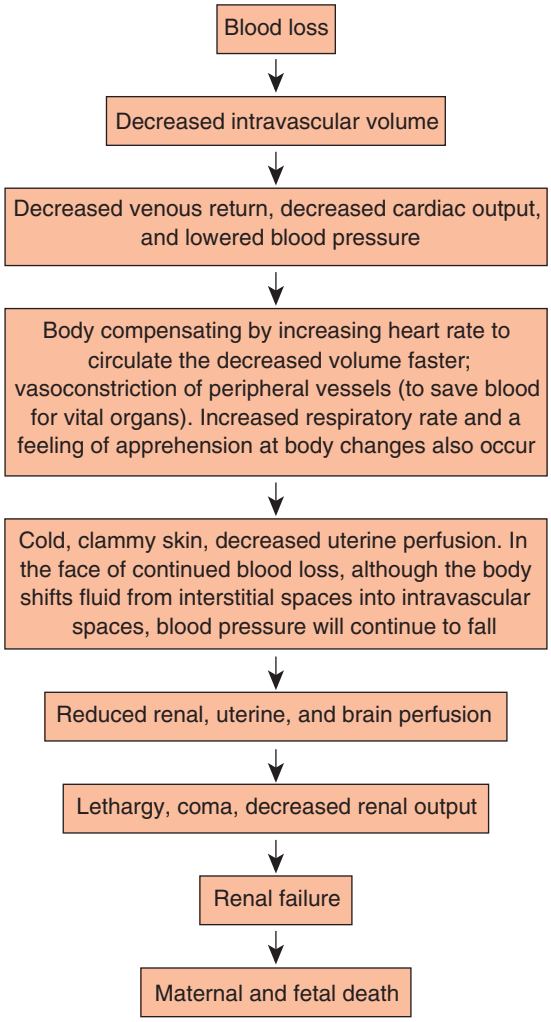

FIGURE 21.1 The process of shock because of blood loss (*hypovolemia*).

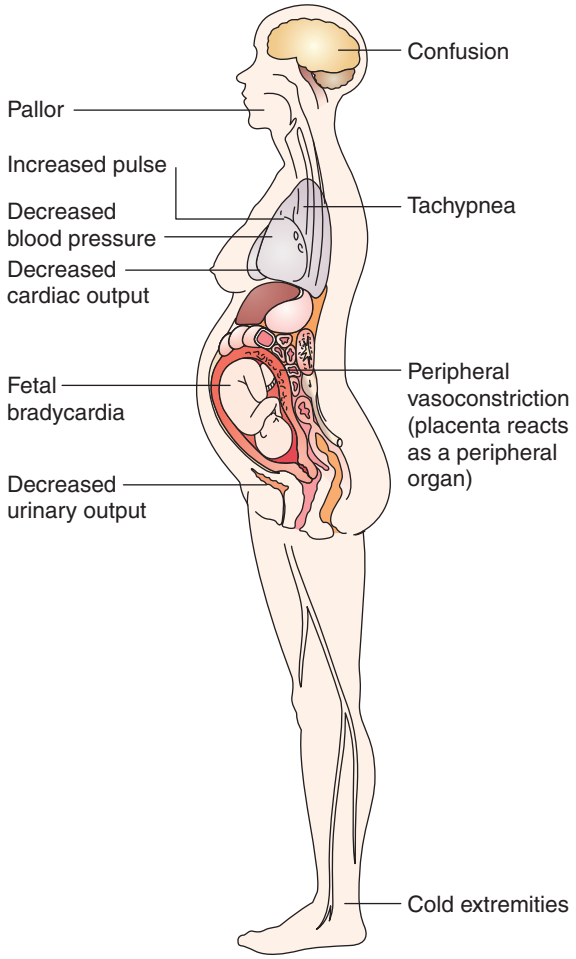
Box 21.2 Assessment

Assessing a Pregnant Woman With Hypovolemic Shock



hypovolemic shock processes begin). Signs of hypovolemic shock (Table 21.2) occur when 10% of blood volume, or approximately 2 units of blood, have been lost; fetal distress occurs when 25% of blood volume is lost (Box 21.2). Because "normal" blood pressure varies from woman to woman, it is important to know the baseline blood pressure for a pregnant woman when evaluating for shock. Inform women of their blood pressure at prenatal visits; for example, "Your blood pressure is 110 over 70—that's normal," not just "Your pressure is normal." Then if blood loss should occur, a woman can supply her baseline pressure.

TABLE 21.2 ✻ Signs and Symptoms of Hypovolemic Shock

Assessment	Significance
Increased pulse rate	Heart is attempting to circulate decreased blood volume
Decreased blood pressure	Less peripheral resistance because of decreased blood volume
Increased respiratory rate	Increases gas exchange to better oxygenate decreased red blood cell volume
Cold, clammy skin	Vasoconstriction occurs to maintain blood volume in central body core
Decreased urine output	Inadequate blood is entering kidneys because of decreased blood volume
Dizziness or decreased level of consciousness	Inadequate blood is reaching cerebrum because of decreased blood volume
Decreased central venous pressure	Decreased blood is returning to heart because of reduced blood volume

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for deficient fluid volume related to bleeding during pregnancy

Outcome Evaluation: Client's blood pressure is maintained at above 100/60 mm Hg; pulse rate is below 100 beats per minute (bpm); only minimal bleeding is apparent; fetal heart rate is maintained at 120 to 160 bpm, with adequate short-term and long-term variability; urine output is greater than 30 mL/hr.

Therapy for hypovolemic shock is aimed at restoring blood volume and halting the source of hemorrhage (Table 21.3). Monitoring urine output is a good gauge of blood loss because kidneys need sufficient arterial blood flow and pressure to function. If they are not producing urine, it suggests that they are not obtaining adequate blood. If the blood deficit continues so blood cannot reach other major organs, multiorgan failure can result (Dambro, 2008). Obtaining hemoglobin and hematocrit levels and securing a blood sample for typing or cross-matching are essential to help not only predict the extent of blood loss but prepare for blood replacement. A woman may have a central venous pressure catheter (measurement of right atrial pressure or the pressure of blood within the vena cava) or a pulmonary capillary wedge catheter (measures the pressure in the left atrium or the filling pressure in the left ventricle) inserted (see Chapter 41). During pregnancy, usual values of these measures differ from the average, so they need to be evaluated in light of the pregnancy. Central venous pressure normally is 4 to 10 mm Hg; during pregnancy it is 1 to 6 mm Hg; pulmonary capillary wedge pressure is normally 4 to 12 mm Hg; it is 6 to 12 mm Hg with pregnancy (Cansino & Lipsett, 2007).

A woman suspected of having serious bleeding will need intravenous fluid replacement such as Ringer's lactate as an early intervention. Use a large-gauge angiocath (16 or 18) for rapid fluid expansion as this will allow a blood transfusion to be administered through the same site as soon as blood is available. If respirations are rapid, administer oxygen by mask and monitor oxygen saturation levels by pulse oximetry. Obtain arterial blood gases as ordered. A woman needs frequent assessments of vital signs and continuous fetal monitoring by an external monitoring device should be started. Urge the woman to lie in a lateral position. If this is not possible, position her on her back, with a wedge under one hip to minimize uterine pressure on the vena cava and prevent blood from being trapped in the lower extremities (supine hypotension syndrome).

TABLE 21.3 Emergency Interventions for Bleeding in Pregnancy

Intervention	Rationale
Alert health care team of emergency situation.	Provides maximum coordination of care
Place woman flat in bed on her side.	Maintains optimal placental and renal function
Begin intravenous fluid such as lactated Ringer's with a 16- or 18-gauge angiocath.	Replaces intravascular fluid volume; intravenous line is established if blood replacement will be needed
Administer oxygen as necessary at 6–10 L/min by face mask.	Provides adequate fetal oxygenation despite lowered maternal circulating blood volume
Monitor uterine contractions and fetal heart rate by external monitor.	Assesses whether labor is present and fetal status; external system avoids cervical trauma
Omit vaginal examination.	Prevents tearing of placenta if placenta previa is cause of bleeding
Withhold oral fluid.	Anticipates need for emergency surgery
Order type and cross-match of 2 units whole blood.	Allows for restoring circulating maternal blood volume if needed
Measure intake and output.	Enables assessment of renal function (will decrease to under 30 mL/hour with massive circulating volume loss)
Assess vital signs (pulse, respirations, and blood pressure every 15 min; apply pulse oximeter and automatic blood pressure cuff as necessary).	Provides baseline data on maternal response to blood loss
Assist with placement of central venous pressure or pulmonary artery catheter and blood determinations.	Provides more accurate data on maternal hemodynamic state
Measure maternal blood loss by weighing perineal pads; save any tissue passed.	Provides objective evidence of amount of bleeding. Saturating a sanitary pad in less than 1 hour is heavy blood loss; tissue may be abnormal trophoblast tissue.
Set aside 5 mL of blood drawn intravenously in a clean test tube; observe in 5 min for clot formation.	Tests for possible blood coagulation problem (disseminated intravascular coagulation; suspect this if no clot forms within time limit)
Assist with ultrasound examination.	Supplies information on placental and fetal well-being
Maintain a positive attitude about fetal outcome.	Supports mother–child bonding
Support woman's self-esteem; provide emotional support to woman and her support person.	Assists problem solving, which is lessened by poor self-esteem.

Spontaneous Miscarriage

Abortion is the medical term for any interruption of a pregnancy before a fetus is viable (able to survive outside the uterus if born at that time). A viable fetus is usually defined as a fetus of more than 20 to 24 weeks of gestation or one that weighs at least 500 g. A fetus born before this point is considered a miscarriage or premature or immature birth (Cootauco & Althaus, 2007).

Elective abortion, discussed in Chapter 6, is the planned medical termination of a pregnancy. When the interruption occurs spontaneously, it is clearer to refer to it as a **miscarriage.**

Spontaneous miscarriage occurs in 15% to 30% of all pregnancies and arises from natural causes (Uzelac & Garmel, 2007). A spontaneous miscarriage is an early miscarriage if it occurs before week 16 of pregnancy and a late miscarriage if it occurs between weeks 16 and 24. For the first 6 weeks of pregnancy, the developing placenta is tentatively attached to the decidua of the uterus; during weeks 6 to 12, a moderate degree of attachment to the myometrium is present. After week 12, the attachment is penetrating and deep. Because of the degrees of attachment achieved at different weeks of pregnancy, it is important to attempt to establish the week of the pregnancy at which bleeding has become apparent. Bleeding before week 6 is rarely severe; bleeding after week 12 can be profuse because the placenta is implanted so deeply. Fortunately, at this time, with such deep placental implantation, the fetus tends to be expelled as in natural childbirth before the placenta separates. Uterine contractions then help to control placental bleeding as it does postpartally. For some women, then, the stage of attachment between weeks 6 and 12 can lead to the most severe, even life-threatening, bleeding.

Causes of Spontaneous Miscarriage

The most frequent cause of miscarriage in the first trimester of pregnancy is abnormal fetal development, due either to a teratogenic factor or to a chromosomal aberration. Between 50% and 80% of fetuses aborted early have structural abnormalities (Crombleholme, 2009). In other miscarriages, immunologic factors may be present or rejection of the embryo through an immune response may occur.

Another common cause of early miscarriage involves implantation abnormalities, as up to 50% of zygotes probably never implant securely because of inadequate endometrial formation or from an inappropriate site of implantation. With inadequate implantation, the placental circulation does not develop adequately, leading to poor fetal nutrition.

Miscarriage may also occur if the corpus luteum on the ovary fails to produce enough progesterone to maintain the decidua basalis. Progesterone therapy may be attempted to prevent this if this cause is documented (Ruis & Altman, 2007).

Systemic infection in a woman may be yet another cause of miscarriage. Rubella, syphilis, poliomyelitis, cytomegalovirus, and toxoplasmosis infections readily cross the placenta. Urinary tract infections are also associated with miscarriage. With an infection, if the fetus fails to grow, estrogen and progesterone production by the placenta falls. This leads to endometrial sloughing. With the sloughing, prostaglandins are released, leading to uterine contraction and cervical dilatation along with expulsion of the products of the pregnancy.

Ingestion of a teratogenic drug is still another cause. For example, isotretinoin (Accutane), a drug commonly prescribed for adolescent acne, if taken early in pregnancy, can lead to miscarriage or fetal abnormality (Karch, 2009). Ingestion of alcohol at the time of conception may also be linked to early pregnancy loss from abnormal fetal growth (Thilo & Rosenberg, 2008).

Because miscarriage can occur from so many causes and because the cause is unlikely to be determined with an early miscarriage, couples may have difficulty understanding why it happened to them (Box 21.3).

Assessment

The presenting symptom of spontaneous miscarriage is almost always vaginal spotting. At the first indication of this, a woman should telephone her health care provider and describe what is happening. Because a nurse often takes this initial call, nurses need to be aware of guidelines for assessing vaginal bleeding quickly during pregnancy (Table 21.4).

The history of the episode is important to help a physician or nurse-midwife diagnose the cause. Knowledge of a woman's actions is important to ensure she did not attempt to self-abort. She may prefer not to mention such an attempt but usually will if asked directly. Ask what she has done about the bleeding to be certain that she has not inserted a tampon to stop vaginal bleeding. If she has, although reporting only slight spotting, she actually has an unknown amount of blood loss and might be bleeding much more heavily than she first reports.

BOX 21.3 ✻ Focus on Family Teaching

Coping With a Spontaneous Miscarriage

Q. Beverly Muzuki tells you, "I had a miscarriage when I was younger, but my doctor called it an abortion. What is the difference?"

A. *Abortion* is the medical term for any pregnancy loss before a fetus is mature enough to live outside the uterus. Think of the word as interchangeable with *miscarriage.*

Q. Did I do something wrong to cause the miscarriage?

A. Early miscarriage is largely not preventable, because it is caused by such things as abnormal chromosome formation or poor uterine implantation—things over which you have no control. Eating a nutritious diet, so you enter a pregnancy in good health, and avoiding cigarette smoking or drinking alcohol are sensible recommendations to reduce your risk of miscarriage. If you had extensive blood loss with your miscarriage, be certain to eat iron-rich foods (such as meat and green vegetables) to help restore red blood cells for a second pregnancy.

TABLE 21.4 ✻ Immediate Assessment of Vaginal Bleeding During Pregnancy

Assessment Factor	Specific Questions to Ask
Confirmation of pregnancy	Does the woman know for certain that she is pregnant (positive pregnancy test or physician/nurse-midwife confirmation)? A woman who has been pregnant before and states that she is sure she is pregnant is probably right, even if she has not yet had this confirmed.
Pregnancy length	What is the length of the pregnancy in weeks?
Duration	How long did the bleeding episode last? Is it continuing?
Intensity	How much bleeding occurred? (Ask the woman to compare it to a common measure [e.g., a tablespoon, a cup].)
Description	Was blood mixed with amniotic fluid or mucus? Was it bright red (fresh blood) or dark (old blood)? Was it accompanied by tissue fragments? Was it odorous?
Frequency	Steady spotting? A single episode?
Associated symptoms	Cramping? Sharp pain? Dull pain? Has she ever had cervical surgery?
Action	What was happening when the bleeding started? What has she done (if anything) to control bleeding?
Blood type	Does she know this? (Rh-negative women will need Rh immune globulin to prevent Rh isoimmunization.)

Therapeutic Management

Depending on the symptoms and the description of the bleeding a woman gives, the physician or nurse-midwife will decide whether she needs to be seen by a health care provider and, if so, whether she should be seen in an ambulatory setting or the hospital.

Threatened Miscarriage

Symptoms of a *threatened miscarriage* begin as vaginal bleeding, initially only scant and usually bright red. A woman may notice slight cramping, but no cervical dilatation is present on vaginal examination. A woman with an apparent threatened miscarriage may be asked to come to the clinic or office to have fetal heart sounds assessed or an ultrasound performed to evaluate the viability of the fetus. Blood for human chorionic gonadotropin hormone (hCG) may be drawn at the start of bleeding and again in 48 hours (if the placenta is still intact, the level in the bloodstream should double in this time). If it does not double, poor placental function is suspected. Avoidance of strenuous activity for 24 to 48 hours is the key intervention, assuming the threatened miscarriage involves a live fetus and presumed placental bleeding. Complete bed rest is usually not necessary. Bed rest may stop the vaginal bleeding but only because blood is pooling vaginally. When a woman does ambulate again, the vaginal blood collection will drain and bleeding will recur.

Women are apt to be extremely worried at the sight of bleeding. They need to talk with a sympathetic, supportive person about how distressed they feel. Be certain to convey concerned assurance that miscarriages happen spontaneously, not because of anything a woman did. Women with threatened miscarriages look for reasons why this could have happened, such as running up a flight of stairs, forgetting to take an iron pill, or getting angry with an older child. Being told that none of these events causes miscarriage can help to minimize the guilt that many women feel.

Most women are disappointed to learn that there is no cure to "hold the pregnancy." In the past, estrogen in the form of diethylstilbestrol (DES) was prescribed for this purpose, but there is no conclusive evidence that this helped, and because DES could be teratogenic, this practice is no longer advocated.

If the spotting with threatened miscarriage is going to stop, it usually does so within 24 to 48 hours after a woman reduces her activity. Once bleeding stops, she can gradually resume normal activities. Coitus is usually restricted for 2 weeks after the bleeding episode to prevent infection and to avoid inducing further bleeding.

As many as 50% of women with a threatened miscarriage continue the pregnancy; for the other 50%, unfortunately, the threatened miscarriage changes to imminent or inevitable miscarriage.

Imminent (Inevitable) Miscarriage

A threatened miscarriage becomes an imminent (inevitable) miscarriage if uterine contractions and cervical dilation occur. With cervical dilation, the loss of the products of conception cannot be halted. A woman who reports cramping or uterine contractions is usually asked to come to the hospital or office, where she is examined. She should save any tissue fragments she has passed and bring them with her so they can be examined. If no fetal heart sounds are detected and an ultrasound reveals an empty uterus or nonviable fetus, a physician may perform a vacuum extraction (dilation and evacuation [D&E]) to ensure that all the products of conception are removed (Uzelac & Garmel, 2007). Be certain the woman has been told that the pregnancy was already lost and that all procedures, such as suction curettage, are to clean the uterus and prevent further complications such as infection, not to end the pregnancy. Save any tissue fragments passed in the labor room, along with any brought from home, so they can be examined for an abnormality such as gestational trophoblastic disease (hydatidiform mole; see later) or for assurance that all the products of conception have been removed from the uterus. After a woman is discharged following the D&E, a woman should assess vaginal bleeding by recording the number of pads she uses. Saturating more than one pad per hour is abnormally heavy bleeding.

Complete Miscarriage

In a complete miscarriage, the entire products of conception (fetus, membranes, and placenta) are expelled spontaneously without any assistance. The bleeding usually slows within 2 hours and then ceases within a few days after passage of the products of conception.

Incomplete Miscarriage

In an incomplete miscarriage, part of the conceptus (usually the fetus) is expelled, but the membrane or placenta is retained in the uterus. The term "incomplete" can be confusing for women. They may interpret it to mean that because the miscarriage is incomplete, the pregnancy will continue. Be careful not to encourage false hopes by also misinterpreting this term.

In an incomplete miscarriage, there is a danger of maternal hemorrhage as long as part of the conceptus is retained in the uterus because the uterus cannot contract effectively under this condition. The physician will usually perform a dilation and curettage (D&C) or suction curettage to evacuate the remainder of the pregnancy from the uterus. Be certain a woman knows that the pregnancy is already lost and that this procedure is being done only to protect her from hemorrhage and infection, not to end the pregnancy.

Missed Miscarriage

In a missed miscarriage, also commonly referred to as **early pregnancy failure,** the fetus dies in utero but is not expelled. Women may also find this term misleading because it suggests that if a miscarriage is "missed," then the pregnancy can continue. A missed miscarriage is usually discovered at a prenatal examination when the fundal height is measured and no increase in size can be demonstrated or when previously heard fetal heart sounds cannot be heard. A woman may have had symptoms of a threatened miscarriage (painless vaginal bleeding), or she may have had no prior clinical symptoms.

An ultrasound can establish the fetus has died. Often the embryo actually died 4 to 6 weeks before the onset of miscarriage symptoms or failure of growth was noted. After the ultrasound, most commonly a D&E will be done. If the pregnancy is over 14 weeks, labor may be induced by a prostaglandin suppository or misoprostol (Cytotec) to dilate the cervix, followed by oxytocin stimulation or administration of mifepristone techniques used for elective termination of pregnancy (Uzelac & Garmel, 2007). If the pregnancy is not actively terminated, miscarriage usually occurs spontaneously within 2 weeks. There is a danger of allowing this normal course to happen, however, because disseminated intravascular coagulation (DIC), a coagulation defect, may develop if the dead (and possibly toxic) fetus remains too long in utero (Linker, 2009).

Most women hope, until the moment the ultrasound shows that their fetus is dead, that their baby is alive. They may need support in accepting the reality of the situation (Box 21.4) and need counseling to accept a future pregnancy because of fears that they may never be able to carry a baby to full term.

Recurrent Pregnancy Loss

In the past, women who had three spontaneous miscarriages that occurred at the same gestational age were called "habitual aborters." They were advised they were apparently too "nervous" or that something was so wrong with their hormones that childbearing was not for them. Today, the term **recurrent pregnancy loss** is used to describe this miscarriage pattern, and a thorough investigation is done to discover the cause of the loss and help ensure the outcome of a future pregnancy. Recurrent pregnancy loss occurs in about 1% of women who want to be pregnant. Although many losses occur for unknown reasons, possible causes include:

- Defective spermatozoa or ova
- Endocrine factors such as lowered levels of protein-bound iodine (PBI), butanol-extractable iodine (BEI), and globulin-bound iodine (GBI); poor thyroid function; or luteal phase defect
- Deviations of the uterus, such as septate or bicornuate uterus

Box 21.4 * Focus on Communication

Beverly's neighbor noticed some vaginal spotting at 10 weeks into her pregnancy. The bleeding stopped spontaneously but her doctor was unable to hear fetal heart tones. An ultrasound revealed a missed miscarriage. You talk to her neighbor after she has received this news.

Less Effective Communication

Nurse: Hello, Vivian. All right if I take your temperature and pulse?
Vivian: I'm sure they're fine. I feel fine.
Nurse: I'm sorry that this happened. It must be upsetting.
Vivian: The bleeding was scary. Made me really nervous that something was wrong with the baby.
Nurse: Bleeding is always scary. I hate to see it.
Vivian: All I want to do now is get this surgery over with so I can get on with having a baby.
Nurse: That's the advantage of being young. There's lots of time for babies. Both temperature and pulse are good. You were right—you are fine.

More Effective Communication

Nurse: Hello, Vivian. All right if I take your temperature and pulse?
Vivian: I'm sure they're fine. I feel fine.
Nurse: I'm sorry this happened. It must be upsetting.
Vivian: The bleeding was scary. Made me really nervous that something was wrong with the baby.
Nurse: Did the doctor talk to you about what she thought the bleeding meant? Or what the ultrasound showed?
Vivian: She said I missed having a miscarriage. I feel really lucky for that.
Nurse: I'll ask your doctor to re-explain what she meant by a missed miscarriage. That term can be confusing.

Because many women want so badly to be pregnant, it can be easy for them to "miss" bad news about a pregnancy. In the above scenario, the nurse was so intent on chatting that she failed to realize her client was misinformed. Better listening skills in the second example revealed a serious misunderstanding of what "missed miscarriage" means.

- Resistance to uterine artery blood flow
- Chorioamnionitis or uterine infection
- Autoimmune disorders such as those involving lupus anticoagulant and antiphospholipid antibodies (Ruis & Altman, 2007)

Complications of Miscarriage

As with full-term childbirth, hemorrhage and infection are two of the most likely complications after miscarriage. The risk for Rh isoimmunization and a woman's psychological state also need to be considered.

Hemorrhage. With a complete spontaneous miscarriage, serious or fatal hemorrhage is rare. With an incomplete miscarriage or in a woman who develops an accompanying coagulation defect (usually DIC), major hemorrhage is a possibility. Monitor vital signs for changes to detect possible hypovolemic shock. If excessive vaginal bleeding is occurring, immediately position a woman flat and massage the uterine fundus to try to aid contraction (see Chapter 17). This may be impossible with an early pregnancy because the small uterus is not palpable above the symphysis pubis. A woman may need a D&C or suction curettage to empty the uterus of the material that is preventing it from contracting and achieving hemostasis. A transfusion may be necessary to replace blood loss. Direct replacement of fibrinogen or another clotting factor may be used to increase coagulation ability.

After a self-limiting complete miscarriage, a woman needs clear instructions on how much bleeding is abnormal (more than one sanitary pad per hour is excessive) and what color changes she should expect in bleeding (gradually changing to a dark color and then to the color of serous fluid as it does with the postpartum woman). She should know that any unusual odor or passing of large clots is also abnormal. If her physician has prescribed an oral medication such as oral methylergonovine maleate (Methergine) to aid uterine contraction, be certain she understands why it is being prescribed and the importance of taking it. Some women repress their feelings, anxious to forget the experience as quickly as possible. Repression helps them to handle their anger or grief at the loss of the pregnancy. Be careful that in repressing the experience, however, a woman does not also repress the memory of her medication and leave herself open to hemorrhage.

Infection. The possibility of infection is minimal when pregnancy loss occurs over a short time, bleeding is self-limiting, and instrumentation is limited. However, there is always a possibility it may occur.

Infection tends to develop in women who have lost appreciable amounts of blood. Such women need especially close observation to rule out this second and possibly fatal complication.

After a miscarriage, be certain a woman knows the danger signs of infection, such as fever, abdominal pain or tenderness, and a foul vaginal discharge. Fever can be a transient reaction to a period of decreased fluid intake that preceded the miscarriage. In other instances, the fever may be a systemic reaction to the miscarriage process. All temperatures higher than 100.4° F (38.0° C) require careful evaluation of avoid overlooking the possibility that infection is developing.

The organism responsible for infection after miscarriage is usually *Escherichia coli* (spread from the rectum forward into the vagina). Caution a woman to wipe her perineal area from front to back after voiding and particularly after defecation to prevent the spread of bacteria from the rectal area. Caution her not to use tampons to control vaginal discharge, because stasis of any body fluid increases the risk of infection. Be careful about using statements such as, "You'll have some vaginal flow now, almost exactly like a menstrual flow." Otherwise, a woman might treat it as a menstrual period and use tampons.

If infection occurs, endometritis (infection of the uterine lining) is the type that usually occurs. It may be more extensive, however, and parametritis, peritonitis, thrombophlebitis, and septicemia can develop. The management of these infections is the same as if they were occurring after the safe birth of a child, so they are discussed in Chapter 25.

Septic Abortion. A septic abortion is an abortion that is complicated by infection (Uzelac & Garmel, 2007). Infection can occur after a spontaneous miscarriage, but more frequently it occurs in women who have tried to self-abort or were aborted illegally using a nonsterile instrument such as a knitting needle. Because the uterus is a warm, moist, dark cavity, infectious organisms, once introduced, grow rapidly in this environment, particularly if products of conception such as necrotic membranes are still present.

A woman has symptoms of fever and crampy abdominal pain, and her uterus feels tender to palpation. Left untreated, such an infection can lead to toxic shock syndrome, septicemia, kidney failure, and death (Vasquez et al., 2007).

Women with septic abortion need immediate, intensive assessment and treatment. Typically, complete blood count, serum electrolytes, serum creatinine, blood type and crossmatch, and cervical, vaginal, and urine cultures are obtained. An indwelling urinary (Foley) catheter may be inserted to monitor urine output hourly to assess kidney function. Intravenous fluid to restore fluid volume and to provide a route for high-dose, broad-spectrum antibiotic therapy is started. A combination of penicillin (gram-positive coverage), gentamicin (gram-negative aerobic coverage), and clindamycin (gram-negative anaerobic coverage) is commonly used.

A central venous pressure or pulmonary artery catheter may be inserted to monitor left atrial filling pressure and hemodynamic status. The removal of all infected or necrotic tissue from the uterus is important, so a D&C or D&E will be performed. Tetanus toxoid given subcutaneously or tetanus immune globulin given intramuscularly will be prescribed for prophylaxis against tetanus.

Infection following a septic abortion can be so severe that a woman needs to be admitted to an intensive care setting for continuing care. Dopamine and digitalis may be necessary to maintain sufficient cardiac output. Oxygen and perhaps ventilatory support may be necessary to maintain respiratory function.

Assuming a woman recovers from such an intense episode, septic abortion may lead to infertility because of uterine scarring or fibrotic scarring of the fallopian tubes. If a woman caused the infection by trying to self-abort, she needs follow-up counseling to assist her to learn better problem-solving methods for the future.

Isoimmunization. Whenever a placenta is dislodged, either by spontaneous birth or by a D&C at any point in pregnancy, some blood from the placental villi (the fetal blood) may enter the maternal circulation. If the fetus was Rh positive and the woman is Rh negative, enough Rh-positive fetal blood may enter the maternal circulation to cause **isoimmunization**—the production of antibodies against Rh-positive blood. If the woman's next child should have Rh-positive blood, these antibodies would attempt to destroy the red blood cells of this infant during the months that infant is in utero (Crowther & Middleton, 2009).

After a miscarriage, because the blood type of the conceptus is unknown, all women with Rh-negative blood should receive Rh (D antigen) immune globulin (RhIG) to prevent the buildup of antibodies in the event the conceptus was Rh positive.

Powerlessness or Anxiety. As with pregnancy loss for any reason, assess a woman's adjustment to a spontaneous miscarriage. Sadness and grief over the loss or a feeling that a woman has lost control of her life is to be expected. Do not forget to assess a partner's feelings as well, or that person's grief over the pregnancy loss can be missed.

Spontaneous miscarriage can be particularly heartbreaking for an older woman, because she realizes that her window of childbearing is limited.

✔ Checkpoint Question 21.1

Beverly Muzuki, the woman you met at the beginning of the chapter, had a miscarriage when she was younger. What would be the best advice to give a woman who tells you she is miscarrying?

a. Lie down and do not move for 24 hours to stop the bleeding.
b. Do not do anything special; early miscarriages happen all the time.
c. Save any clots or material passed for your health care provider.
d. Use a tight tampon to put pressure on your cervix and stop the bleeding.

Ectopic Pregnancy

An **ectopic pregnancy** is one in which implantation occurs outside the uterine cavity. The implantation may occur on the surface of the ovary or in the cervix. The most common site (in approximately 95% of such pregnancies) is in a fallopian tube (Fig. 21.2). Of these fallopian tube sites, approximately 80% occur in the ampullar portion, 12% occur in the isthmus, and 8% are interstitial or fimbrial (Yates & King, 2007).

With ectopic pregnancy, fertilization occurs as usual in the distal third of the fallopian tube. Immediately after the union of ovum and spermatozoon, the zygote begins to divide and grow. Unfortunately, because an obstruction is present, such as an adhesion of the fallopian tube from a previous infection (chronic salpingitis or pelvic inflammatory disease), congenital malformations, scars from tubal surgery, or a uterine tumor pressing on the proximal end of the tube, the zygote cannot travel the length of the tube. It lodges at a strictured site along the tube and implants there instead of in the uterus.

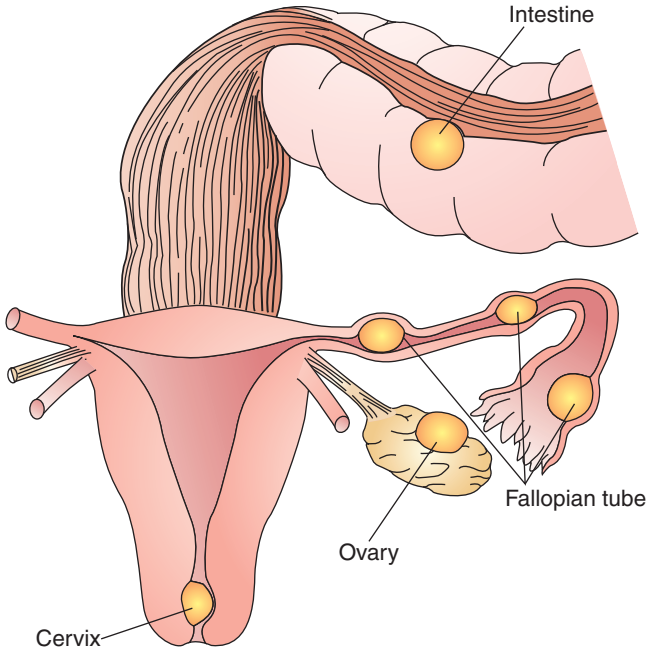


FIGURE 21.2 Sites at which an ectopic pregnancy may occur.

Approximately 2% of pregnancies are ectopic; it is the second most frequent cause of bleeding early in pregnancy. The incidence is increasing because of the increasing rate of pelvic inflammatory disease, which leads to tubal scarring. It occurs more frequently in women who smoke compared with those who do not. There is some evidence that intrauterine devices (IUDs) used for contraception may slow the transport of the zygote and lead to an increased incidence of tubal or ovarian implantation. The incidence also increases following in vitro fertilization. Women who have one ectopic pregnancy have a 10% to 20% chance that a subsequent pregnancy will also be ectopic. This is because salpingitis that leaves scarring is usually bilateral. Congenital anomalies such as webbing (fibrous bands) that block a fallopian tube may also be bilateral. For unknown reasons, oral contraceptives used before pregnancy reduce the incidence of ectopic pregnancy (Burkman, 2007).

Assessment

With ectopic pregnancy, there are no unusual symptoms at the time of implantation. The corpus luteum of the ovary continues to function as if the implantation were in the uterus. No menstrual flow occurs. A woman may experience the nausea and vomiting of early pregnancy, and a pregnancy test for hCG will be positive. Many ectopic pregnancies are diagnosed by an early pregnancy ultrasound. Magnetic resonance imaging (MRI) is also effective to use for this.

If not revealed by an ultrasound, at weeks 6 to 12 of pregnancy (2 to 8 weeks after a missed menstrual period), the zygote grows large enough to rupture the slender fallopian tube or the trophoblast cells actually break through the narrow base. Tearing and destruction of the blood vessels in the tube result. The extent of the bleeding that occurs depends on the

number and size of the ruptured vessels. If implantation is in the interstitial portion of the tube (where the tube joins the uterus), rupture can cause severe intraperitoneal bleeding. Fortunately, the incidence of tubal pregnancies is highest in the ampullar area (the distal third), where the blood vessels are smaller and profuse hemorrhage is less likely. However, continued bleeding from this area may, in time, result in a large amount of blood loss. Therefore, a ruptured ectopic pregnancy is serious regardless of the site of implantation.

A woman usually experiences a sharp, stabbing pain in one of her lower abdominal quadrants at the time of rupture, followed by scant vaginal spotting. The amount of bleeding evident with a ruptured ectopic pregnancy often does not reveal the actual amount present, however, because the products of conception from the ruptured tube and the accompanying blood may be expelled into the pelvic cavity rather than into the uterus. With this type of rupture, blood does not reach the vagina to become evident. With placental dislodgment, progesterone secretion stops and the uterine decidua begins to slough, causing additional bleeding. If internal bleeding progresses to acute hemorrhage, a woman may experience lightheadedness and rapid pulse, signs of shock.

Any woman with sharp abdominal pain and vaginal spotting needs to be evaluated by her health care provider to rule out the possibility of ectopic pregnancy. When helping determine the possibility of an ectopic pregnancy, ask a woman whether she has pain or vaginal bleeding. Occasionally, a woman will move suddenly and pull one of her round ligaments, the anterior uterine supports. This can cause a sharp, but momentary and innocent, lower quadrant pain. However, it would be rare for this phenomenon to be reported in connection with vaginal spotting.

By the time a woman with a ruptured ectopic pregnancy arrives at the hospital or physician's office, she may already be in severe shock, as evidenced by a rapid, thready pulse, rapid respirations, and falling blood pressure. Leukocytosis may be present, not from infection but from the trauma. Temperature is usually normal. A transvaginal ultrasound will demonstrate the ruptured tube and blood collecting in the peritoneum. Either a falling hCG or serum progesterone level suggests that the pregnancy has ended. If the diagnosis of ectopic pregnancy is in doubt, a physician may insert a needle through the posterior vaginal fornix into the cul-de-sac under sterile conditions to see whether blood can be aspirated. A laparoscopy or culdoscopy can be used to visualize the fallopian tube if the symptoms alone do not reveal a clear picture of what has happened. However, ultrasonography alone usually reveals a clear-cut diagnostic picture (Yates & King, 2007).

If a woman waits for a time before seeking help, gradually her abdomen becomes rigid from peritoneal irritation. Her umbilicus may develop a bluish tinge (Cullen's sign). A woman may have continuing extensive or dull vaginal and abdominal pain; movement of the cervix on pelvic examination may cause excruciating pain. There may be pain in her shoulders from blood in the peritoneal cavity causing irritation to the phrenic nerve. A tender mass is usually palpable in Douglas' cul-de-sac on vaginal examination.

Therapeutic Management

Some ectopic pregnancies spontaneously end before they rupture and are reabsorbed over the next few days, requiring no treatment. It is difficult to predict when this will happen, so when an ectopic pregnancy is revealed by an early ultrasound, some action is taken. An unruptured ectopic pregnancy can be treated medically by the oral administration of methotrexate followed by leucovorin (Hajenius et al., 2009). Methotrexate, a folic acid antagonist chemotherapeutic agent, attacks and destroys fast-growing cells. Because trophoblast and zygote growth is so rapid, the drug is drawn to the site of the ectopic pregnancy (see Chapter 53 for a general discussion of chemotherapy agents of this type). Women are treated until a negative hCG titer is achieved. A hysterosalpingogram or ultrasound is usually performed after the chemotherapy to assess whether the tube is fully patent. Mifepristone, an abortifacient, is also effective at causing sloughing of the tubal implantation site. The advantage of these therapies is that the tube is left intact, with no surgical scarring that could cause a second ectopic implantation.

If an ectopic pregnancy ruptures, it is an emergency situation (Stevens & Gilbert-Cohen, 2007). Keep in mind the amount of blood evident is a poor estimate of the actual blood loss. A blood sample needs to be drawn immediately for hemoglobin level, typing and cross-matching, and possibly hCG level for immediate pregnancy testing, if pregnancy has not yet been confirmed. Intravenous fluid using a large-gauge catheter to restore intravascular volume is begun. Blood then can be administered through this same line when matched.

The therapy for a ruptured ectopic pregnancy is laparoscopy to ligate the bleeding vessels and to remove or repair the damaged fallopian tube. A rough suture line on a fallopian tube may lead to another tubal pregnancy, so either the tube will be removed or suturing on the tube is done with microsurgical technique.

If a tube is removed, a woman is theoretically only 50% fertile, because every other month, when she ovulates from the ovary next to the removed tube, sperm cannot reach the ovum on that side. However, this is not a reliable contraceptive measure. Research in rabbits has shown that translocation of ova can occur—that is, an ovum released from the right ovary can pass through the pelvic cavity to the opposite (left) fallopian tube and become fertilized, and vice versa.

As with miscarriage, women with Rh-negative blood should receive Rh (D) immune globulin (RhIG) after an ectopic pregnancy for isoimmunization protection in future childbearing.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Powerlessness related to early loss of pregnancy secondary to ectopic pregnancy

Outcome Evaluation: Client states she feels sad at pregnancy loss but is able to deal with situation; has returned to previous level of activities and has forward-thinking plans.

A woman who has had an ectopic pregnancy not only has grief stages to work through (she has lost a child) but also may have problems of diminished self-image and a sense of powerlessness to resolve if surgery included removal of a fallopian tube. She may believe that she is now "half a woman" if she equated reproductive structures and childbearing

with being feminine. Encourage her to verbalize her concerns about this and future childbearing. The process of working through grief and role images takes weeks to months. It should begin in the hospital, however, where a woman has professional people to help her through the first days and to determine whether she will need further counseling.

Abdominal Pregnancy

Very rarely after an ectopic pregnancy ruptures—so rarely that the instances are difficult to document—the products of conception are expelled into the pelvic cavity with a minimum of bleeding. The placenta continues to grow in the fallopian tube, spreading perhaps into the uterus for a better blood supply; or it may escape into the pelvic cavity and implant on an organ such as an intestine. The fetus will grow in the pelvic cavity (an abdominal pregnancy). This can also occur if a uterus ruptures because an old uterine scar ruptures during pregnancy (Teng, Kumar, & Ramli, 2007).

In an abdominal pregnancy, the fetal outline is easily palpable through the abdomen because it is directly below the abdominal wall, not inside the uterus. A woman may not be as aware of movements as she would be normally, or she may experience painful fetal movements and abdominal cramping with fetal movements.

A woman may report she noticed sudden lower quadrant pain earlier in the pregnancy. An ultrasound or MRI will reveal the fetus outside the uterus.

The danger of abdominal pregnancy is that the placenta will infiltrate and erode a major blood vessel in the abdomen, leading to hemorrhage. If implanted on the intestine, it may erode so deeply that it causes bowel perforation and peritonitis. The fetus is also at high risk because without a good uterine blood supply, nutrients may not reach the fetus in adequate amounts. The survival rate in an abdominal pregnancy is only approximately 60% because of poor nutrient supply. In infants who do survive, there is an increased threat of fetal deformity or growth restriction from an inadequate nutrient supply.

At term, the infant must be born through laparotomy. The placenta is often difficult to remove after birth if it has implanted onto an abdominal organ such as the intestine. It may be left in place, therefore, and allowed to absorb spontaneously in 2 or 3 months. A follow-up ultrasound can be used to detect whether this has occurred, or a woman can be treated with methotrexate to help the placenta absorb. This therapy may not be effective because the remaining trophoblasts are no longer fast-growing.

✔ Checkpoint Question 21.2

Suppose Beverly Muzuki was discovered to have an ectopic pregnancy. What advice would you give her?

a. Most ectopic pregnancies go to completion, although the newborn is small.
b. If she must have a fallopian tube removed, she will be sterile afterward.
c. She will have a continuous nagging pain through the rest of pregnancy.
d. Ectopic pregnancy can be either medically or surgically treated.

Gestational Trophoblastic Disease (Hydatidiform Mole)

Gestational trophoblastic disease is abnormal proliferation and then degeneration of the trophoblastic villi (Garg & Giuntoli, 2007). As the cells degenerate, they become filled with fluid and appear as clear fluid-filled, grape-sized vesicles. The embryo fails to develop beyond a primitive start. Abnormal trophoblast cells must be identified because they are associated with choriocarcinoma, a rapidly metastasizing malignancy (Fig. 21.3).

The incidence of gestational trophoblastic disease is approximately 1 in every 1500 pregnancies. The condition tends to occur most often in women who have a low protein intake, in women older than age 35 years, in women of Asian heritage, and in blood group A women who marry blood group O men (Aghajanian, 2007).

Two types of molar growth can be identified by chromosome analysis. With a *complete mole,* all trophoblastic villi swell and become cystic. If an embryo forms, it dies early at only 1 to 2 mm in size, with no fetal blood present in the villi. On chromosomal analysis, although the karyotype is a normal 46XX or 46XY, this chromosome component was contributed only by the father or an "empty ovum" was fertilized and the chromosome material was duplicated (Fig. 21.4A).

With a *partial mole,* some of the villi form normally. The syncytiotrophoblastic layer of villi, however, is swollen and misshapen. A macerated embryo of approximately 9 weeks' gestation may be present and fetal blood may be present in the villi. A partial mole has 69 chromosomes (a triploid formation in which there are three chromosomes instead of two for every pair, one set supplied by an ovum that apparently was fertilized by two sperm or an ovum fertilized by one sperm in which meiosis or reduction division did not occur). This could also occur if one set of 23 chromosomes was supplied by one sperm and an ovum that did not undergo reduction division supplied 46 (see Fig. 21.4B).

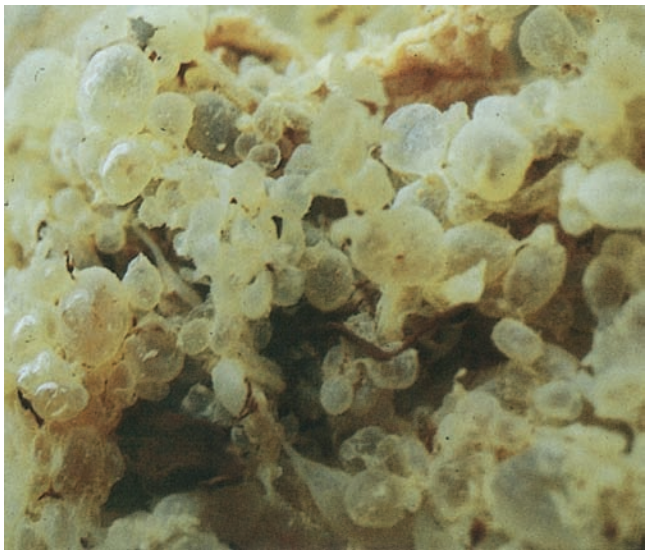

FIGURE 21.3 Gestational trophoblastic disease (hydatidiform mole). (From Rubin, E., & Farber, J. L. [1994]. Pathology [2nd ed.]. Philadelphia: JB Lippincott.)

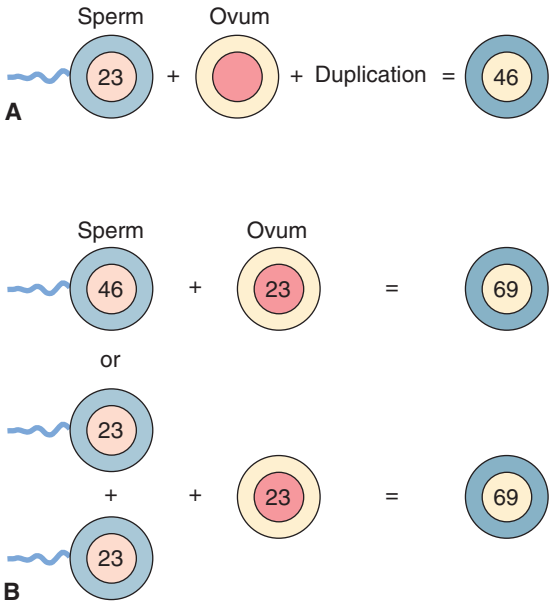

FIGURE 21.4 Formation of gestational trophoblastic disease (hydatidiform mole). (**A**) Complete mole. (**B**) Partial mole.

In contrast to complete moles, partial moles rarely lead to choriocarcinoma. Although still above average, hCG titers are lower in partial than in complete moles; titers also return to normal faster after mole evacuation.

Assessment

Because proliferation of the trophoblast cells occurs so rapidly with this condition, the uterus tends to expand faster than normally. This causes the uterus to reach its landmarks (just over the symphysis brim at 12 weeks, at the umbilicus at 20 to 24 weeks) before the usual time. This rapid development is also diagnostic of multiple pregnancy or a miscalculated due date, however, so this finding must be evaluated carefully. Because hCG is produced by the trophoblast cells that are overgrowing, a serum or urine test of hCG for pregnancy will be strongly positive (1 to 2 million IU compared with a normal pregnancy level of 400,000 IU).

Results continue to be strongly positive after day 100 of pregnancy, when the level of hCG normally would begin to decline. This fact must be evaluated carefully also, however, because highly positive test results can be characteristic of multiple pregnancies with more than one placenta. The nausea and vomiting of early pregnancy is usually marked, probably because of the high hCG level present. Symptoms of pregnancy-induced hypertension such as hypertension, edema, and proteinuria are ordinarily not present before week 20 of pregnancy. With gestational trophoblastic disease, they may appear before this time. An ultrasound will show dense growth (typically a snowflake pattern) but no fetal growth in the uterus. No fetal heart sounds are heard because there is no viable fetus.

At approximately week 16 of pregnancy, if the structure was not identified earlier by ultrasound, it will identify itself with vaginal bleeding. This may begin as spotting of dark-brown blood or as a profuse fresh flow. As the bleeding progresses, it is accompanied by discharge of the clear fluid-filled vesicles. This is why it is important for any woman who begins to miscarry at home to bring any clots or tissue passed to the hospital with her. The presence of clear fluid-filled cysts changes the diagnosis from miscarriage to gestational trophoblastic disease.

Therapeutic Management

Therapy for gestational trophoblastic disease is suction curettage to evacuate the mole.

Following mole extraction, women should have a baseline pelvic examination, a chest radiograph, and a serum test for the beta subunit of hCG. After surgery, hCG levels remain high. Half of women still have a positive reading at 3 weeks; one-fourth still have a positive test result at 40 days. The hCG is then analyzed every 2 weeks until levels are again normal. After that, serum hCG levels are assessed every 4 weeks for the next 6 to 12 months. Gradually declining hCG titers suggest no complication is developing. Levels that plateau for three times or increase suggest that a malignant transformation is occurring. A woman should use a reliable contraceptive method such as an oral contraceptive agent for 12 months so that a positive pregnancy test (the presence of hCG) resulting from a new pregnancy will not be confused with increasing levels and a developing malignancy. After 6 months, if hCG levels are still negative, a woman is theoretically free of the risk of a malignancy developing. By 12 months, she could plan a second pregnancy. Although the development of gestational trophoblastic disease means that a pregnancy never materialized and that a fetus never formed, a woman may experience the same feeling of loss after its evacuation that she would have experienced after the loss of a true pregnancy: she did, after all, believe she was pregnant. In addition, she is faced with the possibility that a malignancy may develop. She also must delay her childbearing plans for a year. If she had already put off having a child for some time, this may seem to be an unbearably long time.

Some physicians give women who have had gestational trophoblastic disease a prophylactic course of methotrexate, the drug of choice for choriocarcinoma. However, because the drug interferes with white blood cell formation (leukopenia), prophylactic use must be weighed carefully. If malignancy should occur, it can be treated effectively in most instances with methotrexate at that time (Garg & Giuntoli, 2007). Dactinomycin is added to the regimen if metastasis occurs.

Women need the opportunity to express their anger and sense of unfairness at this type of event. They may feel inadequate because something went wrong with the pregnancy. They may wonder whether it will happen again or whether they will ever be able to have children. Unfortunately, women who have one incidence of gestational trophoblastic disease have an increased risk of a second molar pregnancy (Aghajanian, 2007). They need early screening with ultrasound during a second pregnancy to be certain this is not happening again.

What if... Beverly Muzuki told you, after having had a gestational trophoblastic disorder, that she did not believe in birth control so she did not intend to take the oral contraceptives prescribed following her mole evacuation? How would you advise her?

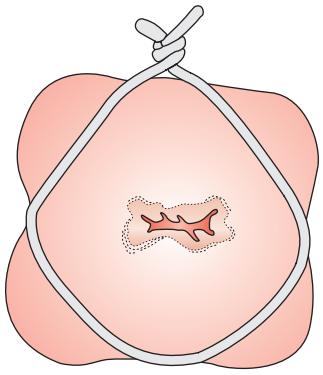

FIGURE 21.5 Shirodkar suture for cervical cerclage.

Premature Cervical Dilatation

Premature cervical dilatation, previously termed an *incompetent cervix,* refers to a cervix that dilates prematurely and therefore cannot hold a fetus until term (Kogan, Ben-Shushan, & Pernoll, 2007). It occurs in about 1% of women. The dilatation is usually painless. Often the first symptom is show (a pink-stained vaginal discharge) or increased pelvic pressure, which may be followed by rupture of the membranes and discharge of the amniotic fluid. Uterine contractions begin, and after a short labor the fetus is born. Unfortunately, this commonly occurs at approximately week 20 of pregnancy, when the fetus is still too immature to survive.

It is often difficult to explain in a particular instance what causes premature dilatation. It is associated with increased maternal age, congenital structural defects, and trauma to the cervix, such as might have occurred with a cone biopsy or repeated D&Cs. Although it may be diagnosed by an early ultrasound before symptoms occur, it is usually diagnosed only after the pregnancy is lost.

After the loss of one child because of premature cervical dilatation, a surgical operation termed **cervical cerclage** can be performed to prevent this from happening in a second pregnancy (Fox & Chervenak, 2008). As soon as an ultrasound confirms that the fetus of a second pregnancy is healthy, at approximately weeks 12 to 14, purse-string sutures are placed in the cervix by the vaginal route under regional anesthesia. This procedure is called a McDonald or a Shirodkar procedure after the surgeons who perfected the technique. The sutures serve to strengthen the cervix and prevent it from dilating (Fig. 21.5).

In a McDonald procedure, nylon sutures are placed horizontally and vertically across the cervix and pulled tight to reduce the cervical canal to a few millimeters in diameter. With a Shirodkar technique, sterile tape is threaded in a purse-string manner under the submucous layer of the cervix and sutured in place to achieve a closed cervix. Although routinely accomplished by a vaginal route, sutures may be placed by a transabdominal route.

With these procedures, the sutures are then removed at weeks 37 to 38 of pregnancy so the fetus can be born vaginally. When a transabdominal approach is used, the sutures may be left in place and a cesarean birth performed.

Women who are discovered to have cervical dilatation but with membranes still intact at a prenatal visit may have emergent cerclage sutures placed in the cervix even at that point as prophylaxis against preterm birth. The success of this procedure is limited, however, compared to preventive suturing. Still newer techniques allow purse-string sutures to be set before a woman becomes pregnant, providing added assurance that she will not begin miscarrying before week 14 of pregnancy.

Be certain to ask women who are reporting painless bleeding (the symptoms of spontaneous miscarriage also) whether they have had past cervical operations, to remind them they may have sutures in place.

Currently, the prognosis for a successful pregnancy after surgical correction for premature cervical dilatation is very favorable. The success rate with both types of cerclage techniques is 80% to 90%. After cerclage surgery, women remain on bed rest (perhaps in a slight or modified Trendelenburg position) for a few days to decrease pressure on the new sutures. Usual activity and sexual relations can be resumed in most instances after this rest period.

Placenta Previa

Placenta previa (Fig. 21.6) is a condition of pregnancy in which the placenta is implanted abnormally in the uterus. It is the most common cause of painless bleeding in the third trimester of pregnancy (Scearce & Uzelac, 2007). It occurs in

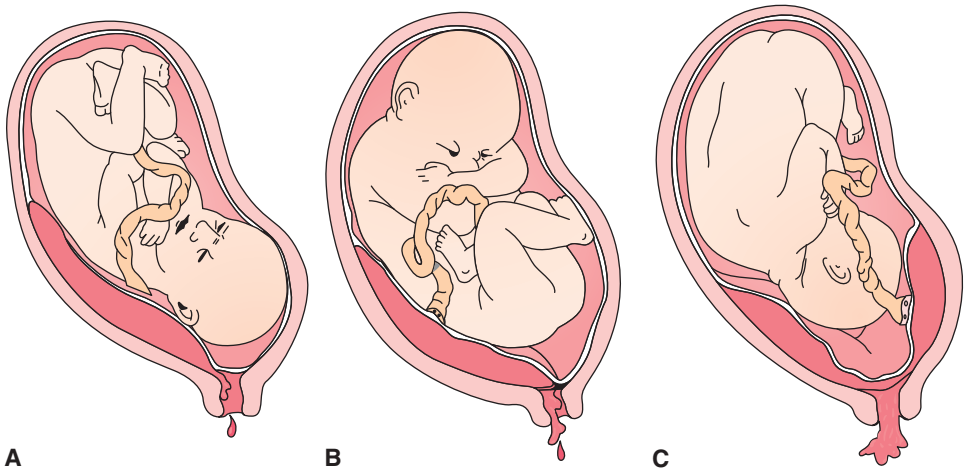

FIGURE 21.6 Degrees of placenta previa: (**A**) low implantation; (**B**) partial placenta previa; (**C**) total placenta previa.

four degrees: implantation in the lower rather than in the upper portion of the uterus (low-lying placenta); marginal implantation (the placenta edge approaches that of the cervical os); implantation that occludes a portion of the cervical os (partial placenta previa); and implantation that totally obstructs the cervical os (total placenta previa). The degree to which the placenta covers the internal cervical os is generally estimated in percentages: 100%, 75%, 30%, and so forth.

Increased parity, advanced maternal age, past cesarean births, past uterine curettage, multiple gestation, and perhaps a male fetus are all associated with placenta previa. The incidence is approximately 5 per 1000 pregnancies. It is thought to occur whenever the placenta is forced to spread to find an adequate exchange surface. An increase in congenital fetal anomalies may occur if the low implantation does not allow optimal fetal nutrition or oxygenation (Arquette & Holcroft, 2007).

Assessment

Because routine ultrasounds are performed so frequently during pregnancy, most instances of placenta previa are diagnosed today before any symptoms occur. Although many low-lying placentas detected on early ultrasounds migrate upward to a noncervical position, the condition is explained to a woman and she is cautioned to avoid coitus, to get adequate rest, and to call her health care provider at any sign of vaginal bleeding. Bleeding with placenta previa begins when the lower uterine segment starts to differentiate from the upper segment late in pregnancy (approximately week 30) and the cervix begins to dilate. The bleeding results from the placenta's inability to stretch to accommodate the differing shape of the lower uterine segment or the cervix. The bleeding that occurs is usually abrupt, painless, bright red, and sudden enough to frighten a woman. It is not associated with increased activity or participation in sports. It may stop as abruptly as it began, so that by the time a woman is seen at the health care site she is no longer bleeding, or it may slow after the initial hemorrhage but continue as continuous spotting.

Therapeutic Management

The bleeding of placenta previa, like that of ectopic pregnancy, is an emergency situation. The site of bleeding, the open vessels of the uterine decidua (maternal blood), places the mother at risk for hemorrhage. Because the placenta is loosened, the fetal oxygen supply may be compromised, placing the fetus at risk also. With the placental loosening, preterm labor (labor that occurs before the end of week 37 of gestation) may begin, posing the additional threat of preterm birth to the fetus.

Immediate Care Measures. To ensure an adequate blood supply to a woman and fetus, place the woman immediately on bed rest in a side-lying position. Be sure to assess:

- Duration of the pregnancy
- Time the bleeding began
- Woman's estimation of the amount of blood—ask her to estimate in terms of cups or tablespoons (a cup is 240 mL; a tablespoon is 15 mL)
- Whether there was accompanying pain
- Color of the blood (red blood indicates bleeding is fresh or is continuing)
- What she has done for the bleeding (if she inserted a tampon to halt the bleeding, there may be hidden bleeding)
- Whether there were prior episodes of bleeding during the pregnancy
- Whether she had prior cervical surgery for premature cervical dilatation

Inspect the perineum for bleeding. Estimate the present rate of blood loss. Weighing perineal pads before and after use and calculating the difference by subtraction is a good method to determine vaginal blood loss. An Apt or Kleihauer-Betke test (test strip procedures) can be used to detect whether the blood is of fetal or maternal origin. *Never* attempt a pelvic or rectal examination with painless bleeding late in pregnancy because any agitation of the cervix when there is a placenta previa may initiate massive hemorrhage, possibly fatal to both mother and child. Obtain baseline vital signs to determine whether symptoms of shock are present. Continue to assess blood pressure every 5 to 15 minutes or continuously with an electronic cuff. Other necessary actions are intravenous fluid therapy using a large-gauge catheter and monitoring urine output frequently, as often as every hour, as an indicator of blood volume adequacy. Attach external monitoring equipment to record fetal heart sounds and uterine contractions. An internal monitor for either fetal or uterine assessment that requires invasion of the cervix, is contraindicated. Hemoglobin, hematocrit, prothrombin time, partial thromboplastin time, fibrinogen, platelet count, type and cross-match, and antibody screen will be assessed to establish baselines, detect a possible clotting disorder, and ready blood for replacement if necessary. Vaginal birth is always safest for an infant. Therefore, it is essential to determine the placenta's location as accurately as possible in the hope that its position will make vaginal birth feasible. If the previa is under 30% by ultrasound, it may be possible for the fetus to be born past it. If over 30%, and the fetus is mature, the safest birth method for both mother and baby is often a cesarean birth (Arquette & Holcroft, 2007).

An abdominal examination may reveal that the fetal head is not engaged because of the interfering placenta. However, this finding gives little indication of how much of the placenta is obscuring the os and preventing the head from engaging. Anticipate the order for a transvaginal ultrasound to detect this. If no previa is detected, the physician may attempt a careful speculum examination of the vagina and cervix to rule out another cause for bleeding, such as ruptured varices or cervical trauma.

Vaginal examinations (actual investigation of dilatation) to determine whether placenta previa exists are done in an operating room or a fully equipped birthing room so that if hemorrhage does occur with the manipulation, an immediate cesarean birth can be carried out to remove the child and the bleeding placenta and contract the uterus. Have oxygen equipment available in case the fetal heart sounds indicate fetal distress, such as bradycardia or tachycardia, late deceleration, or variable decelerations.

Continuing Care Measures. The point at which a diagnosis of placenta previa is made and the age of the gestation dictate the final management. If labor has begun, bleeding is continuing, or the fetus is being compromised (measured by the response of the fetal heart rate to contractions), birth must be accomplished regardless of gestational age. If the bleeding has

stopped, the fetal heart sounds are of good quality, maternal vital signs are good, and the fetus is not yet 36 weeks of age, a woman is usually managed by expectant watching. As many as half of all women with bleeding from placenta previa are managed this way.

Typically, a woman remains in the hospital on bed rest for close observation for 48 hours. If the bleeding stops, she can be sent home with a referral for bed rest and home care. Careful assessment of fetal heart sounds is made and laboratory tests, such as hemoglobin or hematocrit, are frequently obtained. Betamethasone, a steroid that hastens fetal lung maturity, may be prescribed for the mother to encourage the maturity of fetal lungs if the fetus is less than 34 weeks' gestation (Box 21.5).

Nursing Diagnoses and Related Interventions

Because the diagnosis of placenta previa with bleeding is an emergency, all goals should reflect the short timeframe of the emergency condition.

Nursing Diagnosis: Fear related to outcome of pregnancy after episode of placenta previa bleeding

Outcome Evaluation: Client discusses concerns with nurse and other health care providers; states hearing fetal heartbeat helps to reassure her about baby's health.

Often it is difficult for a woman who has experienced bleeding late in a pregnancy to wait for the baby to come to term, wondering whether her infant will be all right. Regardless of her outward appearance, most likely she is experiencing severe emotional stress. She cannot help but wonder if the next bleeding she experiences will kill her, the infant, or both. She may become so worried about the safety of her child that she begins to think of her baby as already dead. If this happens, she might begin to neglect her diet or her supplementary vitamins because "it doesn't matter any more." Listening to fetal heart sounds and being reassured that they are in a healthy range is helpful. She also needs to be able to talk to someone about her fears so she does not feel alone with her concerns.

Birth

As soon as the fetus reaches 37 weeks of age (2500 g), an amniocentesis analysis for lung maturity shows a positive result (a favorable lecithin–sphingomyelin ratio), bleeding occurs again, labor begins, or the fetus shows symptoms of distress, the fetus needs to be born (Scearce & Uzelac, 2007).

On the day of birth, a woman needs a great deal of support. It is one thing to talk about being ready for surgery; it is another to be truly ready. She may be as frightened as she was the evening her bleeding first began. If the pregnancy is past 36 weeks at the time of the initial bleeding, a birth decision will generally be made immediately. If the placenta previa is found to be total, birth through the placenta is impossible and the baby must be born by cesarean birth. If the placenta previa is partial, the amount of the blood loss, the condition of the fetus, and a woman's parity will influence the birth decision. With a cesarean birth for placenta previa, although the skin incision is still a transverse (bikini) one, the uterine cut must be made high, possibly vertically above the low implantation site of the placenta. If an ultrasound clearly reveals the placental location, a transverse uterine incision may be possible.

After birth, most women inspect their child carefully. A woman may worry that because of the problem with placental implantation, there might be something wrong with her child. During the postpartum period, she needs adequate time with her child to be certain he or she is all right.

Any woman who has had a placenta previa is more prone than normal to postpartum hemorrhage because the placental site is in the lower uterine segment, which does not contract as efficiently as the upper segment. Also, because the uterine blood supply is less in the lower segment, the placenta tends to grow larger than it would normally, leaving a larger denuded surface area when it is removed. As a second complication, a woman is more likely to develop endometritis because the placental site is close to the cervix, the portal of entry for pathogens.

BOX 21.5 ✻ Focus on Pharmacology

Betamethasone (Celestone)

Action: Betamethasone is a corticosteroid that acts as an anti-inflammatory and immunosuppressive agent. It is given to pregnant women 12 to 24 hours before birth to hasten fetal lung maturity if a fetus is less than 34 weeks' gestation and help prevent respiratory distress syndrome in the newborn (Karch, 2009).

Pregnancy Risk Category: C

Dosage: 12–12.5 mg IM initially; may be repeated in 24 hours and again in 1 to 2 weeks

Possible Adverse Effects: Burning, itching, and irritation at the injection site; swelling, tachycardia, headache, dizziness, weight gain, sodium and fluid retention; increased risk of infection if used long term

Nursing Implications

- Explain the purpose of the drug to the client.
- Administer the initial dose IM. Anticipate the need for repeat dosing within 24 hours and again in 1 to 2 weeks.
- Assist with measures to halt preterm labor if indicated.
- Continue to monitor client's vital signs and fetal heart rate for changes.
- If client is also receiving a tocolytic agent, be alert for possible cardiac decompensation as a result of a drug–drug interaction. Observe for signs such as increased pulse, decreased blood pressure, and presence of edema.
- Assess for signs and symptoms of possible infection with long-term use.
- Instruct client about the possibility that a repeat dose may be necessary.

Premature Separation of the Placenta (Abruptio Placentae)

Unlike placenta previa, in **premature separation of the placenta** (also called *abruptio placentae;* Fig. 21.7), the placenta

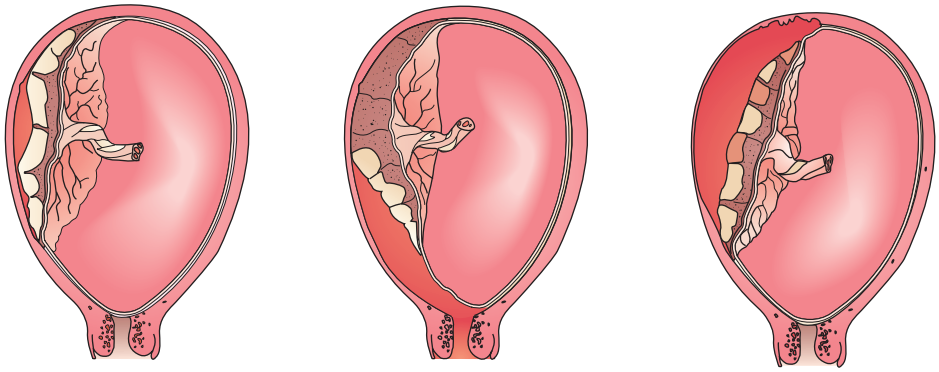

FIGURE 21.7 Premature separation of the placenta.

appears to have been implanted correctly. Suddenly, however, it begins to separate and bleeding results. Premature separation of the placenta occurs in about 10% of pregnancies and is the most frequent cause of perinatal death (Arquette & Holcroft, 2007). The separation generally occurs late in pregnancy; it may occur as late as during the first or second stage of labor. Because premature separation of the placenta may occur during an otherwise normal labor, it is important always to be alert to the amount and kind of vaginal bleeding a woman is having in labor. Listen to her description of the kind of pain she is experiencing to help detect this grave complication.

The primary cause of premature separation is unknown, but certain predisposing factors have been identified, including high parity, advanced maternal age, a short umbilical cord, chronic hypertensive disease, pregnancy-induced hypertension, direct trauma (as from an automobile accident or intimate partner abuse), vasoconstriction from cocaine or cigarette use, and thrombophilitic conditions that lead to thrombosis such as autoimmune antibodies, protein C, and factor V Leiden (a common inherited thrombophilia that occurs in 5% of whites and 1% of blacks [Szymanski & Aina-Mumuney, 2007]). It may be caused by **chorioamnionitis,** which is an infection of the fetal membranes and fluid (Nath et al., 2007).

Premature separation of the placenta may also follow a rapid decrease in uterine volume, such as occurs with sudden release of amniotic fluid. Usually the fetal head is low enough in the pelvis that it prevents loss of the total volume of the amniotic fluid at one time, so normally a rapid reduction in amniotic fluid does not occur when membranes rupture.

Assessment

A woman experiences a sharp, stabbing pain high in the uterine fundus as the initial separation occurs. If labor begins with the separation, each contraction will be accompanied by pain over and above the pain of the contraction. In some women, additional pain is not evident with contractions but tenderness can be felt on uterine palpation.

Heavy bleeding usually accompanies premature separation of the placenta, like placenta previa, although it may not be readily apparent. There will be external bleeding only if the placenta separates first at the edges and blood escapes freely from the cervix. If the center of the placenta separates first, blood can pool under the placenta, and although bleeding is intense, it is hidden from view. Whether blood is evident or not, signs of shock usually follow quickly because of the blood loss. The uterus becomes tense and feels rigid to the touch. If blood infiltrates the uterine musculature, **Couvelaire uterus** or uteroplacental apoplexy, forming a hard, boardlike uterus with no apparent, or minimally apparent, bleeding present occurs. As bleeding progresses, a woman's reserve of blood fibrinogen may be used up in her body's attempt to accomplish effective clot formation, and disseminated intravascular coagulation (DIC syndrome) can occur (see later).

If a woman is being admitted to the hospital after experiencing symptoms at home, assess the time the bleeding began, whether pain accompanied it, the amount and kind of bleeding, and her actions to detect if trauma could have led to the placental separation. Initial blood work should include hemoglobin level, typing and cross-matching, and a fibrinogen level and fibrin breakdown products to detect DIC. For a quick assessment of blood clotting ability, draw 5 mL and place it in a clean, dry test tube. Stand it aside untouched for 5 minutes. At the end of this time, if a clot has not formed, suspect an interference with blood coagulation.

Therapeutic Management

Separation of the placenta is an emergency situation (Neilson, 2009). A woman needs a large-gauge intravenous catheter inserted for fluid replacement and oxygen by mask to limit fetal anoxia. Monitor fetal heart sounds externally and record maternal vital signs every 5 to 15 minutes to establish baselines and observe progress. The baseline fibrinogen determination is followed by additional determinations up to the time of birth. Keep a woman in a lateral, not supine, position to prevent pressure on the vena cava and additional interference with fetal circulation. It is important not to disturb the injured placenta any further. Therefore, do not perform any abdominal, vaginal, or pelvic examination on a woman with a diagnosed or suspected placental separation.

For better prediction of fetal and maternal outcome, the degrees of placental separation can be graded (Table 21.5). Unless the separation is minimal (grades 0 and 1), the pregnancy must be terminated because the fetus cannot obtain

TABLE 21.5 ✻ Premature Separation of the Placenta: Degrees of Separation

Grade	Criteria
0	No symptoms of separation were apparent from maternal or fetal signs; the diagnosis that a slight separation did occur is made after birth, when the placenta is examined and a segment of the placenta shows a recent adherent clot on the maternal surface.
1	Minimal separation, but enough to cause vaginal bleeding and changes in the maternal vital signs; no fetal distress or hemorrhagic shock occurs, however.
2	Moderate separation; there is evidence of fetal distress; the uterus is tense and painful on palpation.
3	Extreme separation; without immediate interventions, maternal shock and fetal death will result.

adequate oxygen and nutrients. If vaginal birth does not seem imminent, cesarean birth is the birth method of choice.

If DIC has developed, cesarean surgery may pose a grave risk because of the possibility of hemorrhage during the surgery and later from the surgical incision. Intravenous administration of fibrinogen or cryoprecipitate (which contains fibrinogen) may be used to elevate a woman's fibrinogen level prior to and concurrently with surgery. With the worst outcome, a hysterectomy might be necessary to prevent exsanguination.

Fetal prognosis depends on the extent of the placental separation and the degree of fetal hypoxia. Maternal prognosis depends on how promptly treatment can be instituted. Death can occur from massive hemorrhage leading to shock and circulatory collapse or renal failure from the circulatory collapse. These factors cause premature separation of the placenta to be a significant cause of both maternal and fetal mortality.

Any woman who has had bleeding before birth is more prone to infection after birth than the average woman. A woman with a history of premature separation of the placenta, therefore, needs to be observed closely for the development of infection in the postpartum period.

✔ Checkpoint Question 21.3

Suppose Beverly Muzuki develops a placenta previa. What would be an important assessment to make with her after her baby's birth?

a. Whether she recognizes that this is inherited and will probably happen again.
b. Assessment of vaginal bleeding, as she is prone to have more than usual.
c. Whether she appears "jittery" or nervous from the prebirth drugs she received.
d. Whether she understands that her uterus has a scar and so will be always weakened.

Disseminated Intravascular Coagulation

DIC is an acquired disorder of blood clotting in which the fibrinogen level falls to below effective limits. Early symptoms include easy bruising or bleeding from an intravenous site. Conditions such as premature separation of the placenta, pregnancy-induced hypertension, amniotic fluid embolism, placental retention, septic abortion, and retention of a dead fetus are all associated with its development (Goldberg & Smith, 2007). Normally, platelets quickly form a seal over a point of bleeding to prevent further loss of blood. Intrinsic and extrinsic clotting pathways then activate and strengthen this plug by fibrin threads to produce a firm, fixed structure. To prevent too much clotting from occurring, at the same time the clot is being formed, thrombin activates fibrinolysin, a proteolytic enzyme, to begin to digest excess fibrin threads (anticoagulation). This lysis results in the release of fibrin degradation products.

DIC occurs when there is such extreme bleeding and so many platelets and fibrin from the general circulation rush to the site that not enough are left in the rest of the body. This results in a paradox: at one point in the circulatory system, the person has increased coagulation, but throughout the rest of the system, a bleeding defect exists. DIC is an emergency because it can result in extreme blood loss. Goals should reflect the presence of the emergency.

Testing clotting time can be done by placing a small amount of blood in a test tube. After 30 minutes, a clot should not only form but retract and the volume of serum in the tube should exceed the size of the clot. If this does not occur, a low fibrinogen level is suggested. For a definite diagnosis, blood needs to be drawn for platelets (will be decreased to $\leq$100,000/μL), prothrombin (will be low because it depends on the conversion of fibrinogen to fibrin), thrombin time (will be elevated because it measures the time necessary for conversion of fibrinogen to fibrin), fibrinogen (will be decreased to $<$150 mg/dL because fibrinogen has been used up), and fibrin split products (will be $>$40 μg/mL reflecting the destruction of fibrinogen or fibrin). A D-dimer is specific for fibrin (not fibrinogen) degradation products and will be abnormal in 90% of patients with DIC (Goldberg & Smith, 2007).

To stop the process of DIC, the underlying insult that began the phenomenon must be halted. When the insult was a complication of pregnancy such as premature separation of the placenta, ending the pregnancy by birthing the fetus and delivering the placenta is part of the solution. Next, the marked coagulation must be stopped so that coagulation factors can be freed and normal clotting function can be restored. This is accomplished by the intravenous administration of heparin to halt the clotting cascade. Heparin must be given cautiously close to birth or postpartum hemorrhage could occur from poor clotting after delivery of the placenta. If bleeding during pregnancy was the stimulus for DIC, a blood or platelet transfusion may be necessary to replace blood or platelet loss. This administration may be delayed, however, until after heparin therapy so the new blood factors are also not consumed by the coagulation process. Antithrombin III factor, fibrinogen, or cryoprecipitate (which contains fibrinogen) can all be used to restore blood clotting. If these are not available, fresh-frozen plasma or platelets can also aid in restoring clotting function.

It can be confusing for a woman with a disorder such as premature separation of the placenta to have her physician tell her one minute that bleeding is what he or she is worried about and to hear the next minute that an anticoagulant such as heparin has been ordered. If a woman understands the action of heparin—to discourage blood coagulation—it seems as if the physician has ordered exactly the wrong medication. Be certain a woman and her support person have a full explanation of what is happening (she has an increased risk of hemorrhage because part of her system has tied up coagulation factors; by releasing them, coagulation can be restored throughout the rest of her body). This helps to instill and maintain confidence in her caregivers.

Evaluation focuses on determining whether a woman's blood coagulation studies are returning to normal and if any anoxia has occurred, particularly in renal or brain cells from occluded coagulated capillaries. Fetal and newborn assessment is important to evaluate the efficiency of the placental circulation in light of increased clotting.

What if... A pregnant client is receiving subcutaneous heparin and asks why she cannot take this drug orally? How would you answer? Would you need to assess her infant after birth for blood coagulation ability?

PRETERM LABOR

Preterm labor is labor that occurs before the end of week 37 of gestation. It occurs in approximately 9% to 11% of all pregnancies. It is responsible for almost two-thirds of all infant deaths in the neonatal period (Cootauco & Althaus, 2007). Any woman having persistent uterine contractions (four every 20 minutes) should be considered to be in labor. A woman is documented as being in actual labor rather than having false labor contractions if she is having uterine contractions that cause cervical effacement over 80% or dilation over 1 cm. Preterm labor is always serious because if it results in the infant's birth, the infant will be immature.

Some women wait before they seek help for preterm labor, unwilling to face the fact that labor contractions have started. Some diagnose their contractions as nothing more than extremely hard Braxton Hicks contractions and think they are innocent. Currently, when there is treatment available to delay labor until a fetus reaches a level of maturity that will allow a newborn to survive in the outside environment, evaluation and the institution of therapy before membranes rupture are vital, as ruptured membranes make it that much more difficult to halt labor.

Why labor begins before a fetus is mature is unclear in most instances. It can happen for unknown reasons, but it is associated with dehydration, urinary tract infection, periodontal disease, and chorioamnionitis. African American women, adolescents, and those who receive inadequate prenatal care are most susceptible (Goldenberg et al., 2008). Women who continue to work at strenuous jobs during pregnancy or perform shift work that leads to extreme fatigue may have a higher incidence than others (Whelan et al., 2007). It tends to occur in pregnancies of women who were born small but the father of their child is overweight, as if the fetus growing faster than its mother can accommodate might trigger preterm birth (Klebanoff, 2008). Intimate partner abuse may be yet another cause (Rodrigues, Rocha, & Barros, 2008). Participating in mild leisure sports activities such as walking may help prevent preterm birth (Box 21.6).

BOX 21.6 * Focus on Evidence-Based Practice

Do leisure sports cause preterm birth?

Most women today participate in some form of leisure sport. To investigate if there is an association between sports participation in the first and second trimesters of pregnancy and preterm birth, researchers assessed the sports histories of 5749 healthy pregnant women seen for prenatal care. The results of the research showed that women who practiced more than one type of sport had a significantly reduced risk of preterm birth compared with women who participated in no sports activities. Women who engaged in light leisure time physical activity had a 24% reduced risk of preterm labor, and those engaged in moderate-to-heavy leisure time activity had a 66% reduced risk. Participation in leisure sports activities, therefore, does not add to the incidence of preterm birth, but may actually help to prevent it beginning.

Could you use the above study to help women judge if they should continue to participate in leisure sports activities during pregnancy?

Source: Hegaard, H. K., et al. (2008). Leisure time physical activity is associated with a reduced risk of preterm delivery. *American Journal of Obstetrics and Gynecology, 198*(2), 180–185.

Common symptoms of early preterm labor include a persistent, dull, low backache; vaginal spotting; a feeling of pelvic pressure or abdominal tightening; menstrual-like cramping; increased vaginal discharge; uterine contractions; and intestinal cramping. Listen carefully to any woman who has these symptoms or believes she is in preterm labor because beginning symptoms of labor are subtle and best recognized by a woman herself. Be certain all women receive information on the signs and symptoms of preterm labor so they do not overlook the more subtle signs.

Therapeutic Management

It is possible to predict which pregnancies will end early by analyzing changes in vaginal mucus, such as the presence of fetal fibronectin, a protein produced by trophoblast cells (Mateus et al., 2007). If this is present in vaginal mucus, it predicts that preterm contractions are ready to occur; absence of the protein predicts that labor will not occur for at least 14 days. A shortened cervix, revealed by ultrasound, may be just as predictive (Cootauco & Althaus, 2007).

Medical attempts can be made to stop labor if the fetal membranes are intact, fetal distress is absent, there is no evidence that bleeding is occurring, the cervix is not dilated more than 4 to 5 cm, and effacement is not more than 50%.

A woman who is in preterm labor is usually first admitted to the hospital and placed on bed rest to relieve the pressure

of the fetus on the cervix. Intravenous fluid therapy to keep her well hydrated is begun because hydration may help stop contractions. If a woman is dehydrated, the pituitary gland is activated to secrete antidiuretic hormone, and this may cause it to release oxytocin as well. Oxytocin strengthens uterine contractions. By keeping a woman well hydrated, therefore, the release of oxytocin may be minimized.

Vaginal and cervical cultures and a clean-catch urine sample are obtained to rule out infection. If a urinary tract infection is present the woman will be started on an antibiotic (Smaill & Vazquez, 2009). She may also receive an antibiotic for group B streptococcus prophylaxis as an infection with this could be fatal in a newborn. A **tocolytic agent,** an agent to halt labor, such as terbutaline may be prescribed. Following this initial therapy, women in preterm labor can be safely cared for at home as long as they can dependably drink enough fluid to remain well hydrated and continue to take an oral tocolytic agent (Box 21.7). Although there is little evidence to show that strict bed rest prevents preterm labor (Sosa et al., 2009), a woman should limit strenuous activities (see Chapter 4 for a discussion of home care). It is important that women also maintain adequate nutrition and do not smoke cigarettes as both poor nutrition and smoking put them at high risk for preterm birth (Dew, 2007).

BOX 21.7 * Focus on Family Teaching

Measures to Help Prevent a Recurrence of Preterm Labor for Women on Bed Rest

Q. Beverly Muzuki has started preterm labor and so is put on bed rest. She asks you, "What else can I do to help prevent having this baby early?"

A. Several actions can be helpful to prevent a recurrence of preterm labor:

- Remain on bed rest except to use the bathroom (lie in a bed or put feet up on a couch or lounge).
- Drink 8 to 10 glasses of fluids daily (keep a pitcher by your bed so you do not have to get up).
- Take your prescribed tocolytic medication on time to maintain a constant blood level. Set an alarm clock as necessary, especially at night.
- Keep mentally active by reading or working on a project to prevent boredom.
- Avoid activities that could stimulate labor, such as nipple stimulation.
- Consult your primary care provider regarding whether sexual relations should be restricted.
- Immediately report signs of ruptured membranes (sudden gush of vaginal fluid) or vaginal bleeding.
- Report signs of urinary tract or vaginal infection (burning or frequency of urination; vaginal itching or pain).
- Report symptoms of pulmonary congestion (cough and difficulty breathing unless upright), which can be effects of tocolytic drugs.
- Keep appointments for prenatal care.

If uterine contractions recur:

- Empty your bladder to relieve pressure on the uterus.
- Lie down on your left or right side to encourage blood return to the uterus.
- Drink two or three glasses of fluid to increase hydration.
- Telephone your health care provider to report the incident and ask for further care measures.

Drug Administration

For reasons not clearly understood, the administration of a corticosteroid to the fetus appears to accelerate the formation of lung surfactant. During the time labor is being chemically halted, therefore, if the pregnancy is under 34 weeks, a woman may be given a steroid (betamethasone) to attempt to hasten fetal lung maturity (two doses of 12 mg betamethasone given intramuscularly 24 hours apart, or four doses of 6 mg dexamethasone given intramuscularly 12 hours apart). Betamethasone is preferred as it leads to lower rates of respiratory distress syndrome or bronchopulmonary dysplasia in newborns (Feldman et al., 2007).

It takes about 24 hours for betamethasone to have an effect, so it is important labor be halted for at least this long. The effect lasts approximately 7 days. If the fetus is not born within that time span, the dose of betamethasone may be repeated, but this is controversial because any corticosteroid can interfere with glucose regulation.

Although calcium channel blockers such as nifedipine (Procardia) or a prostaglandin antagonist such as indomethacin (Indocin) can be used as tocolytic agents, these are not drugs of choice because of their side effects. Although not as serious a concern as once believed, decreased fetal urine output, resulting in oligohydramnios (a pregnancy with less than the average amount of amniotic fluid; refer to discussion later) and premature closure of the fetal ductus arteriosus with resultant fetal pulmonary hypertension can occur, after indomethacin administration (Karch, 2009). Magnesium sulfate, once a popular drug to halt contractions, is no longer recommended because of its many side effects (Simhan & Caritis, 2007).

Beta-sympathomimetic drugs are yet another tocolytic option. Beta-1 receptor sites are found in adipose tissue, heart, liver, pancreatic islet cells, and gastrointestinal smooth muscle. Beta-2 receptor sites are found in uterine smooth muscle, bronchial smooth muscle, and blood vessels. All of these drugs act to halt contractions by coupling with adrenergic receptors on the outer surface of the membrane of myometrial cells. This releases adenylcyclase, which triggers the conversion of adenosine triphosphate into cyclic adenosine monophosphate. This substance is responsible for reducing the intracellular concentration of calcium through protein binding. With a lowered intracellular calcium concentration, muscle contraction is ineffective and uterine contractions halt. An ideal tocolytic drug is one that acts entirely on beta-2 receptor sites and so does not cause any cardiac or gastrointestinal symptoms.

Ritodrine hydrochloride (Yutopar) and terbutaline (Brethine) are examples of drugs that act almost entirely on beta-2 receptor sites and so have only mild hypotensive and tachycardiac effects. Of these two drugs, terbutaline is more frequently used. As a beta-2 receptor, it causes blood vessels and bronchi to relax along with the uterine muscle. As a result, hypotension can occur. This causes the heart rate to increase to move blood more effectively. Hypokalemia may

also occur from a shift of potassium into cells, and blood glucose and accompanying plasma insulin levels may increase. Pulmonary edema may occur. Headache, because of the dilatation of cerebral blood vessels, is a common side effect; nausea and emesis also may occur. These are side effects to be observed for but are not reasons to discontinue therapy. Terbutaline should be used cautiously in women with diabetes mellitus and thyroid dysfunction. In a woman who is predisposed to develop gestational diabetes, terbutaline can raise her blood sugar glucose so much that she becomes overtly diabetic, which further complicates her pregnancy.

Before a tocolytic drug is administered, obtain baseline blood data (hematocrit, serum glucose, potassium, sodium chloride, and P_{CO_2}). An electrocardiogram may be scheduled. An external uterine and fetal monitor should be in place.

When administering terbutaline, mix the drug with Ringer's lactate rather than a dextrose solution to prevent any unnecessary hyperglycemia. Administer it as a piggyback connected to a main intravenous solution so that it can be stopped immediately if effects such as tachycardia or arrhythmias occur. Use microdrip tubing and an infusion pump to ensure a consistent, accurate flow rate.

After an initial flow rate is calculated and started, this rate may be increased every 10 minutes until uterine activity halts or side effects become extreme. Assess pulse and blood pressure approximately every 15 minutes while the flow rate is being increased and thereafter every 30 minutes until contractions halt. Assess for chest pain and dyspnea. Auscultate the lungs for rales to detect signs of pulmonary edema. Promptly report a pulse rate of more than 120 beats per minute, blood pressure below 90/60 mm Hg, chest pain, dyspnea, rales, or cardiac arrhythmias. Obtain hematocrit and serum electrolyte levels every 4 hours or as ordered during administration. Be certain to assess the total parenteral intake, because an excess can lead to pulmonary edema. Measure intake and output and obtain daily weights to rule out retention of fluid or edema. Observe the fetal heart rate closely for tachycardia (heart rate over 160 beats per minute), late decelerations, or variable decelerations that suggest possible uterine bleeding or the need for emergency birth of the fetus rather than continuation of the pregnancy.

After contractions halt, a tocolytic infusion usually is continued for 12 to 24 hours, and then oral administration of terbutaline is begun. The first oral dose is given 30 minutes before the intravenous infusion is discontinued to prevent any drop in the serum concentration. After this initial stabilization, a woman will continue to take an oral tocolytic until 37 weeks' gestation or until fetal lung maturity is established by amniocentesis. Before hospital discharge, teach a woman how to take her pulse before each dose of medication and to call if her pulse rate is more than 120 beats per minute or if she experiences palpitations or extreme nervousness.

Women must set their alarm clocks so they awaken at night to take the around-the-clock dose prescribed. Otherwise, their serum level of medication in the morning could be too low to be effective. Caution them that if they forget a dose, they must take a pill as soon as they remember and then space their doses accordingly from that time. They should not double the dose to make up for the missed pill because extreme tachycardia could result.

Terbutaline may also be administered subcutaneously by continuous pump. This allows for home drug administration using lower doses of medicine. Oral terbutaline therapy has the potential of prolonging labor an average of 2 weeks. With subcutaneous pump infusions, labor can be delayed an average of 8 to 9 weeks. Similar to an insulin pump, a terbutaline pump contains a syringe filled with the drug. A small polyethylene catheter leads from the pump to a subcutaneous needle. When the needle is inserted into the subcutaneous tissue of the abdomen or the thigh, the pump automatically injects a continuous low dose of medication subcutaneously. The pump can be set to "bolus" an injection of the drug at the time of day when contractions tend to occur the most. A woman could manually trigger the pump to inject extra medicine (within set limits) if she should begin to feel contractions. Like insulin pumps, the pump can be carried in a sash around the waist or kept in a pocket of clothing. Pumps should never get wet, so the syringe should be removed from the pump while a woman showers. For tub bathing, she should remove both the pump and needle and replace the needle immediately afterward.

Fetal Assessment

In addition to supervising tocolytic therapy, be certain to assess overall fetal welfare daily in a woman trying to delay preterm labor (see Focus on Nursing Care Planning Box 21.8). A woman may be instructed to use a daily fetal movement count or "count to 10" test. Teach her how to do this before hospital discharge so she can continue it when she is at home. The typical fetus moves 10 times in an hour. To evaluate fetal movement, a woman lies down on her left side and times the number of minutes it takes for her to feel 10 fetal movements (about an hour) or counts the number of fetal movements she feels in 1 hour (the average is 10 to 12). If the time it takes to feel 10 fetal movements is twice what it was the day before or if she feels fewer than 5 movements during an hour (half of what she should feel), she monitors again for a second hour. If at the end of this second hour fetal activity is still under 10 per hour, she should report it immediately. Because of the variation of movements among normal, healthy fetuses, different perinatal centers use different protocols for counting fetal movements. What standard is accepted as normal also varies.

Labor That Cannot Be Halted

In some women, preterm labor is too far advanced when they are first seen in a health care facility for it to be halted. Usually, if membranes have ruptured or the cervix is more than 50% effaced and more than 3 to 4 cm dilated, it is unlikely labor can be halted. The rupturing of membranes, especially, can be thought of as a "point of no return" in stopping or delaying labor because of the increased risk of infection that begins from that point.

If the fetus is very immature at the time labor cannot be halted, a cesarean birth may be planned to reduce pressure on the fetal head and reduce the possibility of subdural or intraventricular hemorrhage from a vaginal birth.

Most women assume that if a fetus is preterm, labor will be shorter than normal because the infant is still so small. This is not necessarily true because the first stage of labor, the longest stage, proceeds exactly as it would with a term pregnancy. The second stage of labor may be shorter because a

BOX 21.8 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Woman in Preterm Labor

Beverly Muzuki is a 20-year-old primipara, 30 weeks pregnant, whom you see in a prenatal clinic. She has had symptoms of a urinary tract infection for the past few days but did not call the clinic because she knew she had an appointment today and thought getting some help for it could wait until she came in. Yesterday she noticed some mild abdominal pain but thought it was irritation from the bladder infection. During the night, she woke twice because of a nagging backache. This morning, she has intermittent sharp uterine contractions. "Why did this happen?" she asks you. "I didn't do anything wrong."

Family Assessment ✻ Client, 20, lives in two-bedroom third-floor university housing. Undeclared major and works as a secretary in Personnel; husband (26) is a campus groundskeeper. Finances rated as, "Who couldn't use more money?"

Client Assessment ✻ Gravida 2, para 0, 30 week pregnancy. Heart rate 88 bpm; respirations 22; blood pressure 130/78. Fetal heart rate 142 bpm; reports positive fetal movements. Uterine contractions every 7 minutes lasting 40 seconds. Intravenous tocolytic therapy with terbutaline prescribed.

Nursing Diagnosis ✻ Risk for injury (maternal and fetal) related to preterm labor and tocolytic therapy

Outcome Criteria ✻ Contractions halt after treatment with tocolytic; fetal heart rate remains within acceptable parameters; fetal lung maturity improves as evidenced by rising lecithin–sphingomyelin ratio; client remains free of signs and symptoms of adverse effects of tocolytic therapy. Client verbalizes concerns and fears; participates in decision making and relaxation measures.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Physician/ nurse	Attach contraction and fetal heart rate monitors for continuous evaluation of contractions and fetal response.	Institute bed rest with client in side-lying position.	Bed rest relieves pressure of the fetus on the cervix. Side-lying position enhances uterine perfusion. Uterine and fetal monitoring provides evidence of fetal well-being.	Client will remain on bed rest until labor contractions halt or further action becomes necessary.
		Consultations		
Physician	Contact ultrasound personnel.	Obtain client consent for ultrasound. Arrange for ultrasound to establish fetal health.	An ultrasound can document fetal health and cervical dilation.	Client agrees to procedure. Completes preprocedure readiness actions.
		Procedures/Medications		
Nurse/ certified nurse's aide	Assess vital signs of client. Obtain history of events leading up to beginning of labor.	Obtain laboratory studies, including complete blood count, hemoglobin and hematocrit, serum electrolytes. Obtain clean-catch urine for culture, vaginal and cervical cultures, and fibronectin as ordered.	Assessment provides a baseline for future comparisons. Urine, vaginal, and cervical cultures help to rule out infection as a causative factor for preterm labor. Fibronectin can help predict whether labor can be halted.	Specimens are sent to lab promptly to ensure rapid assessment.

(continued)

BOX 21.8 ✻ Focus on Nursing Care Planning (continued)

		Procedures/Medications		
Physician/ nurse	Assess for contraindications to betamethasone administration. Obtain reports of urine and cervical cultures and fibronectin.	Administer betamethasone to aid fetal lung maturity and an antibiotic for urinary tract infection as prescribed.	Betamethasone, a steroid, helps to decrease the risk of respiratory distress syndrome should birth of the fetus become necessary. An antibiotic decreases urinary tract infection.	Client agrees to betamethasone and antibiotic administration.
Nurse	Establish strength, duration, and frequency of baseline uterine contractions.	Administer terbutaline as ordered, as an IV piggyback. Use microdrip tubing and an infusion pump. Continue infusion for 12–24 hours after cessation of contractions.	Terbutaline is a beta-2 selective agonist that acts as a uterine relaxant, helping to halt preterm contractions.	Uterine contractions halt within 1 hour of terbutaline therapy.
Nurse	Continue maternal and fetal vital sign assessment.	Monitor client's vital signs closely, every 15 minutes during adjustment of flow rate and then every 30 minutes until contractions cease. Auscultate lungs for changes in breath sounds. Assess for chest pain and dyspnea. Monitor fetal heart rates and patterns every 15 to 30 minutes.	Maternal pulse over 120 beats per minute or persistent tachycardia or tachypnea, chest pain, dyspnea, or adventitious breath sounds may indicate impending pulmonary edema. Fetal tachycardia or late or variable decelerations indicate possible uterine bleeding or fetal distress, which requires emergency birth.	Client's and fetal vital signs remain within normal parameters during infusion.
		Nutrition		
Nurse	Obtain hematocrit and serum electrolyte levels every 4 hours or as ordered. Monitor IV fluid total every hour during infusion, keeping intake to 100 mL/hour or less.	Assist with or insert an IV line. Begin IV fluid therapy as ordered.	Hematocrit, electrolyte levels, and IV intake measures the client's fluid volume status. If fluid intake is greater than 100 mL/hour, overload may occur, placing the client at risk for pulmonary edema.	IV fluid improves hydration, which may help to minimize contractions.
		Patient/Family Education		
Nurse	Assess client's knowledge of preterm labor.	Instruct client about preterm labor and about steps to be taken to counteract the process.	A well-informed client can participate more fully in her own care.	Client states the cause of preterm labor cannot always be identified; describes the part she can play in halting process.

		Psychosocial/Spiritual/Emotional Needs		
Nurse	Assess anxiety level of client over preterm labor. Assess for possible feelings of guilt related to cause of preterm labor.	Assist client with using relaxation techniques, such as muscle relaxation, breathing, and music. Provide frequent updates about progress. Allow client to verbalize feelings and concerns.	Relaxation techniques help to decrease anxiety and fear, enhancing feelings of control. Frequent updates about progress help to minimize fear about the unknown. Client may feel responsible for preterm labor because of UTI.	Client verbalizes her feelings about this crisis in her life. Demonstrates anxiety but at a level that allows her to cooperate with caregivers.
Nurse	Determine whether client wants a support person to be with her.	Contact support person as necessary.	The presence of a support person can offer additional comfort to a client.	Client names a support person she wants notified about hospital admission.
		Discharge Planning		
Nurse	Assess client's home surroundings to determine whether they are appropriate for bed rest and continuing monitoring at home.	Change tocolytic therapy to oral form as prescribed, administering first oral dose 30 minutes before discontinuing IV infusion. Contact home care nurse service to provide monitoring at home.	Administering oral dose prior to discontinuation of IV infusion maintains consistent serum drug concentrations for effective control. Home monitoring requires professional supervision.	Client states that she feels her home and support system will be adequate for home care with self-monitoring. Agrees on appointment for first home visit with home care nurse service.

small infant can be pushed through the dilated cervix and the birth canal more easily. Because the second stage takes at most 1 hour, however, this means the difference will not be more than 30 minutes to 1 hour. Unless a woman is given this explanation, she may worry not only that her labor is preterm but also that something is going wrong because it is lasting so long.

Because of the increased risk for prolapse of the cord around a small head, artificial rupture of the membranes is not done as a rule in preterm labor until the fetal head is firmly engaged. Delaying rupture of the membranes is another factor that may prolong the first stage of labor.

Analgesic agents are administered with caution during preterm labor because of the immaturity of the fetus. The immature infant will have enough difficulty breathing at birth without the additional burden of being sedated from a drug such as meperidine (Demerol). If a woman wants pain relief, an epidural is preferable.

Continuously monitor uterine contractions and fetal heart sounds during preterm labor. A woman can feel reassured by the evidence of the monitor screen or graph or the projected sound that although her infant is likely to be small, heart tones seem to be of good quality and the infant is reacting well to labor.

A woman may assume that because her infant's head is small, an episiotomy will not be needed for birth, and she will be able to avoid the discomfort of postpartum stitches. Although the head of a preterm infant is smaller than that of a mature infant, it is also more fragile. Excessive pressure could result in a subdural or intraventricular hemorrhage that could be fatal. That means a woman may actually need an episiotomy incision larger than usual. Forceps are another measure that may be used at birth to reduce pressure on the fetal head.

Following birth, the cord of the preterm infant is usually clamped immediately rather than waiting for pulsations to stop. This is because an immature infant has a difficult time excreting the large amount of bilirubin that will be formed if this extra blood is added to the circulation. The extra amount of blood could also overburden the circulatory system.

Nursing Diagnoses and Related Interventions

Examples of nursing diagnoses for a woman with preterm labor that cannot be halted include:

- Fear related to uncertain outcome of pregnancy
- Pain related to labor contractions
- Situational low self-esteem related to inability to carry pregnancy to term
- Risk for fetal injury related to preterm birth

Be certain that the outcomes established for care are realistic. Although many measures are available to help the preterm baby adjust to birth, a baby born preterm will be at risk for a variety of health

problems, especially difficulty with respirations (see Chapter 26).

Nursing Diagnosis: Situational low self-esteem related to feelings of responsibility for preterm labor

Outcome Evaluation: Client expresses feelings and worries to nurse; states it is unknown why labor began, but she knows she is not responsible for her labor beginning prematurely.

A woman in preterm labor is undergoing an extreme crisis situation. She cannot help asking herself, "What did I do to cause this?" Time spent taking the initial history or timing contractions presents an opportunity to bring the concern out in the open: "Did Dr. Smith explain to you labor sometimes begins early this way without any reason? Some women worry they did something to bring on preterm labor. Have you had any thoughts like that?"

A woman in preterm labor that cannot be halted needs a support person with her because she is apt to be more concerned than the average woman about labor. She needs frequent assurance during labor that she is breathing well with contractions or just that she is "doing well." She may not be mentally prepared for labor because it has come unexpectedly. During the postpartum period, she may need continued reassurance. Helping rebuild self-esteem this way can better prepare her to be a parent to her preterm infant.

✔ Checkpoint Question 21.4

Beverly Muzuki is in preterm labor. When you see her in the emergency department, what should be your first action?

a. Keep her walking so the fetal head puts harder pressure on the cervix.
b. Ask her to lie down in a side-lying position and assess her contractions.
c. Obtain blood for a human chorionic gonadotropin hormone assessment.
d. Caution her to not allow anyone to start IV fluid; dehydration halts contractions.

PRETERM RUPTURE OF MEMBRANES

Preterm rupture of membranes is rupture of fetal membranes with loss of amniotic fluid during pregnancy before 37 weeks (Mercer et al., 2007). The cause of preterm rupture is unknown, but it is associated with infection of the membranes (chorioamnionitis). It occurs in 5% to 10% of pregnancies. If rupture occurs early in pregnancy, it poses a major threat to the fetus as, after rupture, the seal to the fetus is lost and uterine and fetal infection may occur. A second complication that can result from preterm membrane rupture is increased pressure on the umbilical cord from the loss of amniotic fluid, inhibiting the fetal nutrient supply, or cord prolapse (extension of the cord out of the uterine cavity into the vagina), a condition that could also interfere with fetal circulation. Cord prolapse is most apt to occur when the fetal head is still too small to fit the cervix firmly. Yet another risk to the fetus of remaining in a non-fluid-filled environment is the development of a Potter-like syndrome or distorted facial features and pulmonary hypoplasia from pressure (Hofmeyr, 2009). Preterm labor may follow rupture of the membranes and end the pregnancy.

Assessment

Rupture of the membranes is suggested by the history. A woman usually describes a sudden gush of clear fluid from her vagina, with continued minimal leakage. Occasionally, a woman mistakes urinary incontinence caused by exertion for rupture of membranes. Amniotic fluid cannot be differentiated from urine by appearance, so a sterile vaginal speculum examination is done to observe for vaginal pooling of fluid. If the fluid is tested with Nitrazine paper, amniotic fluid causes an alkaline reaction on the paper (appears blue) and urine causes an acidic reaction (remains yellow). The fluid can also be tested for ferning, or the typical appearance of a high-estrogen fluid on microscopic examination (amniotic fluid shows this; urine does not). The presence of a high level of alpha-fetoprotein (AFP) in the vagina is also diagnostic (Shahin & Raslan, 2007). If there is still a question regarding whether the membranes have ruptured, an ultrasound may be ordered to assess the amniotic fluid index. Because preterm rupture of membranes is associated with vaginal infection, cultures for *Neisseria gonorrhoeae, Streptococcus* B, and *Chlamydia* are usually taken. Blood is drawn for white blood count and C-reactive protein, which increase with membrane rupture. Avoid doing routine vaginal examinations because the risk of infection rises significantly when digital examinations are performed after preterm rupture of membranes.

If a fetus is estimated to be mature enough to survive in an extrauterine environment at the time of rupture and labor does not begin within 24 hours, labor contractions are usually induced by intravenous administration of oxytocin so the infant is born before infection can occur.

Therapeutic Management

If labor does not begin and the fetus is not at a point of viability, a woman is placed on bed rest either in the hospital or at home and administered a corticosteroid to hasten fetal lung maturity. Prophylactic administration of broad-spectrum antibiotics during this period may both delay the onset of labor and reduce the risk of infection in the newborn sufficiently to allow the corticosteroid to have its effect. Women positive for *Streptococcus* B need intravenous administration of penicillin or ampicillin to reduce the possibility of this infection in the newborn. A woman with no signs of infection may be administered a tocolytic agent if labor contractions begin (Mercer, 2007). Although its effectiveness is not well documented, a woman might be given an amnioinfusion (see Chapter 23) to reduce pressure on the fetus or cord and allow a term birth (Hofmeyr, 2009).

Following endoscopic intrauterine procedures, membranes can be resealed by use of a fibrin-based commercial sealant so they are again intact. This is a future possibility for premature rupture of the membranes also.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for infection related to preterm rupture of membranes without accompanying labor

Outcome Evaluation: Maternal white blood cell count remains below 20,000/mm^3; maternal temperature is less than 100.4° F (38.0° C) while awaiting fetal maturity.

An infection can be dangerous for both the mother and fetus. If at home, a woman is asked to take her temperature twice a day and to report a fever (a temperature greater than 100.4° F [38.0° C]), uterine tenderness, or odorous vaginal discharge. She should refrain from tub bathing, douching, and coitus because of the danger of introducing infection. The white cell count will need to be assessed frequently, perhaps as often as daily. A count of more than 18,000 to 20,000/mm^3 suggests infection.

Before a woman is discharged to home care, be certain she knows how to read a thermometer, she has specific instructions regarding what degree of temperature she should report, and she understands what degree of bed rest is expected of her. Help her make arrangements for a daily white blood cell count through a laboratory service or home care nurse.

Many misconceptions about the difficulty of labor after preterm rupture of the membranes (dry labor) exist. Every day, a woman hopes the fetus is ready to be born, ending the long wait, yet she is also afraid to begin labor because of these stories. You can assure her that because amniotic fluid is always being formed, there is no such thing as a "dry labor."

PREGNANCY-INDUCED HYPERTENSION

Pregnancy-induced hypertension (PIH) is a condition in which vasospasm occurs during pregnancy in both small and large arteries. Signs of hypertension, proteinuria, and edema develop. It is unique to pregnancy and occurs in 5% to 7% of pregnancies (Bailis & Witter, 2007). Despite years of research, the cause of the disorder is still unknown although it is highly correlated with the antiphospholipid syndrome or the presence of antiphospholipid antibodies (Clark, Silver, & Branch, 2007). Originally it was called toxemia because researchers pictured a toxin of some kind being produced by a woman in response to the foreign protein of the growing fetus, the toxin leading to the typical symptoms.

A condition separate from chronic hypertension, PIH tends to occur most frequently in women of color or with a multiple pregnancy, primiparas younger than 20 years or older than 40 years, women from low socioeconomic backgrounds (perhaps because of poor nutrition), those who have had five or more pregnancies, those who have hydramnios (overproduction of amniotic fluid; refer to discussion later), or those who have an underlying disease such as heart disease, diabetes with vessel or renal involvement, and essential hypertension.

Pathophysiologic Events

The symptoms of PIH affect almost all organs. The vascular spasm may be caused by the increased cardiac output that occurs with pregnancy and injures the endothelial cells of the arteries or the action of prostaglandins (notably decreased prostacyclin, a vasodilator, and excessive production of thromboxane, a vasoconstrictor and stimulant of platelet aggregation). Normally, blood vessels during pregnancy are resistant to the effects of pressor substances such as angiotensin and norepinephrine, so blood pressure remains normal during pregnancy. With PIH, this reduced responsiveness to blood pressure changes appears to be lost. Vasoconstriction occurs and blood pressure increases dramatically.

With hypertension, the cardiac system can become overwhelmed because the heart is forced to pump against rising peripheral resistance. This reduces the blood supply to organs, most markedly the kidney, pancreas, liver, brain, and placenta. Poor placental perfusion may reduce the fetal nutrient and oxygen supply. Ischemia in the pancreas may result in epigastric pain and an elevated amylase–creatinine ratio. Spasm of the arteries in the retina leads to vision changes. If retinal hemorrhages occur, blindness can result.

Vasospasm in the kidney increases blood flow resistance. Degenerative changes develop in kidney glomeruli because of back-pressure. This leads to increased permeability of the glomerular membrane, allowing the serum proteins albumin and globulin to escape into the urine (proteinuria). The degenerative changes also result in decreased glomerular filtration, so there is lowered urine output and clearance of creatinine. Increased kidney tubular reabsorption of sodium occurs. Because sodium retains fluid, edema results. Edema is further increased because as more protein is lost, the osmotic pressure of the circulating blood falls and fluid diffuses from the circulatory system into the denser interstitial spaces to equalize the pressure (Fig. 21.8). Extreme edema can lead to cerebral and pulmonary edema and seizures **(eclampsia).**

Yet another effect is that arterial spasm causes the bulk of the blood volume in the maternal circulation to be pooled in the venous circulation, so a woman has a deceptively low arterial intravascular volume. In addition, thrombocytopenia or a lowered platelet count occurs as platelets cluster at the sites of endothelial damage. Measuring hematocrit levels helps to assess the extent of plasma loss to the interstitial space or the extent of the edema (the higher the hematocrit, the more is being lost). A hematocrit level above 40% suggests significant fluid loss into interstitial spaces.

Assessment

Although women may have additional symptoms such as vision changes, typically hypertension, proteinuria, and edema are considered the classic signs of PIH. Of the three, hypertension and proteinuria are the most significant as extensive edema occurs only after the other two are present. Symptoms rarely occur before 20 weeks of pregnancy (Box 21.9).

PIH is classified as gestational hypertension, mild pre-eclampsia, severe pre-eclampsia, and eclampsia, depending on how far development of the syndrome has advanced (Table 21.6). Any woman with a high risk for PIH should be observed carefully for symptoms at prenatal visits. She needs instructions about what further symptoms to watch for so she can alert her clinician if additional symptoms occur between visits.

Gestational Hypertension

A woman is said to have gestational hypertension when she develops an elevated blood pressure (140/90 mm Hg) but has no proteinuria or edema. Perinatal mortality is not increased with simple gestational hypertension, so no drug therapy is necessary.

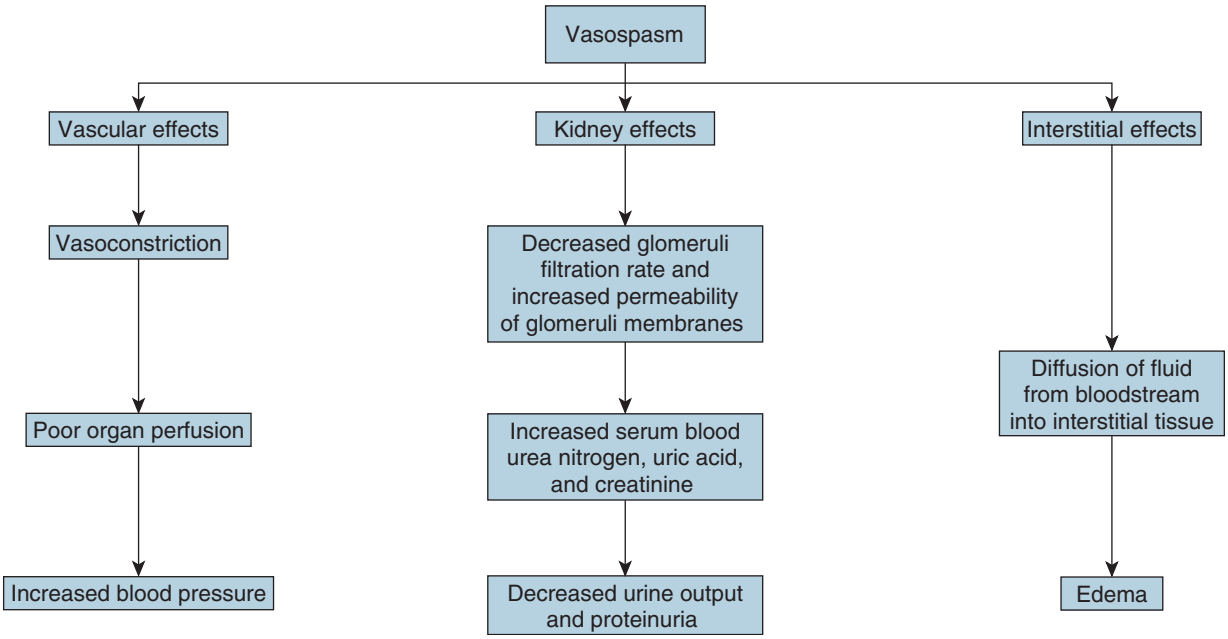

FIGURE 21.8 Physiologic changes with pregnancy-induced hypertension.

Mild Pre-eclampsia

If a seizure from PIH occurs, a woman has eclampsia, but any status above gestational hypertension and below a point of seizures is **pre-eclampsia.** A woman is said to be mildly pre-eclamptic when she has proteinuria and blood pressure rises to 140/90 mm Hg, taken on two occasions at least 6 hours apart. The diastolic value of blood pressure is extremely important to document because it is this pressure that best indicates the degree of peripheral arterial spasm present.

A second criterion for evaluating blood pressure is a systolic blood pressure greater than 30 mm Hg and a diastolic pressure greater than 15 mm Hg above prepregnancy values. This rule is helpful, but the value of 140/90 mm Hg is a more useful cutoff point when there are no baseline data available, such as when a woman seeks prenatal care late in pregnancy.

Average blood pressures in American women are shown in Appendix G. According to these averages, a woman younger than age 20 could have a blood pressure of 98/61 mm Hg and still be within normal limits. If her blood pressure were elevated 30 mm Hg systolic and 15 mm Hg diastolic, it would be only 128/76 mm Hg. This is well beneath the traditional warning point of 140/90 but would represent hypertension for her.

With mild pre-eclampsia, in addition to the hypertension a woman has proteinuria (1+ or 2+ on a reagent test strip on a random sample). Many women show a trace of protein during pregnancy. Actual proteinuria is said to exist when it registers as 1+ or more (this represents a loss of 1 g/L).

Occasionally women have orthostatic proteinuria (on long periods of standing, they excrete protein; at bed rest, they do not). If proteinuria is present without other signs of PIH (no hypertension and no edema), check to see when the specimen was obtained. Ask her to bring in a first morning urine sample. This may reveal that orthostatic proteinuria, not pre-eclampsia, may be the cause of protein in her urine.

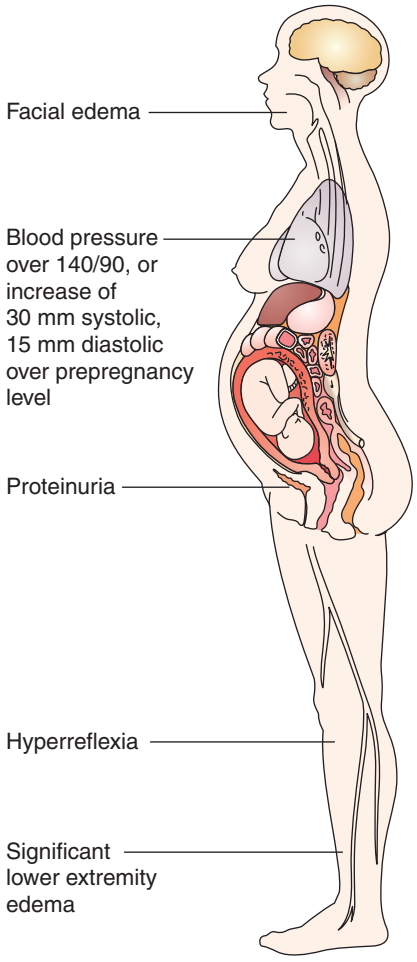
Edema develops, as mentioned, because of the protein loss, sodium retention, and lowered glomerular filtration rate. The edema is not just the typical ankle edema of pregnancy but begins to accumulate in the upper part of the body. A weight gain of more than 2 lb/wk in the second trimester or 1 lb/wk in the third trimester usually indicates abnormal tissue fluid retention. This is likely to be the first symptom a woman notices, or it may be discovered when a woman is weighed at a prenatal visit. Noticeable edema may or may not be present when this sudden increase in weight first occurs.

Severe Pre-eclampsia

A woman has passed from mild to severe pre-eclampsia when her blood pressure rises to 160 mm Hg systolic and 110 mm Hg diastolic or above on at least two occasions 6 hours apart at bed rest (the position in which blood pressure is lowest) or her diastolic pressure is 30 mm Hg above her prepregnancy level. Marked proteinuria, 3+ or 4+ on a random urine sample or more than 5 g in a 24-hour sample, and extensive edema are also present.

With severe pre-eclampsia, the extreme edema is most readily palpated over bony surfaces, such as over the tibia on the anterior leg, the ulnar surface of the forearm, and the cheekbones, where the sponginess of fluid-filled tissue can be palpated against bone. If there is swelling or puffiness at these points to a palpating finger but the swelling cannot be indented with finger pressure, the edema is nonpitting. If the tissue can be indented slightly, this is 1+ pitting edema; moderate indentation is 2+; deep indentation is 3+; and

Box 21.9 Assessment
Assessing the Woman With Pregnancy-Induced Hypertension



indentation so deep it remains after removal of the finger is 4+ pitting edema.

Further assess edema by asking a woman if she has noticed any swelling anywhere in her body. Most women at the end of pregnancy have edema of the feet at the end of the day. They report this as difficulty fitting into their bedroom slippers, or kicking off their shoes at dinnertime and then not being able to put them back on again. This is a normal discomfort of pregnancy. However, edema that has progressed to the upper extremities or the face is abnormal. Women report upper extremity edema as "my rings are so tight I can't get them off" and facial edema as "when I wake in the morning, my eyes are swollen shut" or "I can't talk until I walk around awhile." This accumulating edema will reduce their urine output to approximately 400 to 600 mL per 24 hours.

Some women have severe epigastric pain and nausea and vomiting, possibly because of abdominal edema or ischemia to the pancreas and liver. If pulmonary edema develops, a woman may report feeling short of breath. If cerebral edema occurs, reports may be voiced of visual disturbances such as blurred vision or seeing spots before the eyes. Cerebral edema also produces symptoms of severe headache and marked hyperreflexia and perhaps **ankle clonus** (a continued motion of the foot).

Eclampsia

This is the most severe classification of PIH. A woman has passed into this stage when cerebral edema is so acute that a grand-mal seizure (tonic-clonic) or coma occurs. With eclampsia, the maternal mortality rate is as high as 20% from causes such as cerebral hemorrhage, circulatory collapse, or renal failure (Bailis & Witter, 2007).

The fetal prognosis with eclampsia is also poor because of hypoxia and consequent fetal acidosis. If premature separation of the placenta from vasospasm occurs, the fetal prognosis is even graver. If a fetus must be born before term, all the risks of immaturity will be faced. In pre-eclampsia, the fetal mortality rate is approximately 10%. If eclampsia develops, the mortality rate increases to as high as 20% (Bailis & Witter, 2007).

TABLE 21.6 ✻ Symptoms of Pregnancy-Induced Hypertension

Hypertension Type	Symptoms
Gestational hypertension	Blood pressure 140/90 or systolic pressure elevated 30 mm Hg or diastolic pressure elevated 15 mm Hg above prepregnancy level; no proteinuria or edema; blood pressure returns to normal after birth
Mild pre-eclampsia	Blood pressure 140/90 or systolic pressure elevated 30 mm Hg or diastolic pressure elevated 15 mm Hg above prepregnancy level; proteinuria of 1–2+ on a random sample; weight gain over 2 lb per wk in second trimester and 1 lb per wk in third trimester; mild edema in upper extremities or face
Severe pre-eclampsia	Blood pressure of 160/110; proteinuria 3–4+ on a random sample and 5 g on a 24-hour sample; oliguria (500 mL or less in 24 hours or altered renal function tests; elevated serum creatinine more than 1.2 mg/dL); cerebral or visual disturbances (headache, blurred vision); pulmonary or cardiac involvement; extensive peripheral edema; hepatic dysfunction; thrombocytopenia; epigastric pain
Eclampsia	Seizure or coma accompanied by signs and symptoms of pre-eclampsia

Nursing Diagnoses and Related Interventions

The nursing diagnoses used with PIH are numerous because the disease has such wide-ranging effects. Some possible nursing diagnoses are:

- Ineffective tissue perfusion related to vasoconstriction of blood vessels
- Deficient fluid volume related to fluid loss to subcutaneous tissue
- Risk for fetal injury related to reduced placental perfusion secondary to vasospasm
- Social isolation related to prescribed bed rest

Nursing Interventions for a Woman With Mild PIH

Clients with mild pre-eclampsia can be managed at home with frequent follow-up care. Regardless of the setting, the care is similar.

Monitor Antiplatelet Therapy. Because of the increased tendency for platelets to cluster along arterial walls, a mild antiplatelet agent, such as low-dose aspirin, may prevent or delay development of pre-eclampsia (Duley et al., 2009). Because aspirin is such a common, over-the-counter drug, women may not appreciate that this is a serious drug prescription for them. Be certain they are taking low-dose aspirin (50–150 mg) as excessive salicylic levels can cause maternal bleeding at the time of birth.

Promote Bed Rest. When the body is in a recumbent position, sodium tends to be excreted at a faster rate than during activity. Bed rest, therefore, is the best method of aiding increased evacuation of sodium and encouraging diuresis. Rest should always be in a lateral recumbent position to avoid uterine pressure on the vena cava and prevent supine hypotension syndrome.

Promote Good Nutrition. A woman needs to continue her usual pregnancy nutrition. At one time, stringent restriction of salt was advised to reduce edema. This is no longer true because stringent sodium restriction may activate the renin-angiotensin-aldosterone system and result in increased blood pressure, compounding the problem.

Provide Emotional Support. It is difficult for a woman with pre-eclampsia to appreciate the potential seriousness of symptoms because they are so vague. Neither high blood pressure nor protein in urine is something she can see or feel. She may be aware that edema is present, but it seems unrelated to the pregnancy: it is her hands that are swollen, not a body area near her growing child.

Women are also used to having severe disorders treated with some form of medication. With mild pre-eclampsia, no medication other than low-dose aspirin is prescribed. This can make a woman underestimate the severity of her situation. She may take instructions such as getting rest lightly. In addition, it is not always easy to comply with an instruction such as to get additional rest during the day. Ninety percent of women of childbearing age work outside their home at least part time. Most women with PIH, therefore, are being asked to take a leave of absence from work. Most working women contribute financially to the running of their household, such as providing a part or all of the mortgage or rent or car payments. If a woman is unmarried, her income is probably her sole support, so it seems difficult to leave work on the basis of a few vague symptoms—a little swelling or a little headache.

Health care providers cannot solve financial problems, but be certain to ask enough questions at health care visits so that financial need, if present, can be determined. Questions such as, "What will it mean to your family if you have to be on bed rest?" and "How long a maternity leave does your work allow?" bring concerns out into the open.

A woman with small children must usually make child care arrangements so she can get sufficient rest. The woman who spends considerable time chauffeuring school-age children to activities may need to investigate car pooling as an alternative. Another may need to discontinue being a volunteer leader or ask her family for more help around the house, such as cleaning or cooking. Ask, "What will it mean to your other children or your husband if you have to rest?" to allow her to begin to face these problems. Remember that having a wife or mother on bed rest is a stress on the total family, so other family members may need support as well.

Women with beginning signs of hypertension will be seen approximately weekly or more frequently for the remainder of pregnancy. Be certain a woman understands that if symptoms worsen before her next health care visit, she should call and report them immediately. Because there is no cure for pre-eclampsia, adherence to bed rest and attempts to reduce symptoms early are crucial.

Nursing Interventions for a Woman With Severe PIH

If the pre-eclampsia is severe (systolic blood pressure of more than 160 mm Hg, diastolic blood pressure of more than 110 mm Hg after a woman has been on bed rest; extensive edema; marked proteinuria [3+ to 4+]; cerebral or visual disturbances; marked hyperreflexia; or oliguria [500 mL per 24 hours or less]), a woman may be admitted to a health care facility. If the pregnancy is 36 weeks or further along or fetal lung maturity can be confirmed by amniocentesis, labor can be induced or a cesarean birth performed to end the pregnancy at this point. If the pregnancy is less than 36 weeks or amniocentesis reveals immature lung function, interventions will be instituted to attempt to alleviate the severe symptoms and allow the fetus to come to term.

Support Bed Rest. With severe pre-eclampsia, most women are hospitalized so that bed rest can be enforced and a woman can be observed more closely than she can be on home care. Visitors are usually restricted to support people such as a husband, father of the child, mother, or older children. Because a loud noise such as a crying baby or a dropped tray of equipment can be sufficient to trigger a seizure initiating eclampsia, a woman with severe pre-eclampsia is admitted to a private room so she can rest as undisturbed as possible. Raise side rails to help prevent injury if a seizure should occur.

Darken the room if possible because a bright light can also trigger seizures. However, the room should not be so dark

that caregivers need to use a flashlight to make assessments. Shining a flashlight beam into a woman's eyes is the kind of sudden stimulation to be avoided.

Stress is another stimulus capable of increasing blood pressure and evoking seizures in a woman with severe pre-eclampsia. Be certain the woman receives clear explanations of what is happening and what is planned. Clear explanations help her accept the need for visitor restrictions and not to "cheat" on bed rest. Allow her opportunities to express her feelings about what is happening or how bewildered she is because the few simple symptoms she noticed 2 weeks ago (increase in weight or increasing edema) have now developed into a syndrome that may be lethal to her baby and possibly to herself.

Monitor Maternal Well-being. Take blood pressure frequently (at least every 4 hours) or with a continuous monitoring device to detect any increase, which is a warning that a woman's condition is worsening. Obtain blood studies such as a complete blood count, platelet count, liver function, blood urea nitrogen, and creatine and fibrin degradation products as ordered to assess renal and liver function and the development of DIC, which often accompanies severe vasospasm. Because a woman is at high risk for premature separation of the placenta and resulting hemorrhage, a blood sample for type and cross-match is usually also obtained.

Daily hematocrit levels are used to monitor blood concentration. This level will rise if increased fluid is leaving the bloodstream for interstitial tissue (edema). Also, anticipate the need for frequent plasma estriol levels (a test of placenta function) and electrolyte levels. A woman's optic fundus is assessed daily for signs of arterial spasm, edema, or hemorrhage.

Obtain daily weights at the same time each day as another evaluation of fluid retention. Ensure that a woman is wearing the same amount of clothing at each weighing so any change in weight is not influenced by a change in the weight of her clothing.

An indwelling urinary catheter may be inserted to allow accurate recording of output and comparison with intake. Urinary output should be more than 600 mL per 24 hours (more than 30 mL/hr); an output lower than this suggests oliguria. Urinary proteins and specific gravity are measured and recorded with voiding or hourly if an indwelling catheter is present. A 24-hour urine sample may be collected for protein and creatinine clearance determinations to evaluate kidney function. A woman with mild pre-eclampsia spills between 0.5 g and 1 g of protein every 24 hours (1+ on a random sample); a woman with severe pre-eclampsia spills approximately 5 g per 24 hours (3+ to 4+ on an individual specimen).

Monitor Fetal Well-being. Generally, single Doppler auscultation at approximately 4-hour intervals is sufficient at this stage of management. However, the fetal heart rate may be assessed continuously with an external fetal monitor. A woman may have a nonstress test or biophysical profile done daily to assess uteroplacental sufficiency (see Chapter 9). Oxygen administration to the mother may be necessary to maintain adequate fetal oxygenation and prevent fetal bradycardia.

Support a Nutritious Diet. A woman needs a diet moderate to high in protein and moderate in sodium to compensate for the protein she is losing in urine. An intravenous fluid line is usually initiated and maintained to serve as an emergency route for drug administration as well as to administer fluid to reduce hemoconcentration and hypovolemia.

Administer Medications to Prevent Eclampsia. A hypotensive drug such as hydralazine (Apresoline), labetalol (Normodyne), or nifedipine may be prescribed to reduce hypertension. These drugs act to lower blood pressure by peripheral dilatation and thus do not interfere with placental circulation. They can cause maternal tachycardia. Therefore, assess pulse and blood pressure before and after administration. Diastolic pressure should not be lowered below 80 to 90 mm Hg or inadequate placental perfusion could occur. Even with these new drugs, magnesium sulfate (Table 21.7), however, still remains the drug of choice to prevent eclampsia (Shilva, Kalra, & Prasad, 2007).

This drug, classified as a cathartic, reduces edema by causing a shift in fluid from the extracellular spaces into the intestine. It also has a central nervous system depressant action (it blocks peripheral neuromuscular transmissions), which lessens the possibility of seizures (Karch, 2009).

To achieve immediate reduction of the blood pressure, magnesium sulfate is first given intravenously in a loading or bolus dose. Given intravenously over 15 minutes, the drug acts almost immediately; unfortunately, the effect lasts only 30 to 60 minutes, so administration must be continuous.

For magnesium sulfate to act as an anticonvulsant, blood serum levels must be maintained at 5 to 8 mg/100 mL. If the blood serum level rises above this, respiratory depression, cardiac arrhythmias, and cardiac arrest can occur. The importance of different serum levels is shown in Box 21.10.

The most evident symptoms of overdose from magnesium sulfate administration include decreased urine output, depressed respirations, reduced consciousness, and decreased deep tendon reflexes (Subramanian, 2008). Because magnesium is excreted from the body almost entirely through the urine, urine output must be monitored closely to ensure adequate elimination. If severe oliguria should occur (less than 100 mL in 4 hours), excessively high serum levels of magnesium can result. Before you administer further magnesium sulfate, therefore, ensure that urine output is above 25 to 30 mL/hr, with a specific gravity of 1.010 or lower. Respirations should be above 12 per minute, a woman should be able to answer questions asked of her such as her name or address, ankle clonus (a continued motion of the foot) should be minimal, and deep tendon reflexes should be present. Make these assessments every hour if a continuous intravenous infusion is being used.

The easiest deep tendon reflex to assess is the patellar reflex (knee jerk). Instructions for initiating this reflex and ankle clonus are shown in Box 21.11. If an epidural block has been given for labor anesthesia, assess the biceps or triceps reflex (see Chapter 34).

In addition to making the above assessments when magnesium sulfate is being given, a solution of 10 mL of a 10% calcium gluconate solution (1 g) should be kept ready nearby for immediate intravenous administration should a woman develop signs and symptoms of magnesium toxicity, as calcium is the specific antidote for magnesium toxicity.

TABLE 21.7 ✻ Drugs Used in Pregnancy-Induced Hypertension

Drug	Indication	Dosage	Comments
Magnesium sulfate Pregnancy risk category B	Muscle relaxant; prevents seizures	Loading dose 4–6 g Maintenance dose 1–2 g/h IV	Infuse loading dose slowly over 15–30 min. Always administer as a piggyback infusion Assess respiratory rate, urine output, deep tendon reflexes, and clonus every hour. Urine output should be over 30 mL/hour and respiratory rate over 12/min. Serum magnesium level should remain below 7.5 mEq/L. Observe for CNS depression and hypotonia in infant at birth and calcium deficit in the mother.
Hydralazine (Apresoline) Pregnancy risk category C	Antihypertensive (peripheral vasodilator); used to decrease hypertension	5–10 mg/IV	Administer slowly to avoid sudden fall in blood pressure. Maintain diastolic pressure over 90 mm Hg to ensure adequate placental filling.
Diazepam (Valium) Pregnancy risk category D	Halt seizures	5–10 mg/IV	Administer slowly. Dose may be repeated q 5–10 min (up to 30 mg/hour). Observe for respiratory depression or hypotension in mother and respiratory depression and hypotonia in infant at birth.
Calcium gluconate Pregnancy risk category C	Antidote for magnesium intoxication	1 g/IV (10 mL of a 10% solution)	Have prepared at bedside when administering magnesium sulfate. Administer at 5 mL/min.

Source: Karch, A. M. (2009). *Lippincott's nursing drug guide.* Philadelphia: Lippincott Williams & Wilkins.

Severe oliguria may be treated by the intravenous infusion of salt-poor albumin. This high-colloid solution will call fluid into the bloodstream from interstitial tissue by osmotic pressure; the kidneys will then excrete the extra fluid along with magnesium sulfate levels.

On the planned day of birth, a pediatrician should be alerted that the woman has been receiving magnesium sulfate. This is because if magnesium sulfate is given intravenously within 2 hours of a baby's birth, the baby may be born with respiratory depression because the drug crosses the placenta. A fetal heart rate monitor may show loss of variability of heartbeat immediately after magnesium therapy; an ultrasound may reveal reduced fetal breathing movements. Observe carefully for other signs of fetal effects, such as late deceleration with labor contractions. Magnesium sulfate is continued for 12 to 24 hours after birth in the woman to prevent eclampsia during this period. The dose is then tapered and discontinued. Breastfeeding usually is delayed until the medication is discontinued. A long-term effect of magnesium sulfate therapy is osteoporosis. A woman may be started on a course of calcium postpartally to decrease this problem.

Nursing Interventions for a Woman With Eclampsia

Degeneration of a woman's condition from severe preeclampsia to eclampsia occurs when cerebral irritation from increasing cerebral edema becomes so acute that a seizure occurs. This usually happens late in pregnancy but can happen up to 48 hours after childbirth. Immediately before a seizure, a woman's blood pressure rises suddenly from additional vasospasm. Her temperature rises sharply to 103° to 104° F (39.4° to 40° C) from increased cerebral pressure. She notices blurring of vision or severe headache (from the increased cerebral edema) and her reflexes become hyperactive. She may experience a premonition that "something is happening." Vascular congestion of the liver or pancreas can lead to severe epigastric pain and nausea. Urinary output may decrease abruptly to less than 30 mL/hour. Eclampsia has actually occurred, however, only when a woman experiences a seizure.

Tonic-Clonic Seizures. An eclamptic seizure is a tonic-clonic type that occurs in stages. After the preliminary signal or aura that something is happening, all the muscles of the woman's body contract. Her back arches, her arms and legs stiffen, and her jaw closes abruptly. She may bite her tongue from the rapid closing of her jaw. Respirations halt because her thoracic muscles are held in contraction. This phase of the seizure, called the tonic phase, lasts approximately 20 seconds. It may seem longer because a woman may grow slightly cyanotic from the cessation of respirations.

During the second (clonic) stage, the woman's bladder and bowel muscles contract and relax; incontinence of urine and feces may occur. Although a woman begins to breathe during this stage, the breathing is not entirely effective. She

BOX 21.10 ✻ Focus on Pharmacology

Magnesium Sulfate

Action: Magnesium sulfate is a central nervous system depressant that acts to block neuromuscular transmission of acetylcholine to halt convulsions. It also halts premature labor, as it relaxes smooth muscle (Karch, 2009).

Pregnancy Risk Category: A

Dosage: Initially, 2–6 g IV administered in a 250-mL solution over a 20-minute period, followed by individually calculated IV infusion at a rate to maintain designated serum levels

- Therapeutic range: 5.0–8.0 mg/100 mL
- Patellar reflex disappears: 8–10 mg/100 mL
- Respiratory depression occurs: 15–20 mg/100 mL
- Cardiac conduction defects occur: More than 20 mg/100 mL

Possible Adverse Effects: Flushing, thirst; with toxicity, absence of deep tendon reflexes, respiratory depression, cardiac arrhythmias, cardiac arrest, and decreased urine output

Nursing Implications

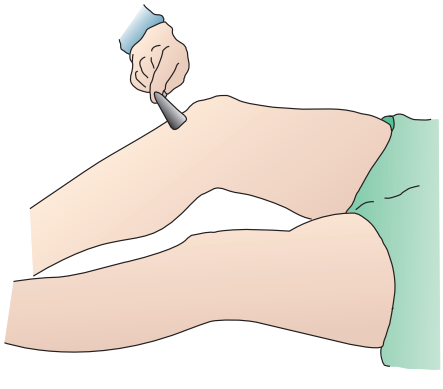
- Administer continuous infusion piggybacked into a main IV line so it can be discontinued immediately without interfering with fluid administration.
- Always use an infusion control device to maintain a regular flow rate.
- Assess maternal blood pressure and fetal heart rate continuously with bolus IV administration.
- Assess deep tendon reflexes every 1–4 hours during continuous infusion. Use patellar reflex. If patient has received epidural anesthesia, use biceps reflex.
- Monitor intake and output every hour during continuous infusion. Urine output should be 30 mL/hr or greater.
- Assess client's level of consciousness, including ability to respond to questions, every hour.
- Obtain serum magnesium levels as indicated, usually every 6 to 8 hours.
- Keep calcium gluconate, the antidote for toxicity, readily available at the bedside.
- Maintain serum blood levels (for anticonvulsant use) at 5–8 mg/100 mL. If blood serum levels rise above this, respiratory depression, cardiac arrhythmias, and cardiac arrest can occur.
- Do not administer additional doses and stop infusion if deep tendon reflexes are absent or if respiratory rate is less than 14 or urine output is less than 30 mL/hr.
- This drug may cause respiratory depression in the newborn if administered close to birth. Alert neonatal care personnel about this possibility.
- Magnesium sulfate may cause osteoporosis in the mother if given over a long time. Supplemental calcium can prevent this outcome.

BOX 21.11 ✻ Eliciting A Patellar Reflex And Ankle Clonus

Patellar Reflex

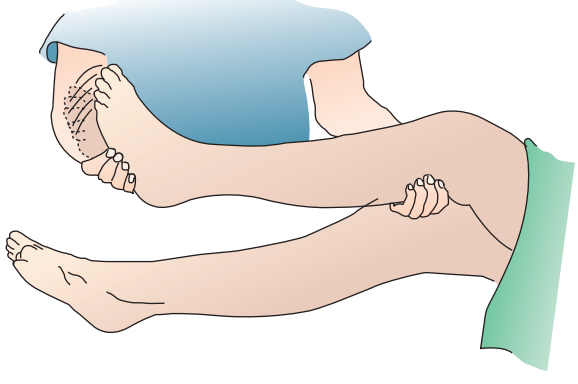
With the woman in a supine position, ask her to bend her knee slightly. Place your hand under her knee to support the leg. Locate the patellar tendon in the midline just below the kneecap. Strike it firmly and quickly with a reflex hammer or the side of your hand. If the leg and foot move, a patellar reflex is present. The reflex is scored as:

0 = No response; hypoactive; abnormal
1+ = Somewhat diminished response but not abnormal
2+ = Average response
3+ = Brisker than average but not abnormal
4+ = Hyperactive; very brisk; abnormal



Ankle Clonus

To elicit ankle clonus, dorsiflex the woman's foot three times in rapid succession. As you take your hand away, observe the foot. If no further motion is present, no ankle clonus is present. If the foot continues to move involuntarily, clonus is present. Although usually just rated as present or absent, it can be rated as:



Mild (2 movements)
Moderate (3–5 movements)
Severe (over 6 movements)

may remain cyanotic. The clonic stage of a seizure lasts up to 1 minute.

The priority care for a woman with a tonic-clonic seizure is to maintain a patent airway. Administer oxygen by face mask to protect the fetus. To prevent aspiration, turn a woman on her side to allow secretions to drain from her mouth. Magnesium sulfate or diazepam (Valium) may be administered intravenously as an emergency measure. Assess oxygen saturation via a pulse oximeter. Apply an external fetal heart monitor if one is not already in place to assess the condition of the fetus. As labor may progress despite the seizure activity, continuously assess fetal heart sounds and uterine contractions. Check for vaginal bleeding to detect placental separation. Evidence that placental separation has occurred will appear first on the fetal heart record; vaginal bleeding will strengthen the presumption.

The third stage of the seizure is the postictal state. During this stage, a woman is semicomatose and cannot be roused except by painful stimuli for 1 to 4 hours. Extremely close observation is as important during the postictal stage as it was during the first two stages, because if the seizure caused premature separation of the placenta, labor may begin during this period but a woman will be unable to report the sensation of contractions. Also, the painful stimulus of contractions may initiate another seizure. Keep a woman on her side so secretions can drain from her mouth. Give her nothing to eat or drink. Remember that with coma, hearing is the last sense lost and the first one regained, so limit conversation as she may be able to hear even though she does not respond. Continuously assess fetal heart sounds and uterine contractions. Continue to check for vaginal bleeding every 15 minutes.

Birth. If the pregnancy is more than 24 weeks along, a decision about birth will be made as soon as a woman's condition stabilizes, usually 12 to 24 hours after the seizure. There is some evidence that a fetus does not continue to grow after eclampsia occurs, so terminating the pregnancy at this point is appropriate for both mother and child. For an unexplained reason, fetal lung maturity appears to advance rapidly with PIH (possibly from the intrauterine stress), so even though the fetus is younger than 36 weeks, the lecithin–sphingomyelin ratio may indicate fetal lung maturity.

Cesarean birth is always more hazardous for the fetus because of the association of retained lung fluid (see Chapter 26). Further, a woman with eclampsia is not a good candidate for surgery. Because her vascular system is low in volume, she may become hypotensive with regional anesthesia, such as an epidural block. The preferred method for birth, therefore, is vaginal. If labor does not begin spontaneously, rupture of the membranes or induction of labor with intravenous oxytocin may be instituted. If this is ineffective and the fetus appears to be in imminent danger, cesarean birth is indicated.

Nursing Interventions During the Postpartum Period

Postpartum hypertension may occur up to 10 to 14 days after birth, although it usually occurs no more than 48 hours after birth. Monitoring blood pressure in the postpartum period and being alert that eclampsia can occur as late as 2 to 3 weeks post birth is essential to detect residual hypertensive or renal disease (Cantey, Tecklenburg, & Titus, 2007). Urge women who had an elevation of blood pressure during pregnancy to return for a postpartum checkup to have their blood pressure evaluated to be certain it has returned to normal.

✔ Checkpoint Question 21.5

If Beverly Muzuki had developed severe pre-eclampsia, what would be the drug you would expect to administer?

a. Magnesium sulfate.
b. Ranitidine (Zantac).
c. A nonsteroidal anti-inflammatory agent.
d. A loop diuretic.

HELLP SYNDROME

HELLP syndrome is a variation of PIH named for the common symptoms that occur: *h*emolysis that leads to anemia, *e*levated *l*iver enzymes that lead to epigastric pain, and *l*ow *p*latelets that lead to abnormal bleeding/clotting and petechia (Guberman, Greenspon, & Goodwin, 2007).

The syndrome occurs in 4% to 12% of patients with PIH. It is a serious syndrome because it results in a maternal mortality rate as high as 24% and an infant mortality rate as high as 35%.

Why some women with severe pre-eclampsia also develop the HELLP syndrome is unknown. It occurs in both primigravidas and multigravidas. It may be associated with antiphospholipid syndrome or the presence of antiphopholipid antibodies (Clark, Silver, & Branch, 2007). In addition to proteinuria, edema and increased blood pressure, additional symptoms of nausea, epigastric pain, general malaise, and right upper quadrant tenderness from liver inflammation occur. Laboratory studies reveal hemolysis of red blood cells (they appear fragmented on a peripheral blood smear), thrombocytopenia (a platelet count $<100{,}000/mm^3$), and elevated liver enzyme levels (alanine aminotransferase [ALT] and serum aspartate aminotransferase [AST]). The liver enzyme levels are elevated from hemorrhage and necrosis of the liver. Because of the low platelet count, women with the HELLP syndrome need close observation for bleeding, in addition to the observations necessary for pre-eclampsia. Complications associated with the syndrome are subcapsular liver hematoma, hyponatremia, renal failure, and hypoglycemia from poor liver function. Mothers are at risk for cerebral hemorrhages, aspiration pneumonia, and hypoxic encephalopathy. Fetal complications can include growth restriction and preterm birth.

Therapy for the condition is to improve the platelet count by transfusion of fresh-frozen plasma or platelets. If hypoglycemia is present, this is corrected by an intravenous glucose infusion. The infant is born as soon as feasible by either vaginal or cesarean birth. Maternal hemorrhage may occur at birth because of poor clotting ability. Epidural anesthesia may not be possible because of the low platelet count and the high possibility of bleeding at the epidural site. Laboratory results return to normal after birth, the same as pre-eclamptic symptoms generally fade, but the experience of developing a

HELLP syndrome is frightening. Women need assurance afterward that symptoms were pregnancy related so will completely fade.

MULTIPLE PREGNANCY

Multiple gestation is considered a complication of pregnancy because a woman's body must adjust to the effects of more than one fetus. The incidence of multiple births has increased dramatically because of the use of in vitro fertilization but still only occurs in 2% to 3% of all births. The rate of twinning in the United States is about 1 in 80 births; triplets, 1 in 8000 (Bush & Pernoll, 2007).

Identical (monozygotic) twins begin with a single ovum and spermatozoon. In the process of fusion, or in one of the first cell divisions, the zygote divides into two identical individuals. Single-ovum twins usually have one placenta, one chorion, two amnions, and two umbilical cords. The twins are always of the same sex. Two thirds of twins are fraternal (dizygotic, nonidentical), the result of the fertilization of two separate ova by two separate spermatozoa (possibly not from the same sexual partner). Double-ova twins have two placentas, two chorions, two amnions, and two umbilical cords. The twins may be of the same or different sex (Fig. 21.9). It is sometimes difficult to determine by ultrasound or at birth whether twins are identical or fraternal because the two fraternal placentas may fuse and appear as one large placenta.

Multiple pregnancies of two to eight children may be single-ovum conceptions, multiple-ova conceptions, or a combination of the two types. Most today occur from multiple ova being implanted as an in vitro fertility process. Naturally occurring multiple pregnancies are more frequent in nonwhites than in whites. The higher a woman's parity and age, the more likely she is to have a multiple gestation. Inheritance appears to play a role in natural dizygotic twinning; this has a familial maternal pattern of occurrence (Bush & Pernoll, 2007).

Assessment

Multiple gestation is suspected early in pregnancy, when the uterus begins to increase in size at a rate faster than usual. Alpha-fetoprotein levels are elevated. At the time of quickening, a woman may report flurries of action at different portions of her abdomen rather than at one consistent spot (where the feet are located). On auscultation of the abdomen, multiple sets of fetal heart sounds are heard, but if one or more fetus has his or her back positioned toward a woman's back, only one fetal heart sound may be heard.

An ultrasound can reveal multiple gestation sacs early in pregnancy. In some instances, early ultrasound examinations reveal multiple amniotic sacs but then later in pregnancy, in as many as 30% of women, only one fetus remains (vanishing twin syndrome) (Anand, Platt, & Pharoah, 2007). Women may grieve for a vanished twin as much as if the baby had died at birth, a feeling that could disrupt pregnancy bonding work.

Therapeutic Management

Women with a multiple gestation are more susceptible to complications of pregnancy such as PIH, hydramnios, placenta previa, preterm labor, and anemia than are women carrying one fetus. They also are more prone to postpartum bleeding because of the additional uterine stretching that must occur. Because a multiple pregnancy usually ends before the normal term, 25% of low-birth-weight babies are from multiple pregnancies. There is a higher risk of congenital anomalies in twins, such as spinal cord defect, than with single births. There is a higher incidence of velamentous cord insertion (the cord inserted into the fetal membranes) with twins than with single births, so the risk of

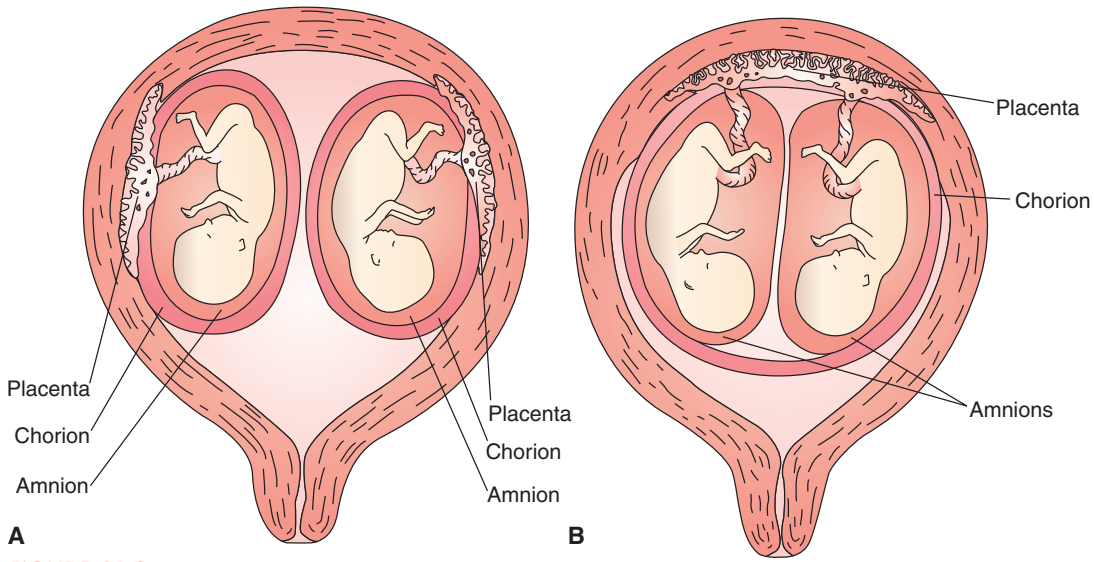


FIGURE 21.9 Multiple gestations. (**A**) Dizygotic twins showing two placentas, two chorions, and two amnions. (**B**) Monozygotic twins with one placenta, one chorion, and two amnions.

bleeding at the time of birth from a torn cord is increased. With monozygotic twins, the fetuses can share vascular communication, possibly leading to overgrowth of one fetus and undergrowth of the second (a twin-to-twin transfusion), resulting in discordant infants (Norton, 2007) (see Chapter 26). If a single amnion is present, there can be knotting and twisting of umbilical cords, causing fetal distress or difficulty with birth. Because of the possibility of these complications, a woman with a twin pregnancy needs closer prenatal supervision than a woman with a single gestation to detect these problems as early as possible. A woman carrying more than two fetuses is at greatest risk (Bush & Pernoll, 2007).

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Fatigue related to increased stress on body functioning secondary to multiple gestation

Outcome Evaluation: Client states she is tired but identifies steps she has taken to minimize fatigue.

Although there is little evidence that strict bed rest helps prolong multiple pregnancies (Crowther, 2009), spend time at health care visits reviewing with a woman with a multiple pregnancy her need for extra rest, especially in a side-lying position during the day, to increase placental perfusion.

Because a woman is carrying a double weight during pregnancy, she may notice extreme fatigue and backache late in each day. She may have more difficulty resting or sleeping than the average woman because of this greater discomfort and increased fetal activity. As the growing uterus compresses her stomach, she may find her appetite decreasing and her intake falling. To compensate and maintain nutrition, a woman may need to eat six small meals a day rather than three large ones. She must be sure to take her iron, folic acid, and vitamin supplements.

Toward the end of pregnancy, a woman may have extreme difficulty ambulating because of her excess weight. Her abdomen may become so stretched that she feels as if she is going to burst.

Beginning with week 28 of pregnancy, a woman may be asked to come to a health care facility for monthly ultrasound examinations or weekly nonstress tests to document normal fetal growth, although this may not be necessary if the pregnancy is going well and the fetuses are growing consistently. If these tests are necessary, be certain appointments are scheduled to conserve her energy as much as possible.

Nursing Diagnosis: Parental role conflict related to recent discovery of multiple (as opposed to single) pregnancy

Outcome Evaluation: Client states she is looking forward to caring for multiple infants (may express concern about her ability to manage their arrival); client identifies changes she is making in preparation now that more than one baby is expected.

A woman with a multiple pregnancy has to work through an additional role change during pregnancy. First, she completes the work to accept she is pregnant, then the work to accept she is having a baby. Then suddenly, at a routine office visit, two or more gestational sacs are seen on ultrasound or two or more sets of heart sounds are heard on auscultation. She is told she is going to have more than one child. Now she has to work through a second role change—for example, becoming a mother of two, not of one, or a mother of four or five. This role change may be difficult to complete, especially if the pregnancy ends early. Because of this, a woman may need extra help after birth to form a close mother–child relationship with her newborns.

Nursing Diagnosis: Fear concerning her own and the babies' health related to risks of multiple pregnancy

Outcome Evaluation: Client accurately states risks of multiple pregnancy; expresses confidence in health care team's ability to care for her and her babies through pregnancy and birth.

In addition to having to work through a role change, a woman with a multiple pregnancy has more reason to fear for her life and the life of her babies than does the average woman. Every woman has heard stories about twins being born so prematurely they did not survive, and about the special danger for the last infant born. If she has not already heard these stories, someone will mention them to her before her due date. Unfortunately, all these risks cannot simply be filed away under the heading of untrue stories: both prematurity and high risk to the last-born infant are real hazards in multiple gestation. Help a woman deal with her fears as positively as possible. It is helpful to tell her there is no indication so far that her babies are in any danger, so right now it is best to continue doing the things that have to be done; if any problems should arise, the health care team and a woman's family will be there to support her.

Sometimes a woman is so fearful her infants will be born too small to survive that she makes no preparations for the infants. She lacks confidence in herself or cannot imagine she will be lucky enough or "good" enough to be able to carry a multiple pregnancy to term. Give her assurance during pregnancy that she is managing well so her self-esteem is maintained at as high a level as possible. When her babies are born and all are healthy, the proof she needs that she "deserved" this or was capable of it will be present in her arms.

Nursing care at the birth of multiple infants is discussed in Chapter 23.

✔ Checkpoint Question 21.6

If a patient developed a HELLP syndrome, what symptoms would be most important to assess for?

a. Rapid, anxious breathing.
b. Ecchymosis or petechiae.
c. Blink reflex.
d. Enlarged thyroid.

HYDRAMNIOS

Usually the amniotic fluid volume during pregnancy is 500 to 1000 mL at term. Excess fluid more than 2000 mL or an amniotic fluid index above 24 cm is considered **hydramnios** (Fortner, Althaus, & Gurewitsch, 2007). Too much amniotic fluid can cause fetal malpresentation because the additional uterine space can allow the fetus to turn to a transverse lie. It also can lead to premature rupture of the membranes from the increased pressure with possible prostaglandin release. Preterm rupture of the membranes adds the additional risks of infection, prolapsed cord, and preterm birth.

Assessment

Amniotic fluid is formed by a combination of the cells of the amniotic membrane and from fetal urine. It is evacuated by being swallowed by the fetus, absorbed across the intestinal membrane into the fetal bloodstream, and transferred across the placenta. Although hydramnios can occur separate from fetal involvement, accumulation of amniotic fluid suggests difficulty with the fetus's ability to swallow or absorb or else excessive urine production. Inability to swallow occurs in infants who are anencephalic or who have tracheoesophageal fistula with stenosis or intestinal obstruction (Smith & Henderson, 2007). Excessive urine output occurs in the fetuses of diabetic women (hyperglycemia in the fetus causes increased urine production).

The first sign of hydramnios may be unusually rapid enlargement of the uterus. The small parts of the fetus are difficult to palpate because the uterus is unusually tense. Auscultating the fetal heart rate is difficult because of the increased amount of fluid surrounding the fetus.

A woman may begin to notice extreme shortness of breath as the overly distended uterus pushes up against her diaphragm. She may develop lower extremity varicosities and hemorrhoids because of poor venous return from the extensive uterine pressure. She will have increased weight gain. Generally, an ultrasound is ordered to document the presence of hydramnios and to discover a reason for the excessive amount of fluid.

Therapeutic Management

Women with severe hydramnios may be admitted to a hospital for bed rest and further evaluation or may be cared for at home. Regardless of the setting, maintaining bed rest helps to increase uteroplacental circulation and reduces pressure on the cervix, which may help prevent preterm labor. Teach a woman to report any sign of ruptured membranes or uterine contractions. Although not common, there is a possibility that straining to defecate could increase uterine pressure and cause rupture of membranes. Help her avoid constipation, therefore, by encouraging her to eat a high-fiber diet. Suggest a stool softener be prescribed if diet alone is ineffective.

Assess vital signs and lower extremity edema frequently, because the extremely tense uterus puts unusual pressure on both the diaphragm and the vessels of the pelvis.

A regimen of a nonsteroidal anti-inflammatory agent may be started to reduce inflammation (Rode et al., 2007). Amniocentesis can be performed to remove some of the extra amniotic fluid. Because amniotic fluid is replaced rapidly, however, this has to be repeated almost daily. If contractions begin, tocolysis may be begun to prevent or halt preterm labor.

Even with these precautions, in most instances of hydramnios, there will be preterm rupture of the membranes because of excessive pressure, followed by preterm birth. To prevent the sudden loss of fluid and the accompanying danger of a prolapsed cord, membranes can be "needled" (a thin needle is inserted vaginally to pierce them) to allow a slow, controlled release of fluid. After birth, the infant must be assessed carefully for factors that may have interfered with the ability to swallow in utero (Touboul et al., 2007).

OLIGOHYDRAMNIOS

Oligohydramnios refers to a pregnancy with less than the average amount of amniotic fluid (Chauhan et al., 2007). As part of the volume of amniotic fluid is formed by the addition of fetal urine, this is usually caused by a bladder or renal disorder in the fetus that interferes with voiding. It can occur from severe growth restriction. Because the fetus is so cramped for space, muscles are left weak at birth, lungs fail to develop (hypoplastic lungs), leading to severe difficulty breathing after birth, and features of the face become distorted (termed Potter's syndrome).

The condition is suspected during pregnancy when the uterus fails to meet its expected growth rate. It is confirmed by ultrasound when the pockets of amniotic fluid are less than average. Amniotransfusion or instillation of fluid into the uterus by amniocentesis procedure can help relieve this concern (Chhabra, Dargan, & Nasare, 2007). Infants need careful inspection at birth to rule out kidney disease and compromised lung development.

POST TERM PREGNANCY

A term pregnancy is 38 to 42 weeks long. A pregnancy that exceeds these limits is prolonged (**post term pregnancy,** *postmature,* or *postdate*). The infant of such a pregnancy is considered postmature, or dysmature, if there is evidence that placental insufficiency has interfered with fetal growth. Post term pregnancy occurs in 3% to 12% of all pregnancies (Fortner, Althaus, & Gurewitsch, 2007).

Included in this group are some pregnancies that appear to extend beyond the due date set for them because of a faulty due date. Women who have long menstrual cycles (40 to 45 days, for example) do not ovulate on day 14 as in a typical menstrual cycle. Because they ovulate 14 days from the end of their cycle, or on day 26 or 31, their children will be "late" by 12 to 17 days.

In other instances, the pregnancy is truly overdue. For some reason, the trigger that initiates labor did not turn on. Prolonged pregnancy can occur in a woman receiving a high dose of salicylates (for severe sinus headaches or rheumatoid arthritis) because salicylate interferes with the synthesis of prostaglandins, which may be responsible for the initiation of labor. It is also associated with myometrial quiescence, or a uterus that does not respond to normal labor stimulation.

Remaining in utero for longer than 2 weeks beyond term creates a danger to a fetus for several reasons. Meconium aspiration is more apt to occur as fetal intestinal contents are more likely to reach the rectum. If the fetus continues to grow, macrosomia could create a birth problem. However,

the usual effect of being post term is lack of growth. A placenta seems to have adequate functioning ability for only 40 to 42 weeks. After that time, it acquires calcium deposits (becomes grade 3). This exposes a fetus to decreased blood perfusion. Such a fetus may suffer from a lack of oxygen, fluid, and nutrients (Neilson, 2007). Oligohydramnios (a decreased amount of amniotic fluid from lessened urine production in the fetus) can lead to variable decelerations from cord compression.

If labor has not begun by 41 weeks, a maternal vaginal fibronectin level, a nonstress test, and/or a biophysical profile may be ordered to document the state of placental perfusion and the amount of amniotic fluid present. If these are normal, it suggests the due date was miscalculated. If the test results are abnormal or the physical examination or biparietal diameter measured on ultrasound suggests the fetus is term size, labor will be induced (Norwitz, Snegovskikh, & Caughey, 2007). Prostaglandin gel or misoprostol (Cytotec) applied to the cervix to initiate ripening, or stripping of membranes followed by an oxytocin infusion are common methods used to begin labor. If oxytocin is ineffective, cesarean birth will be necessary. Monitor the fetal heart rate closely during labor to be certain placental insufficiency is not occurring from aging of the placenta. Nursing care for the post term infant at birth is discussed in Chapter 26.

PSEUDOCYESIS

In **pseudocyesis** (false pregnancy), nausea and vomiting, amenorrhea, and enlargement of the abdomen occur in either a nonpregnant woman or a man (Ayakannu et al., 2007). There are several theories regarding why the phenomenon occurs: wish-fulfillment theory suggests a woman's desire to be pregnant actually causes physiologic changes to occur; conflict theory suggests a desire for and fear of pregnancy create an internal conflict leading to physiologic changes; and depression theory attributes the cause to major depression. In any event, a woman's body responds with physiologic symptoms such as breast tenderness and an enlarging abdomen. Her abdomen can become so enlarged that she appears to be 7 or 8 months pregnant. On physical examination, however, it is obvious only the abdomen, not the uterus, is enlarged. Ultrasound imaging will rule out pregnancy. Both men and women with the disorder need psychological counseling to help them better handle their needs.

ISOIMMUNIZATION (RH INCOMPATIBILITY)

Approximately 15% of white and 10% of African Americans in the United States are missing the Rh (D) factor in their blood or have an Rh-negative blood type. **Rh incompatibility** occurs when an Rh-negative mother (one negative for a *D* antigen or one with a *dd* genotype) carries a fetus with an Rh-positive blood type (*DD* or *Dd* genotype). For such a situation to occur, the father of the child must either be homozygous (*DD*) or heterozygous (*Dd*) Rh-positive. If the father of the child is homozygous (*DD*) for the factor, 100% of the couple's children will be Rh-positive (*Dd*). If the father is heterozygous for the trait, 50% of their children can be expected to be Rh-positive (*Dd*). Although this is basically a problem that affects the fetus, it causes such concern and apprehension in a woman during pregnancy that it becomes a maternal problem as well.

Because people who have Rh-positive blood have a protein factor (the *D* antigen) that Rh-negative people do not, when an Rh-positive fetus begins to grow inside an Rh-negative mother who is sensitized, it is as though her body is being invaded by a foreign agent. Her body reacts in the same manner it would if the invading factor were a substance such as a virus: she forms antibodies against the invading substance. The Rh factor exists as a portion of the red blood cell, so these maternal antibodies cross the placenta and cause red blood cell destruction (hemolysis) of fetal red blood cells (Fig. 21.10). A fetus can become so deficient in red blood cells that sufficient oxygen transport to body cells cannot be maintained. This condition is termed **hemolytic disease of the newborn** or **erythroblastosis fetalis.** Management of the infant born with this condition is discussed in Chapter 26.

Theoretically, there is no connection between fetal blood and maternal blood during pregnancy, so the mother should

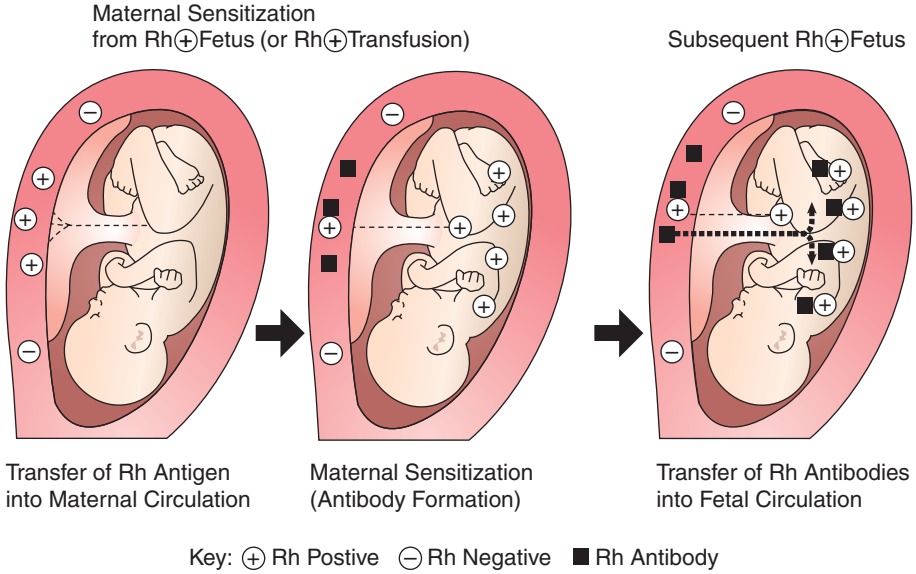

FIGURE 21.10 Maternal antibody formation against the Rh antigen.

not be exposed to fetal blood. It is well documented, however, that an occasional villus ruptures, allowing a drop or two of fetal blood to enter the maternal circulation. Procedures such as amniocentesis or percutaneous umbilical blood sampling can also cause this. During a first pregnancy this effect is small. As the placenta separates after birth of the first child, there is an active exchange of fetal and maternal blood from damaged villi. Therefore, most of the maternal antibodies formed against the Rh-positive blood are not formed during pregnancy but in the first 72 hours after birth, making them a threat to a second pregnancy.

Assessment

All women with Rh-negative blood should have an anti-D antibody titer done at a first pregnancy visit. If the results are normal or the titer is minimal (normal is 0; a ratio below 1:8 is minimal), the test will be repeated at week 28 of pregnancy. If this is also normal, no therapy is needed.

If a woman's anti-D antibody titer is elevated at a first assessment (1:16 or greater), showing Rh sensitization, the well-being of the fetus in this potentially toxic environment will be monitored every 2 weeks (or more often) by Doppler velocity of the fetal middle cerebral artery, a technique that can predict when anemia is present or fetal red cells are being destroyed (Valcamonico et al., 2007).

If the artery velocity remains high, a fetus is not developing anemia and most likely is an Rh-negative fetus. If the reading is low, it means a fetus is in danger, and immediate birth will be carried out providing the fetus is near term. If not near term, efforts to reduce the number of antibodies in the woman or replace damaged red cells in the fetus are begun.

Therapeutic Management

To reduce the number of maternal Rh (D) antibodies being formed, Rh (D) immune globulin (RhIG), a commercial preparation of passive Rh (D) antibodies against the Rh factor, is administered to women who are Rh-negative at 28 weeks of pregnancy. These cannot cross the placenta and destroy fetal red blood cells because the antibodies are not the IgG class, the only type that crosses the placenta. RhIG is given again by injection to the mother in the first 72 hours after birth of an Rh-positive child to further prevent the woman from forming natural antibodies. Because RhIG is passive antibody protection, it is transient, and in 2 weeks to 2 months, the passive antibodies are destroyed. Only those few antibodies that were formed during pregnancy are left. For this reason, every pregnancy is like a first pregnancy in terms of the number of antibodies present, ensuring a safe intrauterine environment for any future pregnancies.

After birth, the infant's blood type will be determined from a sample of the cord blood. If it is Rh-positive—Coombs' negative, indicating that a large number of antibodies are not present in the mother—the mother will receive the RhIG injection. If the newborn's blood type is Rh-negative, no antibodies have been formed in the mother's circulation during pregnancy and none will form, so passive antibody injection is unnecessary.

Although in future years the problem of Rh sensitization will be greatly reduced, it currently remains a complication of pregnancy, particularly in women who gave birth to a first child in an undeveloped nation where they did not receive passive anti-D antibodies. Any woman who does not receive a RhIG injection after an induced abortion, miscarriage, ectopic pregnancy, or amniocentesis can also have antibody formation begin.

Intrauterine Transfusion

To restore fetal red blood cells, blood transfusion can be performed on the fetus in utero. This is done by injecting red blood cells, by amniocentesis technique, directly into a vessel in the fetal cord or depositing them in the fetal abdomen where they migrate into the fetal circulation.

Blood used for transfusion in utero is either the fetus's own type (determined by percutaneous blood sampling) or group O negative if the fetal blood type is unknown. From 75 to 150 mL of washed red cells are used, depending on the age of the fetus. After deposition of the blood in the cord or abdomen, the cannula is withdrawn and a woman is urged to rest for approximately 30 minutes while fetal heart sounds and uterine activity are monitored.

Obviously, intrauterine transfusion is not without risk. A cord blood vessel could be lacerated by the needle, or the uterus may be so irritated by the invasive procedure that labor contractions begin. For the fetus who is severely affected by isoimmunization, however, such a risk is no greater than that of leaving the fetus untreated in a destructive intrauterine environment. The mother receives an RhIG injection after the transfusion to help reduce increased sensitization from any blood that might have been exchanged. Transfusion is sometimes done only once during pregnancy, or it may be repeated as often as every 2 weeks. As soon as fetal maturity is reached, as shown by a mature lecithin–sphingomyelin ratio, birth will be induced.

After birth, the infant may require an exchange transfusion to remove hemolyzed red blood cells and replace them with healthy blood cells (see Chapter 26). A woman needs to discuss her plans for further childbearing and should be provided with contraceptive information if she believes the strain of this pregnancy, the constant feeling of wishing that everything was all right but never being certain that it was, is more than she wants to endure again.

FETAL DEATH

Obviously, one of the most severe complications of pregnancy is fetal death. The most likely causes include chromosomal abnormalities, congenital malformations, infections such as hepatitis B, immunologic causes, and complications of maternal disease. If fetal death occurs before the time of quickening, a woman will not be aware the fetus has died because she is not able to feel fetal movements. This type of fetal death may be discovered at a routine prenatal visit when no fetal heartbeat can be heard. A real-time ultrasound will reveal no fetal heartbeat is present.

That a fetus has died early in intrauterine life may first be revealed by the natural miscarriage that occurs. A woman begins painless spotting, gradually accompanied by uterine contractions with cervical effacement and dilatation. The fetus is born lifeless and emaciated. Carefully observe all women who give birth to a dead fetus for excess bleeding because if the fetus has been dead in utero for any length of time, the risk for the development of DIC increases.

If a fetus dies in utero past the point of quickening, a woman becomes aware that fetal movements are suddenly absent. She may lie down or sit in a position that she knows usually causes fetal movement. Unable to believe that something could have happened, she may attribute the lack of movement to "sleeping" or "saving enough strength to be born." Because she is denying what is happening, it may be a full 24 hours before she calls the health care facility to report the apparent lack of fetal movement. On assessment, no fetal heartbeat can be heard. An ultrasound will confirm the absence of a fetal heartbeat.

If labor does not begin spontaneously, it will be induced through a combination of prostaglandin gel such as misoprostol (Cytotec) applied to the cervix to effect cervical ripening and oxytocin administration to begin uterine contractions (Neilson, Hickey, & Vazquez, 2009). Blood for coagulation studies to detect DIC should be obtained.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Powerlessness related to fetal death

Outcome Evaluation: Client and support person express meaning of pregnancy loss; identify support people/family with whom they can share grief.

Going through labor knowing a fetus is dead is difficult. A woman grieves for both her dead child and her inability to carry a pregnancy to term. She may wonder what she could have done to cause this such as forget to take an iron supplement or paint a crib or may worry she is not as good a woman as others. Give her opportunities to express how she feels about this loss. "This must be a very difficult day for you" is the kind of statement that opens up the topic for discussion. If there are older children, it might be a help to explore how a woman plans to explain the fetal death to them.

Ask a couple about their desire for clergy or religious rites, such as baptism. Encourage a support person to remain with a woman during labor, but remember the support person is grieving, too. Although this is a difficult time, expressing grief makes the birth real, ends the pregnancy, and allows the couple to begin rebuilding their life.

Labor involving a dead fetus is the same as for a live fetus because every fetus is basically a passive participant during labor. It may be difficult for a woman to use controlled breathing exercises, although encouraging her to use them is helpful in making the experience one of controllable pain. If a woman wishes a high level of analgesia or an epidural, she may have it because there is no fetus to protect from narcotic effects, although too much may lead to poor uterine involution in the postpartum period.

Ask if the parents wish to see the child. If they do, wash away obvious blood, swaddle the baby as if he or she were a well newborn, and bring the baby to them. Point out particularly endearing features of the child that may provide a focus for memories. Some parents want to keep a lock of the child's hair. Others want to keep the hospital identification bracelet or to take a photograph. Parents may want to name the child. All of these measures help to make the death real to parents and let them begin the healthy process of grieving (Chambers & Chan, 2009).

If the child has a congenital anomaly that led to the death, prepare them for this before bringing the child to them, and explain how the anomaly affected the child. Explain hospital procedures such as when the body will be released or what additional permission for autopsy is needed. Different communities have different laws concerning whether burial for an immature fetus is necessary. Consult local health department regulations so you can serve as a resource person for parents concerning this.

A woman needs to remain for only a short stay in the hospital, assuming no complications with labor developed. Many couples ask how soon it will be safe for them to have another child. For the answer to this, they need to consult with their obstetrician or nurse-midwife about why this fetal death occurred. For some couples, beginning a second pregnancy immediately is a good recommendation. For others, waiting for an interval of time (perhaps 6 months) is better as this gives them more time to work through their grief before starting a new pregnancy. This helps prevent the new baby from becoming a "replacement baby" or someone to take the place of the dead infant rather than a unique individual in his or her own right. This is important in years to come because replacement children are rarely able to live up to the image of what the dead baby would have been if only that baby had lived.

Prepare the couple for the possibility that they may feel sad on the day the infant would have been born if the pregnancy had been carried to term, or if they visit a friend's child of the age their child would have been. Be certain before a woman is discharged from the hospital that she has a support person she can rely on during the following week or month, when the full impact of the fetal loss registers. Be certain she has a return appointment for a gynecologic checkup so her physiologic and psychological health can be evaluated at that time.

✔ Checkpoint Question 21.7

Suppose Beverly Muzuki is Rh negative. Under what circumstance would she be eligible for Rh (D) immune globulin (RhIG) following her child's birth?

a. If she had a multiple pregnancy.
b. If her fetus was found to be Rh negative.
c. If her fetus's heartbeat was tachycardic.
d. If her fetus's blood type was Rh positive.

Key Points for Review

- Vaginal bleeding during pregnancy is always serious until ruled otherwise because it has the potential to diminish the blood supply of both the mother and fetus.

- The amount of bleeding which is evident may not be truly indicative of the amount of bleeding occurring as hidden, internal bleeding may also be happening. As a rule, women with bleeding during pregnancy should be positioned on their side to improve placental circulation.
- Spontaneous miscarriage is the loss of a pregnancy before viability of the fetus (20 to 24 weeks). The majority of these early pregnancy losses are attributed to chromosomal abnormalities. Miscarriages are classified as threatened, imminent, complete, incomplete, missed, or recurrent pregnancy loss. Women who have a spontaneous miscarriage at home should bring any tissue passed to the hospital for an analysis for gestational trophoblastic disease.
- Ectopic pregnancy is pregnancy implantation outside the uterus, usually in a fallopian tube. If discovered before the tube ruptures, methotrexate or mifepristone can be administered to cause the conceptus to be reabsorbed. If not discovered early, sharp lower quadrant pain occurs at about 6 to 12 weeks as the tube ruptures. Surgery is done to remove the conceptus and repair the tube to halt bleeding.
- Gestational trophoblastic disease is abnormal overgrowth of trophoblast cells. If not discovered by an ultrasound early in pregnancy, bleeding and expulsion of the abnormal growth occur at about the 16th week of pregnancy. Women need close follow-up after this because it can lead to choriocarcinoma, a malignancy.
- Premature cervical dilatation occurs when the cervix dilates early in pregnancy, before viability of the fetus. Sutures (cervical cerclage) can be placed to prevent the cervix from dilating prematurely this way again in a second pregnancy.
- Placenta previa is low implantation of the placenta so that it crosses the cervical os. If this is not discovered before labor, cervical dilatation may cause the placenta to tear, causing severe blood loss. Women who have symptoms of placenta previa (painless vaginal bleeding in the third trimester) should not have vaginal examinations done to prevent disruption of the low-implanted placenta.
- Premature separation of the placenta (abruptio placentae), placental separation from the uterus before the fetus is born, usually occurs late in pregnancy. This separation immediately cuts off blood supply to the fetus. Women with increased parity, those with previous uterine surgery, and those who use cocaine are at highest risk for this. Often it is manifested by sudden, sharp fundal pain, then a continuing dull pain and vaginal bleeding.
- Disseminated intravascular coagulation is a blood disorder that may occur with any trauma, so it can accompany such conditions as premature separation of the placenta and pregnancy-induced hypertension. Blood coagulation is so extreme at one point in the circulatory system that clotting factors are used up, resulting in their absence in the remainder of the system. Beginning symptoms of this include easy bruising, petechiae, and oozing from intravenous sites. Heparin is used to stop the local coagulation and free up clotting factors for systemic use.
- Preterm labor is labor that occurs after 20 weeks and before the end of the 37th week of pregnancy. A woman is said to be in preterm labor when she has had uterine contractions every 10 minutes for 1 hour and cervical dilatation begins. Common tocolytics, drugs that can halt labor, are beta-sympathomimetic agents such as terbutaline (Brethine).
- Preterm rupture of the membranes is tearing of the fetal membranes with loss of amniotic fluid before the pregnancy is at term. After rupture, there is a high risk of fetal and uterine infection (chorioamnionitis) and preterm birth.
- Pregnancy-induced hypertension is a unique disorder that occurs with pregnancy with three classic symptoms: hypertension, edema, and proteinuria. It is categorized as pre-eclampsia or eclampsia. If mild (blood pressure not over 140/90), treatment is bed rest and perhaps low-dose aspirin. If severe (blood pressure over 160/110), bed rest plus administration of magnesium sulfate is necessary. If a seizure occurs, the condition becomes eclampsia. Helping prevent the disease from progressing to this stage is an important nursing responsibility.
- The HELLP syndrome is a unique form of pregnancy-induced hypertension marked by hemolysis of red blood cells, elevated liver enzymes, and a low platelet count.
- Multiple gestation puts an additional strain on a woman's physical resources and may lead to preterm birth with immaturity of her infants. Helping a woman plan adequate nutrition and rest during pregnancy are nursing responsibilities.
- Post term pregnancy is pregnancy that extends beyond 42 weeks. As the placenta deteriorates at this time, it can cause a fetus to receive decreased nutrients.
- Hydramnios is overproduction of amniotic fluid (above 2000 mL), a condition that can lead to ruptured membranes and premature birth because of increased intrauterine pressure. Oligohydramnios is the lessened amount of fluid and suggests a renal disorder exists in the fetus.
- Isoimmunization (Rh incompatibility) is a possibility when a woman who is Rh negative is sensitized and carries a fetus who is Rh positive. Maternal antibodies form and destroy fetal red blood cells, leading to anemia, edema, and jaundice in the newborn. Being certain women are screened for blood type and antibody titer early in pregnancy is a nursing responsibility.

CRITICAL THINKING EXERCISES

1. Beverly Muzuki is the woman you met at the beginning of the chapter who was in preterm labor at 30 weeks of pregnancy. Beverly discounted the symptoms she was having because she did not think they could be early labor. What are the signs of early labor that you would have liked her to have been more aware of?
2. Suppose Beverly is bleeding because of placenta previa; everyone else on the unit is at lunch, and you are alone.

You know you should not do a pelvic examination with a placenta previa. How would you estimate the amount of blood she has lost? How would you determine that blood loss was not affecting the fetus?

3. Suppose Beverly is placed on home care after preterm rupture of membranes at 30 weeks of pregnancy. What assessments would you want to do to ensure she is not developing chorioamnionitis? Suppose she tells you she is too busy to stay on bed rest at home? What suggestions would you give her so she could best achieve bed rest? Does she have an ethical obligation to her fetus to rest? What about a legal obligation?
4. Examine the National Health Goals related to complications of pregnancy. Most government-sponsored money for nursing research is allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to the Muzuki family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to sudden pregnancy complications. Confirm your answers are correct by reading the rationales.

Chapter 22

Nursing Care of a Pregnant Family With Special Needs

KEY TERMS

- autonomic dysreflexia
- emancipated minor
- substance dependent

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Identify the characteristics and the risks of pregnancy of a pregnant woman who has special needs such as one who has been injured, an adolescent, a woman over age 40, one who is physically or cognitively challenged, or a woman who is drug dependent.
2. Identify National Health Goals related to women with special needs that nurses can be instrumental in helping the nation achieve.
3. Use critical thinking to analyze ways that nursing care of a pregnant woman with a special need can be optimally family centered.
4. Assess a woman with special needs during pregnancy.
5. Formulate nursing diagnoses related to pregnancy for a woman with special needs.
6. Identify expected outcomes for a pregnant woman with special needs.
7. Plan nursing care to address the special needs of women at the extremes of the childbearing spectrum, have a physical or cognitive challenge, have been injured, or are substance dependent.
8. Implement nursing care for a woman with special needs such as encouraging her to remain ambulatory during pregnancy.
9. Evaluate outcomes for effectiveness and achievement of care.
10. Identify areas related to care of a pregnant woman with special needs that would benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of the risks of pregnancy for women with special needs with nursing process to achieve quality maternal and child health nursing care.

Mindy Carson,16 years old and 15 weeks pregnant, was in an automobile accident on her way into prenatal clinic this morning. She received a 4-inch laceration on one leg. The father of Mindy's baby is a college student. He does not want Mindy to keep her baby after the birth because he does not want to get married until he finishes graduate school. Mindy insists she is old enough to be a parent and wants to keep her baby. Mindy's mother accuses the father of sharing methamphetamines with Mindy. She is worried Mindy has been working as a prostitute to support her drug habit. Mindy turns to you and asks you what you would recommend she do.

Previous chapters discussed high-risk pregnancies for women who are ill when they become pregnant and for those who develop an illness while pregnant. This chapter presents information about women who do not fit the description of the average pregnant woman—a well young adult who maintains a healthy lifestyle. Representative of such women are very young adolescents, women who have waited until midlife to have their first child, those who are physically or cognitively challenged, those who are accidentally injured, and those who are drug dependent.

What type of immediate assessment does Mindy need? Is she old enough to be a parent? What qualities would you look for in her to decide if she is ready to parent?

The United States has a high teenage birth rate, although this has decreased in recent years from a high of 71 per 1000 to about 41 per 1000 teenagers (National Center for Health Statistics [NCHS], 2009). In contrast, as more and more women delay beginning a family until their 30s, the birth rate for women over age 40 is steadily increasing. It is currently as high as 17 per 1000 (NCHS, 2009). Adolescents require special consideration during pregnancy because they are physically and psychosocially immature. Women over age 40 may need special consideration also because they can have difficulty adjusting psychosocially to a first pregnancy and the physical changes that are required.

The pregnancy rate also is increasing among women who are physically or cognitively challenged, including those with conditions such as cerebral palsy that might have precluded pregnancy a few years ago. Physical and cognitive conditions present a challenge to childbearing and childrearing but do not necessarily prevent women from establishing their own families. Supportive nursing care that considers the limitations imposed by a particular disability, while focusing on the normal aspects of childbearing and childrearing and a woman's strengths, helps to make these pregnancies successful.

Women who are drug dependent or who are injured are other categories of high-risk women who require a great deal of nursing support and care. Ideally, a woman would give up substance abuse for the health of a fetus, but that may not be possible. When this does not happen, every effort must be made to provide enough prenatal care and attention to protect the fetus in other ways. Women who are injured in automobile accidents or from intimate partner abuse can have substantial blood loss that threatens the health of the fetus. They need rapid emergency department assessment and care to be certain that fetal health is protected.

Women with special needs have become such a large number of pregnant women that National Health Goals related to them have been established (Box 22.1).

BOX 22.1 ✻ Focus on National Health Goals

Several National Health Goals have been formulated to improve the health of women with special needs during pregnancy. These are:

- Reduce the pregnancy rate among adolescent females to no more than 43 per 1000 adolescents from a baseline of 68 per 1000.
- Increase abstinence from alcohol, cigarettes, and illicit drugs among pregnant women to 100% from baselines of 90% (alcohol), 87% (cigarette smoking), 96% (binge drinking), and 96% (illicit drugs) (http://www.nih.gov).

Nurses can help the nation achieve these goals by teaching accident prevention and the dangers of substance abuse and the complications, both psychological and physical, of teenage pregnancy.

Topics for possible research investigation might include the most effective way to impress adolescents about the dangers of substance abuse, and the ideal birth control measure for adolescents (i.e., one that would actually be used). As more and more women over age 40 are becoming pregnant, the effects of pregnancy on this age group and their adjustment to it also need to be investigated.

Nursing Process Overview

For Care of a Pregnant Woman With Special Needs

Assessment

Assessing the strengths and weaknesses of individual women is always crucial to establish an accurate nursing diagnosis and realistic outcomes as well as planning effective nursing care. When a woman has a special need, assessment becomes even more important. Establishing as thorough a database as possible early in pregnancy helps to predict the risks a woman may be exposed to when pregnancy is affected by age extremes, physical or cognitive challenges, an accidental injury, or an unhealthy lifestyle.

When caring for a woman who is physically challenged, keep in mind that physical disabilities occur in degrees; therefore, first establish the impact of the disability on a woman's lifestyle before offering any guidance for care measures during pregnancy. The capacity of a woman with special needs to adapt to pregnancy depends both on her physical capabilities and on her ability to persevere against odds to overcome obstacles. Be certain to assess physical strengths as well as limitations and psychosocial strengths as well as challenges. A woman with a spinal cord injury, for example, is likely to have developed ways of coping in daily life that may never occur to someone who has not experienced that disability.

For some drug-dependent women, pregnancy may be the impetus they need to break a drug habit. All that other women can accomplish is to reduce their drug use. In both instances, encourage a woman to keep coming for prenatal care. As long as a woman feels comfortable with you during regular visits, you may be able to establish a trusting relationship that will eventually provide her with the confidence to try a more healthful pattern of living.

Nursing Diagnosis

Nursing diagnoses established for pregnant women with special needs differ in degree, but not in substance, from the nursing diagnoses established for all pregnant women. For example, if a pregnant adolescent is still growing, nutrition is an important issue for both her and her fetus. Examples of nursing diagnoses for women with special needs are:

- Risk for imbalanced nutrition related to combined needs of adolescence and pregnancy
- Risk for fetal injury related to drug and alcohol use
- Impaired physical mobility related to physical disability
- Risk for injury related to unstable balance
- Impaired verbal communication related to spastic muscle functioning
- Impaired home maintenance related to a sensory challenge
- Readiness for enhanced family coping, related to commitment to have a child in the face of a disabling condition

Outcome Identification and Planning

Be especially careful to establish realistic outcomes given a woman's particular condition or situation. An adolescent, for instance, cannot achieve independent decision making if she is not mature enough to do this. A woman who is visually challenged may not be able to read a digital display on a glucometer or use a wall clock to time contractions no matter how much she would like to.

Often, a pregnant woman with a special need already has significant stressors to deal with in her life. Adolescence, for example, is a period of growth and change that can be stressful for both the teenager and her family. The physically challenged woman constantly copes with a condition that must be considered in all activities, even if she has adjusted completely to the limitations the disability imposes. The drug-dependent woman is confined by a life-threatening habit. A woman who has been injured in an accident may have to temporarily restructure her life to accommodate a hospital admission.

Pregnancy brings with it a whole new set of stressors that can be overwhelming if a woman has no outside support. Planning for a pregnant woman with a special need, therefore, often involves identifying support people to help with this added stress. This support can come from family, friends, a professional organization, or health care providers. If a woman is not totally independent in her care, some planning may be required with her support person, who may be the person who actually carries out the proposed action. At the same time, be sure not to ignore a woman and plan around her. Only if she approves of the plan can pregnancy be the enjoyable experience she had planned it would be. This principle applies to any woman, but especially one with special needs.

A major problem encountered when planning with a pregnant adolescent is that she may have difficulty accepting the reality of her pregnancy, and so she may not be interested in attending prenatal care. Some primiparas older than 40 years may have delayed pregnancy to pursue further education or a career. Remember that a woman who has been submerged in a career instead of the world of babies and homemaking may, like the adolescent, be less informed about normal pregnancy findings or healthful pregnancy practices than a younger woman. Be certain you do not equate a woman's knowledge in one field, such as chemistry or law, with her knowledge of good prenatal care.

Plans should include ways to strengthen confidence and self-esteem, crucial attributes for a new mother. These also are areas in which a woman with a special need, especially one who perceives herself as too young or too old or who has experienced physical dysfunction, may not have developed fully. Drug dependence may also be related to feelings of lowered self-worth, which may have been intensified if the drug-dependent woman has tried unsuccessfully to limit her drug intake in the past.

Being certain that plans are established in a wide range of areas helps to ensure that planning is comprehensive. Remember to include safe care of the newborn in plans as well, as once an infant is born, it may be too late to make these plans in a comprehensive manner. The Department of Health and Human Services (DHHS) has initiated a special program to help reduce teenage pregnancy (http://www.girlpower.gov) that is helpful to use for referral as is The Substance Abuse & Mental Health Services Internet site (http://www.SAMHSA.gov). The Narcotics Anonymous site can be helpful to women who are drug dependent (http://www.NA.org). Alcoholics Anonymous is the standby for women with alcohol dependence (http://www.AA.org). Women who feel they will be injured by an intimate partner can locate shelters for abused women by calling their local police department or using the Salvation Army Web site (http://www.shelterforwomen.net).

Implementation

Interventions for the high-risk pregnant woman include promoting a healthy pregnancy and preventing pregnancy complications. Care focuses on teaching and encouraging a woman with any special need to determine how best to manage her pregnancy according to her particular situation.

A high proportion of adolescents do not seek prenatal care early in pregnancy because they deny they are pregnant. Others may not feel comfortable in a health care facility at which mainly adults are seen. The same may be true of a woman with drug dependency who fears reprisals from health care providers regarding her drug use. An ultrasound following an injury may first reveal that a woman is pregnant. She needs to be scheduled for prenatal care. A nonjudgmental, welcoming attitude that focuses on the pregnancy and the baby, while avoiding recriminations about a woman's youth or circumstances, is essential to attracting such women to prenatal care and keeping them coming for regular visits. They hear from a friend that the staff members at the clinic are helpful, not judgmental, and then take the first step into the facility.

For women who are physically challenged, modifications may be necessary for some interventions associated with typical pregnancy-related procedures. For example, it may be necessary to modify a pelvic examination when a woman cannot place her legs in table stirrups. Modifying procedures promotes individualized care for all women, improving overall nursing care.

Outcome Evaluation

Evaluation of nursing interventions for the care of a pregnant woman with a special need often focuses on a woman's physical and emotional readiness for childbearing, maintenance of fetal health, and a woman's ability to provide a safe and healthy environment for her newborn. The following are examples:

- Client states she will use walker to maintain balance during pregnancy.
- Adolescent lists a weekly intake of adequate calories, even with frequent meals at fast-food restaurants.
- Family members state they have been able to adjust to changing demands of pregnancy in mother who is physically challenged.
- Client reports to methadone maintenance clinic daily and reports no other drug use.
- Client states that she is able to manage a rest period daily even in light of busy work and travel schedule.
- Client states she is able to carry out usual lifestyle activities in spite of cast on injured arm.

THE PREGNANT ADOLESCENT

Adolescent pregnancy is not a new phenomenon. Historically, it was common for women to marry as early as age 12 or 13 and have their first baby at age 15. In today's society, however, marriage and childbearing are life situations that are thought of as belonging to later years. Teenage pregnancies still continue, however. Reasons for the high number of them include:

- Earlier age of menarche in girls (the average age is 12.4 years; many girls begin menstruating at age 10 and so are ovulating and able to conceive by age 11)
- Increase in the rate of sexual activity among teenagers
- Lack of knowledge about (or failure to use) contraceptives or abstinence
- Desire by young girls to have a child

Having an equally young sexual partner can contribute to pregnancy incidence as in this situation, neither partner may be well versed in contraceptive options (Buston, Williamson, & Hart, 2007). In addition, some adolescents become pregnant as the result of rape or incest (Kandakai & Smith, 2007).

Failure of adolescents to obtain adequate knowledge of contraceptive measures or abstinence is an issue that can be addressed by health care providers. As protective measures are easy to use, the average adolescent should not have difficulty following instructions. Adolescents are also capable of using emergency contraceptive measures correctly and safely. Access to emergency contraception is not associated with increased rates of unprotected intercourse or with higher rates of pregnancy or sexually transmitted infections (Haynes, 2007). Unfortunately, providing this type of information does not always resolve the problem because adolescents may lack money to purchase protection such as birth control pills or a diaphragm. In addition, the egocentric phenomenon of adolescence makes a sexually active teenager believe she will not become pregnant: "It won't happen to me." On the other hand, some adolescent girls actually plan pregnancy. They believe being pregnant will free them from an intolerable school or home situation and give them someone to love and someone to love them. This puts a tremendous responsibility on a newborn to furnish love and change a girl's life, and child abuse can occur when the newborn cannot meet such expectations (Records, 2007).

At one time, pregnant unmarried girls were sent to a "secret" home or shelter where they would stay throughout their pregnancy, give birth, place the child for adoption, and return home as if nothing had happened to them. Today, pregnant teenagers remain at home, attend prenatal clinics, or come to physicians' offices just as older women. They give birth in birthing rooms at hospitals, and as many as 90% keep their babies (NCHS, 2009). Few give birth in alternative birth centers because the risk of cephalopelvic disproportion makes adolescent pregnancies high risk. Home birth is not recommended for the same reason. Offering increased guidance during pregnancy and for child care during the following years can be an important nursing role.

Developmental Tasks of Adolescence

Adolescence is a vulnerable time for pregnancy because the developmental tasks of pregnancy are superimposed on those of adolescence. The developmental tasks of the average adolescent are fourfold: to establish a sense of self-worth or a value system, to emancipate from parents, to adjust to a new body image, and to choose a vocation (Erikson, 1963). A girl in the process of separating from her parents may be devastated by the reality of someone else being dependent on her. She may need her parents' financial help more than ever to obtain prenatal care and buy clothing for her new baby. If she must depend on her parents' health insurance, she may feel virtually trapped into dependence. Helping adolescents to make their own health care decisions at health care visits helps to foster a sense of independence in the middle of this forced dependency. Consider, for example, the decision that the adolescent must make about where to place a medication reminder chart: if it hangs in the kitchen, her mother may monitor it; in her bedroom or in her school locker, she alone will monitor it. An adolescent may not be able to choose when she comes for care (her mother has the car to drive her only on Tuesday afternoons), but during a visit she can do many things to feel independent, such as weigh herself, hold a mirror to view her pelvic examination, or be interviewed apart from her parent.

Parents may have difficulty allowing a daughter to make her own health care decisions this way. You may need to remind them that a pregnant adolescent is regarded as an **emancipated minor** or a *mature minor*—a person capable of making health care decisions—and so may sign permission for her own care. Soon she will be caring for an infant, so she needs this practice in independence and responsibility.

Pregnancy may interfere with the development of a healthy sexual relationship and cause difficulty in establishing future intimate relationships if a girl realizes that her current relationship has led to a situation detrimental to her. To prevent this, it is useful to help her view the pregnancy as a growth-producing experience. Most people can point to a day in their life when they "grew up" (perhaps a day a parent became ill or the day they left home for college). This pregnancy can be that "growing-up" revelation or a growth-producing experience for her.

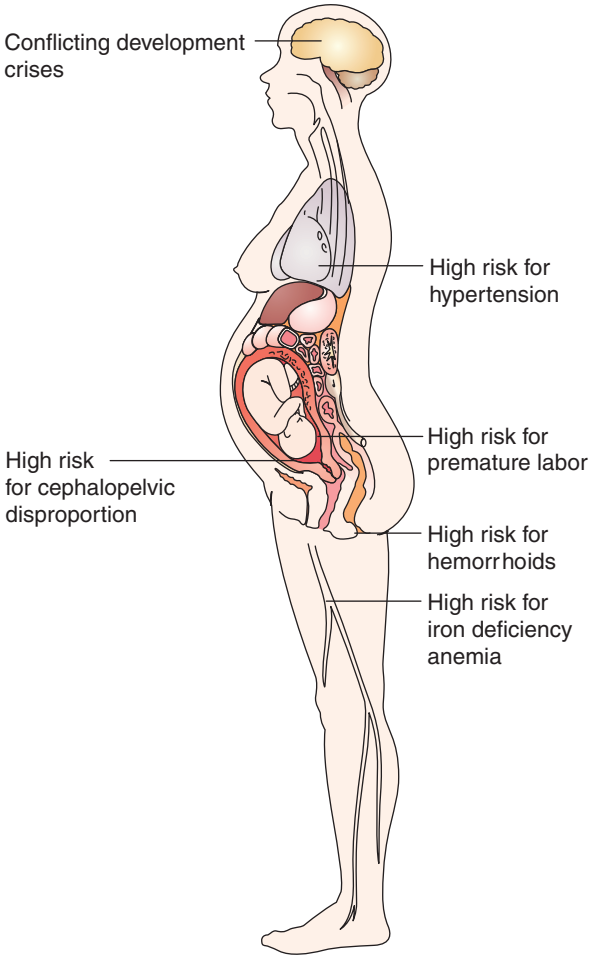
Establishing a value system or sense of identity can be difficult if health care personnel treat a pregnant adolescent as though she is irresponsible. Encouraging her to continue school is crucial to her self-esteem and to her future, as well as to the future of her unborn child. Many schools have special programs for pregnant adolescents that include aspects of prenatal care.

Prenatal Assessment

Adolescents are considered high-risk clients because they have a high incidence of pregnancy-induced hypertension, iron-deficiency anemia, and premature labor (Box 22.2). They also have a higher incidence of low-birth-weight infants, a disproportion between fetal and pelvic size, and a high rate of intimate partner abuse (Datner et al., 2007). Early and consistent prenatal care is essential to their health and the health of their baby.

Unfortunately, many adolescents do not seek prenatal care until late in their pregnancies as not seeking prenatal care is a way of protecting the pregnancy—if she doesn't tell anyone, no one can suggest she terminate the pregnancy. After the sixth month, abortion is no longer a possibility, so she can feel free to come for care without being subjected to this pressure.

Box 22.2 Assessment
Assessing the Pregnant Adolescent for Complication Risk



Other factors contributing to the lack of prenatal care include:

- Denial she is pregnant
- Lack of knowledge of the importance of prenatal care
- Dependence on others for transportation
- Feeling awkward in a prenatal setting (an adult setting)
- Fear of a first pelvic examination
- Difficulty relating to authority figures

A primary nursing or case management approach that minimizes the number of health care providers a teenager is exposed to may be the most effective method for providing care during the prenatal period. Some adolescents do well in group prenatal care because it allows them to interact with a peer group. If a community does not have a facility designed especially for adolescents, all settings should accommodate adolescents' needs, eliminating this reason for poor prenatal care.

Health History

Take a detailed health history at the first prenatal visit of an adolescent to establish individual risks. This is best done without the girl's parents present. The girl needs practice in being responsible for her own health, and having to account for her health practices helps her do this. It also helps prevent her from fabricating an answer to please a parent.

Some adolescents come to a facility with concerns such as "weight gain" or "feeling tired all the time" rather than saying they are pregnant, hoping health care providers will think of pregnancy as a possible reason for their symptoms. This is part denial and part pregnancy protection. Always be alert to the possibility of pregnancy when an adolescent describes symptoms that are vague and hard to define. If the importance of what she is saying when she mentions feeling "tired" or "nauseated" is missed, she may ask if someone will feel her stomach. If told this is not necessary for any of the symptoms she has mentioned, she may describe bigger symptoms, such as "terrible stomach pain." Think of possible pregnancy when you hear such a "growing" history.

Many adolescents want to keep their world totally separate from the adult world and, to keep it separate, they do not voluntarily share information with adults. When interviewing adolescents, be certain to press for the responses needed to assess safely. Do not accept statements such as "I eat okay" as a nutrition history or "I'm a very active person" as a history of rest and activity. Ask for details.

If an adolescent delayed seeking health care, ask for the reason for this at her first prenatal visit. Acknowledge that "protecting" the pregnancy is a desirable motive, but that continuing with prenatal care is much more beneficial.

If a parent does accompany a girl, ask the parent separately what, if any, concerns he or she wishes to discuss. A young adolescent is still a daughter, and a parent may be as concerned about her health during this pregnancy as the parent was at health visits when the girl was being seen for a cold or a sports injury.

A baby's father may accompany a teenage girl into the clinic or office to have the pregnancy diagnosis established. Because he is not married to her, he does not have a legal right to participate in her decision concerning pregnancy, abortion, or adoption, but he may not be devoid of feelings for the girl or the baby. If he is an adolescent, he may feel sorrow that because of his age he cannot provide adequately for the girl and baby. If a complication occurs, he may feel genuine grief. Allowing him to offer support in the current pregnancy helps him to learn more about himself and better define his role (Parra-Cardona, Sharp, & Wampler, 2008). Be sure he receives compassionate education on preventing further pregnancies until he is more mature.

Often, adolescent girls have not talked much to many pregnant women, so they may need extra teaching to help them become aware of common pregnancy symptoms such as urinary frequency, fatigue, and breast tenderness. Asking what symptoms an adolescent is having, and reassuring her they are part of a normal pregnancy, can help prevent her from attempting to treat them with potentially teratogenic over-the-counter medications.

As pregnancy progresses, listen for signs of "nest-building" behavior during a pregnancy history. An adolescent girl may not have the financial resources to buy clothing or a baby bed. She may reveal nest-building feelings by asking an increasing number of questions about newborns. Offer suggestions, such as making one article of clothing for the baby or saving her own money for one article—activities that promote active

involvement in the pregnancy and provide a measure of nest-building behavior (the girl who, week after week, spends her money on something else is probably not as involved in the pregnancy as the girl who puts away even 1 dollar each week toward a pair of baby shoes).

Some adolescents have difficulty telling their parents about the pregnancy. Role-playing or simulation may be an effective technique to help them prepare to do this. Some girls report on a second visit that their parents were not nearly as angry as they had anticipated. Instead, their parents reacted as if they had been waiting to hear this news, having accepted it as inevitable months before.

Family Profile. Adolescents may leave home if their family disapproves of their pregnancy, joining the ranks of homeless or adolescent runaways. Others do not leave home but separate themselves emotionally from their family. Trying to manage by themselves leaves adolescents with tremendous financial strain and a devastating sense of loneliness. Be sure to ask a girl at prenatal visits where she is living, what is the source of her income, and whom she would call if she suddenly became ill.

Asking about home life may reveal a dysfunctional family or an incest relationship as the cause of the pregnancy. If the girl is under legal age, incest is considered child abuse. Know your local and state laws on this topic and make the necessary report.

Because of family relationship problems, a girl may need help in making arrangements for the next few months of her pregnancy and for child care afterward. Will her parents allow her to live at home during the pregnancy? If not, is there a relative she may go to? What kind of financial support does she need? Family and social supports for pregnant adolescents have been shown to be important influences on the maintenance of a healthy pregnancy lifestyle and help prevent low birth weight in their children (Kaplan & Love-Osborne, 2008).

Be certain to ask if the girl is planning to continue with school. Pregnancy is an egocentric time when outside interests do not always seem important. Help her to see that the months of pregnancy will go by faster if she is busy. Remaining in school is a way of helping her stay busy. It also is important in preparing for the future, because a high school education will be necessary to obtain marketable skills to support herself and her baby. Once she has given birth, returning to school may be difficult because she may have child care problems and because she may feel she is more mature than the other girls (or the other girls may make her feel this way). Any school that obtains federal money cannot discriminate against students because they are physically challenged. Many states interpret pregnancy as physically challenging, so in those states a girl cannot be forced to leave school (or even asked to go to an alternate school) because of pregnancy. You may need to advocate for a girl with a school committee for a proper school placement.

Day History. Adolescents may be unwilling to provide a detailed day history unless its purpose is well explained. Tell a pregnant teenager the purpose of the history is to learn more about her as a whole person, not to discover if she is doing things during the day she should not do. Adolescents are private people; to allow you to walk through their adolescent world for a day is a breach of adolescent philosophy. Ask in particular about nutritional practices, sleep, daily activity, use of drugs, and whether she has friends who can support her through this experience.

Be certain to include questions about her medication history. Ask if she is taking anything over the counter. Some adolescents take acne medication that is potentially teratogenic, such as tetracycline or isotretinoin (Accutane) (Karch, 2009). Some take frequent doses of over-the-counter cold remedies or herbal supplements. Impress upon adolescents the importance of not taking any medication—even nonprescription—without prior approval from their physicians or nurse-midwives during pregnancy. Pregnancy can become an important growth experience if it provides the motivation some adolescents need to withdraw from recreational drug use.

Physical Examination

Physical examination procedures with pertinent adolescent findings are discussed in Chapter 34. Be certain to explain procedures as you do the examination. A statement such as "Oh, you're starting to have colostrum," a positive finding of pregnancy, may be frightening to an adolescent who does not know what colostrum is. A better way to phrase such a finding might be, "Your breasts are healthy. You're already beginning to produce early breast milk. Later on we'll talk about the importance of breast milk for newborns." This kind of feedback makes a health examination a learning experience and relieves anxiety for adolescents, who tend to be very concerned about body appearance. It is an effective way to encourage healthy behavior patterns.

Adolescents are at an increased risk for pregnancy-induced hypertension, probably because of immature blood vessels or an immune response to the foreign protein of their fetus (Clark, Silver, & Branch, 2007). Few adolescents are told the results of blood pressure determinations at health maintenance visits, so they do not know what is their typical finding. Obtain a baseline blood pressure at the first prenatal visit and make a point of informing the girl of her blood pressure reading to encourage active health care participation in the future. Adolescents are often active in a waiting room—walking to get a magazine, returning it, or looking out the window; be certain that the girl has 15 minutes of rest before you take a blood pressure or the recording will be falsely high.

Use a Doppler technique to obtain fetal heart tones, if possible, because hearing the fetal heart helps an adolescent acknowledge the reality of her pregnancy. For the same reason, make a point of assessing fundal height from visit to visit to show the baby is growing.

Adolescents who use drugs may be reluctant to supply a urine specimen for testing because they are afraid you are secretly looking for evidence of drug use. In this instance, you may receive a cupful of water in place of a urine specimen. If in doubt regarding the substance you are testing, check the specific gravity. The specific gravity of water is 1.000, whereas urine specific gravity ranges from 1.003 to 1.030.

Many adolescents like to weigh themselves at prenatal visits as weight gain in early pregnancy is proof they are pregnant. It is good practice to make a note of the clothing a girl is wearing the first time she is weighed (e.g., jeans, T-shirt) so later weight determinations can be compared accurately. Be

certain she knows a healthy weight gain is important for fetal growth and that this weight can be lost afterward.

✔ Checkpoint Question 22.1

Mindy Carson is still an adolescent. What is a task of adolescence, according to Erikson, that she needs to complete to be ready to become a mother?

a. Establish a value system.
b. Grow to her final height.
c. Prepare clothes for the baby.
d. Finish her education.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Health-seeking behaviors related to special care necessary for healthy adolescent pregnancy

Outcome Evaluation: Client states she feels confident in her ability to take care of herself and avoid pregnancy complications, and asks questions about her pregnancy.

Pregnancy Education

Adolescents need a great deal of health teaching during pregnancy because they do not know many common measures of care that an older woman has learned from experience. They are also often unwilling to follow health care advice that makes them different in any way from their peers. On the other hand, adolescents often do not have well-established health practices, so they are adaptable.

Adolescent girls may respond to health teaching that is directed to their own health more than to that of a fetus inside them: "Eat a high-protein diet because protein makes your hair shiny (or prevents split fingernails)" often leads to better adherence than a statement such as "Protein is good for your baby." "Taking the iron supplement should make you feel less tired" is better than "It will help build the baby's blood supply," for the same reason. These are truthful statements and they appeal to an adolescent's preoccupation with self. In addition, this type of health teaching is the only form to which an adolescent who is denying her pregnancy can respond.

Adolescents also need instructions about possible discomforts and changes associated with pregnancy, and measures to relieve them. (See Chapter 12 for a complete discussion.) Many adolescents develop hemorrhoids during pregnancy because the disproportion of their body size to a fetus puts extra pressure on pelvic vessels, causing blood to pool in rectal veins. Assure girls that this is a pregnancy-related phenomenon that will resolve when the pregnancy is over.

Adolescents may also develop many striae across the sides of their abdomens because so much stretching of the abdominal skin occurs. Assure them again that, because of skin elasticity, these marks will probably fade after pregnancy. Chloasma, excess pigment deposition on the face and neck, appears at the same rate in adolescents as in older women. Adolescents, however, may be more conscious of this pigment because overall they are more conscious and concerned about their facial appearance. Suggesting a cover makeup and offering reassurance the pigmentation will fade after pregnancy can help.

Nutrition

Good nutrition can be a major problem during an adolescent pregnancy because many girls enter pregnancy with poor nutritional stores from years of eating a less-than-optimal diet. Lack of good nutrition can result in preterm birth and low-birth-weight newborns. The younger the girl is, the more likely she is to have a low-birth-weight infant. To prevent these complications, a girl should eat a sufficient diet to allow for the growth of a fetus and also provide for the needs of her own growing body. Otherwise, protein, iron, folic acid, and vitamin A and C deficiencies may become acute. She may need to gain more weight than does the mature woman to supply adequate nutrients.

As more and more children are obese today than ever before because of overeating and lack of exercise, many adolescents enter pregnancy overweight or obese. This can lead to macrosomia or overgrowth in a fetus, a situation that leads to an increase in the number of cesarean births (Zhang et al., 2008). Such adolescents should not actively restrict nutrients during pregnancy, however, because although they are obese, their body may be deficient in protein and vitamins.

Many adolescent girls eat poorly during pregnancy because they simply do not know what constitutes good nutrition. Some girls have little choice in what foods are prepared at home. To change a dietary pattern, you may have to talk to the person who does the cooking in the family.

Besides eating the right amount of food, a pregnant adolescent should be sure to eat proper foods, possibly abandoning a food fad she has been following. Some girls are so peer-oriented they balk at substituting a glass of orange juice for a cola beverage because no one else they know drinks orange juice. The best you may be able to accomplish is to secure her agreement to switch to noncaffeinated soft drinks.

Many adolescents eat at least one meal a week at a fast-food restaurant. Remember that if the girl is attending school, she eats at least one meal away from home each day. If she travels by school bus, she may have to leave by 6:00 or 7:00 in the morning, so she needs suggestions on how to construct a quick but healthy breakfast. If she leaves home this early, she will have a long wait until lunchtime. Suggest midmorning snacks, such as fruit, that also supply vitamins, not just empty calories. Be certain nutrition education includes how to "brown-bag" or buy a nutritious cafeteria lunch (type A school lunches are discussed in Chapter 32).

Adolescents traditionally do not take medicine conscientiously, so they may need frequent reminders that vitamin and iron supplements intended to complement nutrition during pregnancy must not only be purchased but also must be taken. Be sure a girl posts a medication reminder chart at home or in her school locker to help increase adherence.

What if... Mindy Carson tells you her daily nutrition consists of a liquid diet beverage for breakfast and lunch and then she has pizza for dinner? Will this typical teenage diet be adequate for her during pregnancy?

Activity and Rest

Adolescents vary greatly in their level of activity. Assess a girl's participation in sports and determine which ones (if any) may have to be discontinued during pregnancy (e.g., diving, gymnastics, touch football). Many girls practice sports not for the enjoyment of the sport but for the feeling of "team" or companionship. You may need to suggest alternative activities (joining the drama or language club, inviting friends over once a week to watch a movie) so they do not suffer from the loss of companionship.

Adolescent girls may not plan enough rest time during pregnancy, especially if they are acting as if nothing is happening to them (Box 22.3). It may help to explore a typical day and suggest ways to rest without compromising social relationships (sitting, talking after school rather than walking through the park).

Physiologic Changes

A young girl may have distorted beliefs about her body. All adolescent girls need substantial education on the physiologic changes that occur during pregnancy. Despite all the health information given to children in school, it is not uncommon to find an adolescent who thinks her baby is growing in her stomach. Such a girl may be unwilling to eat large meals during pregnancy for fear of suffocating or drowning her fetus. In addition, specific information about labor and delivery is essential to counteract all the "scare stories" girls may be hearing from their peers. Gaining this type of knowledge is another way that pregnancy can be a growth experience. At the end of the pregnancy, this adolescent will know a great deal more about her body and her ability to monitor her health than her average classmate.

Childbirth Preparation

Adolescents have a strong need for peer companionship. When they become pregnant, they often are cut off from fellow adolescents. This makes them "ripe," therefore, to join a class of adolescents in preparation for childbirth. They are excellent students because being a student is age-appropriate for them. They have enough childish magical belief operating that they are not skeptical about whether prepared childbirth will work. In fact, believing that prepared childbirth will work is an important component in a successful prepared childbirth experience, so this becomes a self-fulfilling prophecy.

Birth Decisions

Pelvic measurements should be taken early and carefully in adolescent girls as cephalopelvic disproportion is a real possibility because of the girl's incomplete pelvic growth (Shields et al., 2007). Most girls who are told their baby will have to be born by cesarean birth respond well to the news, and many are relieved, because surgery seems controlled and simple compared with the agonies of labor they imagine. When a cesarean birth must be scheduled because of cephalopelvic disproportion or poor fetal growth, the information should be shared with the girl and her parents as soon as possible. Adolescents want to know the truth. They tend to regard the withholding of information not as protection but as an indication they are being treated as children.

Plans for the Baby

Adolescents may need additional time at prenatal visits to talk to a good listener about how they feel about being pregnant and becoming a mother. Scared? Bewildered? Numb? Happy? Be certain they know all the options available to them: keeping the baby, placing the baby in a temporary foster home or adoption. Adolescents, like all women, should be encouraged to breastfeed (Britton et al., 2009). Breast tissue matures with pregnancy, so even the very young adolescent is physically capable of breastfeeding.

Complications of Adolescent Pregnancy

As mentioned earlier, adolescent pregnancy carries the increased incidence of pregnancy-induced hypertension, iron-deficiency anemia, preterm labor, and cephalopelvic disproportion (see Box 22.2). Fortunately, with conscientious prenatal care, these complications can be minimized.

BOX 22.3 ✻ Focus on Communication

Mindy Carson is 16 years old and pregnant. You talk to her at a prenatal clinic.

Less Effective Communication

Nurse: Hello, Mindy. How are you feeling?
Mindy: Good, but always tired. You know.
Nurse: You should try and rest more.
Mindy: Right.
Nurse: Why don't you ask your boyfriend to help you more?
Mindy: I'll do that.
Nurse: Or stop working at the fast food restaurant. That'll leave you time to rest more.
Mindy: Right. Great solution.
Nurse: Glad I could be of help.

More Effective Communication

Nurse: Hello, Mindy. How are you feeling?
Mindy: Good, but always tired. You know.
Nurse: Are you getting enough sleep?
Mindy: How can I? I work every day after school.
Nurse: Is there anyone who could help you out more? Your boyfriend? A friend?
Mindy: I'm pretty much alone since I got pregnant.
Nurse: As long as you're coming to this clinic, you're not alone. Tell me about a typical day and let's investigate together what could be done.

In the first scenario, the nurse was so intent on problem solving she forgot the first step of effective problem solving—identify the exact problem that needs solving. In the second scenario, when the nurse continues to assess rather than offer advice, she is able to identify the problem.

Pregnancy-Induced Hypertension

Because adolescents are more prone to pregnancy-induced hypertension than the average woman, establishing a baseline blood pressure is important (see Chapter 21). It is particularly important if an adolescent has not had her blood pressure measured since a preschool or school-age checkup as long as 10 years earlier.

The best intervention for reducing an increasing blood pressure during pregnancy is bed rest, preferably in a side-lying position. Bed rest may be difficult for a teenager to achieve because she easily grows bored and being confined to bed limits her interactions with peers and school activities. Many girls on bed rest at home may rest better if they are lying on the living room couch, where they can be aware of household activity, rather than in an upstairs bedroom, where they have to get up time and again to see what is happening. Also, it is easier for a parent to encourage bed rest if a girl is within eyesight. If called too many times to the distant bedroom for small tasks, a parent tends to say, "Get up and get it yourself this time."

Help to establish a specific routine of bed rest—does it mean being strictly confined to bed or sitting up part of the day in a lounge chair with legs elevated? Can she take a shower? Use the bathroom? Knowing the exact rules from the beginning helps prevent misunderstandings and hurt feelings.

Girls on bed rest need activities to keep them busy. These can include homework or listening to music. If the end of the pregnancy is near, a girl may be able to have a friend bring her homework assignments. If the bed rest period will be longer than 2 weeks, however, she may need to make arrangements for home tutoring. You may need to advocate for her with her school system for this service (remembering that only rarely can it be denied on the basis of pregnancy). "Assignments" from the health care agency, such as reading about appropriate toys and games for infants, is also a way to occupy time. Frequent telephone calls from the health care facility show concern and offer an opportunity to enforce health teaching points. Be certain a girl does not interpret being placed on bed rest as being ill. This can cause her to reduce her nutritional intake or to curtail body hygiene.

Although its effect is controversial, low-dose aspirin therapy may be prescribed to help reduce symptoms of hypertension of pregnancy (Barton & Sibai, 2008). Keep in mind adolescents often are not reliable at taking daily medicine, particularly if it seems as unimportant as aspirin. Help a girl make a medicine reminder chart to promote adherence to this aspect of care.

If the hypertension continues after a period of bed rest at home (or if the symptoms of pregnancy-induced hypertension are advanced when they are first discovered), a girl may be admitted to the hospital so bed rest can be better enforced. As soon as the fetus is mature, labor will be induced or a cesarean birth scheduled.

Iron-Deficiency Anemia

Many adolescent girls are deficient in iron because their low protein intake cannot balance the amount of iron lost with menstrual flows. Deficiency is revealed by chronic fatigue, pale mucous membranes, and a hemoglobin level less than 11 g/dL. As if the girl's body has identified a mineral lack, iron-deficiency anemia is associated with pica, or the ingestion of inedible substances (Mills, 2007). Cravings for ice cubes or blackboard chalk may develop because of this.

A pregnancy compounds iron-deficiency anemia because a girl must now supply enough iron for fetal growth and her increasing blood volume. All pregnant women should take an iron and folic acid supplement (folic acid is important for red blood cell growth and prevention of neural tube defects) and these are especially important for the adolescent (Bernstein & Weinstein, 2007).

Help an adolescent plan a daily time for taking her iron supplement. Review with her how many iron-rich foods she needs to eat daily in addition to this. An iron supplement is not a supplement until her dietary intake is already strong in iron-rich foods.

As soon as the body has iron, it will begin forming immature red blood cells (reticulocytes) rapidly. A reticulocyte count may be obtained in 2 weeks to evaluate these levels and provide evidence that the iron supplement is being taken. If the reticulocyte count is not elevated by 2 weeks, it implies a girl did not take the supplement. Taking a stool swab and assessing it for the black tinge of an iron supplement or reassessing her serum iron level are other methods of assessing for adherence.

Preterm Labor

Adolescents are at high risk for preterm labor, probably because their uteruses are not fully grown (Muram, 2007). Review the signs of labor with them by the third month of pregnancy. Stress that labor contractions begin as only a sweeping contraction no more intense than menstrual cramps. Also, any vaginal bleeding is suspicious of labor and should be reported. Adolescent girls have gained much of their knowledge of labor from television (where a woman suddenly announces she is in labor and within 15 minutes gives birth). Therefore, they may dismiss light contractions as simple discomfort, not realizing they might be the start of labor. Adolescents who recognize labor contractions early can seek care to have premature labor halted.

Complications of Adolescent Labor, Birth, and the Postpartum Period

Cephalopelvic Disproportion

Cephalopelvic disproportion is suggested by lack of engagement at the beginning of labor, a prolonged first stage of labor, and poor fetal descent. Adolescent labor does not differ from labor in the older woman if cephalopelvic disproportion is absent. Graphing labor progress is a good way to detect labor that is becoming abnormal. Be certain an adolescent has a support person with her in labor so she can relax and breathe effectively with contractions. If this person is also an adolescent, you may need to serve as the true support person, or at least spend considerable time coaching so this person can support the girl in labor.

Postpartum Hemorrhage

Young adolescents are more prone to postpartum hemorrhage than the average woman because if a girl's uterus is not yet fully developed, it becomes overdistended by pregnancy. An overdistended uterus does not contract as readily as a normally distended uterus in the postpartum period, allowing

bleeding to occur (Poggi, 2007). Adolescents also may have more frequent or deeper perineal and cervical lacerations than older women because of the size of the infant in relation to their body. On the other hand, young adolescents are generally healthy and have supple body tissue that allows for adequate perineal stretching. If a laceration does occur, it usually heals readily without complication.

Inability to Adapt Postpartally

The immediate postpartum period may be an almost unreal time for an adolescent (Holub et al., 2007). Giving birth is such a stress and a major crisis that all women have difficulty integrating it into their life. It may be particularly difficult for the adolescent. The girl may "block out" the hours of labor as if they did not happen. If she was particularly frightened by labor, she may have received a narcotic, so her memory of the labor hours may not be clear. Urge her to talk about labor and birth to make the happening real to her; otherwise, postpartum depression is more apt to occur (Haessler & Rosenthal, 2007).

Lack of Knowledge About Infant Care

Adolescents show the same positive bonding behavior with their infants as their more mature counterparts (Fig. 22.1). They may, however, lack knowledge of infant care. Although they may consider themselves to be knowledgeable in child care because they have babysat for a neighbor's child or a younger sibling, they can be overwhelmed in the postpartum period to realize that when the baby is their own, child care is not as simple as it once seemed. When the child cries, they cannot hand it to someone else; at the end of 4 hours, when they are tired of caring for the baby, they cannot leave and walk away. Although these things were most likely discussed with an adolescent during pregnancy, these feelings may not become prominent until the child is actually born. Spend time with a girl observing how she handles her infant. Demonstrate bathing and changing the baby as appropriate. Model good parenting behaviors whenever possible by being aware of how you hold and care for the child.

FIGURE 22.1 A new adolescent mother begins to bond with her infant. (Photograph by John Gallagher, with permission of University of Pennsylvania Medical Center, Philadelphia, PA.)

Unfortunately, most adolescent mothers do not breastfeed. This is related to their perception of breastfeeding as something that will "tie me down" and the reality (in many instances) that they will be returning to school full-time soon after birth. Education about the importance of breastfeeding and tips for how to incorporate it into a busy lifestyle can increase the number of adolescents who breastfeed (see Chapter 19). Help young mothers who do not choose to breastfeed to find a feeding method that is satisfying to them and safe for the infant as part of the process of becoming a young, but effective, new mother (see Focus on Nursing Care Planning Box 22.4).

✔ Checkpoint Question 22.2

Mindy Carson was placed on an iron supplement because her hemoglobin level was below normal. What is a common test to demonstrate adherence to an iron supplement?

a. Assessing if her skin appears darker.
b. Assessing her blood reticulocyte count.
c. Analyzing her urine for iron deposits.
d. Measuring if she has grown in height.

THE PREGNANT WOMAN OVER AGE 40

The incidence of women delaying their first pregnancy until their late 30s or early 40s is increasing. Twelve percent of births in the United States today are to women over age 35; 2% to 4% are to women over age 40 (NCHS, 2009). In the past, it was assumed a woman of this age was past the optimal age for childbearing and was at risk for many complications. Today, with the exception of a greater incidence of chromosomal abnormality, there is little evidence of serious complications in women older than age 40 as long as prenatal care is begun early in the pregnancy.

A woman over age 40 is more likely than a younger woman to have a previously diagnosed condition, such as hypertension, varicosities, or hemorrhoids. In addition, by age 40, a woman usually has a major role change to undertake during pregnancy, because she often is well established in a career or has an accustomed routine at home or in her community. She needs to think through how this pregnancy and childrearing are going to fit into and change her life. Although she may feel rich in the number of support people she perceives around her, she may discover she has few "pregnancy support" people because she does not have many friends her age who are also having babies—some may be close to becoming grandparents. The only things these friends remember of pregnancy and labor are their particular highs and lows, and the care they received may not reflect current practice. This may leave a woman without access to the daily "shop talk" of other pregnant women, or someone to turn to with questions such as whether the backache she is experiencing or frequent need to urinate is normal. On the other hand, because many women delay childbearing today, she may be one of a sizable group of women in her community experiencing pregnancy at this stage of life.

Developmental Tasks and Pregnancy

The developmental challenge of the over-40 age group is to expand their awareness or develop generativity—that is, a sense

BOX 22.4 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Pregnant Adolescent

Mindy Carson, 16 years old and 15 weeks pregnant, was in an automobile accident on her way into prenatal clinic this morning. She received a 4-inch laceration on one leg. The father of Mindy's baby is a college student. He does not want Mindy to keep her baby after the birth because he does not want to get married until he finishes graduate school. Mindy insists she is old enough to be a parent and wants to keep her baby. Mindy's mother accuses the father of sharing methamphetamines with Mindy. She's worried Mindy has been working as a prostitute to support her drug habit.

Family Assessment ✻ Lives with family in second-floor apartment above convenience store, which parents own and run. Attends school but is "ready to drop out." Cares for 5-year-old sister after school while parents work downstairs.

Client Assessment ✻ Pale, tired-appearing adolescent female. Failed to come for two previous appointments. Admits to methamphetamine use since becoming pregnant. Hinted she might be using prostitution as income source. Parents want her to end pregnancy; client wants to continue pregnancy because "Now I can eat anything I want since I'm eating for two." Unhappy with arguing that is happening between parents and boyfriend. Says, "I'm coming apart at the seams."

Nursing Diagnosis ✻ Altered family processes related to the stress of adolescent pregnancy

Outcome Criteria ✻ Client and family members demonstrate positive coping mechanisms by communicating effectively; client identifies plans for self and infant; clarifies relationship desired with father of child. Baby's father participates in pregnancy activities as desired; client halts unhealthful practices.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Assess the reason client states she is ready to drop out of school.	Discuss with client advantages of staying in school during pregnancy.	It is difficult for young women to support themselves and an infant without at least a high school education.	Client contracts to stay in school through graduation if possible.
		Consultations		
Social worker/ nurse	Investigate client's options for schooling if she no longer feels comfortable in her local public school.	Contact the client's school (with her permission) to explore options for her for continued school attendance.	Discussion promotes active problem solving and positive adaptation.	Client and school personnel agree on a course of action that will optimally benefit the client.
Social worker/ nurse	Assess what community resources are available for withdrawal for methamphetamine users.	Discuss the advantages of a withdrawal program during pregnancy.	Almost all substances cross the placenta and reach the fetus.	Client attends sessions for withdrawal from methamphetamines.
		Procedures/Medications		
Nurse	Assess what client expects from prenatal care and if she understands the importance of regular attendance.	Discuss importance of prenatal care for adolescents, who are prone to complications because of immature body development.	Prenatal care is the best safeguard against complications of pregnancy and the best chance that they will be prevented or alleviated as soon as they appear.	Client attends all future prenatal care appointments; Participates in discussions at these times.

Nurse	Assess what drugs client is taking.	List for medical personnel the possible drugs to which the fetus has been exposed.	Recreational drugs can lead to fetal growth restriction or birth defect.	Client agrees to a drug therapy program during pregnancy to reduce recreational drug use.
		Nutrition		
Nutritionist/ nurse	Assess 24-hour dietary recall with client.	Examine diet to see if it contains all essential nutrients for pregnancy.	"Eating for two" does not mean eating more: it means eating more nutritious foods.	Client's 24-hour recall history at next visit shows improvement in necessary nutrients for healthy pregnancy.
		Patient/Family Education		
Nurse	Assess what client means by "I'm coming apart at the seams" in reference to her lack of support.	Reinforce understanding of those involved about the client's need for support. Instruct them in ways to offer support.	Additional help may be required to cope with the added demands of pregnancy.	Client states she is receiving adequate support from her family or boyfriend or health care providers to sustain her throughout the pregnancy.
		Psychosocial/Spiritual/Emotional Needs		
Nurse	Assess if client's disagreement with family over continuing pregnancy is a major stressor.	Assist client with ways to adapt to changes of pregnancy and responsibility for fetal safety. Support client's decision to continue pregnancy.	Adolescence is a highly stressful time, especially without parental support, so change can be difficult if not anticipated.	Client states she is open to changes she knows will occur with pregnancy; will ask health care providers for additional suggestions as needed.
		Discharge Planning		
Nurse	Assess what would be the best days for client and boyfriend to attend prenatal care.	Set up follow-up visits with client and support person; plan teaching strategies and discussion of all parties' needs and concerns as appropriate.	Prenatal care can help detect and prevent complications of pregnancy.	Client attends prenatal care regularly during remainder of pregnancy.

of moving away from themselves and becoming involved with the world or community (Erikson, 1963). Some people assume that once they reach adulthood, the way they are is the way they will always be. They are amazed to find that their bodies change (e.g., men may lose their hair; women and men both gain weight) and so do their interests. They find themselves joining committees and clubs, coaching Little League teams, or organizing fundraising or community events.

A woman in this age group who is pregnant may begin to feel ambivalent during pregnancy, because she may want to continue with community activities, yet also wants to concentrate on the baby inside her. You may need to help her balance her life so she can manage crossing two life phases this way.

What is perceived as the best time in life to have children is culturally influenced. In developing countries, many people believe having children while young allows parents to grow with children. In other cultures, such as the United States, many believe delaying childbirth until a family is financially secure is best. Delaying childbirth too long, however, is not approved. Because of these various beliefs, what you believe may not be the belief of a family for whom you provide care. What may be a catastrophe to you may seem like a blessing to someone else (and vice versa). Assess couples by history and observation to determine if childbearing appears to be timed correctly for them. If not, they may need extra time to accept a pregnancy and adapt to becoming parents.

Women who have a child after age 40 fall into one of two groups: those who are having their final child and those who have delayed childbearing because of education or a career and are having their first child. Many adults over the age of 40 care for aging parents. This additional responsibility may make it difficult for a woman to complete the psychological work of pregnancy. It also may create extra strain on her finances and time (creates a "sandwich generation," or one pressured by responsibilities by both older and younger family members). Worries also include having enough energy, arranging for child care, and financial strain.

Prenatal Assessment

A woman over age 40, like all women, should begin prenatal care early in pregnancy. Fortunately, most women of this age group are well informed about the advisability of early prenatal care and have adequate health insurance, so they do seek an early appointment. A few mistakenly believe their lack of menstruation is the result of early menopause so do not seek an early health care consultation.

Health History

Ask women in this age group about their present symptoms of pregnancy, how they feel about the pregnancy, and how it fits into their lifestyle. If a woman did not realize she was pregnant, she may have self-medicated. Ask if she has been taking any medication or herbal remedies to relieve reported symptoms, such as nausea or fatigue. Because a woman is functioning well in a business world does not mean she has a healthy pregnancy lifestyle. Do not accept answers such as "I drink socially" or "I take the usual drugs" without exploring what those phrases mean specifically.

Family Profile. Some women over age 40 who are pregnant for the first time have recently changed their life pattern (married or became involved in a long-term sexual relationship) or have decided to have a child, perhaps through in vitro fertilization, without a spouse before they are no longer able to conceive. Whereas a younger woman often waits a while after marrying to become pregnant, a woman over age 40 often plans to become pregnant immediately after marriage because she senses her reproductive time clock ticking. Because of this, she may find herself making many adjustments at once (not only to a new life partner, house or apartment, and perhaps community, but also to a pregnancy).

Identify a woman's source of income. If she has a well-paying job, stopping work because of a pregnancy complication may greatly reduce her family's income. Also evaluate how many people are financially or emotionally dependent on her (such as children from a former marriage, elderly parents, an elderly neighbor, or fellow workers who count on her). During pregnancy, when a woman often needs extra emotional support, feeling responsible for so many people can be difficult.

Day History. Ask specifically about a woman's job and estimate the amount of walking or back strain it entails. Ask about recent diet or exercise programs. If a woman belongs to a health club, remind her that the use of saunas and hot tubs for longer than 10 minutes at a time is contraindicated during pregnancy because of possible hyperthermia and teratogenic effects of extreme heat on a developing fetus. Identify personal habits, such as cigarette smoking and alcohol consumption, that may be detrimental to a fetus to determine if counseling to halt or decrease these habits could be effective.

Physical Examination

A woman over age 40 needs a thorough physical examination at her first prenatal visit to establish her general health and to identify any problems, particularly circulatory disturbances she may have. Inspect her lower extremities thoroughly for varicosities, because these are more common in women over age 40 (Box 22.5). Obtain a urine specimen and test it for specific gravity, glucose, and protein to evaluate overall renal function and the possibility of gestational or type 2 diabetes, because older women are more prone than younger women to develop these conditions.

Assess a woman's breasts for any abnormalities, as women over age 40 are in a higher-risk group for breast cancer than are younger women. Ask if she has had yearly mammograms. In addition, assess for fetal heart sounds and fetal movement at prenatal visits because gestational trophoblastic disease (hydatidiform mole) is also more common in women over age 40 (see Chapter 21).

Chromosomal Assessment

Women over 35 are offered a triple-screen (alpha-fetoprotein [AFP], human chorionic gonadotropin, and unconjugated estriol levels) drawn on blood serum at the 15th week of pregnancy to detect whether an open spinal cord or chromosomal

BOX 22.5 ✻ Focus on Family Teaching

Tips on Preventing Varicose Veins

Q. Mindy says to you, "My mother was old when she had me so developed terrible varicose veins. How can I stop that from happening to me?

A. Although the following activities are not foolproof, incorporating them into your day helps prevent the development of varicose veins:

- Find opportunities during the day, such as a coffee or lunch break, to elevate your legs.
- Be certain your diet includes vitamin C, because this is important to strengthen vein walls.
- Rest in a side-lying position with your body tipped slightly forward (Sims' position). This allows leg veins to drain and empty.
- Avoid long periods of standing in one place by taking "walk breaks"; active muscle contraction helps venous return.
- Avoid sitting with your legs crossed.
- Do not wear anything constricting, such as knee-high stockings, on your lower legs.
- If you wear support hose, put them on before you get out of bed in the morning, before veins become swollen, for best results.

defect could be present in the fetus, because their risk for Down syndrome is so much higher than it is in younger women, an incidence of about 1 in 1000 compared to 1 in 1500 in younger women (Ball et al., 2007). If this test is positive, an amniocentesis will be scheduled at the 16th week of pregnancy. Be certain a woman is prepared for these studies and receives support during them. Alert her that false-positive results can occur with AFP testing, which is why amniocentesis is important. Many women of this age group do not begin nest-building until these tests confirm that their child will be healthy.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Health-seeking behaviors related to special care necessary for healthy pregnancy

Outcome Evaluation: Client states she feels confident in self-care and her ability to decrease possible complications of pregnancy.

Be certain to adapt prenatal teaching to fit an older woman's lifestyle. If she had not planned on ever being pregnant, she may have isolated herself through the years from "mothering" activities and so, despite her years, may know little about pregnancy and newborn care. In terms of knowledge, this puts her at the same level as the adolescent. Others have read so extensively that they may know more theoretical information than a woman who has already given birth. Be certain to review information about possible discomforts of pregnancy (see Chapter 12). A pregnant woman over age 40 is prone to hemorrhoids because she may have some rectal varicosities present at the beginning of pregnancy. Pain from rectal distention may, in fact, be one of the primary symptoms she reports at a first visit. Review measures to increase comfort.

Varicosities, like hemorrhoids, develop readily in a woman over age 40 because she may have had some tendency toward them even before the pregnancy. As with hemorrhoids, her best approach during pregnancy is to prevent varicosities.

Record on a woman's chart any degree of varicosity formation during pregnancy so nurses caring for her during the postpartum period can take special precautions to prevent thrombophlebitis as with venous stasis present after birth, a woman is even more prone to develop this complication immediately postpartum.

Pregnancy Education

Childbirth education classes oriented toward the older woman provide important information on pregnancy and bring these women and their support people together. A woman over age 40, like any other pregnant woman, needs access to health care personnel who can supply her with factual information during a pregnancy. She also needs additional support while she works through this role change in her life.

Nutrition

Assess the number of meals a woman eats outside her home each week, including those she packs for lunch or eats in restaurants. She may need tips on how to adjust pregnancy nutrition so she can obtain the same nutrition whether she prepares meals at home or eats them at an office or community function. Urge her to substitute a caffeine-free soft drink in place of an alcoholic beverage. In some offices, large amounts of coffee are consumed. Urge her to substitute milk or juice or decaffeinated coffee. Many women this age normally drink little milk. Rather than getting used to milk again, a woman may appreciate suggestions on other ways to ingest calcium, such as puddings or yogurt.

Prenatal Classes

Because a pregnant woman over age 40 may be unique in her circle of friends, she may feel shut out of her usual group because of the pregnancy. This makes her ready, therefore, to join a childbirth preparation or prenatal exercise class where she is "one of the group" (Fig. 22.2).

Be certain a woman plans (or the couple plans together) to set aside a specific time every day to do breathing exercises in preparation for labor. Otherwise, a busy woman may never find time to get to them and will be unprepared in labor.

Complications of Pregnancy for a Woman Over Age 40

The complications of pregnancy most likely to occur in a woman over age 40—hypertension of pregnancy, preterm or post term birth, and cesarean birth—are related to the fact that the woman's circulatory system may not be as competent as when she was younger or her body tissues may not be as elastic as they were once (Box 22.6).

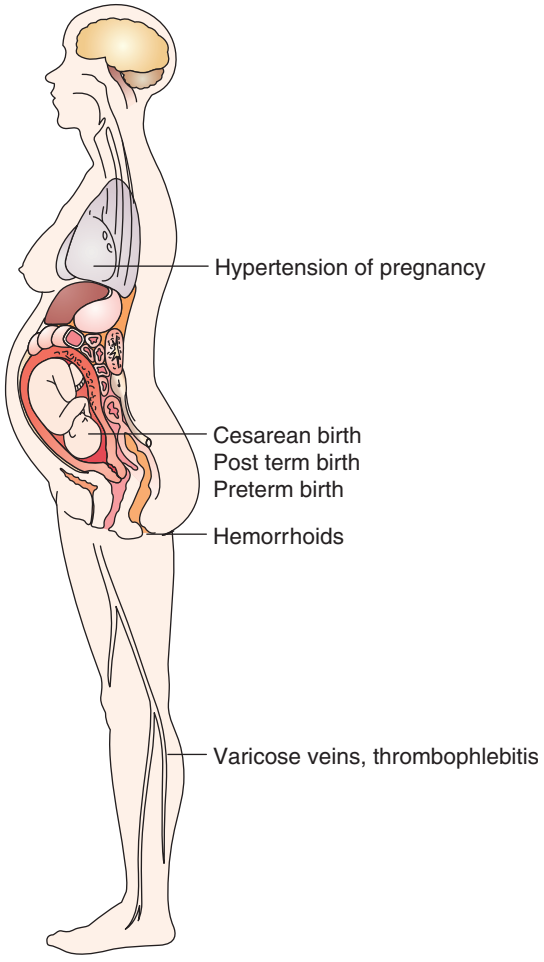
Pregnancy-Induced Hypertension

A woman over age 40 may have a higher incidence of pregnancy-induced hypertension than a younger woman, possibly related to blood vessel inelasticity or because hypertension tends to occur more frequently in nulliparas than in

FIGURE 22.2 Exercise classes during pregnancy provide women with an opportunity to interact with other pregnant women while benefiting from a carefully monitored workout. (© Kathy Sloane.)

Box 22.6 Assessment

Assessing the Pregnant Woman Over 40 for Complications



multiparas as well as those with already elevated blood pressure (Bailis & Witter, 2007). At any age, the best way to reduce the symptoms of pregnancy-induced hypertension is for a woman to rest for a good portion of each day. If a woman works full-time, stopping work may be difficult or impossible for her, not only because she believes she may miss out on a promotion or risk losing her job, but also because her income is important to her family and she is used to being productive, not merely resting all day. To allow her to rest effectively, you may need to help her plan activities she can accomplish on bed rest, such as reworking a school course outline, restructuring her office filing system, or working at a hobby she has wanted to pursue but never had time for before.

Complications of Labor, Birth, and the Postpartum Period for a Woman Over Age 40

Complications that occur with a woman over age 40 related to birth or the immediate period after birth also are the results of a body that may not be as elastic as it was when the woman was younger.

Failure to Progress in Labor

Labor in an older primipara may be prolonged because cervical dilatation may not occur as spontaneously as in a younger woman. Graphing labor progress is a good method to use to determine when labor is becoming prolonged. Many women this age may need a cesarean birth if labor is overly prolonged and places a fetus at risk. Encourage a woman to verbalize how she is feeling about her progress throughout labor to allow for reassurance and prompt intervention should problems arise. Urge her support person to be present for the birth to offer needed support. Keep in mind that some older men may not be as comfortable in a birthing room as their younger counterparts would be because when they were younger, men were excluded from watching births.

Difficulty Accepting the Event

Women over age 40 may begin to have second thoughts about childbearing this late in life as the reality of a new baby registers with them during the intrapartal and postpartum periods. Although they may have read a great deal about babies during pregnancy, they may wish they had read more or were as confident with this phase of their life as they are about other areas such as their home, office, or classroom. Review plans for child care and postpartum rest, with an emphasis on helping women learn to balance their lives, especially if they are planning on returning to work soon after the birth. They might appreciate help making child care arrangements. You can assure them that day care for preschool children has positive socialization results (Zoritch, Roberts, & Oakley, 2009).

Postpartum Hemorrhage

Just as the cervix may not dilate as readily during an older woman's labor, the uterus may not contract as readily in the postpartum period because of inelasticity. Therefore, an older woman may be at higher risk for postpartum hemorrhage (Poggi, 2007). She may be more prone to perineal-anal tears because her perineum is less subtle (Fitzgerald et al., 2007). Close observation is essential. Because a woman over age 40 may be an independent woman who is interested in self-care, she may ask for little help. Be sure to assess the amount of her lochial flow to detect this complication.

✔ *Checkpoint Question 22.3*

Women over 40 are at increased risk for developing pregnancy-induced hypertension. The reason for this is:

a. Many are overweight before they enter pregnancy.
b. They drink more fluids daily than younger women.
c. They do not exercise much, so edema fluid accumulates.
d. Their blood vessels are not as elastic as those of younger women.

THE PREGNANT WOMAN WHO IS PHYSICALLY OR COGNITIVELY CHALLENGED

In the past, women with conditions such as vision, hearing, cognitive, neurologic, or orthopedic challenges were sheltered by their families to such an extent that women with

TABLE 22.1 ✻ Areas of Planning With Physically or Cognitively Challenged Women During Pregnancy

Area	Assessment and Planning Guidelines
Transportation	Ask if a woman has transportation for prenatal care and for emergencies.
Pregnancy counseling	Assess the special modifications of care that will need to be made depending on a woman's special challenge. Use additional visual or auditory aids to make your teaching points clear.
Support person	Determine who is the woman's support person. In some instances, a woman's condition requires so much assistance during pregnancy that one support person will not be enough. If necessary, contact community agencies to lend additional support, with her consent.
Health	Do not lose track of a woman's primary health problem. For example, a woman with cerebral palsy may need to continue an active muscle exercise program during pregnancy for her primary illness.
Work	Assess whether a woman works outside her home and, if work is discontinued during pregnancy, what she could substitute for a social contact activity. Women with physical or cognitive challenges may be lonely because they do not have a wide range of friends or social contacts.
Recreation	Assess whether her level of activity is adequate, and make concrete suggestions within her limitations for increasing it. Many women with a physically challenging condition lead a rather sedentary life (partly because they do not have many social contacts).
Self-esteem	Assess a woman's level of self-esteem: it may be low because of repeated failures in her life. Give praise at prenatal visits and help her make pregnancy a growth experience.

even moderately physically challenging conditions could not meet potential sexual or marriage partners and so did not become pregnant. In addition, most people believed these individuals should not become pregnant. Today, women with varying degrees of disability attend public schools, work in offices, join community organizations, establish sexual relationships, marry, and plan pregnancies just like everyone else. Urge women with a physical or cognitive disability or illness to come for preconceptual care so medicines they are taking can be evaluated and careful planning for safe pregnancy care can be started early (Thierry, 2007). Because these women (and in some instances also their support persons) face special problems related to their conditions, nursing care during pregnancy must be designed with these special concerns in mind so the woman's and her family's problems and needs can be addressed and met (Piotrowski & Snell, 2007).

Table 22.1 lists general areas of care that are important in planning for the physically or cognitively challenged woman who is pregnant.

Rights of the Physically or Cognitively Challenged Person

There are ethical and legal considerations related to women with disabilities and pregnancy. By federal law, physically disabled persons must have freedom of access to public buildings by means of ramps or handrails. All public health care facilities must be in compliance with these laws both in terms of physical facilities and in the true spirit of the law: that is, people should be made to feel psychologically welcome as well as physically able to reach the inside of the building. Under the same law, a hospital cannot deny care to a person with a disability even though the disabling condition complicates treatment considerably, possibly requiring extra personnel and time. A woman with a disability has full rights to her child, so the baby cannot be taken from her at birth without her full consent. Likewise, she cannot be forced to terminate a pregnancy or undergo sterilization unless that is her informed decision.

Modifications for Pregnancy

Explore with women at a first prenatal visit the exact nature of their disability and their general self-image to identify what modifications they may need in care during pregnancy. Some women who are physically or cognitively challenged maintain high self-esteem despite severe limitations and are able to modify, grow, and learn with a pregnancy, whereas others have a poor sense of self-esteem that will make this particularly difficult for them. For many of them, pregnancy will become a special event, a 9-month announcement to everyone that, despite their seeming limitations, they are equal to other women and capable of participating in one of life's miracles. If a woman is housebound, be certain that she is taking a prenatal vitamin containing vitamin D as she is probably not receiving as much sun exposure as usual (More, 2007).

Safety Measures to Explore

Safety is a key area of concern when caring for a pregnant woman who is physically or cognitively challenged. Be sure to assess areas such as emergency contact persons, suppliers of transportation, and individual considerations such as mobility, elimination, and possible autonomic responses. Be certain that a woman reviews any medicine she is taking for her primary condition with her primary care provider to be certain that this will continue to be safe during pregnancy. Women with recurrent seizures, for example, may need to have their dose of antiseizure medicine reduced during pregnancy because these may be teratogenic (Adab et al., 2009).

Emergency Contacts. Evaluate the client's ability to contact someone in case of pregnancy-related emergency. Does a woman have a telephone she can reach readily? Does she know how to activate the emergency medical system (911) in

her community? If a woman's speech is not clear, evaluate whether she will be understood while using a telephone to call for help in an emergency. Some women with limited mobility, such as those with spinal cord injury or cerebral palsy, have a specially designed telephone contact system in their home that connects to a paramedic or hospital emergency service through a beeper system. Check that they intend to maintain this throughout pregnancy. Women who are hearing challenged use a specially equipped telephone (a TDD device) that prints out messages for them.

Transportation. Assess a client's ability to come for prenatal care. If a woman depends on a support person for transportation to a health care facility, appointments may have to be arranged according to that person's schedule to prevent missed appointments. If a woman does not drive, who would transport her if a pregnancy emergency should occur? Women with cognitive or vision challenges, for example, may not qualify for a driver's license and so may need someone, such as a family member or friend, to drive. Women with spinal cord injury may have difficulty transferring into the specially equipped, hand-controlled car they usually drive as pregnancy progresses.

Mobility. All women who use wheelchairs are taught to press with their hands against the armrests and lift their buttocks up off the wheelchair seat for 5 seconds every hour. This prevents the formation of pressure ulcers on the buttocks and posterior thighs. Encourage a pregnant woman to continue to perform this maneuver during pregnancy as the increased weight of a fetus increases her risk for pressure ulcer formation from compression. In addition, severe hip flexion from sitting in a wheelchair limits venous return from the lower extremities. For at least 1 hour every morning and afternoon, encourage women who ambulate by wheelchair to decrease the sharp bend at their knees that results from sitting in the chair, to promote venous return and help prevent varicosities and thrombi formation. Adjusting the footrests of the wheelchair so a woman's legs are not sharply bent at the knees accomplishes this.

If balance is a problem, a woman may need re-evaluation at the midpoint of pregnancy as the weight of her abdomen increases. She may need to use crutches if she did not use them before, or use a wheelchair if she was ambulatory with crutches or a walker before pregnancy. Keep in mind that a woman who is physically challenged achieved the degree of ambulation that she first presents with usually after years of physical therapy and strengthening of leg and arm muscles. Help her see that reducing her degree of independence during pregnancy is not a step backward for her but a step forward, allowing her to have a safe pregnancy without the danger of falling (Fig. 22.3).

Elimination. When mobility is an effort, a woman may not drink as much as usual or use a bathroom as frequently as she would if those actions were effortless. Encourage a high fluid intake and frequent voiding, however, to prevent urinary tract infections. Women with spinal cord injury who use an indwelling catheter are at especially high risk for contracting urinary tract infections during pregnancy. Women who perform self-catheterization or change their own indwelling catheter may be unable to continue to do this late in pregnancy because the increasing size of their abdomen interferes with their ability to see or reach their perineum comfortably. If this happens, it may be necessary for a woman to arrange for a support person, a home care nurse, or a home health aide to do this for her.

FIGURE 22.3 During pregnancy, a woman who is physically challenged may need to use a wheelchair to help safeguard herself against injury. Assure her that she may still enjoy her independence and daily activities, such as caring for an older child. (© Keith/Custom Medical Stock Photograph.)

Autonomic Responses. In a woman who has a high spinal cord injury (cervical or high thoracic), observe for **autonomic dysreflexia** during pregnancy, labor, and the immediate postpartum period. This is an exaggerated autonomic response to stimuli. Any irritating condition, such as a distended bladder, increasing uterine size, labor contractions, or breastfeeding, may initiate the response (Smeltzer, 2007). Without upper motor neuron control to reverse the phenomenon, extreme symptoms such as severe hypertension (300/160 mm Hg), throbbing headache, flushing of the skin and profuse diaphoresis above the level of the spinal lesion, nausea, and bradycardia may occur. Immediate action is necessary to protect against cerebrovascular accident or intraocular damage. Elevate a woman's head to reduce cerebral pressure and locate the irritating stimulus (usually a distended bladder or bowel). If bladder distention is the cause, the woman needs bladder pressure relieved by catheterization if an indwelling catheter is not in place. If a catheter is in place, check to see why it is not draining, then encourage it to drain by unkinking or flushing to allow urine to flow freely again. Anticipate the need for an antihypertensive agent to alleviate the extreme hypertension, although as soon as the source of irritation is removed, symptoms typically fade quickly.

Prenatal Care Modifications to Meet Specific Needs

Physical examination may need to be modified depending on individual circumstances for women with disabilities (Richman, 2007). Although women with disabilities have been followed by health care providers most of their life, they may never have had a pelvic examination before and so need clear instructions about why it is needed and what it will consist of. Many obstetric examining tables are built for the comfort of the examiner and are too high for a woman to transfer to from a wheelchair by simply sliding onto the table.

To help a woman move to the table, a ramp from the physical therapy department may be necessary so the wheelchair can be elevated to the level of the table. Woman with spinal cord injury or cerebral palsy may be unable to maintain their legs in a lithotomy position because of either hip flexion contracture or laxness of leg support. This means a dorsal recumbent, rather than a lithotomy, position may be required for a pelvic examination.

Women who are cognitively challenged may not be aware how they became pregnant. If a woman became pregnant because she was taken advantage of sexually, she may need some time to talk and work through this experience before she can allow a pelvic examination.

If a visually challenged woman brings a guide dog with her to a health care visit, remember that although the dog's chief function is to offer direction, its instinct causes it to become a woman's protector. In this role, the dog may feel threatened by people who try to pet it. Petting a guide dog also distracts it from safeguarding its owner.

When interviewing or teaching visually challenged women, be certain not to use your hands to illustrate points ("I'll need a urine sample of at least this much urine [measured with your fingers]"). Do not use colors as descriptions of objects ("put on the blue gown"). Use demonstration aids that allow a woman to feel or touch instead. When helping with or performing physical assessment, let a woman know you are closing the door or drawing a curtain to ensure privacy. Always alert a woman when you are going to touch her, so as not to startle her. Otherwise, you may find yourself facing a growling guide dog that rises to protect her.

If a woman is hearing impaired, she may not be able to see the examiner's face during a pelvic examination. This means any question asked of her during this time will not be understood because she cannot see the examiner's lips to lip read (O'Hearn, 2007).

Pregnancy Education

Modify health teaching to meet each woman's specific needs. For a woman who is cognitively challenged, for example, instructions about pregnancy may need to be limited to those few items crucial for safety, such as "do not drink alcohol or take any medicine."

If a woman and her support person are both visually challenged, pamphlets about pregnancy care will not be useful. If the support person can see, offer the pamphlets to him or her, suggesting the support person read them to the pregnant woman as a shared activity. This will not only be helpful to her but also make the partner a more informed support person. Many visually challenged women have tape recorders supplied by Recording for the Blind and Dyslexic (http://www.rfbd.org), a national, nonprofit, voluntary organization. Call the local association and ask if they have any material already recorded on pregnancy or breastfeeding that they can supply. If not, make a tape recording of any information you particularly want a woman to remember or she seems concerned about. Supply the health care facility telephone number at the beginning of the tape for an easy reminder in an emergency, and perhaps the date of her next visit as well.

Nutritional education is another area that should be designed based on each client's specific challenges and usual routine. A visually challenged woman or one who ambulates by wheelchair, for example, may prepare her own breakfast and lunch, meals that do not require a stove. The one hot meal a woman eats is one a support person cooks in the evening. Nutrition counseling for two meals daily, therefore, needs to center on foods that can be prepared without cooking.

Activity and exercise, important for any pregnant woman, are crucial for a woman who is physically challenged. If mobility is a concern, exercise can be very reduced in bad weather. In this case, be sure a woman understands that walking around her home or apartment can provide the same level of exercise as if she were walking around the block or exercising at a health club.

Although labor and her child's birth may be modified somewhat because of a woman's physical condition, gaining general knowledge about labor and birth and participating in a shared experience with her partner are still valuable. Urge women to attend childbirth preparation classes if at all possible. If a woman is not working outside her home, she may have more time than others to practice breathing exercises and enter labor more adept at using such a method to control pain in labor than other women.

If a woman is severely hearing challenged, she may not have heard the many spot television announcements on not smoking or drinking alcohol during pregnancy; she may need more time at prenatal visits so this can be discussed. In addition, lip reading is a difficult skill to learn, so many hearing-challenged persons cannot do this with ease. Even if a woman is skilled at this, she may not be able to decipher new words such as amniotic, gestation, or edema. Show her the printed words so she can see what your lip motion represents when presenting new pregnancy terms. If a woman uses sign language, she may bring an interpreter with her to translate. Be certain to talk to her, not the interpreter, when interviewing.

Modifications for Labor and Birth

Women who are physically or cognitively challenged will need adaptations in preparation for labor and birth. Helpful suggestions are:

- A woman with a spinal cord injury may not be able to feel uterine contractions. Late in pregnancy, she will need to palpate her abdomen periodically for tightening or the presence of contractions so she is aware of beginning labor.
- Women with muscle spasticity or spinal cord injury may not be able to push effectively for the second stage of labor and so may need cesarean or forceps birth.
- If a woman cannot assume a lithotomy position because of hip contracture, vaginal delivery from a Sims' or dorsal recumbent position is best.
- Braille watches used by visually challenged persons may not have second hands. They may need to time the length of contractions by counting rather than timing them by a watch.
- During labor, the hearing-challenged woman cannot hear information on how she is progressing if you are not directly facing her. If she needs to communicate with her support person in sign language, act as an advocate to keep her hands unencumbered by equipment such as intravenous lines. Remember she cannot hear her infant cry at birth. Hand the infant to her as soon as possible after birth so she can see and feel the baby is crying and breathing well.

- Be certain to identify the usual sounds of birthing rooms (the beeping of a monitor, the swish of a central supply routing system, and so forth) for the visually challenged woman. Hearing sounds and not being able to identify them can be frightening.

Modifications for Postpartum Care

After birth, be sure to assess and teach:

- Whether a woman desires contraceptive information.
- Whether she needs additional support to be successful at breastfeeding.
- Whether she has a return appointment for both herself and her infant for follow-up care and that the arrangements are within her capabilities, transportation, and understanding.

Women with disabilities generally feel a need to space pregnancies so be certain that they receive information on their contraceptive choices as these may be different than for nonhandicapped women (Frost & Darroch, 2008). A woman with poor hand control, for example, might not be able to effectively insert a diaphragm; a woman who is cognitively challenged might not understand the importance of taking an oral contraceptive every day.

Modifications for Planning Child Care

Allow for extra time during the first days after birth for mother–child interaction. For example, after birth, a woman who is cognitively challenged may need extra time to understand the transition from "being pregnant" to "having a baby." She may have difficulty learning to judge when her infant is hungry. She may need extra supervision to be certain she does not leave the baby unprotected on a bed. A woman with a spinal cord disability may be particularly interested in inspecting her baby's back. A visually challenged woman will probably want to reassure herself her baby can see. Be sure to give her baby to her as soon as possible after birth so she can touch the baby and feel for intact body parts. If the birthing room is cold, explain to her that you want to rewrap the baby to prevent chilling, not because her touching is wrong or because you are trying to hide an imperfection in the baby.

Breastfeeding has special advantages for women who are physically or cognitively challenged because it is the method of feeding that is not only best for the baby, but also requires the least preparation effort on the mother's part. For a woman who is visually challenged and unable to read printed instructions, breastfeeding eliminates formula errors. For a woman who uses a wheelchair, it eliminates trips to the refrigerator. However, breastfeeding may not be possible for a woman with muscle spasticity because the let-down reflex, which depends on muscle relaxation, may not occur. Be certain that women who are cognitively challenged understand they need to feed until the infant is satisfied, not until they are tired of feeding.

Encourage women to think through what baby care equipment will be best for them. Some infant crib rails lower by pressure on a foot pedal. Others use a waist-high lever. A woman who ambulates by wheelchair usually finds the waist-high lever most convenient because she can reach this most easily. Some women will need a referral for home care follow-up and possibly the use of a home health aide to ensure safe child care.

If a woman has difficulty with mobility, ask how she anticipates carrying her infant. Using an anterior baby sling is usually effective with a wheelchair. Women who are mobile by crutches or a walker can place the baby in a small wagon and pull it. Some women lie on their back on the floor, place the baby on their chest, and scoot across the floor. The important point is not how a woman carries her baby but that she has thought through a safe and comfortable way to do this.

Urge a visually challenged woman to make eye contact when talking to her infant. Many visually challenged people do not turn on lights in their home because they do not perceive the difference between light and dark. Encourage a woman to develop a habit of turning on lights after dinner because her infant will need light to develop vision. If her support person also is visually challenged, suggest she check with a close friend or neighbor monthly to see that light bulbs have not burned out.

One of the biggest worries for the hearing-impaired woman is that she will not be able to hear her baby crying. Help her plan to bring the infant's crib or bassinet close to her bed so she can feel the vibration of the baby's stirring and waking. Urge her to talk to her infant as she gives care so the infant is introduced to sounds and words. Some women whose speech is severely affected by their hearing disorder are reluctant to speak to strangers. Assure her that her infant is not a stranger and will quiet readily to the sound of her voice. The child may develop her speech pattern because of this. Being spoken to and sung to during the first year is important for overall development, however, so this is still preferable to living in a world of silence.

Some women who are cognitively challenged may have been raised in a group home and only recently moved to their own apartment. Unlike those raised at home, these women may have unusual difficulty making plans for child care because they have never seen the care of young children. You have a legal obligation to investigate whether a newborn will receive safe care before hospital discharge. Be certain to ask enough questions so that you are sure a woman who is severely cognitively challenged, for example, has a responsible friend or partner to help her with child care.

✔ Checkpoint Question 22.4

Women with high thoracic spinal cord injury can develop autonomic dysreflexia during labor. The best action to take for this would be:

a. Ask her to lie flat and take deep breaths.
b. Elevate her legs to restore her blood pressure.
c. Give a prescribed hypotensive medicine.
d. Talk to her calmly to reduce her anxiety.

A WOMAN WHO IS SUBSTANCE DEPENDENT

Substance dependence is a growing health problem in women of childbearing age, so its incidence during pregnancy is increasing. As many as 10% to 20% of pregnant women use illegal drugs during pregnancy (NCHS, 2009). The use of cocaine, amphetamines, and multiple drugs has increased dramatically in recent years. Adolescents have an increased rate of inhalant abuse and binge drinking.

Substance abuse is defined as the inability to meet major role obligations, an increase in legal problems or risk-taking behavior, or exposure to hazardous situations because of an addicting substance. A person is **substance dependent** when he or she has withdrawal symptoms following discontinuation of the substance, combined with abandonment of important activities, spending increased time in activities related to substance use, using substances for a longer time than planned, or continued use despite worsening problems because of substance use.

Typically, substance-dependent women are thought to be in the younger age group, as the overall incidence of drug use is highest in this group. However, any woman could be substance dependent so all pregnant women need to be assessed for the possibility of this.

A mark of a woman with a substance abuse problem is that she may come late in the pregnancy for prenatal care because she is afraid her drug use will be discovered and she will be reported to authorities. If she is using a drug that sustains her for only a few hours, she cannot wait long at a health care facility to be seen for an appointment. She may have difficulty following prenatal instructions for proper nutrition because although she may desire to eat well, she may lack sufficient money to buy both drugs and nutritious food, and choosing drugs over food makes her nutrition inadequate. She may not have money for supplemental vitamins or iron preparations for the same reason.

Illicit drugs tend to be of small molecular weight, so they readily cross the placenta. As a result, a fetus of an addicted mother has a drug concentration of about 50% that of the mother. Because this can lead to fetal effects, drug abuse can account for fetal abnormalities or preterm birth (Dew, 2007). If a woman uses injected drugs, the risk for hepatitis B or human immunodeficiency virus (HIV) infection increases. Additionally, a woman may earn money to buy drugs through prostitution, which increases the risk for sexually transmitted infection and poses an additional threat to a fetus.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for injury to self and fetus related to chronic substance abuse

Outcome Evaluation: Client states she has enrolled in a substance abuse treatment program and consequently has reduced or is no longer abusing drugs.

Women who are substance dependent need anticipatory guidance and nursing support all during pregnancy, as this is a long time to change and then maintain a new lifestyle. Often, women who abuse substances have few effective support people with whom they feel free to discuss their problems or concerns or who can answer their questions about pregnancy. Because of their numerous needs, they require a multidisciplinary team approach not only from pregnancy health care providers but substance abuse treatment providers as well. Fortunately, with good support and active participation in a treatment program, pregnancy can become a stimulus for drug withdrawal and a maturing and growth experience for a woman.

If a woman is still abusing a drug by the time she begins labor, her infant may experience drug withdrawal symptoms after birth (usually nervousness, irritability or lethargy, and possibly seizures; see Chapter 26). Breastfeeding is usually not encouraged for women with substance abuse because just as all drugs cross the placenta to some extent, they also are all excreted into breast milk. Women receiving methadone as part of their drug treatment can breastfeed as only a small amount of this drug is excreted in breast milk (Jansson et al., 2008). In some states, women who test positive for drug abuse, either during pregnancy or at the time of birth, are reported to state child protective agencies; they may be accused of child abuse and jailed, and their infant may be placed in foster care. Be certain you are familiar with agency and state policy concerning these directives (Wright & Walker, 2007).

What if... Mindy Carson tells you she is not using drugs during pregnancy, but when she opens her purse, you notice several packets of white powder inside? What would you do?

Common Substances Abused During Pregnancy

Recreational drugs commonly used in pregnancy are those commonly used by women in their childbearing years: cocaine, amphetamines, marijuana, phencyclidine, inhalants, opiates, and alcohol.

Cocaine

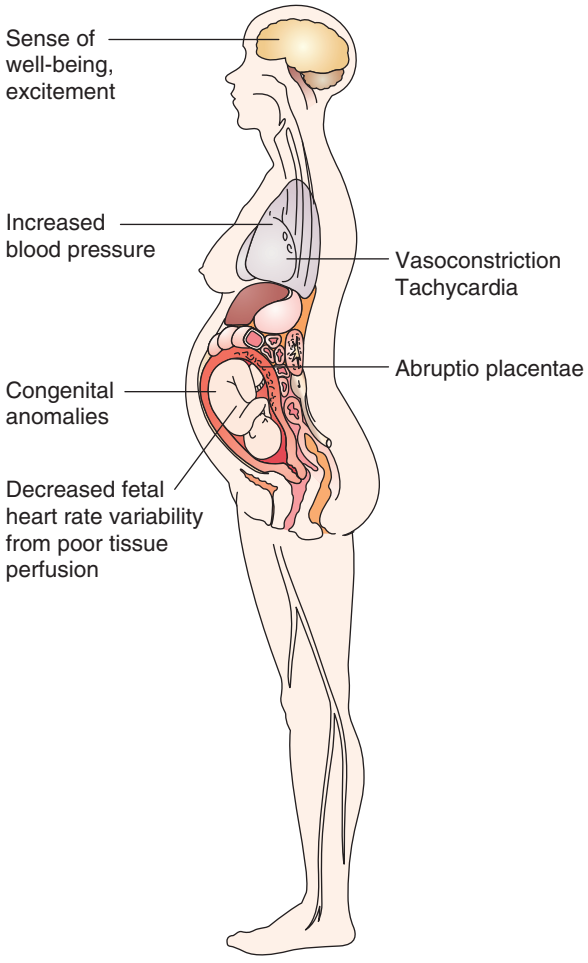
Cocaine is derived from *Erythroxylum coca,* a plant grown almost exclusively in South America. When sniffed into the nose or smoked in a pipe, cocaine is absorbed across the mucous membranes to affect the central nervous system. As a result, sudden vasoconstriction occurs. Respiratory and cardiac rates and blood pressure increase rapidly in response to the vasoconstriction. Immediate death may result from cardiac failure. Alkaloidal cocaine (crack), a concentrated mixture, produces an even more rapid and intense "high" when inhaled.

Cocaine has become one of the most frequently abused drugs during pregnancy, and its use is exceptionally harmful during pregnancy because the extreme vasoconstriction that occurs can severely compromise placental circulation, leading to premature separation of the placenta, which then results in preterm labor or fetal death (Box 22.7). Infants born to cocaine-dependent women may suffer the immediate effects of intracranial hemorrhage and a withdrawal syndrome of tremulousness, irritability, and muscle rigidity. Long-term effects are not well documented, but learning defects are suspected (Accornero et al., 2007).

Counseling women to discontinue cocaine use during pregnancy is often disappointing. The effects of the drug are so intense that it is difficult for addicted women to withdraw. Cocaine use can be detected by urinalysis because the metabolites of cocaine can be detected in urine up to 1 week after use.

Box 22.7 Assessment

Assessing the Pregnant Cocaine-Abusing Woman



Amphetamines

Methamphetamine (speed) has a pharmacologic effect similar to cocaine. Its use is becoming more common because it is easily and cheaply manufactured (Wu, 2007). Ice, a rock type of methamphetamine that is smoked, can produce high concentrations of drug in the maternal circulation. Newborns whose mothers used the drug show jitteriness and poor feeding at birth and may be growth restricted.

Marijuana and Hashish

Both marijuana and hashish are obtained from the hemp plant, cannabis. When smoked, they produce tachycardia and a sense of well-being. Although not advised, some women use marijuana to counteract nausea in early pregnancy. These drugs are frequently part of polydrug abuse, so their effects on fetal development are not well documented (Bernstein & Weinstein, 2007). They are associated with loss of short-term memory and an increased incidence of respiratory infection in adults. A frequent user may not be able to breastfeed because of reduced milk production and the risk to the newborn from excretion of the drug in the milk.

Phencyclidine

Phencyclidine (PCP) is an animal tranquilizer that is a frequently used street drug in polydrug abuse. It causes increased cardiac output and a sense of euphoria. It has the potential for causing long-term hallucinations (flashback episodes). PCP tends to leave the maternal circulation and concentrate in fetal cells, so it may be particularly injurious to a fetus.

Narcotic Agonists

Narcotic agonists, used for the treatment of pain (e.g., morphine or meperidine [Demerol]) and cough suppression (codeine), are also widely abused because of their potent analgesic and euphoric effect. Heroin, a raw opiate, is the main opiate used recreationally to the point of dependence, and its use is increasing in incidence in young adults. A short-acting narcotic, heroin is inactive until it crosses the blood–brain barrier (which it does more quickly than morphine). It may be administered intradermally ("skin popping"), through inhalation ("snorting"), or intravenously ("shooting"). It produces an immediate and short-lived feeling of euphoria followed by sedation. Pregnancy complications related to its use include pregnancy-induced hypertension and, because narcotics are often injected with shared needles, phlebitis, subacute bacterial endocarditis, and hepatitis B and HIV infection.

Withdrawal symptoms include nausea, vomiting, diarrhea, abdominal pain, hypertension, restlessness, shivering, insomnia, body aches, and muscle jerks. Withdrawal symptoms may begin as soon as 6 hours after the last drug dose and can continue for several days. Their severity and duration depend on the amount of drug used daily and the length of the dependence period.

Heroin abuse in the pregnant woman can result in fetal opiate dependence and severe withdrawal symptoms in the infant after birth. Infants of opiate-abusing women tend to be small for gestational age and have an increased incidence of fetal distress and meconium aspiration. They will have the same withdrawal symptoms after birth as the mother would if she abruptly stopped taking the drug.

Because the fetus is exposed to drugs that must be processed by the liver during pregnancy, the fetal liver is forced to mature faster than normally. For this reason, newborns of substance-abusing women seem better able to cope with bilirubin at birth than other babies; hyperbilirubinemia is therefore rarely a problem. Fetal lung tissue also appears to mature more rapidly than usual, apparently from the stress of the intrauterine drug exposure. Therefore, although an infant is born preterm, the chance that he or she will develop a condition such as respiratory distress syndrome is less than average.

If possible, an opiate-dependent woman should be enrolled in a methadone maintenance program during pregnancy (Goff & O'Connor, 2007). As this is an analgesic, women receiving methadone may need stronger prescriptions for pain relief in labor or postpartum than others (Meyer et al., 2007). Infants of women taking methadone do not escape withdrawal symptoms at birth, and some infants appear to have more severe reactions to methadone withdrawal than to heroin withdrawal. Because a woman is being provided an oral drug legally, however, a fetus is at least ensured better

nutrition, better prenatal care, and less exposure to pathogens such as hepatitis B and HIV. If a methadone program is not available, women may be treated with buprenorphine. Suboxone is a combination of naloxone and buprenorphine, an analgesic similar to morphine in action (Mattick et al., 2009). Drug withdrawal symptoms for this in the newborn and accompanying nursing care are discussed in Chapter 26.

Inhalants

Inhalant abuse refers to the "sniffing" or "huffing" of aerosol drugs. Frequently abused substances include airplane glue, cooking sprays, and computer keyboard cleaner. Most of these substances contain freon as a propellant and can lead to severe respiratory and cardiac irregularities. The effect of these drugs during pregnancy is not well documented, but they appear to have effects similar to alcohol abuse (Elias, Chun-Hui Tsai, & Manchester, 2008). The respiratory depression they can cause could be enough to limit the fetal oxygen supply to a serious level.

Alcohol

Although alcohol can be legally purchased and is served generously at social functions, it is just as detrimental to fetal growth as illegal drugs. Excessive use tends to occur in women with impulsive personalities (Magnusson, Goransson, & Heilig, 2007). There is little documentation regarding how much alcohol must be ingested before fetal alcohol syndrome, a syndrome with significant facial features, possible cognitive challenges and memory deficits, occurs, so women are advised to drink no alcohol during pregnancy (Crombleholme, 2009). When discussing alcohol ingestion with young adults, be certain to talk about binge drinking (five or more alcohol drinks on one occasion) to be certain a woman does not believe this type of occasional drinking is safe during pregnancy.

✔ Checkpoint Question 22.5

Mindy Carson tells you she takes methamphetamine almost daily. A fetus of a drug-addicted mother receives approximately what percentage of the mother's drug concentration?

a. 20%.
b. 50%.
c. 70%.
d. 100%.

TRAUMA AND PREGNANCY

Trauma (injury by force) is a phenomenon that seems remote from pregnancy because pregnant women usually take extra safety precautions to protect their body. However, trauma in women occurs at a high incidence during the childbearing years because, for this age group, automobile accidents, homicide, and suicide are among the leading causes of death. During pregnancy, the incidence of trauma is 6% to 7% (as many as 250,000 pregnant women experience trauma per year). A high incidence occurs during the last trimester because of poor balance and fainting from hyperventilation. Orthopedic injuries such as broken wrists or sprained ankles occur because a pregnant woman's sense of balance is altered (Box 22.8). In an automobile accident, a pregnant woman is often the front-seat passenger, and this is the passenger who, in an accident, often receives the most severe injury. Other women seen in emergency departments have suffered intimate partner abuse (Rodrigues, Rocha, & Barros, 2008).

BOX 22.8 ✻ Focus on Evidence-Based Practice

What are the most common types of injuries seen in pregnant women?

Women become high risk for tripping and falling in late pregnancy because their balance becomes unstable. They also can be so busy reworking pregnancy tasks that they are responsible for automobile accidents. To investigate what are the common types of injuries which occur, nurse researchers analyzed the records of 100,051 women seen for injuries during pregnancy. Overall, of the 100,000 women, one in seven sought hospital care for pregnancy-associated injuries at some point in pregnancy, and rates were as high as one in four for some subgroups. Most women (91%) were seen in emergency departments.

More than 4% of women had a motor vehicle collision, the leading cause of injury. The risk for injury was significantly higher among women who were adolescents, black non-Hispanic, and those who had less than a high school education than with other groups. The researchers recommend that preparation for childbirth classes include information on accident prevention.

Would the above study be helpful to mention when discussing accident prevention with pregnant women?

Source: Nannini, A., et al. (2008). Injury: a major cause of pregnancy-associated morbidity in Massachusetts. *Journal of Midwifery and Women's Health, 53*(1), 3–10.

Preventing Accidents

Accidents occur more frequently in people under stress than in those with little stress in their lives because, under stress, people concentrate on the stressor, not their immediate surroundings. Because pregnancy is a life event that may cause stress in a family's life, a woman and her family should take extra precautions for safety during this time. Pregnancy counseling should include education about ways to avoid accidents and trauma such as automobile seat belt use (Pavone & Hueppchen, 2007) (Box 22.9).

Physiologic Changes in Pregnancy That Affect Trauma Care

In an emergency situation, for physical assessment to be meaningful you must consider the physiologic changes that normally occur with pregnancy. A primary rule to remember is that after a traumatic injury, a woman's body will maintain her own homeostasis at the expense of the fetus. To maintain blood pressure in the face of hemorrhage, for example, a woman's body will use peripheral vasoconstriction. As the uterus is a peripheral organ in a shock response, the blood supply to the uterus can be greatly diminished and

BOX 22.9 ✻ Focus on Family Teaching

Preventive Measures to Reduce Accidents During Pregnancy

Q. Mindy tells you, "I feel so clumsy since I'm pregnant. What can I do to make sure I don't hurt my baby?"

A. To help reduce your risk for accidental injury during pregnancy, follow these guidelines:

- Do not stand on stepstools or stepladders (it is difficult to maintain balance on a narrow base).
- Keep small items such as footstools out of pathways (a pregnant woman has difficulty seeing her feet).
- Avoid throw rugs without a nonskid backing.
- Use caution stepping in and out of a bathtub.
- Do not overload electrical circuits (it is difficult for a pregnant woman to escape a fire because of poor mobility).
- Do not smoke, so falling asleep with a cigarette will not be a problem.
- Do not take medicine in the dark, so you can clearly read the label.
- Avoid working to a point of fatigue, because this lowers judgment.
- Avoid long periods of standing, because this can lead to a drop in your blood pressure, causing you to feel dizzy and faint.
- Always use a seat belt while driving or as a passenger in an automobile.
- Refuse to ride with anyone in an automobile who has been drinking alcohol or whose judgment might be impaired.

the nutrient supply to the fetus greatly compromised (see Fig. 21.1, Chapter 21).

A woman's total plasma volume increases during pregnancy from approximately 2600 mL to 4000 mL at term. This increase serves as a safeguard to a woman if trauma with bleeding should occur because a woman can lose more blood than normally (up to 30% of her blood volume) before hypovolemia is clinically evident. This also means, however, that fluid replacement volume will undoubtedly have to be higher because a pregnant woman needs more fluid than a nonpregnant woman to restore her circulatory volume. Central venous pressure (normal is 0 to 5 cm H_2O in a nonpregnant state) is increased to 2 to 7 cm H_2O. Although a woman needs a large amount of replacement fluid, this means her circulation can also be overwhelmed more easily than normal by intravenous fluid infusion.

To accommodate the increased vascular load of pregnancy, cardiac output increases from 1 L/min early in pregnancy to 6 to 7 L/min in the second trimester. This volume circulates through the placenta at a rapid rate: approximately one-sixth of the total blood volume is present in the placenta at all times. This fact makes a uterine laceration always potentially serious, because up to one-sixth of blood volume can be quickly lost.

To move this increased blood volume adequately through the circulation, a woman's heart rate increases 15 to 20 beats above normal, so a pulse rate of 80 to 95 is not unusual. Based on this, following an accident during pregnancy, do not assume a rapid pulse rate indicates hemorrhage. In addition, since the heart is displaced by the elevated diaphragm, an electrocardiogram taken after an accident will show a left-axis deviation or the pattern may look distorted from the usual while this is normal during pregnancy.

Peripheral venous pressure in the pregnant woman is unchanged. However, it tends to be higher in the lower extremities because of compression by the uterus on the vena cava that causes back-pressure. As a result, lacerations of the legs or perineum bleed much more profusely than usual. Peripheral blood flow in general is increased because of decreased peripheral vascular resistance (the effect of estrogen and decreased sympathetic activity all through pregnancy). As a result, the pregnant woman can be in severe shock, yet her extremities will still not feel cold and clammy.

During pregnancy, the leukocyte count rises (to 20,000 mm^3 at term), so using this measure as a sign of infection after an open wound is problematic. The serum albumin level decreases during pregnancy, making the large loss that normally occurs with burns a more serious response than usual. Serum liver enzyme levels (i.e., serum glutamic-oxaloacetic transaminase, serum glutamate pyruvate transaminase, and lactate dehydrogenase) remain the same during pregnancy. This means, if these are elevated after trauma, liver trauma can still be detected. Since levels of alkaline phosphatase, a substance also usually helpful in detecting liver trauma, are three to four times greater in the pregnant woman at term than normally (from placental origin), this marker loses its importance. Pancreatic amylase levels remain unchanged during pregnancy, so the pancreas can be evaluated as usual.

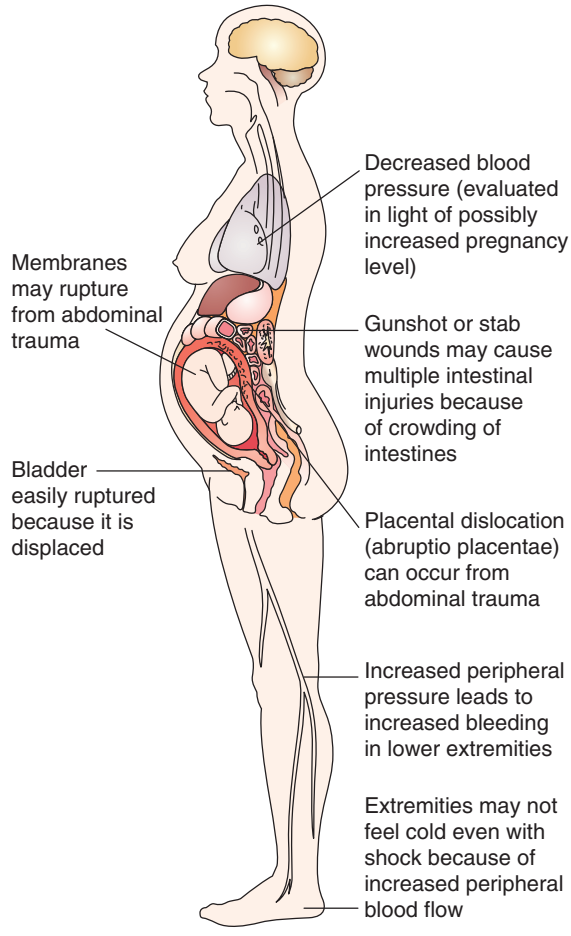
Abdominal pain is difficult to localize during pregnancy because organs are pushed aside by the growing uterus. The abdomen often feels tense during pregnancy, so the important findings of guarding and rigidity of the abdominal wall may be lost. Bleeding into the abdominal cavity with an abdominal injury is apt to be forceful and extreme because of the increased pressure in the pelvic vessels. A procedure such as a needle paracentesis to assess for bleeding into the abdominal cavity is potentially dangerous because the bowel, dislocated from its usual position, can be easily punctured. Culdocentesis, or needle aspiration through the posterior vaginal fornix into the peritoneal cavity, may be done instead. Peritoneal lavage (the process of inserting a peritoneal dialysis catheter into the abdominal cavity, adding a quantity of an isotonic solution, aspirating it again, and analyzing it for blood or urine) may reveal bleeding or bladder rupture best.

The bladder of a pregnant woman is extremely susceptible to rupture because it is the most anterior organ and is elevated abnormally. After abdominal trauma, an indwelling bladder catheter is often inserted to assess for blood in the urine (Box 22.10).

Psychosocial Considerations

When a pregnant woman is seen at a health care facility after an accident, she is apt to be apprehensive and frightened, both for herself and for her fetus. She is worried not only about what has happened but also about what could have

Box 22.10 Assessment
Assessing the Effects of Trauma in the Pregnant Woman



happened (if the knife had slipped an inch farther, if the automobile had been moving faster, if she had fallen from further up the stepladder) and about what medical care will be required (Does she need a radiograph? If she does, will this be safe for the fetus?). She may feel guilty about her carelessness (if she were really a good mother, she would have had her seat belt fastened or would not have tried to stand on a stepladder to hang drapes alone). A feeling of guilt lowers her self-esteem and can increase her level of stress. Remember, people under stress do not process information well and may not perceive correctly the information given to them. Always try to review information with a woman before discharge from an emergency department to be certain she has the facts of her injury and understands the follow-up care necessary.

Assessment

Assessment of an injured pregnant woman must be done quickly yet thoroughly and should include both her psychological and physical status. A pregnant woman may be so concerned with her fetus' health that she does not realize she is injured. Another woman might not even consider the possibility that her fetus could be injured until someone asks if she has felt the fetus move since the accident (not realizing that a loss of blood from her leg would affect uterine blood flow). Assessment, therefore, should be done concurrently with supportive reassurance ("Your blood pressure is low, but the fetal heartbeat sounds good") to try to relieve her fear of fetal damage. Use a Doppler to assess fetal heart tones if possible to demonstrate to a woman as well as yourself that the fetus still appears to be well. External monitoring of fetal heart rate and uterine contractions best rules out fetal distress and preterm labor.

In an emergency situation, a woman needs her support people around her. Locate them as necessary and also assess their reaction to the trauma.

Health History

In an emergency situation, a few minutes spent attempting to calm a woman and move her past her initial fright is time well spent unless symptoms of major body system disturbances require immediate efforts to be directed elsewhere. Reducing a woman's level of anxiety can enhance her ability to cooperate with the history and physical assessment.

Take a brief pregnancy history as well as a trauma history (i.e., length of pregnancy or any complications). Ask specifically if fetal heart tones have been heard by an examiner during the pregnancy, if she has felt the fetus move since the accident, if she has any sensation of tightening or pain in her abdomen or back that could be uterine contractions, and if she knows what her prepregnancy and pregnancy blood pressures have been to help evaluate the extent of blood loss from the trauma.

Document the circumstances of the trauma: what happened, the time of the injury, signs and symptoms of injury she is experiencing, and actions she has taken to counteract these.

If a woman fell, for example, how far did she fall? (A fall from the top of a stepladder is more likely to be serious than a fall from a low rung.) What body part did she land on? (Landing on her abdomen may be very serious, although she may be in less pain than if she injured a wrist in the fall.) For an automobile accident, ask how fast the car was traveling, if she was thrown from the car, or if the windshield broke (generally in automobile accidents, windshields are broken from the impact of a head striking the windshield; a woman will need to be assessed for a head injury).

As a final measure, evaluate whether a woman's degree of injury is in proportion to the history. Injuries out of proportion to the history (a woman states she tripped on her front steps, but you notice all her extremities are ecchymotic and her jaw is broken) suggest intimate partner abuse rather than a simple accident (Records, 2007). It is important to identify such women as they can have an increased incidence of postpartal depression and perhaps an increased risk of wanting to harm themselves (Tiwari et al., 2008). See Chapter 55 for care of an abused woman. Analyze also whether a woman seemed to be using a sensible degree of caution for the circumstances. If not, assess her awareness of common safety measures. In rare situations, this may reveal a woman who self-inflicted an injury in an attempt to end an unwanted pregnancy. A naive adolescent, for example, may attempt to end a pregnancy by a deliberate fall or poisoning, which she then reports as an accident.

Physical Examination

Accidents become fatal when lung, heart, kidney, or brain function becomes inadequate; fetal health is in jeopardy when uteroplacental function is impaired. Following trauma, therefore, it is important to evaluate these body systems first (Table 22.2). All women who receive a blow to their abdomen need to be evaluated for complications such as premature separation of the placenta, although the incidence of this occurring is actually small (Cahill et al., 2008).

With multiple trauma, a nasogastric tube is usually passed to empty the stomach. A Foley catheter is inserted to assess urine output and to rule out a ruptured bladder (blood would return or urine would be blood-tinged if bleeding were occurring).

To prevent supine hypotension syndrome, be certain a woman does not lie supine for an examination. If she must lie on her back, manually displace the uterus from the vena cava by placing a rolled towel or blanket under her right side to tip her body approximately 15 degrees to the side. If surgery is necessary, the operating room table can be tipped to achieve this same effect.

TABLE 22.2 ✻ Initial Assessments After Trauma During Pregnancy

Body System	Assessment
Respiratory system	Quality of respirations (labored or even?)
	Rate of respirations
	Sounds of obstruction (wheezing, retractions, coughing?)
	Color (cyanotic?)
	Oxygen hunger (inability to lie flat, nasal flaring?)
Cardiovascular system	Color (pallor from hemorrhage?)
	Gross bleeding
	Pulse rate (increases with hemorrhage)
	Blood pressure (decreases with hemorrhage)
	Feeling of apprehension from altered vascular pressure?
Nervous system	Level of consciousness (woman answers questions coherently?)
	Pupils (equal and reacting to light?)
	Bruises or bump on head or spinal column
	Loss of motion or sensory function in a body part
Renal system	Bruising on anterior abdominal wall over bladder or on back over kidneys
	Blood in urine
Uterine-fetal system	Bradycardia, tachycardia, or absence of fetal heart tones or loss of variability on fetal monitor
	Vaginal bleeding
	Clear (amniotic) fluid leaking from vagina
	Bruising on abdomen over uterus

Nursing Diagnoses and Related Interventions ✻

Planning in an emergency always involves two phases: planning for immediate care to stabilize the woman and planning for ongoing care to bring her back to wellness. Nursing care during the initial phase of an emergency focuses on stabilizing a woman's body systems and protecting the fetus. Examples of nursing diagnoses that would be appropriate are:

- Fear related to threat of injury to the fetus
- Risk for fetal injury related to apparent suicide attempt
- Ineffective tissue perfusion related to severed artery
- Ineffective breathing pattern related to lung lacerated by gunshot wound

Once the immediate emergency phase has passed, nursing diagnoses focus on preventing additional injury or alleviating emotional distress. Examples are:

- Risk for infection related to loss of skin integrity from knife wound
- Situational low self-esteem related to occurrence of accident
- Powerlessness related to seriousness of the injury sustained or inability to prevent accident from occurring

Therapeutic Management

Implementations in emergency situations must be done quickly yet it must always be remembered that a woman's primary health condition is that she is pregnant. If respirations are not present or are ineffective, cardiopulmonary resuscitation (CPR) should begin, the same as with any person (see Box 20.3, Chapter 20). To be certain a woman has not just fainted, try to rouse her by calling her name or shaking her shoulders. If she does not respond, assess whether her airway is obstructed by holding your cheek next to her nostrils and assessing for air exchange. Look in her mouth for a foreign object. If she is not breathing, pull her chin forward and, using a resuscitation bag, administer two breaths. Although an enlarged uterus puts considerable pressure on the diaphragm and consequently the lungs, only normal pressure is necessary to inflate the lungs fully in a resuscitation attempt. Assess cardiovascular function by palpating the carotid pulse. If this is not palpable or the pupils are fixed, heart function must also be supplemented. Begin external heart massage at a rate of two breaths to every 15 heart compressions (one rescuer) or one breath to every 5 heart compressions for two rescuers (the same as for all adults). Cardiac massage may be awkward late in pregnancy because of the size of the uterus, but undue pressure should not be necessary to create heart action. Cardioversion is done according to usual agency protocol.

After assessment of the level of consciousness and cardiovascular and respiratory status, if there has been blood loss, a central line may be inserted and lactated Ringer's or another isotonic solution infused to restore fluid volume or provide an open line for emergency medication.

If hypotension is present, it must be corrected quickly to maintain a pressure gradient across the placenta. However, any antihypotensive agent that achieves increased blood pressure by causing peripheral vasoconstriction is contraindicated (vessels in the uterus would constrict and cut off the fetal blood supply). Ephedrine is the drug of choice with a pregnant woman to restore blood pressure in an emergency situation because it has a minimal peripheral vasoconstrictive effect. Dopamine in low doses is a second drug that can be used. After emergency interventions, care depends on the specific injury or trauma present.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for ineffective tissue perfusion related to blood loss from trauma

Outcome Evaluation: Client's blood pressure remains above 100/60 mm Hg; pulse below 100 beats per minute; no signs of labor are present; fetal heart rate is 120 to 160 beats per minute; nonstress test shows good variability.

Open Wounds

Several types of open wounds occur with trauma. Because the white blood cell count is normally elevated during pregnancy, a single count is a poor indicator of the presence or extent of infection in wounds. However, serial measurements can be used to assess if infection is occurring.

Lacerations. A laceration (a jagged cut) may involve only the skin layer or may penetrate to deeper subcutaneous tissue or tendons. Lacerations generally bleed profusely. Halt bleeding by putting pressure on the edges of the laceration (this is difficult to achieve in the lower extremities because venous pressure is greatly increased in pregnancy). After cleaning, the area is sutured through each layer of tissue involved to approximate the edges. For sutures to be used, a local anesthetic such as lidocaine (Xylocaine) is necessary. Because this has only a local effect, it is safe to use during pregnancy. If the laceration is superficial and a woman is nervous about the use of an anesthetic, the edges can be approximated with a butterfly strip. This will allow it to heal, although with a slightly more noticeable scar.

Puncture Wounds. A puncture wound results from penetration of a sharp object such as a nail, splinter, nail file, or knife. Puncture wounds bleed little—an advantage in terms of minimizing blood loss but not in terms of wound cleaning. A puncture wound is usually not sutured because suturing would create a sealed, unoxygenated cavity below the sutures with a space where tetanus bacilli could grow. If a woman has had a tetanus immunization within the past 10 years, tetanus toxoid is administered. If a woman has not had a tetanus immunization within 10 years (the usual condition), tetanus toxoid plus immune tetanus globulin are administered. These are both safe to administer during pregnancy.

Puncture wounds are frightening because the average woman knows they can cause internal harm. Stab wounds usually occur with the added association of violence.

Knife wounds cause deep penetration and are often directed into the abdomen. They may easily reach the depth of the uterus, possibly directly cutting the fetus. Most stab wounds of the abdomen, however, occur in the upper quadrants of the abdomen, above the uterus, and are more apt to strike the liver or pancreas. To determine the depth and extent of a wound, a fistulogram may be done. This involves inserting a thin catheter into the wound; the wound is then filled with a radiopaque solution. A radiograph of the area filled by the solution reveals the extent of the puncture. If the peritoneal cavity was perforated, dye will outline the intestines. If there is a suspicion of bleeding into the abdominal cavity, a celiotomy or an exploratory surgical procedure into the abdominal cavity may be performed. Surgery this close to the uterus usually does not result in disruption of the pregnancy. If the diaphragm was cut, the intestines may herniate into the chest cavity (diaphragmatic hernia) because of the increased abdominal pressure from the enlarged uterus, causing acute shortness of breath. After surgical repair of an injured diaphragm, cesarean birth may be planned to avoid strain on the newly repaired diaphragm during labor. The uterus appears to have a natural resistance to infection, so even if it is punctured, infection in the uterus rarely occurs.

Animal or Snake Bites. Pregnant women are occasionally bitten by venomous snakes but rarely are bitten by any animal but a dog. Animal bites produce a form of puncture wound, so if the rabies immunization status of the dog is known, the wound is washed and treated as a puncture wound. If the dog cannot be located or is proved to be rabid after 48 hours of observation, a woman must be administered rabies immune globulin and vaccine. Pregnancy is not a contraindication to rabies immunization because contracting the disease would be fatal (Bernstein & Weinstein, 2007). The same is true of anti-venom serum for snake bites (Olson, 2009).

Caution pregnant women to avoid contact with unfamiliar dogs to prevent bites. If a woman is camping in a remote location, caution her to avoid feeding any wild animals such as squirrels and raccoons for the same reason.

Blunt Abdominal Trauma

Blunt trauma occurs generally from automobile accidents, when a woman's abdomen strikes the steering wheel or dashboard, or from someone kicking or punching her abdomen. No visible break is present in the skin. After the injury, the underlying tissue becomes edematous; broken underlying blood vessels ooze and form ecchymoses or a hematoma at the site. To assess if there is abdominal bleeding, a diagnostic peritoneal lavage may be done by introducing a small amount of normal saline by a syringe into the peritoneum and then withdrawing it to see if blood is evident. Ultrasound may also be used.

Careful assessment that the pregnancy has not been harmed must be made because a traumatic blow to the abdomen could cause dislodgement of the placenta (abruptio placentae) or

preterm labor. Palpate the uterus for any abnormal contours that would suggest edema or internal bleeding, and listen for fetal heart tones. Use Doppler to help assure a woman that her fetus is unharmed. Real-time ultrasound may also be helpful in showing that the uterus and placenta are intact. A pelvic examination is usually performed to assess for vaginal bleeding or seepage of clear fluid that would suggest rupture of the amniotic membranes. If a woman reports uterine contractions, attach uterine and fetal monitors to estimate the strength and effect of contractions on the fetal heart rate and also determine if preterm labor has begun. A tocolytic such as terbulaline can be administered to halt preterm labor if it has been demonstrated that the uterine environment is still intact (see Chapter 21 for a full discussion of tocolysis).

The possibility that placental blood will enter the maternal circulation with uterine trauma is a threat to an Rh-negative woman. Rh-negative women are therefore typically administered Rh immune globulin after abdominal trauma. The presence of fetal blood cells in the maternal bloodstream can be documented by a Kleihauer-Betke test (on staining, maternal cells remain colorless; fetal cells turn purple-pink).

Gunshot Wounds

A woman may receive a gunshot wound because she was an intended victim or because she was an innocent bystander. Occasionally, a woman attempts suicide by a gunshot wound. Assessment of the wound includes inspection for the point where the bullet entered the body and the point where it exited (the entry wound is small but the exit wound is large because as a bullet slows, it begins to tumble, enlarging the space it occupies). The uterine wall is so thick during pregnancy that it may trap a bullet, so there may be no exit point from a woman's body if the uterus was punctured. If the bullet entered high in the abdomen, the intestines will surely be injured because so many loops of these are compressed above the uterus.

Gunshot wounds are surgically cleaned and débrided, and a woman is treated with a high-dose antibiotic. Ampicillin, a drug that is safe to administer during pregnancy, is frequently prescribed. If a bullet enters the uterus, the incidence of fetal mortality is high, especially if the placenta is torn by the bullet. After providing emergency care to a woman for the injury, it is important to investigate carefully the circumstances of the injury. Since President Lincoln's assassination, gunshot wounds must be reported to the police. Stay with a woman as necessary while she recounts her history of the incident again for law enforcement officers.

Poisoning

Pregnant women are not apt to swallow a poison, although this can occur accidentally, especially if a woman wakes at night and attempts to take medicine in the dark. Food poisoning from inadequately refrigerated or undercooked foods can occur. Some women poison themselves as a suicide attempt.

Poisoning in the pregnant woman is managed the same as in any other person. A woman should telephone a local poison control center, state she is pregnant and what she accidentally swallowed, and follow the specific recommendation of personnel at the poison control center. In an emergency department, activated charcoal is the drug of choice to neutralize stomach poison.

After a woman has been treated and the emergency of the poisoning is over, investigate carefully the circumstances of the poisoning to help a woman learn about safety with medications or food or to discover possible suicidal intent.

Choking

If a pregnant woman chokes on a piece of meat or any foreign object blocks her airway, attempting to dislodge the object with a sudden upward thrust to the upper abdomen is difficult. This is because of a lack of space between the uterus and the end of the sternum and because the average person cannot reach from the rear around a woman's enlarged abdomen. Late in pregnancy, therefore, a rescuer might use successive chest thrusts instead. Box 22.11 describes how to perform chest thrusts for a pregnant woman.

Orthopedic Injuries

Because a woman has poor balance late in pregnancy, it is easy for her to trip; when she falls, she automatically reaches out a hand to cushion the fall and to prevent landing on her abdomen. Because of her extra weight, this can cause a serious wrist injury (a Colles fracture). Apply ice to the area to decrease swelling as an immediate first-aid measure. If she has limited motion, a radiograph may be necessary to determine whether a fracture is present. Assure a woman that a radiograph of an extremity is safe during pregnancy as long as her abdomen is shielded during the radiation exposure. Delegate someone to accompany her to the radiography department and remain with her (outside the actual x-ray room) to ensure that lead protection is offered. Also caution this person to be alert for signs of preterm labor that could suddenly develop as a result of an undetected injury.

Because women of childbearing age are usually healthy, healing of fractures or torn ligaments generally occurs quickly and without complications. Be certain a woman can identify good calcium food sources if she has a fracture so both she and the fetus can have adequate calcium for new bone growth.

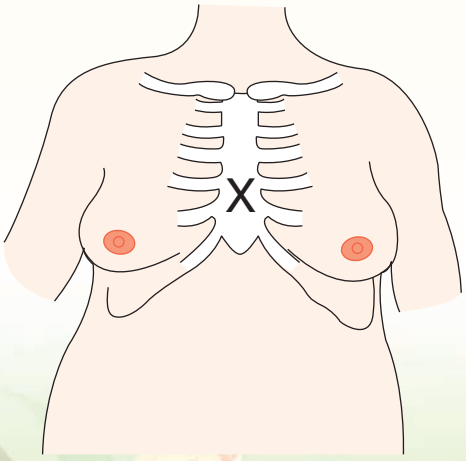
Because many more adolescent girls and young adult women participate in sports today than ever before, an increasing number of women of childbearing age have weakened knee cartilage or ligaments (formerly thought of only as a football injury). During pregnancy, when all body cartilage softens, combined with the excessive abdominal weight a woman carries, a woman may dislocate her knee or strain a knee ligament again.

Any woman who has had a previous knee injury should have it re-evaluated early in pregnancy. A support device such as a knee immobilizer may be required for the last 3 months of pregnancy to keep the joint from dislocating or the ligament from tearing again. Discuss with her the advantage of prevention because if a ligament cannot sustain her added weight and tears again, she will fall. She can be assured that having a knee immobilizer in place at the time of birth will not interfere with birth; if a lithotomy position and stirrups for birth are necessary, a modified stirrups position can be devised for her.

The laxness of body cartilage may also cause separation of the symphysis pubis if a woman falls with her legs outspread. Many women experience some nagging suprapubic joint pain during pregnancy. A suture separation this way, however, is very painful, especially on walking or turning. To avoid pain and allow the cartilage to heal, a woman needs to remain on bed rest at home for 4 to 6 weeks. If separation of

Box 22.11 Nursing Procedure ✻ Chest Thrusts for the Pregnant Woman

Purpose: To relieve tracheal aspiration

Plan	Principle
For Conscious Victim in Standing Position	***For Conscious Victim in Standing Position***
1. Stand behind the woman and encircle her chest with your arms.	**1.** Proper positioning ensures proper placement of chest pressure and prevents inadvertent injury to underlying body structures.
	
2. Place the thumb side of your fist on the middle of the woman's sternum.	**2.** Placement of fist against the chest ensures a solid structure for compression.
	


3. Grab the fist with the other hand and perform backward thrusts until the foreign body is expelled.	**3.** Pressure on the chest compresses the ribs, increasing chest and lung pressure. This increased pressure forces an object lodged in the airway to move upward.

(continued)

Box 22.11 Nursing Procedure ✻ Chest Thrusts for the Pregnant Woman (continued)

Plan	Principle
For Unconscious Victim in Supine Position	***For Unconscious Victim in Supine Position***
1. Place the woman in the same position as for external heart compressions (heel of the hand on the lower sternum).	**1.** Loss of consciousness interferes with the woman's ability to maintain an upright position.
	
2. Follow Steps 2 and 3 as with standing victim.	**2.** Compression of the chest forces the object lodged in the airway to move upward. Chest compression can be as effective in the supine position as in the standing position.

the symphysis pubis is present at the time of birth, this will make labor very painful, especially the pelvic division of labor as the fetus is pushed through the pelvic ring.

Burns

Burns are dangerous in the pregnant woman not only because of the thermal injury that occurs but because of inhalation of carbon monoxide gases from the fire, which could lead to extreme fetal hypoxia as carbon monoxide crosses the placenta in place of oxygen.

In addition, smoke is irritating to lung tissue and can result in extensive lung edema; this can cause additional fetal hypoxia because of the lack of oxygen–carbon dioxide exchange space in the mother. Because fluid and electrolyte losses can be great with burns, hypotension from hypovolemia or an electrolyte imbalance can occur. In response to a severe trauma such as a burn, prostaglandins are produced, possibly causing preterm labor. Both maternal and fetal prognoses are poor if burns cover more than 50% of body surface area. Fortunately, few women of childbearing age experience this degree of burn in the United States.

Interestingly, burn tissue heals more quickly than normal during pregnancy. This is probably related to the overall increased metabolism and possibly to the increased corticosteroid serum level that prevents inflammation and damage to tissue from the pressure of edema.

Postmortem Cesarean Birth

If a pregnant woman does not survive serious trauma, it may still be possible for her child to be born safely by a postmortem cesarean birth (Phelan, Roller, & Minei, 2008). This is usually attempted if the fetus is past 24 weeks and less than 20 minutes has passed since the mother died. Infant survival is best in these circumstances if no more than 5 minutes has passed. By general practice, no consent is necessary for this procedure because the fetus is assumed to want to live but cannot give consent. A classic cesarean incision is used. Personnel should be available to resuscitate the newborn immediately.

✔ Checkpoint Question 22.6

Mindy received a laceration on her leg from an automobile accident. Why are lacerations of lower extremities potentially more serious in pregnant women than in others?

a. A woman is less able to keep the laceration clean because of her fatigue.
b. Increased bleeding can occur from uterine pressure on lower extremity veins.
c. Lacerations can provoke allergic responses because of gonadotropic hormone.
d. Healing is limited during pregnancy, so these will not heal until after birth.

Key Points for Review

- Adolescent pregnancy is a major concern, because although it is decreasing in incidence, it still occurs at a high rate and can interfere with the development of both an adolescent and fetus. Nursing care needs to be individualized to meet the prepartal, intrapartal, and postpartum needs of this age group. Helping adolescents view a pregnancy as a growth experience can help them mature in their ability to parent.
- Women who delay childbearing until age 40 may need additional discussion time at prenatal visits to help them incorporate a pregnancy into their lifestyle. They may need reminders to save time during the day for rest, particularly if at risk for pregnancy-induced hypertension or varicosities.
- Women who are physically, cognitively, visually, or hearing challenged or who have a spinal cord injury are apt to have special needs during pregnancy that must be addressed by health care providers. Providing time for discussion early in pregnancy so these needs can be identified and anticipated is an important role for nurses.
- Women who are physically or cognitively challenged may need help in adjusting their usual regimen to pregnancy. Be certain they are aware of how to contact help in an emergency. Ensure that all medications they are taking for their primary disorder are safe for use during pregnancy.
- A woman who is substance dependent presents a unique challenge during pregnancy. Encouraging her to decrease or halt her drug intake to safeguard the health of a fetus is a short-term goal. Addressing her need to decrease drug intake for the remainder of her life so she can be a quality parent is a long-term goal.
- A fetus of a woman who is substance dependent is at high risk because of the direct effects of the drug and the indirect effects of an unhealthy lifestyle. Women should be encouraged to join drug reduction maintenance programs if possible to reduce fetal risk.
- Trauma in pregnancy results from sources such as violence, automobile accidents, and falls. Women with traumatic injuries need to be carefully assessed to determine if intimate partner abuse was the cause of the trauma.

CRITICAL THINKING EXERCISES

1. Mindy, the 16-year-old girl you met at the beginning of the chapter who is 15 weeks pregnant, tells you she is old enough to be a responsible parent and plans to keep her baby. What clues would you look for to see if her self-evaluation is correct?
2. Mindy makes friends with Clara, a 44-year-old woman, at the prenatal clinic. Clara works at a desk job as a stockbroker. She eats most of her meals at restaurants. Mindy lives at home and attends school. Both have inactive lifestyles. Mindy "experiments" with methamphetamine. Clara takes no drugs but acetaminophen (Tylenol). How would what you teach to prevent pregnancy complications differ for these two clients?
3. Mindy was seen in an emergency department after an automobile accident. Following a severe injury of this kind, what body systems would you assess first?
5. Examine the National Health Goals related to women with special needs. Most government-sponsored funds for nursing research is allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to the Carson family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to pregnant families with special needs. Confirm your answers are correct by reading the rationales.

Chapter 23

Nursing Care of a Family Experiencing a Complication of Labor or Birth

KEY TERMS

- amnioinfusion
- amniotic fluid embolism
- augmentation of labor
- battledore placenta
- dysfunctional labor
- dystocia
- external cephalic version
- forceps birth
- hypertonic uterine contractions
- hypotonic uterine contractions
- induction of labor
- oxytocin
- pathologic retraction ring
- placenta accreta
- placenta circumvallata
- placenta marginata
- placenta succenturiata
- precipitate labor
- umbilical cord prolapse
- uterine inversion
- vacuum extraction

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Define the terms *dystocia* and *dysfunctional labor* and how common deviations in the power (force of labor), the passage, or the passenger can cause dystocia or dysfunctional labor.
2. Identify National Health Goals related to complications of labor that nurses could help the nation achieve.
3. Use critical thinking to analyze ways to maintain family-centered nursing care when deviations from the normal in labor or birth occur.
4. Assess a woman in labor and during birth for deviations from the normal labor process.
5. Formulate nursing diagnoses related to deviations from normal in labor and birth.
6. Identify expected outcomes associated with deviations from normal labor and birth and resultant complications.
7. Plan nursing interventions to help the family meet expected outcomes when complications of labor occur.
8. Implement nursing care related to complications of labor or birth such as preparing the family for a cesarean birth.
9. Evaluate expected outcomes for achievement and effectiveness of care.
10. Identify areas related to complications of labor that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate the knowledge of deviations of normal in labor and birth with nursing process to achieve quality maternal and child health nursing care.

Roseann Bigalow, a 28-year-old woman about to give birth to her first baby, is admitted to a birthing room. Her contractions have been 5 minutes apart for 10 hours. She feels more pain in her back than in her abdomen, "like my spine is tearing apart." A contraction monitor shows contractions are hypotonic. An ultrasound shows the fetus is above average in weight and in an occipitoposterior position. Her husband asks you if the reason Roseann's labor is taking so long is because she's overweight.

Previous chapters discussed pregnancy and normal labor and birth. This chapter adds information about what happens when complications of labor occur. Nurses play a vital role in making labor safe. The sooner a complication in labor is recognized, the better is the chance the situation can be corrected and both fetal and maternal health can be protected.

How would you answer Mr. Bigalow?

Although labor often proceeds without any deviation from the normal, many potential complications can occur. A difficult labor—**dystocia**—can arise from any of the four main components of the labor process: (a) the power, or the force that propels the fetus (uterine contractions), (b) the passenger (the fetus), (c) the passageway (the birth canal), or (d) the psyche (the woman's and family's perception of the event). The earlier in labor that a complication is recognized, the better is the chance that it can be resolved (Buhimschi, 2009).

Because complications can occur at any point in labor, continuous monitoring of a laboring woman and fetus and providing emotional support for her and her family are essential. The hours of labor are stressful even when everything is proceeding normally. Be sure to reassure a woman in labor that everything is going smoothly and that both she and her fetus appear to be doing well. If a complication arises and assurances cannot be given as freely, a woman needs someone who is knowledgeable about the deviation and its treatment as well as a person who understands her feelings of helplessness. Nurses play a key role in providing this type of skilled physical and emotional care.

National Health Goals related to attempts to decrease maternal complications and prevent infant injury are shown in Box 23.1.

BOX 23.1 ✻ Focus on National Health Goals

A number of National Health Goals speak directly to complications of labor.

- Reduce the number of cesarean births among low-risk women to no more than 15 per 100 births from a baseline of 18 per 100.
- Reduce the maternal mortality rate to no more than 3.3 per 100,000 live births from a baseline of 7.1 per 100,000.
- Reduce the rate of maternal complications during hospitalized labor and birth to no more than 24 per 100 births from a baseline of 31.2 per 100 births (http://www.nih.gov).

Nurses can help the nation achieve these goals by helping identify women in labor who are developing a complication; by assisting with cesarean births and uterine monitoring; and by being alert to the preliminary symptoms of uterine rupture, which accounts for a substantial number of maternal deaths during labor. Further nursing research is needed to explore whether breech and occipitoposterior positions can be effectively prevented by position changes during pregnancy.

Nursing Process Overview

For a Woman With a Labor or Birth Complication

Assessment

One of the major assessments used to detect deviations from normal in labor and birth is fetal and uterine monitoring. Working with such apparatus involves explaining its importance to a woman and her partner, winning their cooperation, and using judgment in reading the various patterns. Typically, monitoring women in labor entails problems not found in other high-risk areas such as an intensive care unit (ICU). In an ICU, the person being monitored has been admitted to the unit because he or she is seriously ill. The person lies still to prevent artifacts on the tracing. However, a woman in labor, who is well except for the complication of labor, may be less accepting of technologic or pharmacologic intervention. She moves about rather than lying still, because she is in pain. Her movement causes artifacts on tracings, requiring frequent adjustment of equipment to achieve a clear tracing. Understanding that this is a normal consequence of labor is essential for effective assessment and continued care.

Nursing Diagnosis

Common nursing diagnoses specific to a woman experiencing a complication during labor or birth refer to specific problems. Some examples might include:

- Fear related to uncertainty of pregnancy outcome
- Anxiety related to medical procedures and apparatus necessary to ensure health of woman and fetus
- Fatigue related to loss of glucose stores through work and duration of labor
- Risk for ineffective tissue perfusion related to excessive loss of blood with complication of labor
- Risk for injury (maternal or fetal) related to effect on woman and fetus of a labor complication and treatment required
- Risk for injury (maternal or fetal) related to labor involving a multiple-gestation pregnancy
- Anticipatory grieving related to nonviable monitoring pattern of fetus

Outcome Identification and Planning

If a complication of labor or childbirth occurs, identification of expected outcomes can be difficult because an outcome that must be included in planning is not what the woman desires. Encouraging a couple to clarify their priorities when a complication occurs is helpful. For example, early in labor, a woman might say that her chief goal is to avoid monitoring equipment or any surgical intervention. If fetal bradycardia occurs, however, monitoring and a cesarean birth may become necessary. If this happens, reminding the woman that her primary goal is really to have a healthy baby can help her accept the change, including whatever interventions are necessary to achieve her ultimate objective. A helpful Internet site for referral about complications in childbirth is The Childbirth Organization (http://www.childbirth.org).

Implementation

If a woman develops a complication of labor or birth, actions to increase the fetal heart rate or strengthen uterine contractions are a priority, possibly an emergency. Interventions must be planned and performed efficiently and effectively, based on the individual circumstances. Be certain to provide psychological reassurance to accompany actions to fully safeguard both the woman and her fetus.

Outcome Evaluation

Evaluation of proposed outcomes may reveal unhappiness, because not every woman who experiences a deviation from the normal in labor and birth will be able to give birth to a healthy child. Some deviations will be too great. Some interventions will not be maximally effective because of individual circumstances. Some infants will die; a few women may be left unable to bear future children. Evaluation may lead to a new analysis that the couple's chief need at that point is to grieve for the child or for a lifestyle that can no longer be theirs. If the outcome is more positive, evaluate the couple for signs that they are able to begin interaction with their child after their harrowing experience.

Examples of outcome achievement might include:

- Client voices confidence that she can cope with the fear she feels about her fetus' welfare.
- Client demonstrates adequate energy during course of labor to maintain effective breathing patterns.
- Client's blood pressure remains higher than 110/60 mm Hg despite excessive blood loss with delivery of the placenta.
- Client begins positive grieving behaviors in response to loss of newborn.

BOX 23.2 ❊ Common Causes of Dysfunctional Labor

- Inappropriate use of analgesia (excessive or too early administration)
- Pelvic bone contraction that has narrowed the pelvic diameter so that a fetus cannot pass such as could occur in a woman with rickets
- Poor fetal position (posterior rather than anterior position)
- Extension rather than flexion of the fetal head
- Overdistention of the uterus, as with multiple pregnancy, hydramnios, or an excessively oversized fetus
- Cervical rigidity (unripe)
- Presence of a full rectum or urinary bladder that impedes fetal descent
- Woman becoming exhausted from labor
- Primigravida status

COMPLICATIONS WITH THE POWER (THE FORCE OF LABOR)

Inertia is a time-honored term to denote that sluggishness of contractions, or the force of labor, has occurred. A more current term used is **dysfunctional labor** (Strehlow & Uzelac, 2007). Dysfunction can occur at any point in labor, but it is generally classified as primary (occurring at the onset of labor) or secondary (occurring later in labor). The risk of maternal postpartal infection, hemorrhage, and infant mortality is higher in women who have a prolonged labor than in those who do not. Therefore, it is vital to recognize and prevent dysfunctional labor to the extent possible (Shields et al., 2007).

Prolonged labor appears to result from several factors. It is most likely to occur if a fetus is large. Hypotonic, hypertonic, and uncoordinated contractions all play additional roles (Box 23.2).

Ineffective Uterine Force

Uterine contractions are the basic force moving the fetus through the birth canal. They occur because of the interplay of the contractile enzyme adenosine triphosphate and the influence of major electrolytes such as calcium, sodium, and potassium, specific contractile proteins (actin and myosin), epinephrine and norepinephrine, oxytocin (a posterior pituitary hormone), estrogen, progesterone, and prostaglandins. About 95% of labors are completed with contractions that follow a predictable, normal course. When they become abnormal or ineffective, ineffective labor occurs.

Hypotonic Contractions

Figure 23.1A illustrates the appearance of normal uterine contractions. With **hypotonic uterine contractions,** the number of contractions is unusually low or infrequent (not more two or three occurring in a 10-minute period). The resting tone of the uterus remains less than 10 mm Hg, and the strength of contractions does not rise above 25 mm Hg (Fig. 23.1B). Hypotonic contractions are most apt to occur during the active phase of labor. They may occur after the administration of analgesia, especially if the cervix is not dilatated to 3 to 4 cm or if bowel or bladder distention prevents descent or firm engagement. They may occur in a uterus that is overstretched by a multiple gestation, a larger-than-usual single fetus, hydramnios, or in a uterus that is lax from grand multiparity. Such contractions are not exceedingly painful, because of their lack of intensity. Keep in mind, however, that the strength of a contraction is a subjective symptom. Some women may interpret these contractions as very painful.

Hypotonic contractions increase the length of labor, because more of them are necessary to achieve cervical dilatation. This can cause the uterus to not contract as effectively during the postpartal period because of exhaustion, increasing a woman's chance for postpartal hemorrhage. In the first hour after birth following a labor of hypotonic contractions, palpate the uterus and assess lochia every 15 minutes to ensure that postpartal contractions are not also hypotonic and therefore inadequate to halt bleeding.

Hypertonic Contractions

Hypertonic uterine contractions are marked by an increase in resting tone to more than 15 mm Hg (see Fig. 23.1C). However, the intensity of the contraction may be no stronger than that associated with hypotonic contractions. In contrast to hypotonic contractions, hypertonic ones tend to occur frequently and are most commonly seen in the latent phase of labor. This type of contraction occurs because the muscle fibers of the myometrium do not repolarize or relax after a contraction, thereby "wiping it clean" to accept a new pacemaker stimulus. They may occur because more than one pacemaker is stimulating contractions. They tend to be more painful than usual, because the myometrium becomes tender from constant lack of relaxation and the anoxia of uterine cells that results. A woman may become frustrated or disappointed with her

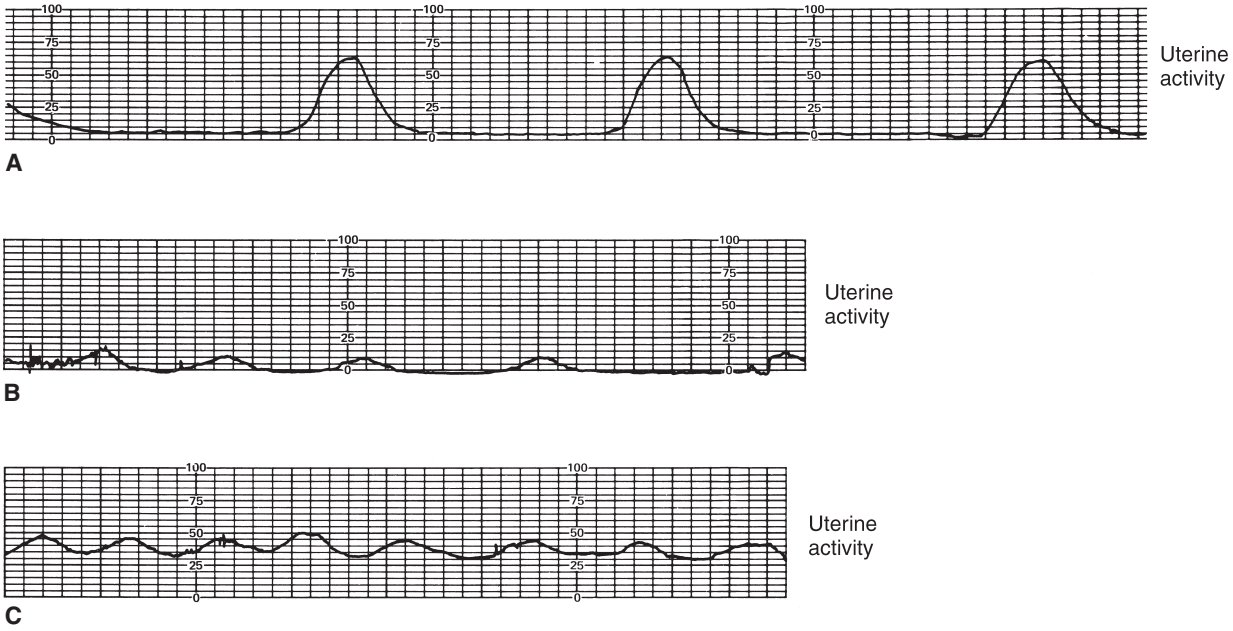

FIGURE 23.1 (**A**) Normal uterine contractions. (**B**) Hypotonic contractions; notice rise in pressure no more than 10 mm Hg. (**C**) Hypertonic contractions; notice the high resting pressure (35–40 mm Hg).

breathing exercises for childbirth, because such techniques are ineffective with this type of contraction.

A danger of hypertonic contractions is that the lack of relaxation between contractions may not allow optimal uterine artery filling; this could lead to fetal anoxia early in the latent phase of labor. Any woman whose pain seems out of proportion to the quality of her contractions should have both a uterine and a fetal external monitor applied for at least 15 minutes to ensure that the resting phase of the contractions is adequate and that the fetal pattern is not showing late deceleration.

If deceleration in the fetal heart rate (FHR) or an abnormally long first stage of labor or lack of progress with pushing ("second-stage arrest") occurs, cesarean birth may be necessary. Both the woman and her support person need to understand that, although the contractions are strong, they are ineffective and are not achieving cervical dilatation. To help identify the difference, hypotonic and hypertonic contractions are compared in Table 23.1.

TABLE 23.1 ✻ Comparison of Hypotonic and Hypertonic Contractions

Criteria	Hypertonic	Hypotonic
Phase of labor	Latent	Active
Symptoms	Painful	Limited pain
Medications used:		
Oxytocin	Unfavorable reaction	Favorable reaction
Sedation	Helpful	Little value

Uncoordinated Contractions

Normally, all contractions are initiated at one pacemaker point high in the uterus. A contraction sweeps down over the organ, encircling it; repolarization occurs; relaxation or a low resting tone is achieved; and another pacemaker-activated contraction begins. With uncoordinated contractions, more than one pacemaker may be initiating contractions, or receptor points in the myometrium may be acting independently of the pacemaker. Uncoordinated contractions may occur so closely together that they do not allow good cotyledon (one of the visible segments on the maternal surface of the placenta) filling. Because they occur so erratically such as one on top of another and then a long period without any, it may be difficult for a woman to rest between contractions or to use breathing exercises with contractions.

Applying a fetal and a uterine external monitor and assessing the rate, pattern, resting tone, and fetal response to contractions for at least 15 minutes (or longer if necessary in early labor) reveals the abnormal pattern. Oxytocin administration may be helpful in uncoordinated labor to stimulate a more effective and consistent pattern of contractions with a better, lower resting tone.

Dysfunctional Labor and Associated Stages of Labor

For a graphic illustration of the most frequent times dysfunctional labor is apt to occur, see Figure 23.2. Regardless of when dysfunctional labor occurs, the effect on a woman and her support person will be the same: anxiety, fear, or discouragement. A woman needs good explanations of what is happening: "We're going to take an ultrasound to check the

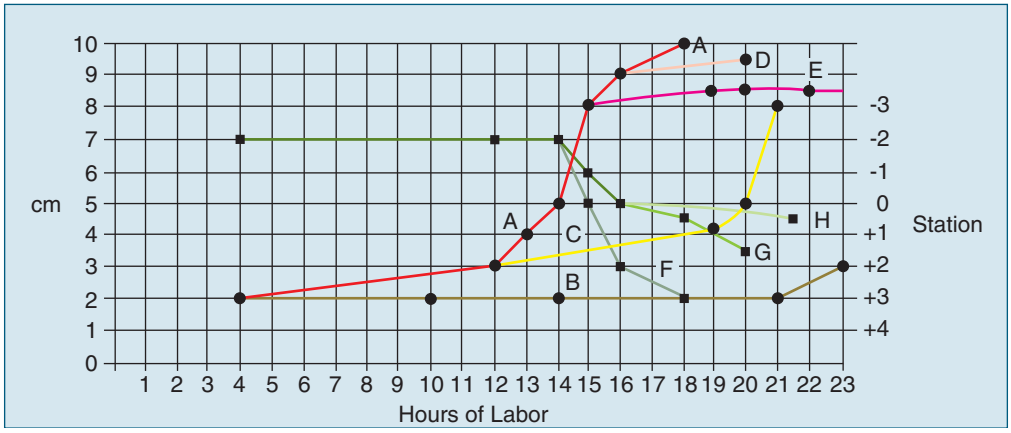

FIGURE 23.2 Graph showing types of abnormal labor. (**A**) Normal labor curve. (**B**) Prolonged latent phase. (**C**) Protracted active-phase dilatation. (**D**) Prolonged deceleration phase. (**E**) Secondary arrest of dilatation. (**F**) Normal descent. (**G**) Prolonged descent. (**H**) Arrest of descent.

baby's position." "This is a drug to make your contractions stronger." "I know resting is the last thing you feel like doing, but that is what I want you to try to do."

Dysfunction at the First Stage of Labor

Dysfunction that occurs with the first stage of labor involves a prolonged latent phase, protracted active phase, prolonged deceleration phase, and secondary arrest of dilatation.

Prolonged Latent Phase. When contractions become ineffective during the first stage of labor, a prolonged latent phase can develop. The normal parameters for the stages of labor are highlighted in Table 23.2. A prolonged latent phase, as defined by Friedman (1978), is a latent phase that is longer than 20 hours in a nullipara or 14 hours in a multipara. This may occur if the cervix is not "ripe" at the beginning of labor and time must be spent getting truly ready for labor. It may occur if there is excessive use of an analgesic early in labor. With a prolonged latent phase, the uterus tends to be in a hypertonic state. Relaxation between contractions is inadequate, and the contractions are only mild (less than 15 mm Hg on a monitor printout) and therefore ineffective. One segment of the uterus may be contracting with more force than another segment.

Management of a prolonged latent phase in labor that has been caused by hypertonic contractions involves helping the uterus to rest, providing adequate fluid for hydration, and pain relief with a drug such as morphine sulfate. Changing the linen and the woman's gown, darkening room lights, and decreasing noise and stimulation can also be helpful. These measures usually combine to allow labor to become effective and begin to progress. If it does not, a cesarean birth or amniotomy (artificial rupture of membranes) and oxytocin infusion to assist labor may be necessary. Because amniotomy is also used in uncomplicated labor, it is discussed in Chapter 15.

Protracted Active Phase. A protracted active phase is usually associated with cephalopelvic disproportion (CPD) or fetal malposition, although it may reflect ineffective myometrial activity. This phase is prolonged if cervical dilatation does not occur at a rate of at least 1.2 cm/hr in a nullipara or 1.5 cm/hr in a multipara, or if the active phase lasts longer than 12 hours in a primigravida or 6 hours in a multigravida (see Fig. 23.2). If the cause of the delay in dilatation is fetal malposition or CPD, cesarean birth may be necessary. Dysfunctional labor during the dilatational division of labor tends to be hypotonic, in contrast to the hypertonic action at the beginning of labor. After an ultrasound to show that CPD is not present, oxytocin may be prescribed to augment labor (see later discussion on augmentation by oxytocin).

Prolonged Deceleration Phase. A deceleration phase has become prolonged when it extends beyond 3 hours in a nullipara or 1 hour in a multipara. Prolonged deceleration phase most often results from abnormal fetal head position. A cesarean birth is frequently required.

TABLE 23.2 ✻ Lengths of Phases and Stages of Normal Labor in Hours

	Nullipara		Multipara	
Phase	*Average*	*Upper Normal*	*Average*	*Upper Normal*
Latent phase	8.6	20.0	5.3	14.0
Active phase	5.8	12.0	2.5	6.0
Second stage	1	1.5	0.25	—*

*There is no limit to the length of the second stage as long as progress is being made and fetal distress is not present.

Secondary Arrest of Dilatation. A secondary arrest of dilatation has occurred if there is no progress in cervical dilatation for longer than 2 hours. Again, cesarean birth may be necessary.

Dysfunction at the Second Stage of Labor

Dysfunction that occurs with the second stage of labor involves prolonged descent and arrest of descent.

Prolonged Descent. Prolonged descent of the fetus occurs if the rate of descent is less than 1.0 cm/hr in a nullipara or 2.0 cm/hr in a multipara. It can be suspected if the second stage lasts over 3 hours in a multipara (Cheng et al., 2007).

With both a prolonged active phase of dilatation and prolonged descent, contractions have been of good quality and proper duration, and effacement and beginning dilatation have occurred, but then the contractions become infrequent and of poor quality and dilatation stops. If everything is normal except for the suddenly faulty contractions and CPD and poor fetal presentation have been ruled out by ultrasound, then rest and fluid intake, as advocated for hypertonic contractions, also apply. If the membranes have not ruptured, rupturing them at this point may be helpful. Intravenous (IV) oxytocin may be used to induce the uterus to contract effectively (see later discussion on induction of labor by oxytocin). A semi-Fowler's position, squatting, kneeling, or more effective pushing may speed descent.

Arrest of Descent. Arrest of descent results when no descent has occurred for 1 hour in a multipara or 2 hours in a nullipara. Failure of descent has occurred when expected descent of the fetus does not begin or engagement or movement beyond 0 station has not occurred. The most likely cause for arrest of descent during the second stage is CPD. Cesarean birth usually is necessary. If there is no contraindication to vaginal birth, oxytocin may be used to assist labor.

✔ Checkpoint Question 23.1

Roseann Bigalow has prolonged labor. What is the most common cause for arrest of descent during the second stage of labor?

a. Cephalopelvic disproportion (CPD).
b. Maternal calcium deficiency.
c. The fetus is asleep during labor.
d. The maternal outlet is narrow.

Nursing Diagnoses and Related Interventions for Dysfunctional Labor

It is impossible to prevent all dysfunctional labor, just as it is impossible to predict the functioning of any woman's hormonal system or individual response to labor. However, a number of nursing interventions can contribute to the progression of normal labor and help change a dysfunctional labor to a functional one.

Nursing Diagnosis: Fatigue and anxiety related to prolonged labor

Outcome Evaluation: Client states that she is able to continue active participation in labor; maintains effective breathing with contractions.

Because labor is work, it can cause a woman to deplete her glucose stores. On a woman's admission to a birthing room, assess the likelihood of glucose depletion by asking the time of her last meal. If she ate breakfast at 8:00 AM and then began labor by 2:00 PM, she is only 6 hours away from a full meal. However, if she last ate at 5:00 PM the preceding evening and did not eat breakfast because she awoke with labor this morning, she is 11 hours away from a full meal. Alert her physician or nurse-midwife to this situation. If the woman is still in early labor, she may be encouraged to drink a high-carbohydrate fluid such as a sports drink or to eat a light meal. IV fluid therapy also may be initiated to provide glucose for energy. Sucking on a lollipop or hard candy during labor can also supply additional glucose.

Although the effect of emotion on labor is difficult to document, it seems that the cervix dilates more rapidly and therefore normal labor is shortened if a woman is neither tense nor frightened. Manage stress by making the transfer from home to the health care facility as untraumatic as possible. Ask directly whether a woman has any concerns. Offer explanations of all procedures. Help the support person feel just as welcome and comfortable as the woman herself. Asking a question such as, "Is labor what you thought it would be?" of both the woman and her support person often helps them to express their concerns. Allow the woman and her support person as many choices as possible to give them a sense of control.

Remember that pain is an exhausting phenomenon. Encourage the use of nonpharmacologic comfort measures such as breathing with the woman, giving back rubs, changing sheets, using cool washcloths, and so forth. Complementary therapies such as aromatherapy or music are also helpful (Smith, 2009).

To increase the blood supply to the uterus and prevent hypotension, urge a woman when she is in bed to lie on her side so that the uterus is lifted off the vena cava. If a woman insists on lying supine, place a hip roll under one or the other of her buttocks to cause her pelvis to "tip" and, at least to some extent, move the uterus to the side.

A full bladder prevents descent of the fetus and may impede uterine contractions. Urge a woman in labor to void every 2 hours to keep the bladder empty and to aid progress.

Nursing Diagnosis: Risk for deficient fluid volume related to length and work of labor

Outcome Evaluation: Urine is free of ketones; specific gravity is between 1.003 and 1.030; skin turgor and serum electrolyte levels are within acceptable parameters.

Low levels of serum electrolytes or body fluid can occur in labor for the same reason as a decreased glucose level—a long interval between eating and the end of labor. Additionally, vomiting and diarrhea occasionally accompany labor so can increase fluid and electrolyte losses. Ask if a woman has had any vomiting or

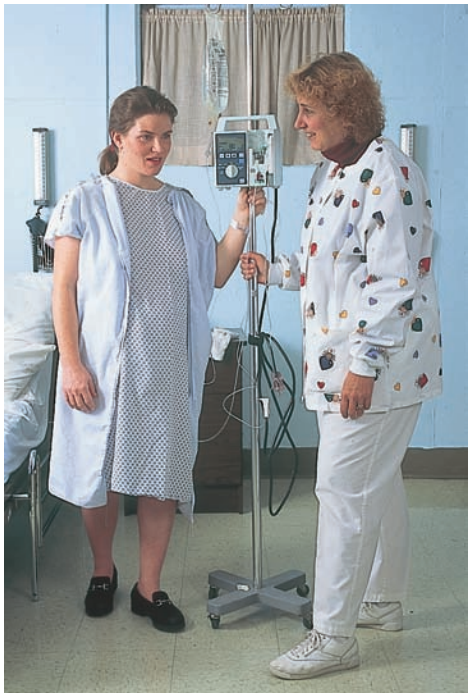

FIGURE 23.3 If intravenous fluid is used for women in labor, it does not need to limit mobility.

diarrhea to determine the possible extent of the problem. One episode of a small amount of diarrhea or vomiting is probably not serious; extended vomiting or diarrhea could lead to serious dehydration. Profuse diaphoresis and hyperventilation that occur with labor can further increase fluid and electrolyte losses through insensible water loss.

Test voidings frequently during labor for glucose, protein, ketones, and specific gravity. Ketones in the urine suggest starvation ketosis. A concentrated specific gravity suggests a lack of fluid. Extreme dehydration not only may slow labor but can lead to increased blood viscosity, possibly increasing the risk for thrombophlebitis during the postpartal period.

Many women react negatively to the idea of IV fluid therapy during labor to restore body fluid, possibly perceiving it as loss of control over their bodies or removal of the "naturalness" of labor and birth. Introduce the idea that IV fluid therapy will be helpful because of her particular complication before arriving with the bag of fluid and tubing. When inserting the IV catheter, try to use an insertion site in a woman's nondominant hand and, if necessary, only a small "reminder" handboard. Assure a woman that she can be out of bed and walking, can turn freely, squat, sit, or use whatever position she prefers during labor with the IV line in place. None of these acts will interfere with the infusion (Fig. 23.3).

Contraction Rings

A contraction ring is a hard band that forms across the uterus at the junction of the upper and lower uterine segments and interferes with fetal descent. The most frequent type seen is termed a **pathologic retraction ring** (Bandl's ring). The ring usually appears during the second stage of labor and can be palpated as a horizontal indentation across the abdomen (Fig. 23.4). It is a warning sign that severe dysfunctional

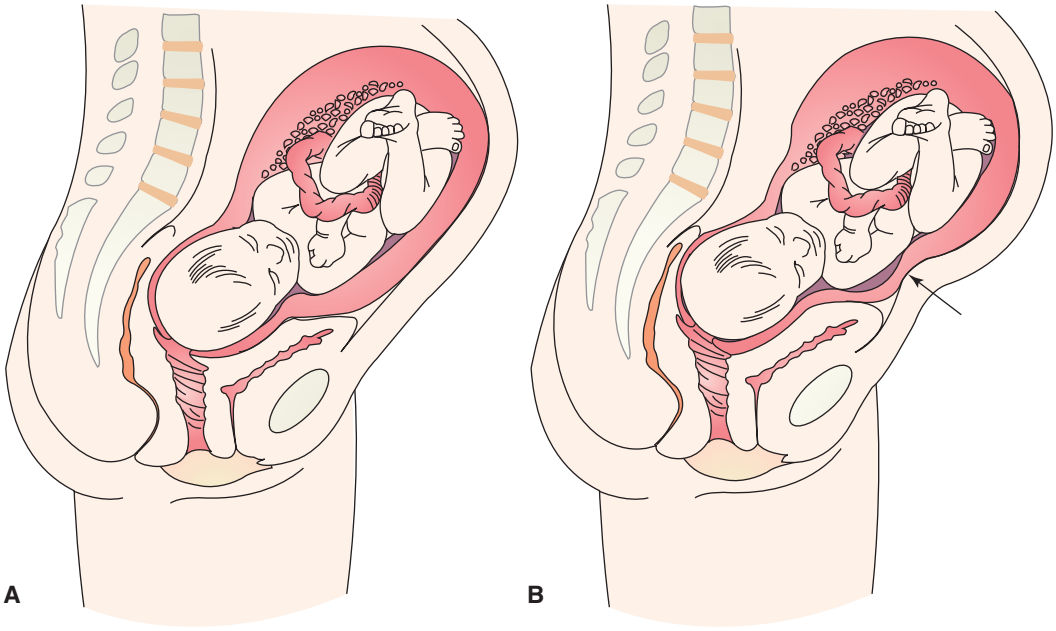

FIGURE 23.4 Pathologic retraction ring. (**A**) Uterus in the normal second stage of labor. Notice how the upper uterine segment is becoming thicker and the lower uterine segment is thinning. A physiologic retraction ring is normally formed at the division of the upper and lower uterine segments. (**B**) Uterus with a pathologic retraction ring (Bandl's ring). The wall below the ring is thin and the abdomen shows an indentation. This constriction is caused by obstructed labor and is a warning sign that if the obstruction is not relieved, the lower segment may rupture.

labor is occurring as it is formed by excessive retraction of the upper uterine segment; the uterine myometrium is much thicker above than below the ring.

When a pathologic retraction ring occurs in early labor, it is usually caused by uncoordinated contractions. In the pelvic division of labor, it is usually caused by obstetric manipulation or by the administration of oxytocin. In either event, the fetus is gripped by the retraction ring and cannot advance beyond that point. The undelivered placenta will also be held at that point.

Contraction rings often can be identified by ultrasound. Such a finding is extremely serious and should be reported promptly. Administration of IV morphine sulfate or the inhalation of amyl nitrite may relieve a retraction ring. A tocolytic can also be administered to halt contractions. If the situation is not relieved, uterine rupture and neurologic damage to the fetus may occur (Lauria et al., 2007). In the placental stage, massive maternal hemorrhage may result, because the placenta is loosened but then cannot deliver, preventing the uterus from contracting.

Most likely, a cesarean birth will be necessary to ensure safe birth of the fetus. Manual removal of the placenta under general anesthesia may be required if the retraction ring does not allow the placenta to be delivered.

Precipitate Labor

Precipitate labor and birth occur when uterine contractions are so strong that a woman gives birth with only a few, rapidly occurring contractions. It is often defined as a labor that is completed in fewer than 3 hours. *Precipitate dilatation* is cervical dilatation that occurs at a rate of 5 cm or more per hour in a primipara or 10 cm or more per hour in a multipara (Strehlow & Uzelac, 2007). Such rapid labor is likely to occur with grand multiparity, or it may occur after induction of labor by oxytocin or amniotomy. Contractions can be so forceful that they lead to premature separation of the placenta, placing the woman at risk for hemorrhage. Rapid labor also poses a risk to the fetus, because subdural hemorrhage may result from the rapid release of pressure on the head. A woman may sustain lacerations of the birth canal from the forceful birth. She also can feel overwhelmed by the speed of labor.

A precipitate labor can be predicted from a labor graph if, during the active phase of dilatation, the rate is greater than 5 cm/hr (1 cm every 12 minutes) in a nullipara or 10 cm/hr (1 cm every 6 minutes) in a multipara. In such instances, a tocolytic may be administered to reduce the force and frequency of contractions.

Caution a multiparous woman by week 28 of pregnancy that, because a past labor was so brief, her labor this time also may be brief. This allows her to plan for appropriately timed transportation to the hospital or alternative birthing center. Both grand multiparas and women with histories of precipitate labor should have the birthing room converted to birth readiness before full dilatation is obtained. Then, even a sudden birth can be accomplished in a controlled surrounding.

What if... Roseann tells you that her sister was only in labor 1 hour when she had her baby, but Roseann is planning to spend the last days of this pregnancy in a mountain cabin 60 miles from the hospital? What would you do?

Induction and Augmentation of Labor

When labor contractions are ineffective, several interventions, such as induction and augmentation of labor with oxytocin or amniotomy (artificial rupture of the membranes), may be initiated to strengthen them (Howarth & Botha, 2009).

Induction of labor means that labor is started artificially. **Augmentation of labor** refers to assisting labor that has started spontaneously but is not effective. Induction may be necessary to initiate labor before the time when it would have occurred spontaneously because a fetus is in danger or because labor does not occur spontaneously and the fetus appears to be at term. The primary reasons for inducing labor include the presence of pre-eclampsia; eclampsia; severe hypertension; diabetes; Rh sensitization; prolonged rupture of the membranes; intrauterine growth restriction; and postmaturity (a pregnancy lasting beyond 42 weeks)—all situations that increase the risk for a fetus to remain in utero. Augmentation of labor or assistance to make uterine contractions stronger may be necessary if the contractions are hypotonic or too weak or infrequent to be effective.

Because augmentation or initiation of labor carries a risk of uterine rupture, decrease in the fetal blood supply from poor cotyledon filling, or premature separation of the placenta, it is used cautiously with women with a multiple gestation, hydramnios, grand parity, maternal age older than 40 years, or previous uterine scars.

Before induction of labor is begun, the following conditions should be present:

- The fetus is in a longitudinal lie.
- The cervix is ripe, or ready for birth.
- A presenting part is engaged.
- There is no CPD.
- The fetus is estimated to be mature by date, demonstrated by a lecithin–sphingomyelin ratio or ultrasound biparietal diameter to rule out preterm birth.

Cervical Ripening

Cervical ripening, or a change in the cervical consistency from firm to soft, is the first step the uterus must complete in early labor. Until this has occurred, dilatation and coordination of uterine contractions will not occur. To determine whether a cervix is "ripe," or ready for dilatation, Bishop (1964) established criteria for scoring the cervix (Table 23.3). Using this scale, if a woman's total score is 8 or greater, the cervix is considered ready for birth and should respond to induction. To "ripen" a cervix, various methods can be instituted. One is known as "stripping the membranes," or separating the membranes from the lower uterine segment manually, using a gloved finger in the cervix. This is an easy procedure performed during an office visit. Possible complications of this mechanical method include bleeding from an undetected low-lying placenta, inadvertent rupture of membranes, and the possibility of infection if membranes should rupture.

The use of hygroscopic suppositories (suppositories of seaweed that swell on contact with cervical secretions) is also a time-honored method. These suppositories can be inserted to gradually and gently urge dilatation (laminaria technique). They are held in place by gauze sponges saturated with povidone-iodine or an antifungal cream. Documentation of how

TABLE 23.3 ✻ Scoring of the Cervix for Readiness for Elective Induction

	Score			
Scoring Factor	***0***	***1***	***2***	***3***
Dilatation (cm)	0	1–2	3–4	3–4
Effacement (%)	0–30	40–50	60–70	80
Station	–3	–2	–1–0	+1–+2
Consistency	Firm	Medium	Soft

many dilators and sponges were placed is important, so it can be documented afterward that none remain.

A more commonly used method of speeding cervical ripening is the application of a prostaglandin gel, such as misoprostol, to the interior surface of the cervix by a catheter or suppository, or to the external surface by applying it to a diaphragm and then placing the diaphragm against the cervix (Alfirevic & Weeks 2009). Additional doses may be applied every 6 hours. Two or three doses are usually adequate to cause ripening. Women should remain in bed in a side-lying position to prevent leakage of the medication, and the FHR should be monitored continuously for at least 30 minutes after each application (perhaps up to 2 hours after vaginal insertion). Side effects are vomiting, fever, diarrhea, and hypertension, so these should also be monitored. Oxytocin induction may be started 6 to 12 hours after the last prostaglandin dose (beginning it sooner might lead to hyperstimulation of the uterus [Karch, 2009]). Even with their side effects, prostaglandins are well accepted by women (Hofmeyr & Gulmezoglu, 2009). As a rule, they should be used with caution in women with asthma, renal or cardiovascular disease, or glaucoma (Box 23.3). They are contraindicated for women who have had past cesarean births (Lawson & Bienstock, 2007).

Induction of Labor by Oxytocin

Administration of **oxytocin** (synthetic form of naturally occurring pituitary hormone) initiates contractions in a uterus at pregnancy term (Archie, 2007). Oxytocin is always administered intravenously, so that, if hyperstimulation should occur, it can be quickly discontinued. Because the half-life of oxytocin is approximately 3 minutes, the falling serum level and effects are apparent almost immediately after discontinuation of IV administration.

Usually a form of oxytocin, such as Pitocin, is mixed in the proportion of 10 IU in 1000 mL of Ringer's lactate. Ten international units of oxytocin is the same as 10,000 milliunits (mU), so each milliliter of this solution contains 10 mU of oxytocin. An alternative dilution method is to add 15 IU of oxytocin to 250 mL of an IV solution; this yields a concentration of 60 mU/1 mL. Physician's orders for administration of oxytocin for induction usually designate the number of milliunits to be administered per minute. Be sure to know the dilution prescribed and recognize the concentration in each milliliter (Box 23.4).

When administering the infusion, "piggyback" the oxytocin solution to a maintenance IV solution such as Ringer's lactate. Then, if the oxytocin needs to be discontinued quickly during the induction, the main IV line can still be maintained. Always attach the oxytocin solution to the infusion port closest to the woman. This way, if it is stopped, little solution remains in the tubing to still infuse. Use an infusion pump to regulate the infusion rate, so that the rate will not change even if a woman changes position. A physician should be immediately available during the entire procedure to ensure safety.

Infusions are usually begun at a rate of 0.5 to 1 mU/min. If there is no response, the infusion is gradually increased every 15 to 60 minutes by small increments of 1 to 2 mU/min until contractions begin. Many women respond with as little as 4 mU/min; most women respond at 16 mU/min. Do not

BOX 23.3 ✻ Focus on Pharmacology

Misoprostol (Cytotec)

Classification: Misoprostol is a synthetic prostaglandin (PGE1 analog).
Action: Produces cervical dilatation
Pregnancy Risk Category: X
Dosage: 50 to 100 μg orally or 25 to 50 μg placed intravaginally in the posterior fornix
Possible Adverse Effects: Uterine hyperstimulation, nonreassuring fetal heart rate pattern, nausea, diarrhea, flatulence, headache

Nursing Implications

- Ensure that the woman's condition is rated as safe for cervical dilatation and vaginal birth (absence of placenta previa, vasa previa, or cephalopelvic disproportion and the fetus is mature) before administration.
- Anticipate the need for a nonstress test to ensure fetal health before the drug is used.
- Continuously monitor uterine activity and fetal heart rate.
- Have an intravenous fluid line and a tocolytic readily available should uterine hyperstimulation occur (Karch, 2009).

BOX 23.4 ✻ Focus on Pharmacology

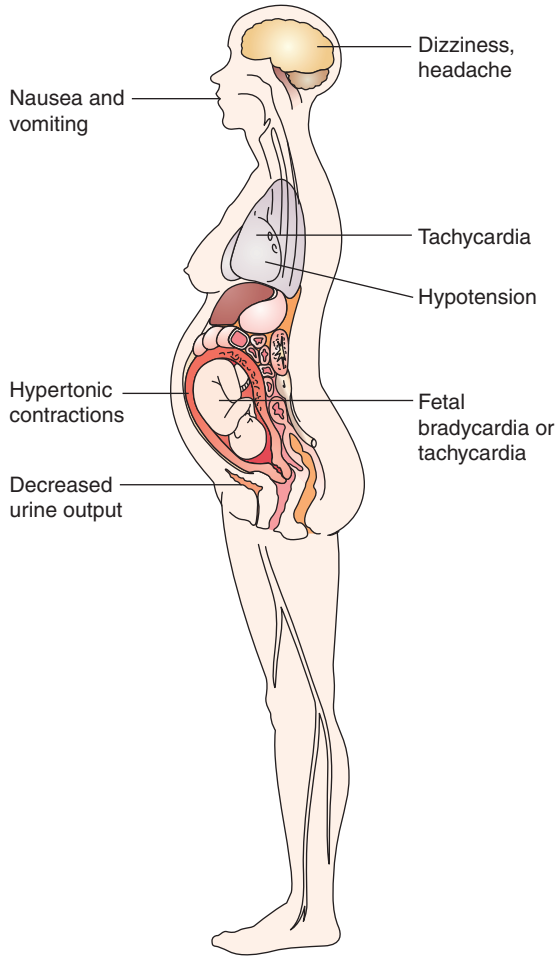
Oxytocin for Labor Induction

Classification: Oxytocin is a synthetic form of the naturally occurring posterior pituitary hormone.
Action: Used to initiate uterine contractions in a term pregnancy
Pregnancy Risk Category: C
Dosage: Initially 1 to 2 mU/min by intravenous (IV) infusion, increased at a rate no more than 1 to 2 U/min at 15- to 30-minute intervals until a contraction pattern similar to normal labor is achieved
Possible Adverse Effects: Nausea, vomiting, cardiac arrhythmias, uterine hypertonicity, tetanic contractions, uterine rupture (with excessive dosages), severe water intoxication, and fetal bradycardia

Nursing Implications

- Prepare IV solution by adding 1 mL (10 IU) to 1000 mL of designated intravenous fluid (resulting solution contains 10 mU/mL).
- Use an infusion pump to ensure accurate control of infusion rate.
- Regulate infusion rate to establish uterine contractions similar to a normal labor pattern.
- Monitor frequency, duration, and strength of contractions.
- Assess maternal pulse and blood pressure, and watch for possible hypertension. If hypertension occurs, discontinue drug and notify physician.
- Continuously monitor fetal heart rate for signs of fetal distress.
- Monitor intake and output and watch for signs of possible water intoxication, such as headache or vomiting. Limit IV fluids to 150 mL/hr.
- Prepare the woman for birth (Karch, 2009)

Box 23.5 Assessment
Assessing the Pregnant Woman for Danger Signs of Oxytocin Administration



increase the rate to more than 20 mU/min without checking for further instructions, because an administration rate greater than this is likely to cause tetanic contractions. Aggressive induction (an increment of 6 mU/min instead of the usual 1 to 2 mU/min) has been suggested as a way to shorten labor and may be used in some research facilities.

After cervical dilatation reaches 4 cm, artificial rupture of the membranes may be performed to further induce labor, and the infusion may be discontinued at that point. For other women, the infusion is continued through full dilatation.

Peripheral vessel dilatation, a side effect of oxytocin, may cause extreme hypotension. To ensure safe induction, take the woman's pulse and blood pressure every 15 minutes. Monitor uterine contractions and FHR conscientiously. (See Box 23.5 for additional assessments for danger signs of oxytocin administration.)

Contractions should occur no more often than every 2 minutes, should not be stronger than 50 mm Hg pressure, and should last no longer than 70 seconds. The resting pressure between contractions should not exceed 15 mm Hg by monitor (Fig. 23.5). If contractions become more frequent or longer in duration than these safe limits, or if signs of fetal distress occur, stop the IV infusion and seek help immediately. Anticipate the need for oxygen administration. Excessive stimulation of the uterus by oxytocin may lead to tonic uterine contractions with fetal death or rupture of the uterus.

If stopping the oxytocin infusion does not stop the hyperstimulation, a beta-adrenergic receptor drug such as terbutaline sulfate (Brethine) or magnesium sulfate may be prescribed to decrease myometrial activity.

Oxytocin has an antidiuretic side effect that can result in decreased urine flow, possibly leading to water intoxication. Water intoxication is first manifested by headache and vomiting. If you observe these danger signs in a woman during induction of labor, report them immediately and halt the infusion. Water intoxication in its most severe form can lead to seizures, coma, and death because of the large shift in interstitial tissue fluid. Keep an accurate intake and output record, and test and record urine specific gravity throughout oxytocin administration to detect fluid retention. Limit the amount of IV fluid being given to 150 mL/hr by ensuring that the main IV fluid line is infusing at a rate not greater than 2.5 mL/min.

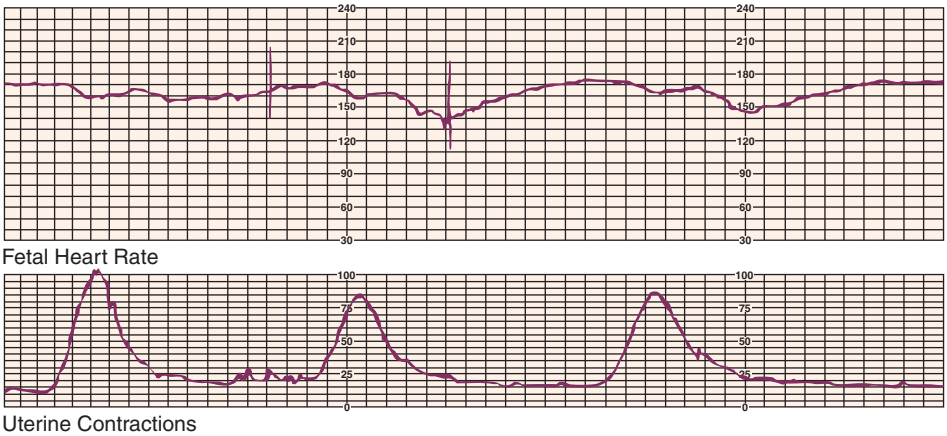


FIGURE 23.5 Hypertonic uterine contractions caused by an oxytocin infusion. Contractions are as high as 100 mm Hg in intensity. Late decelerations and an FHR of 170 beats per minute baseline are present.

Women may worry that induced labor will be more painful or "so different" from normal labor that breathing exercises will be worthless, or that it will progress so fast it will be harmful to the fetus. Induced labors do tend to have a slightly shorter first stage than the average unassisted labor. However, this is an advantage to a woman, not a disadvantage. Once contractions begin by this method, they are basically normal uterine contractions. You can assure the woman of this, so that she does not fight the contractions or become unnecessarily tense, which could prevent her from using her breathing techniques effectively. Induction of labor with oxytocin can predispose a newborn to hyperbilirubinemia and jaundice. Observe the infant closely for these conditions during the first few days of life.

Augmentation by Oxytocin

Augmentation of labor is required if labor contractions begin spontaneously but then become so weak, irregular, or ineffective (hypotonic) that assistance is needed to strengthen them (Box 23.6).

Precautions regarding oxytocin augmentation are the same as for primary induction of labor. A uterus may be very responsive or respond very effectively to oxytocin used as augmentation (see the Focus on Nursing Care Planning Box 23.7). Be certain that the drug is increased in small increments only and that fetal heart sounds are well monitored during the procedure.

Active Management of Labor

A technique of active management of labor began in Europe and has spread to some centers in the United States. It includes the aggressive administration of oxytocin (increases of 6 mU/min rather than 1 or 2 mU/min) to shorten labor to 12 hours, which presumably reduces the incidence of cesarean birth and postpartal infection. The maximum dosage of oxytocin used may be as high as 36 to 40 mU/min. Active management is controversial because it violates the tradition of birth as a normal, procedure-free process. Because it can shorten labor, it has the potential to reduce the number of postpartal fevers that occur from infection or dehydration.

Uterine Rupture

Rupture of the uterus during labor, although rare, is always a possibility (Scearce & Uzelac, 2007). It is always serious, because it accounts for as many as 5% of all maternal deaths. Uterine rupture occurs when a uterus undergoes more strain than it is capable of sustaining. Rupture occurs most commonly when a vertical scar from a previous cesarean birth or hysterotomy repair tears (it occurs in less than 1% of women who have a low transverse cesarean scar from a previous pregnancy; about 4% to 8% of women who have a classic cesarean incision) (Szymanski & Bienstock, 2007). Contributing factors may include prolonged labor, abnormal presentation, multiple gestation, unwise use of oxytocin, obstructed labor, and traumatic maneuvers of forceps or traction. When uterine rupture occurs, fetal death will follow unless immediate cesarean birth can be accomplished. In these instances, fetal outcome can be optimal.

Impending rupture may be preceded by a pathologic retraction ring (see earlier discussion) and by strong uterine contractions without any cervical dilatation. To prevent rupture when these symptoms are present, anticipate the need for an immediate cesarean birth. If a uterus should rupture, the woman experiences a sudden, severe pain during a strong labor contraction, which she may report as a "tearing" sensation.

BOX 23.6 ✻ Focus on Family Teaching

Understanding Augmentation of Labor

Q. Roseann Bigalow says to you, "My doctor said she's going to augment my labor. What did she mean by that?"

A. Augmentation of labor is used when labor contractions are ineffective. It can shorten labor and avoid the necessity of cesarean birth. The drug used is oxytocin, a synthetic form of the hormone naturally released by your body during labor. It is administered intravenously. Once labor contractions begin by this method, they are the same as naturally occurring contractions. You will be able to use your prepared breathing exercises with them.

BOX 23.7 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Woman Experiencing Dysfunctional Labor

Roseann Bigalow, a 28-year-old woman about to give birth to her first baby, is admitted to a birthing room. Her contractions have been 5 minutes apart for 10 hours. She feels more pain in her back than in her abdomen, "like my spine is tearing apart." A contraction monitor shows contractions are hypotonic. An ultrasound shows the fetus is above average in weight and in an occipitoposterior position. Her husband asks you if the reason Roseann's labor is taking so long is because she's overweight.

Family Assessment ✻ Roseann has been married for 2 years. Present pregnancy planned. Husband, 34 years old, owns a car dealership. Roseann works as salesperson in dealership. Finances rated as "no problem."

Client Assessment ✻ Client G1P0 in latent stage of labor. Membranes artificially ruptured approximately 1 hour ago. Cervix dilatated 4 cm, 80% effaced. Internal electronic fetal monitor in place. Contractions every 5 minutes, with peak strength at 20–25 mm Hg and a duration of 10 seconds. FHR at 130 to 140 bpm with beat-to-beat variability present. Client and partner visibly apprehensive, watching monitor intensely.

Client vital signs within normal parameters. Ringer's lactate IV solution infusing at 150 mL/hr via infusion pump. Client NPO, asking for something to eat "to keep up strength." Pelvic ultrasound reveals fetus in occipitoposterior position. Oxytocin ordered at 1 mU/min; increase 1 mU/min at 15-min intervals.

Nursing Diagnosis ✻ Risk for injury (maternal and fetal) related to prolonged labor with ineffective contractions and requiring oxytocin

Outcome Criteria ✻ Client's vital signs remain within acceptable parameters; FHR and fetal heart patterns within acceptable limits; contractions increase after oxytocin administration without becoming hypertonic; labor progresses without signs and symptoms of maternal or fetal distress. Urine output is at least 30 mL/hr; urine specific gravity 1.010–1.030.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Assess what position allows client the most comfort with a occipitoposterior fetal position.	Encourage client to lie on her side or on hands and knees as much as possible. Encourage partner to apply back massage.	A side-lying position enhances placental perfusion. Back massage can aid comfort. A hands and knees position may encourage fetal rotation.	Client determines position of comfort. Requests massage if helpful with contractions.
		Consultations		
Physician	Assess whether resident physician coverage will be available for oxytocin administration.	Discuss need for oxytocin administration because of prolonged labor.	Oxytocin administration requires a physician's presence.	Resident physician will be available during oxytocin infusion time.
		Procedures/Medications		
Nurse/ Physician/ Nurse-Midwife	Assess client's vital signs, fetal heart rate, contraction strength and frequency.	Begin piggybacked IV oxytocin administration as ordered, using an infusion control device.	Oxytocin stimulates uterine contractions. Piggybacking the solution with an infusion control device allows for accurate dosing. Should an emergency arise, the infusion can be stopped immediately.	Oxytocin solution infuses at prescribed rate. Client's blood pressure remains <150/90 mm Hg; FHR is 120–160 bpm; no late decelerations occur.

		Nutrition		
Nurse	Assess intake and output and test urine for specific gravity.	Monitor the IV fluid infusion and adjust rate as ordered.	Intake and output and urine specific gravity are reliable indicators of fluid volume status. Inadvertent administration of too rapid a rate or too great an amount of IV fluid can increase the risk of fluid overload.	Client shows no symptoms of water intoxication: headache, lethargy, confusion, or a change in level of consciousness.
Nurse	Assess what measure client feels would relieve dry mouth best in light of NPO status.	Suggest hard candy or ice chips.	Fluid restrictions may be necessary to minimize the risk for increased fluid overload.	Client states she is comfortable while minimizing fluid intake.
		Patient/Family Education		
Nurse	Explore the meaning of prolonged labor with the couple. Assess for possible feelings related to "cause" of prolonged labor.	Encourage couple to verbalize feelings and concerns. Allow time for questions and answers.	Exploration, verbalization, and active questioning provide a safe outlet for feelings, help to increase the partner's awareness of needs, and open lines of communication.	Client and partner are able to discuss their feelings with caregivers. They state that they understand prolonged labor is not anyone's fault.
		Psychosocial/Spiritual/Emotional Needs		
Nurse	Assess what the couple thought labor would be like.	Include couple in the treatment process; provide frequent updates about labor progress.	Frequent updates about progress help to minimize the feelings of fear about the unknown.	Couple state they feel well informed about progress in labor.
		Discharge Planning		
Nurse	Assess whether labor experience was tolerable for couple in light of a complication.	Provide time for couple to "debrief" their labor experience.	Discussing or "putting a fence around" an experience helps to integrate it into other life events.	Couple state they feel comfortable with labor outcome.

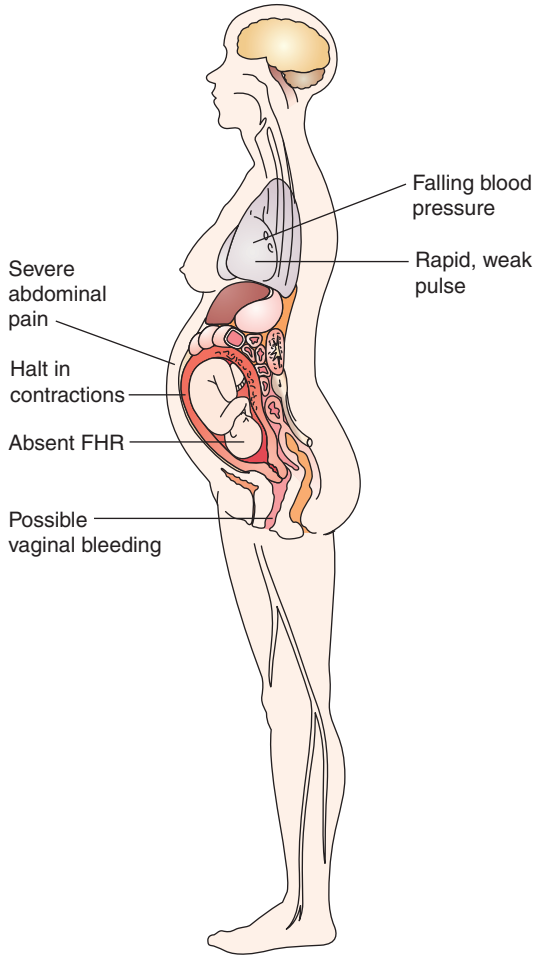
Rupture can be complete, going through the endometrium, myometrium, and peritoneum layers, or incomplete, leaving the peritoneum intact. With a complete rupture, uterine contractions will immediately stop. Two distinct swellings will be visible on the woman's abdomen: the retracted uterus and the extrauterine fetus. Hemorrhage from the torn uterine arteries floods into the abdominal cavity and possibly into the vagina. Signs of shock begin, including rapid, weak pulse; falling blood pressure; cold and clammy skin; and dilatation of the nostrils from air hunger. Fetal heart sounds fade and then are absent.

If the rupture is incomplete, the signs of rupture are less evident. With an incomplete rupture, a woman may experience only a localized tenderness and a persistent aching pain over the area of the lower uterine segment. However, fetal heart sounds, a lack of contractions, and the changes in the woman's vital signs will gradually reveal fetal and maternal distress (Box 23.8). Uterine rupture can be confirmed by ultrasound (Has et al., 2008).

Because the uterus at the end of pregnancy is such a vascular organ, uterine rupture is an immediate emergency situation, comparable to splenic or hepatic rupture. Administer emergency fluid replacement therapy as ordered. Anticipate use of IV oxytocin to attempt to contract the uterus and minimize bleeding. Prepare the woman for a possible laparotomy as an emergency measure to control bleeding and achieve a repair. The viability of the fetus depends on the extent of the rupture and the time elapsed between rupture and abdominal extraction. A woman's prognosis depends on the extent of the rupture and the blood loss.

Most women are advised not to conceive again after a rupture of the uterus, unless the rupture occurred in the inactive lower segment. The physician, with consent, may perform a cesarean hysterectomy (removal of the damaged uterus) or

Box 23.8 Assessment
Assessing the Pregnant Woman With Complete Uterine Rupture



tubal ligation at the time of the laparotomy; both procedures result in loss of childbearing ability. A woman may have difficulty giving her consent at this time, because it is unknown whether her present baby will live. If blood loss was acute, she may be nonresponsive because of decreased cerebral perfusion from hypotension. If this has happened, the woman's support person must be the one who gives this consent, relying on the information provided by the operating surgeon to decide whether a functioning uterus can be saved.

Be prepared to offer information to the support person and to inform him or her about fetal outcome, the extent of the surgery, and the woman's safety as soon as possible. Initially, a woman and her support person will probably be thankful that her life was saved. However, they may become almost immediately angry that the rupture occurred, especially if the fetus died and the woman will no longer be able to have children. Allow them time to express these emotions without feeling threatened. Explaining to them about the death of the fetus is very difficult; utilize clergy or counselors as needed to help begin the coping process. The parents may want to plan a funeral, as oftentimes the babies are full term. They are grieving for the loss of both the child and their fertility as a couple. The couple is also dealing with an unexpected surgery to the mother, causing stressors that they did not plan for both financially and emotionally.

Inversion of the Uterus

Uterine inversion refers to the uterus turning inside out with either birth of the fetus or delivery of the placenta. It is a rare phenomenon, occurring in about 1 in 20,000 births (Poggi, 2007). It may occur if traction is applied to the umbilical cord to remove the placenta or if pressure is applied to the uterine fundus when the uterus is not contracted. It may also occur if the placenta is attached at the fundus so that, during birth, the passage of the fetus pulls the fundus down.

Inversion occurs in various degrees. The inverted fundus may lie within the uterine cavity or the vagina, or, in total inversion, it may protrude from the vagina. When an inversion occurs, a large amount of blood suddenly gushes from the vagina. The fundus is not palpable in the abdomen. If the loss of blood continues unchecked for longer than a few minutes, the woman will show signs of blood loss: hypotension, dizziness, paleness, or diaphoresis. Because the uterus is not contracted in this position, bleeding continues, and exsanguination could occur within a period as short as 10 minutes.

Never attempt to replace an inversion, because handling of the uterus may increase the bleeding. Never attempt to remove the placenta if it is still attached, because this only creates a larger surface area for bleeding. In addition, administration of an oxytocic drug only compounds the inversion or makes the uterus more tense and difficult to replace. An IV fluid line needs to be started, if one is not already present (use a large-gauge needle, because blood will need to be replaced). If a line is already in place, open it to achieve optimal flow of fluid to restore fluid volume. Administer oxygen by mask, and assess vital signs. Be prepared to perform cardiopulmonary resuscitation (CPR) if the woman's heart should fail from the sudden blood loss. The woman will immediately be given general anesthesia or possibly nitroglycerin or a tocolytic drug intravenously, to relax the uterus. The physician or nurse-midwife then replaces the fundus manually. Administration of oxytocin after manual replacement helps the uterus to contract and remain in its natural place. Because the uterine endometrium was exposed, a woman will need antibiotic therapy to prevent infection. She needs to be informed that cesarean birth will probably be necessary in any future pregnancy, to prevent the possibility of repeat inversion.

✔ Checkpoint Question 23.2

Suppose a woman experiences a uterine inversion and the placenta is still attached. What would be your best action?

a. Remove the placenta manually so that the uterus contracts.
b. Attempt to replace the uterus so that it becomes compressed.
c. Increase the woman's intravenous fluid to help restore blood loss.
d. Give an emergency bolus of an oxytocin such as Pitocin IV.

Amniotic Fluid Embolism

Amniotic fluid embolism occurs when amniotic fluid is forced into an open maternal uterine blood sinus through some defect in the membranes or after membrane rupture or

partial premature separation of the placenta (Schoening, 2007). Previously, it was thought that particles such as meconium or shed fetal skin cells in the amniotic fluid entered the maternal circulation and reached the lungs as small emboli. Now, it is recognized that a humoral or anaphylactoid response is the more likely cause. This condition may occur during labor or in the postpartal period. The incidence is about 1 in 20,000 births; it accounts for at least 10% of maternal deaths in the United States (Szymanski & Bienstock, 2007). It is not preventable because it cannot be predicted. Possible risk factors include oxytocin administration, abruptio placentae, and hydramnios.

The clinical picture is dramatic. A woman, in strong labor, sits up suddenly and grasps her chest because of sharp pain and inability to breathe as she experiences pulmonary artery constriction. She becomes pale and then turns the typical bluish gray associated with pulmonary embolism and lack of blood flow to the lungs. The immediate management is oxygen administration by face mask or cannula. Within minutes, she will need CPR. CPR may be ineffective, however, because these procedures (inflating the lungs and massaging the heart) do not relieve the pulmonary constriction. Therefore, blood still cannot circulate to the lungs. Death may occur within minutes.

A woman's prognosis depends on the size of the embolism, the speed with which the emergency condition was detected, and the skill and speed of emergency interventions. Even if the woman survives the initial insult, the risk for disseminated intravascular coagulation (DIC) is high, further compounding her condition. In this event, she will need continued management that includes endotracheal intubation to maintain pulmonary function and therapy with fibrinogen to counteract DIC. Most likely, she will be transferred to an ICU. The prognosis for the fetus is guarded, because reduced placental perfusion results from the severe drop in maternal blood pressure. Labor often begins or the fetus is born immediately by cesarean birth.

BOX 23.9 ✻ Focus on Evidence-Based Practice

Is human papillomavirus (HPV) associated with preterm birth?

It is well documented that HPV is associated with the development of cervical cancer. To analyze whether it also could be responsible for some preterm births, researchers inspected placenta cells for the presence of HPV in placentas from three groups of women: those who had had a spontaneous preterm delivery, those who had had severe pre-eclampsia requiring early birth of their child, and, as a control group, those who had had an uncomplicated term birth. Results showed that HPV was present more frequently in placentas from spontaneous preterm births than in placentas from term births ($p = 0.03$). Identification of HPV in placentas from women with pre-eclampsia was not significantly different than placentas from term births. Researchers found that HPV infection caused cell death of placental trophoblast cells which reduce the ability of the placenta to invade into the uterine wall for firm attachment. Thus, HPV infection may cause placental dysfunction. and is associated with adverse pregnancy outcomes, including spontaneous preterm birth.

Would the above study suggest another reason to advise adolescent girls to have an HPV vaccine (Gardasil)?

Source: Gomez, L. M., et al. (2008). Placental infection with human papillomavirus is associated with spontaneous preterm delivery. *Human Reproduction, 23*(3), 709–715.

PROBLEMS WITH THE PASSENGER

Birth complications may arise if an infant is immature or preterm (Box 23.9). Complications may also occur if the maternal pelvis is so undersized, such as occurs in early adolescence or in women with altered bone growth from a disease such as rickets that its diameters are smaller than the fetal skull diameters. It also can occur if the umbilical cord prolapses, if more than one fetus is present, or if a fetus is malpositioned or too large for the birth canal.

Prolapse of the Umbilical Cord

In **umbilical cord prolapse,** a loop of the umbilical cord slips down in front of the presenting fetal part (Fig. 23.6).

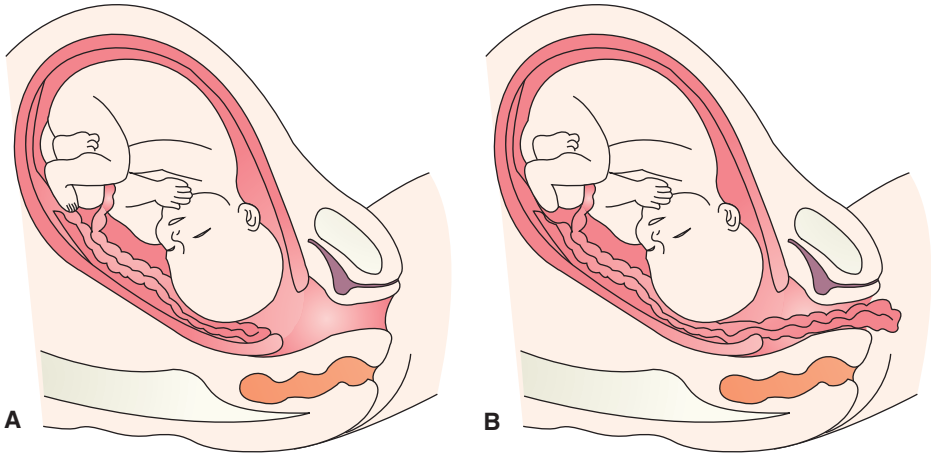


FIGURE 23.6 Prolapse of the umbilical cord. (**A**) The cord is prolapsed but still within the uterus. (**B**) The cord is visible at the vulva. In both instances the fetal nutrient supply is being compromised, although only a cord such as that shown in B would be visible. Both prolapses could be detected by fetal monitoring.

Prolapse may occur at any time after the membranes rupture if the presenting fetal part is not fitted firmly into the cervix. It tends to occur most often with:

- Premature rupture of membranes
- Fetal presentation other than cephalic
- Placenta previa
- Intrauterine tumors preventing the presenting part from engaging
- A small fetus
- Cephalopelvic disproportion preventing firm engagement
- Hydramnios
- Multiple gestation

The incidence is about 0.5% of cephalic births; this rises as high as 15% to 20% with breech or transverse lies (Kish & Collea, 2007).

Assessment

In rare instances, the cord may be felt as the presenting part on an initial vaginal examination during labor. It may also be identified in this position on an ultrasound. When this happens, cesarean birth is necessary before rupture of the membranes occurs. Otherwise, membrane rupture would cause the cord to slide down into the vagina from the pressure exerted by the amniotic fluid. More often, however, cord prolapse is first discovered only after the membranes have ruptured, when a variable deceleration FHR pattern suddenly becomes apparent. The cord may be visible at the vulva.

To rule out cord prolapse, always assess fetal heart sounds immediately after rupture of the membranes whether this occurs spontaneously or by amniotomy.

Therapeutic Management

Cord prolapse automatically leads to cord compression, because the fetal presenting part presses against the cord at the pelvic brim. Management is aimed at relieving pressure on the cord, thereby relieving the compression and the resulting fetal anoxia. This may be done by placing a gloved hand in the vagina and manually elevating the fetal head off the cord, or by placing the woman in a knee–chest or Trendelenburg position, which causes the fetal head to fall back from the cord. Administering oxygen at 10 L/min by face mask to the woman is also helpful to improve oxygenation to the fetus. A tocolytic agent may be prescribed to reduce uterine activity and pressure on the fetus. Amnioinfusion (see later) is yet another way to relieve pressure on the cord (Hofmeyr, 2009).

If the cord has prolapsed to the extent that it is exposed to room air, drying will begin, leading to atrophy of the umbilical vessels. Do not attempt to push any exposed cord back into the vagina. This may add to the compression by causing knotting or kinking. Instead, cover any exposed portion with a sterile saline compress to prevent drying.

If the cervix is fully dilated at the time of the prolapse, the physician may choose to birth the infant quickly, possibly with forceps, to prevent fetal anoxia. If dilatation is incomplete, the birth method of choice is upward pressure on the presenting part, applied by a practitioner's hand in the woman's vagina, to keep pressure off the cord until the baby can be born by cesarean birth. Prolapsed cord is always an emergency situation, because the reduced blood flow to the fetus can quickly cause fetal harm.

Amnioinfusion. **Amnioinfusion** is the addition of a sterile fluid into the uterus to supplement the amniotic fluid (Chhabra, Dargan, & Nasare, 2007). The technique neither shortens nor prolongs labor; it just prevents additional cord compression. For this, a sterile catheter is introduced through the cervix into the uterus after rupture of the membranes. It is attached to intravenous tubing, and a solution of warmed normal saline or lactated Ringer's solution is rapidly infused. Initially, approximately 500 mL is infused, and then the rate is adjusted to infuse the least amount necessary to maintain a monitor pattern without variable decelerations. Throughout the procedure, urge a woman to lie in a lateral recumbent position to prevent supine hypotension syndrome.

Help maintain strict aseptic technique during insertion and while caring for the catheter. Continuously monitor FHR and uterine contractions internally during the infusion. Record maternal temperature hourly to detect infection. Be sure the solution is warmed to body temperature before the infusion, to prevent chilling of the woman and fetus. This can be done by placing the bag of fluid on a radiant heat warmer or by using a blood/fluid warmer before administration.

Because there will be a continuous flow of the infusing solution out of the woman's vagina during the procedure, change her bed frequently. Also assess that there is constant drainage. If vaginal leakage should stop, it usually means that the fetal head is firmly engaged and all fluid being infused is being held in the uterus. This is dangerous because it could lead to hydramnios (presence of excessive amniotic fluid) and possibly uterine rupture.

Fetal Blood Sampling. Although obtaining a fetal oxygen saturation level by inserting a fetal oximeter into the uterus to rest next to the fetal cheek or obtaining a positive response to scalp stimulation usually supplies the information as to whether a fetus is becoming acidotic (see Chapter 15), this information can also be obtained by scalp blood or fetal blood sampling (Lawson & Bienstock, 2007).

The oxygen saturation, partial pressures of oxygen (P_{O_2}) and carbon dioxide (P_{CO_2}), pH, bicarbonate excess, and hematocrit of fetal blood may all be determined during labor if a sample of capillary blood is taken from the fetal scalp as it presents at the dilated cervix. After cervical dilatation of 3 to 4 cm and rupture of the membranes, the fetal head is visualized by the use of an amnioscope—a small, cone-shaped instrument with a light source at the far end. The scalp is cleaned with povidone-iodine and sprayed with silicon. A small scalpel is introduced vaginally into the cervix, and the fetal scalp is nicked. The silicon causes blood to form in beads, which are caught by a capillary tube. The incision is then compressed until the bleeding has stopped. After the procedure, the woman must be observed after two or three contractions to be certain that no new fetal scalp bleeding occurs.

Although a blood sample obtained in this way may be analyzed for many parameters, usually only the pH results are necessary. If the fetus is hypoxic, the pH will fall (become acidotic). A scalp blood pH greater than 7.25 is considered normal for a fetus during labor. A pH between 7.21 and 7.25 should be remeasured in 30 minutes. A scalp blood pH lower than 7.20 is acidotic and signifies a level of fetal distress. This technique may be used to verify a heart rate pattern on a monitor that is becoming ominous. It can also be used to

verify that no acidosis is occurring, even if a monitor rate is showing decreased variability.

Fetal blood sampling involves no pain for the woman, but it may involve an uncomfortable sensation of pressure because of the examining hand in the vagina. Infants who have had internal scalp blood samples taken should not be born by vacuum extraction, because this procedure can lead to renewed bleeding at the puncture site.

Multiple Gestation

A woman with a multiple gestation usually causes a flurry of excitement in a birthing room. Additional personnel are needed for the birth (as many nurses to attend to possibly immature infants as there are infants, plus additional pediatricians or neonatal nurse practitioners). In the middle of all the preparatory activity, it is easy to forget that a woman having a multiple birth may be more frightened than excited. Be sure to focus on her needs as well as those of her babies. Twins may be born by cesarean birth to decrease the risk that the second fetus will experience anoxia; this also is often the situation in multiple gestations of three or more, because of the increased incidence of cord entanglement and premature separation of the placenta (Fortner, Althaus, & Gurewitsch, 2007).

Anemia and pregnancy-induced hypertension occur at higher-than-usual incidences during multiple gestations. To detect these, be certain to assess the woman's hematocrit level and blood pressure closely during labor or while waiting for cesarean surgery.

If a woman with a multiple gestation will be giving birth vaginally, she is usually instructed to come to the hospital early in labor. The first stage of labor does not differ greatly from that of a woman with a single-gestation pregnancy. Coming to a hospital this early in labor, however, will make labor seem long. Urge the woman to spend the early hours of labor engaged in an activity such as playing cards or reading, to make the time pass more quickly. Multiple pregnancies often end before full term, so the woman may not yet have practiced breathing exercises. The early hours of labor can be used for this as well. During labor, support the woman's breathing exercises to minimize the need for analgesia or anesthesia; this helps to minimize any respiratory difficulties the infants may have at birth because of their immaturity.

If possible, monitor each FHR by a separate fetal monitor during labor. Because the babies are usually small, firm head engagement may not occur, increasing the risk for cord prolapse after rupture of the membranes. Because of the multiple fetuses, abnormal fetal presentation may occur. Uterine dysfunction from a long labor, an overstretched uterus, unusual presentation, and premature separation of the placenta after the birth of the first child may also be more common.

Most twin pregnancies present with both twins vertex. This is followed in frequency by vertex and breech, breech and vertex, and then breech and breech (Fig. 23.7). Multiple gestations of three or more fetuses have extremely varied presentations. After the first infant is born, both ends of the baby's cord are tied or clamped permanently, rather than with cord clamps, which could slip. This prevents hemorrhage

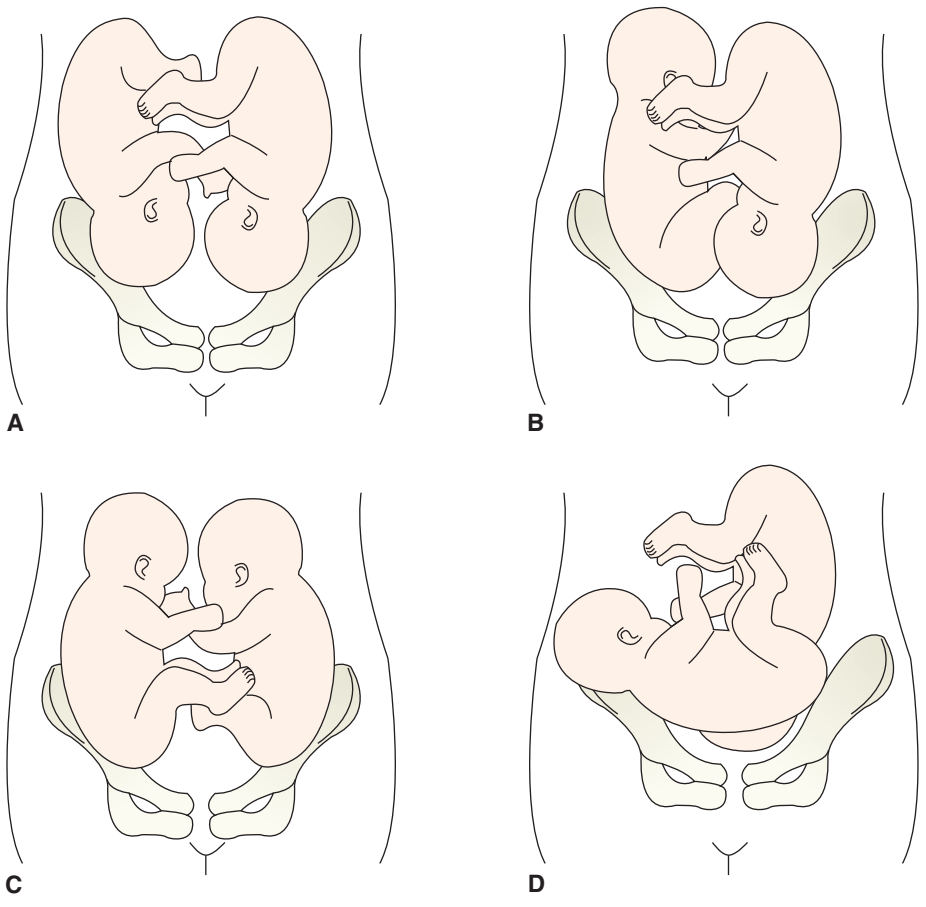

FIGURE 23.7 Four different twin presentations. (**A**) Both infants vertex. (**B**) One infant vertex and one breech. (**C**) Both infants breech. (**D**) One infant vertex and one in a transverse lie.

through an open cord end if additional infants have shared the placenta. The first infant is identified as *A,* and newborn care is started. In singleton pregnancies oxytocin usually is given immediately to contract the uterus and minimize bleeding after an infant is born; with this woman, however, it will not be given, to avoid compromising the circulation of the infants not yet born.

After the birth of the first child, the lie of the second fetus is determined by external abdominal palpation or ultrasound. If the presentation is not vertex, external version may be attempted to make it so (Longo & Hankins, 2007). If this is not successful, a decision for a breech birth or cesarean birth must be made (Cruikshank, 2007). If the infant will be born vaginally, an oxytocin infusion may be begun at this point to assist uterine contractions, thereby shortening the time span between births. If uterine relaxation is needed, nitroglycerin, an uterine relaxant, may be administered.

Occasionally, the placenta of the first infant separates before the second fetus is born, and there is sudden, profuse bleeding at the vagina. This creates a risk for the woman. The uterus cannot contract as it normally would, because it is still full with the second twin, so it is difficult to halt the bleeding. If the separation of the first placenta caused loosening of additional placentas, or if a common placenta is involved, the fetal heart sounds of the other fetuses will register distress immediately. They need to be born at once if they are to survive. For this reason, with most multiple gestations today, if all of the fetuses are not vertex presentations, they will be born by cesarean birth.

Parents usually want to inspect multiple-gestation infants thoroughly after birth. The time allowed for this inspection depends on the infants' weights and conditions. Some parents worry that the hospital will confuse their infants through improper identification. Review with them the measures used to ensure correct identification.

Even though women have known for months that they are having multiple infants, many have difficulty believing that this has really happened. They feel a need to recount over and over their surprise and to view all their infants together to prove to themselves that it is true. If parents are unable to inspect their infants thoroughly immediately after birth because of the infants' low birthweights and the danger of chilling, they need the opportunity to do so as soon as possible, to dispel any fears they had throughout pregnancy that the babies would be born less than perfect.

Assess the woman carefully in the immediate postpartal period, because the uterus that has been overly distended owing to the multiple gestation may have more difficulty contracting than usual, placing her at risk for hemorrhage from uterine atony (lacking normal tone). In addition, the risk for uterine infection increases if labor or birth was prolonged. The infants need careful assessment to determine their true gestational age and whether a phenomenon such as twin-to-twin transfusion could have occurred (see Chapter 26).

Problems With Fetal Position, Presentation, or Size

Occipitoposterior Position

In approximately one tenth of all labors, the fetal position is posterior rather than anterior. That is, the occiput (assuming

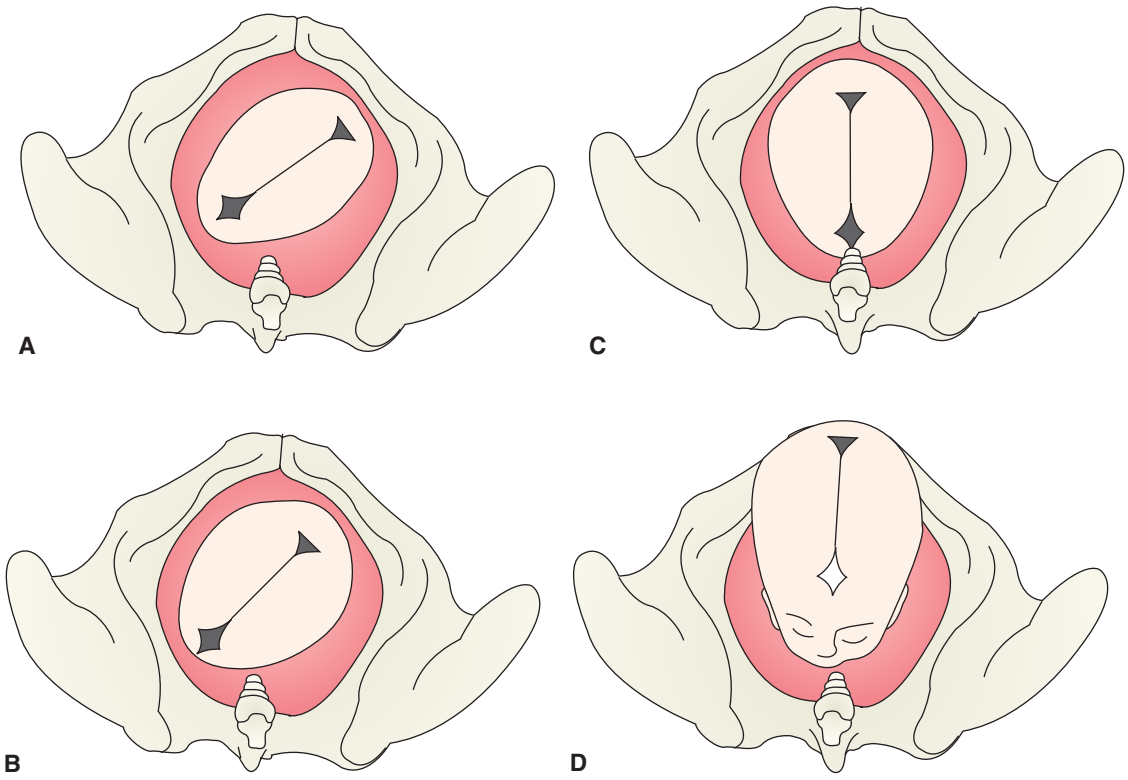

FIGURE 23.8 Left occipitoanterior (LOA) rotation. (**A**) A fetus in a cephalic presentation, LOA position. View is from the outlet. The fetus rotates 90 degrees from this position. (**B**) Descent and flexion. (**C**) Internal rotation complete. (**D**) Extension; the face and chin are born.

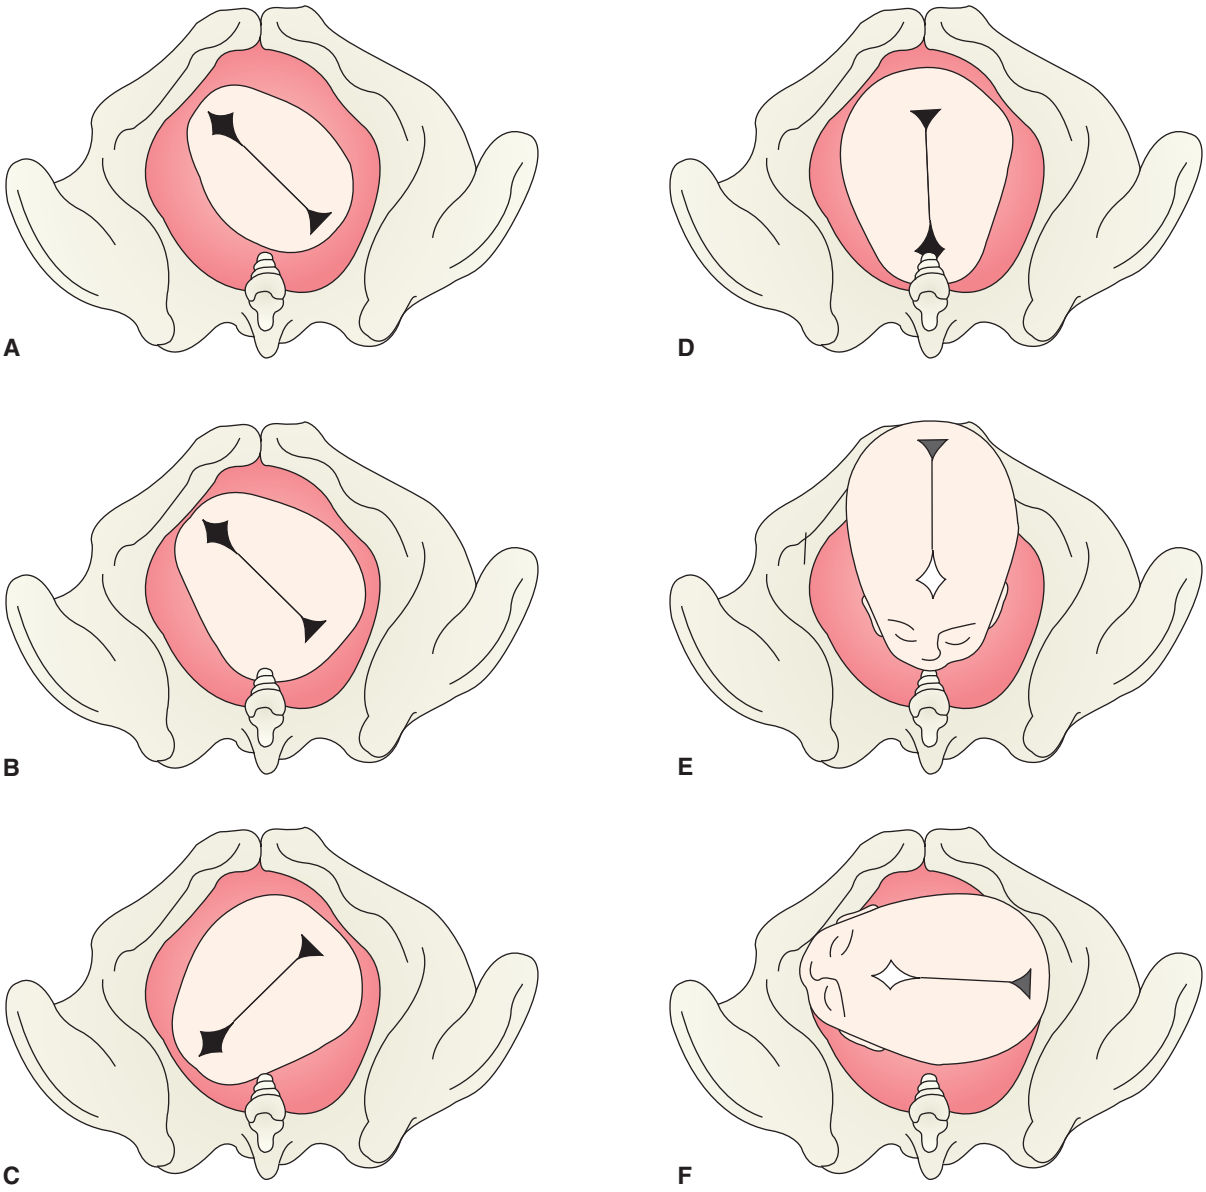

FIGURE 23.9 Left occipitoposterior (LOP) rotation. (**A**) Fetus in a cephalic presentation, LOP position. View is from outlet. The fetus rotates 135 degrees from this position. (**B**) Descent and flexion. (**C**) Internal rotation beginning. Because of the posterior position, the head will rotate in a longer arc than if it were in an anterior position. (**D**) Internal rotation complete. (**E**) Extension; the face and chin are born. (**F**) External rotation; the fetus rotates to place the shoulders in an anteroposterior position.

the presentation is vertex) is directed diagonally and posteriorly, either to the right (ROP) or to the left (LOP). In these positions, during internal rotation, the fetal head must rotate, not through a 90-degree arc (Fig. 23.8), but through an arc of approximately 135 degrees (Fig. 23.9). Rotation from a posterior position can be aided by having the woman assume a hands and knees position, squatting, or lying on her side (on her left side if the fetus is right occiput posterior; on her right side if the fetus is left occiput posterior). Theoretically, shifting the weight from right to left or "lunging" or swinging her body right to left while elevating her left foot on a chair widens the pelvic path and makes fetal rotation easier. This is unproved, however, and is tiring for women in labor.

Posterior positions tend to occur in women with android, anthropoid, or contracted pelves. A posterior position is suggested by a dysfunctional labor pattern such as a prolonged active phase, arrested descent, or fetal heart sounds heard best at the lateral sides of the abdomen.

A posteriorly presenting head does not fit the cervix as snugly as one in an anterior position. Because this increases the risk of umbilical cord prolapse, the position of the fetus is confirmed by vaginal examination or by ultrasound. The majority of fetuses presenting in posterior positions, if they are of average size and in good flexion and aided by forceful uterine contractions, rotate through the large arc, arrive at a good birth position for the pelvic outlet, and are born satisfactorily with only increased molding and caput formation.

FIGURE 23.10 With a posterior fetal position, a woman may feel extensive back pressure. Pressure on her lower back by her support person may help relieve this problem. (© Kathy Sloane.)

Because the arc of rotation is greater, it is usual for the labor to be somewhat prolonged (Strehlow & Uzelac, 2007).

Because the fetal head rotates against the sacrum, a woman may experience pressure and pain in her lower back owing to sacral nerve compression. These sensations may be so intense that she asks for medication for relief, not for her contractions but for the intense back pressure and pain. Applying counterpressure on the sacrum by a back rub may be helpful in relieving a portion of the pain (Fig. 23.10). Applying heat or cold, whichever feels best, also may help. Lying on the side opposite the fetal back or maintaining a hands-and-knees position may help the fetus rotate (Ridley, 2007). During a long labor of this type, be certain a woman voids approximately every 2 hours to keep her bladder empty, because a full bladder could further impede descent of the fetus. Be aware of how long it has been since the woman last ate. During a long labor, she may need an an oral sports drink or IV glucose solution to replace glucose stores used for energy.

If contractions are ineffective, or if the fetus is larger than average or not in good flexion, rotation through the 135-degree arc may not be possible. Uterine dysfunction may result from maternal exhaustion. The fetal head may arrest in the transverse position (transverse arrest), or rotation may not occur at all (persistent occipitoposterior position). In these instances, the fetus must be born by cesarean birth.

During labor, a woman needs a great deal of support to prevent her from becoming panicked about the length of the labor. Paradoxically, women who are best prepared for labor are often most frightened when deviations occur, because things are not going "by the book"—not happening just as described by the instructor of the course they attended or the book they read. Provide frequent reassurance that, although their pattern of labor is not "textbook," it is within safe, controlled limits. If forceps are used to help the fetus rotate, this places a woman at risk for cervical lacerations, hemorrhage, and infection in the postpartum period.

Breech Presentation

Most fetuses are in a breech presentation early in pregnancy. However, by week 38, a fetus normally turns to a cephalic presentation. Although the fetal head is the widest single diameter, the fetus's buttocks (breech), plus the legs, actually take up more space. The fact that the fundus is the largest part of the uterus is probably the reason why, in approximately 97% of all pregnancies, the fetus turns so that the buttocks and lower extremities are in the fundus.

There are several types of breech presentation: complete, frank, and footling (see Chapter 15). Breech presentation may occur for any of the reasons shown in Box 23.10. Breech presentation is more hazardous to a fetus than a cephalic presentation, because there is a higher risk of:

- Anoxia from a prolapsed cord
- Traumatic injury to the aftercoming head (possibility of intracranial hemorrhage or anoxia)
- Fracture of the spine or arm
- Dysfunctional labor
- Early rupture of the membranes because of the poor fit of the presenting part

The inevitable contraction of the fetal buttocks from cervical pressure often causes meconium to be extruded into the amniotic fluid before birth. This, unlike meconium staining that occurs because of fetal anoxia, is not a sign of fetal distress but is expected from the buttock pressure. Such meconium excretion can, however, lead to meconium aspiration if the infant inhales amniotic fluid.

Assessment. With a breech presentation, fetal heart sounds usually are heard high in the abdomen. Leopold's maneuvers and a vaginal examination usually reveal the presentation. If the breech is complete and firmly engaged, the tightly stretched gluteal muscles of the fetus may be mistaken on vaginal examination for a head; the cleft between the buttocks may be mistaken for the sagittal suture line. If the presentation is unclear, ultrasound clearly confirms a breech

BOX 23.10 ✻ Causes of Breech Presentation

- Gestational age less than 40 weeks
- Abnormality in a fetus, such as anencephaly, hydrocephalus, or meningocele. (In a fetus with hydrocephalus, the widest fetal diameter is the head, so it retains the most "comfortable" position.)
- Hydramnios that allows for free fetal movement, so that the fetus fits within the uterus in any position
- Congenital anomaly of the uterus, such as a midseptum, that traps the fetus in a breech position
- Any space-occupying mass in the pelvis, such as a fibroid tumor of the uterus or a placenta previa, that does not allow the head to present
- Pendulous abdomen. If the abdominal muscles are lax, the uterus may fall so far forward that the fetal head comes to lie outside the pelvic brim, causing a breech presentation.
- Multiple gestation. The presenting infant cannot turn to a vertex position.
- Unknown factors

presentation. Such a study also gives information on pelvic diameters, fetal skull diameters, and evidence of possible placenta previa causing the breech presentation.

In a breech birth, the same stages of flexion, descent, internal rotation, expulsion, and external rotation occur as in a vertex birth. Always monitor FHR and uterine contractions continuously, if possible, during this time. This allows early detection of fetal distress from a complication such as prolapsed cord and allows for prompt intervention.

Birth Technique. If the infant will be born vaginally, a woman is allowed to push after full dilatation is achieved, and the breech, trunk, and shoulders are born (Fig. 23.11). As the breech spontaneously emerges from the birth canal, it is steadied and supported by a sterile towel held against the infant's inferior surface (see Fig. 23.11C). The shoulders present to the outlet with their widest diameter anteroposterior. If they are not born readily, the arm of the posterior shoulder may be drawn down by passing two fingers over the infant's shoulder and down the arm to the elbow, then sweeping the flexed arm across the infant's face and chest and out. The other arm is delivered in the same way. External rotation is allowed to occur, to bring the head into the best outlet diameter.

Birth of the head is the most hazardous part of a breech birth. Because the umbilicus precedes the head, a loop of cord passes down alongside the head. The pressure of the head against the pelvic brim automatically compresses this loop of cord.

A second danger of a breech birth is intracranial hemorrhage. With a cephalic presentation, molding to the confines of the birth canal occurs over hours. With a breech birth, pressure changes occur instantaneously. Tentorial tears, which can cause gross motor and mental incapacity or lethal damage to the fetus, may result. The infant who is born suddenly to reduce the duration of cord compression may suffer an intracranial hemorrhage. In contrast, the infant who is born gradually to reduce the possibility of intracranial injury may suffer hypoxia.

To aid in birth of the head, the trunk of the infant is usually straddled over the physician's right forearm (see Fig. 23.11D). Two fingers of the physician's right hand are placed in the infant's mouth. The left hand is slid into the woman's vagina, palm down, along the infant's back. Pressure is applied to the occiput to flex the head fully.

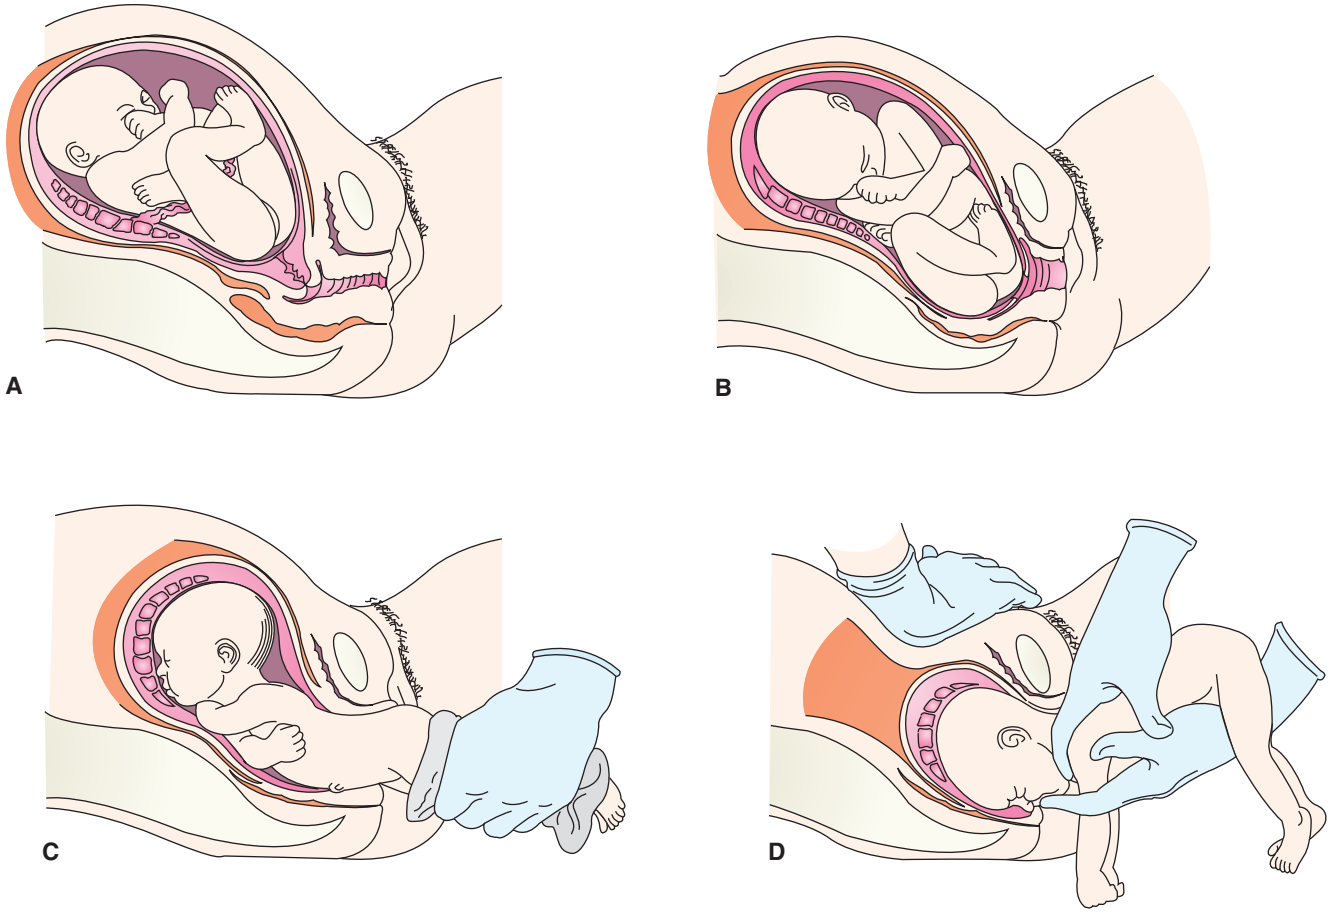

FIGURE 23.11 Breech birth. (**A**) Position before labor; left sacroposterior. (**B**) Descent and internal rotation. (**C**) Legs being born; the shoulders turn to present to the anteroposterior diameter. (**D**) The head is born. External rotation has put the anteroposterior diameter of the head in line with the anteroposterior diameter of the woman's pelvis. The head is born by gentle pressure to flex the head fully and by gentle traction to the shoulders upward and outward. Additional pressure might be applied by an assistant to the abdominal wall to ensure head flexion.

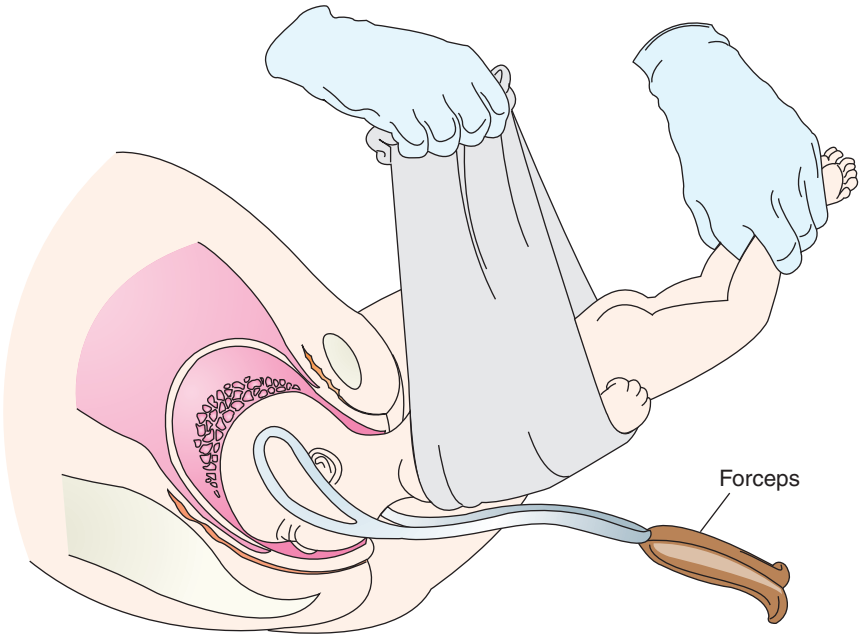

FIGURE 23.12 With Piper forceps used for a breech birth, traction is applied directly to the head, so damage to the infant's neck is avoided.

Gentle traction applied to the shoulders (upward and outward) delivers the head. An aftercoming head may also be delivered by the aid of Piper forceps to control flexion and the rate of descent (Fig. 23.12). The difficulty with birth of the head is the reason why planned cesarean birth is the usual method of birth for many breech-presentation infants today (Kish & Collea, 2007).

Parents of a breech baby usually inspect their child a little more closely than do the average parents. They, as well as the person who makes the initial physical assessment of the infant, are looking for a possible reason for the breech presentation. An infant who was born from a frank breech position tends to keep his or her legs extended and at the level of the face for the first 2 or 3 days of life. The infant who was a footling breech may tend to keep the legs extended in a footling position for the first few days. Be sure to point out to the parents that this is normal, so that they do not misinterpret the unusual posture of their infant as more than it is.

What if . . . Roseann's baby was presenting breech and you noticed that when her membranes ruptured, the amniotic fluid was green-stained? Is this an emergency situation?

Face Presentation

A fetal head presenting at a different angle than expected is termed *asynclitism.* Face and brow presentations are examples. Face (chin, or mentum) presentation is rare, but when it does occur, the head diameter the fetus presents to the pelvis is often too large for birth to proceed. A head that feels more prominent than normal, with no engagement apparent on Leopold's maneuvers, suggests a face presentation. It is also suggested when the head and back are both felt on the same side of the uterus with Leopold's maneuvers. The back is difficult to outline in this presentation because it is concave. If the back is extremely concave, fetal heart tones may be transmitted to the forward-thrust chest and heard on the side of the fetus where feet and arms can be palpated. A face presentation is confirmed by vaginal examination when the nose, mouth, or chin can be felt as the presenting part.

A fetus in a posterior position, instead of flexing the head as labor proceeds, may extend the head, resulting in a face presentation; this usually occurs in a woman with a contracted pelvis or placenta previa. It also may occur in the relaxed uterus of a multipara or with prematurity, hydramnios, or fetal malformation. It is a warning signal. Something abnormal is usually causing the face presentation.

When a face presentation is suspected, an ultrasound is done to confirm it; if indicated, the pelvic diameters are measured. If the chin is anterior and the pelvic diameters are within normal limits, it may be possible for the infant to be born without difficulty (perhaps after a long first stage of labor, because the face does not mold well to make a snugly engaging part). If the chin is posterior, cesarean birth is usually the method of choice; otherwise, it would be necessary to wait for a long posterior-to-anterior rotation to occur. Such rotation could result in uterine dysfunction or a transverse arrest.

Babies born after a face presentation have a great deal of facial edema and may be purple from ecchymotic bruising. Observe the infant closely for a patent airway. In some infants, lip edema is so severe that they are unable to suck for a day or two. Gavage feedings may be necessary to allow them to obtain enough fluid until they can suck effectively. They may be transferred to a NICU for 24 hours. Reassure the parents that the edema is transient and will disappear in a few days, with no aftermath.

Brow Presentation

A brow presentation is the rarest of the presentations. It occurs in a multipara or a woman with relaxed abdominal muscles.

It almost invariably results in obstructed labor, because the head becomes jammed in the brim of the pelvis as the occipitomental diameter presents. Unless the presentation spontaneously corrects, cesarean birth will be necessary to birth the infant safely. Brow presentations also leave an infant with extreme ecchymotic bruising on the face. On seeing this bruising over the same area as the anterior fontanelle, or "soft spot," parents may need additional reassurance that the child is well after birth.

Transverse Lie

Transverse lie occurs in women with pendulous abdomens, with uterine fibroid tumors that obstruct the lower uterine segment, with contraction of the pelvic brim, with congenital abnormalities of the uterus, or with hydramnios. It may occur in infants with hydrocephalus or another abnormality that prevents the head from engaging. It may also occur in prematurity if the infant has room for free movement, in multiple gestation (particularly in a second twin), or if there is a short umbilical cord.

A transverse lie usually is obvious on inspection, because the ovoid of the uterus is found to be more horizontal than vertical. The abnormal presentation can be confirmed by Leopold's maneuvers. An ultrasound may be taken to further confirm the abnormal lie and to provide information on pelvic size.

A mature fetus cannot be delivered vaginally from this presentation. Often, the membranes rupture at the beginning of labor. Because there is no firm presenting part, the cord or an arm may prolapse, or the shoulder may obstruct the cervix. Cesarean birth is necessary.

Oversized Fetus (Macrosomia)

Size may become a problem in a fetus who weighs more than 4000 to 4500 g (approximately 9 to 10 lb). Babies of this size complicate up to 10% of all births and are most frequently born to women who enter pregnancy with diabetes or develop gestational diabetes (Campaigne & Conway, 2007). Large babies are also associated with multiparity, because each infant born to a woman tends to be slightly heavier and larger than the one born just before.

An oversized infant may cause uterine dysfunction during labor or at birth because of overstretching of the fibers of the myometrium. The wide shoulders may pose a problem at birth, because they can cause fetal pelvic disproportion or even uterine rupture from obstruction. If the infant is so oversized that he or she cannot be born vaginally, cesarean birth becomes the birth method of choice. The large size of a fetus may be missed in an obese woman, because the fetal contours are difficult to palpate and obesity does not necessarily indicate a larger-than-usual pelvis. Pelvimetry or ultrasound can be used to compare the size of the fetus with the woman's pelvic capacity.

The perinatal mortality rate of larger infants is substantially increased to about 15%, compared with the normal 4%. In addition, a large infant born vaginally has a higher-than-normal risk of cervical nerve palsy, diaphragmatic nerve injury, or fractured clavicle because of shoulder dystocia. Postpartally, the woman has an increased risk of hemorrhage, because the overdistended uterus may not contract as readily as usual.

Shoulder Dystocia

Shoulder dystocia is a birth problem that is increasing in incidence along with the increasing average weight of newborns (Strehlow & Uzelac, 2007). The problem occurs at the second stage of labor, when the fetal head is born but the shoulders are too broad to enter and be born through the pelvic outlet. This is hazardous to the woman because it can result in vaginal or cervical tears. It is hazardous to the fetus if the cord is compressed between the fetal body and the bony pelvis. The force of birth can result in a fractured clavicle or a brachial plexus injury for the fetus.

Shoulder dystocia is most apt to occur in women with diabetes, in multiparas, and in post-date pregnancies. The problem often is not identified until the head has already been born and the wide anterior shoulder locks beneath the symphysis pubis. The condition may be suspected earlier if the second stage of labor is prolonged, if there is arrest of descent, or if, when the head appears on the perineum (crowning), it retracts instead of protruding with each contraction (a turtle sign).

Although there is no evidence-based data, asking a woman to flex her thighs sharply on her abdomen (McRobert's maneuver) may widen the pelvic outlet and allow the anterior shoulder to be born. Applying suprapubic pressure may also help the shoulder escape from beneath the symphysis pubis and be born (Athukorala, Middleton, & Crowther, 2009).

Fetal Anomalies

Fetal anomalies of the head such as hydrocephalus (fluid-filled ventricles) or anencephaly (absence of the cranium) can also complicate birth because the fetal presenting part does not engage the cervix well (see Chapter 27 for a discussion of these).

PROBLEMS WITH THE PASSAGE

Still another reason that dystocia can occur is a contraction or narrowing of the passageway or birth canal. This can happen at the inlet, at the midpelvis, or at the outlet. The narrowing causes CPD, or a disproportion between the size of the fetal head and the pelvic diameters. This results in failure to progress in labor.

Inlet Contraction

Inlet contraction is narrowing of the anteroposterior diameter to less than 11 cm, or of the transverse diameter to 12 cm or less. It usually is caused by rickets in early life or by an inherited small pelvis. Rickets is rare in developed countries but can occur among immigrants who were raised in an undeveloped country where milk supplies were not plentiful. In primigravidas, the fetal head normally engages between weeks 36 to 38 of pregnancy. If this occurs before labor begins, it is proof that the pelvic inlet is adequate. Following the general rule that "what goes in, comes out," a head that engages or proves it fits into the pelvic brim will probably also be able to pass through the midpelvis and through the outlet.

If engagement does not occur in a primigravida, then either a fetal abnormality (larger-than-usual head) or a pelvic abnormality (smaller-than-usual pelvis) should be suspected.

As a rule, engagement does not occur in multigravidas until labor begins. For these women, previous birth of a full-term infant vaginally without problems is proof that their birth canals are adequate.

Every primigravida should have pelvic measurements taken and recorded before week 24 of pregnancy. Based on these measurements and the assumption the fetus will be of average size, a birth decision can be made.

With CPD, because the fetus does not engage but remains "floating," malposition may occur, further complicating an already difficult situation. Should the membranes rupture, the possibility of cord prolapse increases greatly.

Outlet Contraction

Outlet contraction is narrowing of the transverse diameter at the outlet to less than 11 cm. This is the distance between the ischial tuberosities, a measurement that is easy to make during a prenatal visit, so the narrow diameter can be anticipated before labor begins. It is also easily reassessed during labor (see Chapter 15).

Trial Labor

If a woman has a borderline (just adequate) inlet measurement and the fetal lie and position are good, her physician or nurse-midwife may allow her a "trial" labor to determine whether labor can progress normally. A trial labor continues as long as descent of the presenting part and dilatation of the cervix continue to occur. Monitor fetal heart sounds and uterine contractions continuously, if possible, during this time. Urge the woman to void every 2 hours so that her urinary bladder is as empty as possible, allowing the fetal head to use all the space available. After rupture of the membranes, assess FHR carefully; if the fetal head is still high, there is an increased danger of prolapsed cord and anoxia to the fetus. If after a definite period (6 to 12 hours) adequate progress in labor cannot be documented, or if at any time fetal distress occurs, the woman will be scheduled for a cesarean birth.

It may be difficult for women to undertake labor they know they may be unable to complete, because the effort subjects them needlessly to pain. Emphasize, but do not overstress, that it is best for their baby to be born vaginally. If the trial labor fails and cesarean birth is scheduled, provide an explanation about why cesarean birth is necessary and now is the best route for the birth of their baby (Box 23.11).

Some women undergoing a trial labor feel as if they themselves are on trial. When dilatation does not occur, they feel discouraged and inadequate, as if they are somehow at fault or have failed. A woman may not be aware of how much she wanted the trial labor to work until she is told it is not working. The support person also may be as frightened and feel as helpless as the woman when a deviation occurs in labor. You can assure a woman and her support person that a cesarean birth will be an alternative, not an inferior, method of birth for them. Because labor is not progressing, it is the best method of choice to allow them to achieve their goal of a healthy mother and healthy child.

BOX 23.11 ✻ Focus on Communication

Roseann Bigalow is having her first baby. Her physician has told her she has a borderline pelvis but he wants her to try a trial labor.

Less Effective Communication

Nurse: Hello, Roseann. Is it all right if I attach a fetal heart rate and uterine contraction monitor so we can observe you closely during labor?
Roseann: Sure. Although I should have this baby any minute. It's already been 10 hours.
Nurse: I thought I heard your doctor say he's thinking of this as a trial labor.
Roseann: Whatever. I told him anything but surgery would be all right.
Nurse: I'm glad you have a positive outlook. That always makes labor seem to go faster.

More Effective Communication

Nurse: Hello, Roseann. Is it all right if I attach a fetal heart rate and uterine contraction monitor so we can observe you closely during labor?
Roseann: Sure. Although I should have this baby any minute. It's already been 10 hours.
Nurse: I thought I heard your doctor say he's thinking of this as a trial labor.
Roseann: Whatever. I told him anything but surgery would be all right.
Nurse: Let's talk about what a trial labor means.

If a woman develops a complication of pregnancy that is referred to by a strange name, it is generally expected that the couple will not understand the term and will need to have it thoroughly explained. If a condition has a common name, such as protracted pelvis or trial labor, however, it is easy to assume that little explanation of the condition is necessary. In reality, couples need explanations about all conditions, because what is common to health care personnel is not common to everyone. In the first scenario, the nurse assumed that she and the woman were talking about the same thing. In the second scenario, the nurse explored a little further and discovered that Roseann was not aware a trial labor might mean she would need surgery.

External Cephalic Version

External cephalic version is the turning of a fetus from a breech to a cephalic position before birth. It may be done as early as 34 to 35 weeks, although the usual time is 37 to 38 weeks of pregnancy (Hofmeyr & Gyte, 2009). For the procedure, FHR and possibly ultrasound are recorded continuously. A tocolytic agent may be administered to help relax the uterus. The breech and vertex of the fetus are located and grasped transabdominally by the examiner's hands on the woman's abdomen. Gentle pressure is then exerted to rotate the fetus in a forward direction to a cephalic lie (Fig. 23.13). Although not always successful, the use of external version can decrease the number of cesarean births necessary from breech presentations (Kish & Collea, 2007). Contraindications to the procedure include multiple gestation, severe oligohydramnios, contraindications to vaginal birth, a cord that wraps around the fetal neck, and unexplained third-trimester bleeding, which might

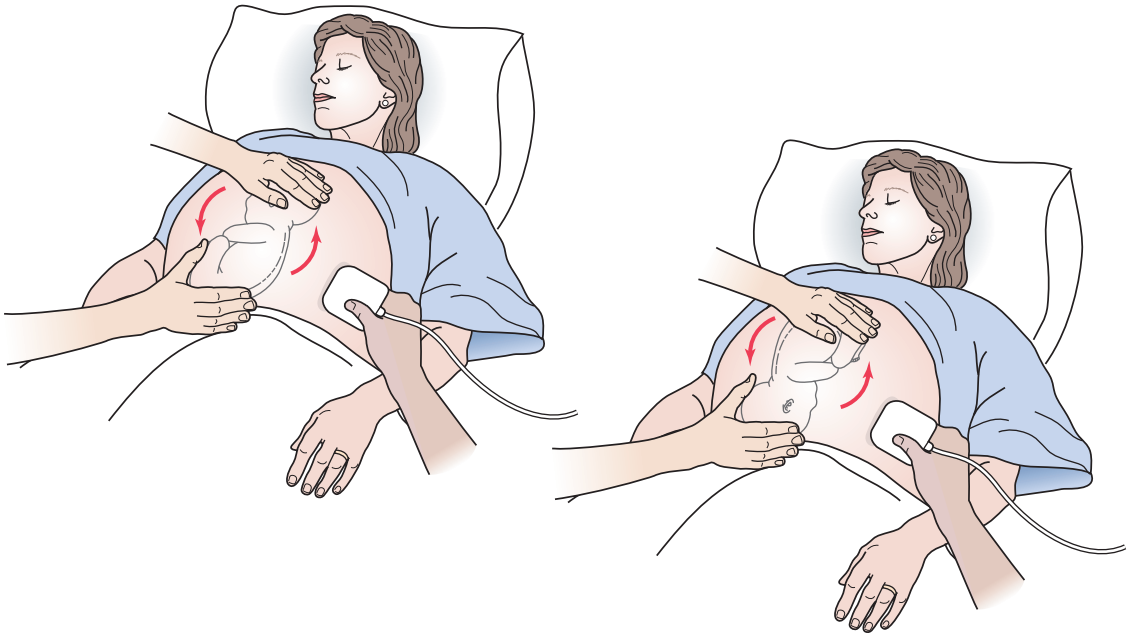

FIGURE 23.13 External cephalic version. The fetus is rotated by external pressure to a cephalic lie. An ultrasound helps guide a safe result.

be a placenta previa. External version can be uncomfortable for a woman because of the feeling of pressure. Women who are Rh negative should receive Rh immunoglobulin after the procedure in case minimal bleeding occurs.

Forceps Birth

Obstetrical forceps are steel instruments constructed of two blades that slide together at their shaft to form a handle. One blade is slipped into the woman's vagina next to the fetal head, and then the other is slipped into place on the other side of the head. Next, the shafts of the instrument are brought together in the midline to form the handle. The physician then applies pressure on the handle to manually extract the fetus from the birth canal.

In years past, babies were routinely born with forceps. Today, the technique is rarely used (about 4% to 8% of births) because it can lead to rectal sphincter tears in the woman which lead to dyspareunia, anal incontinence, or increased urinary stress incontinence in women (Mous, Muller, & De Leeuw, 2008). Forceps may be necessary, however, if any of the following conditions occur:

- A woman is unable to push with contractions in the pelvic division of labor such as might happen with a woman who receives regional anesthesia or has a spinal cord injury.
- Cessation of descent in the second stage of labor occurs.
- A fetus is in an abnormal position or is immature.
- A fetus is in distress from a complication such as a prolapsed cord.

Although forceps appear as if they would put forceful pressure on the fetal head, the pressure registers on the steel blades rather than the head so they actually reduce pressure. Reducing pressure in this way can avoid subdural hemorrhage in a fetus as the fetal head reaches the perineum, which is why forceps may be used with preterm birth (Incerpi, 2007).

A **forceps birth** is a forceps outlet procedure in which the forceps are applied after the fetal head reaches the perineum. The term *low forceps birth* may be used to indicate that the fetal head is at a +2 station or more. If the fetal head is engaged but at less than +2 station, the procedure is called a *midforceps birth.* This type of forceps extraction is rarely justified, because it has been associated with birth trauma to both the woman and the fetus, and cesarean birth involves less risk. Some anesthesia, at least a pudendal block, is necessary for forceps application to achieve pelvic relaxation and reduce pain. Usually, an episiotomy is performed to prevent perineal tearing due to pressure on the perineum.

Before forceps are applied,

- Membranes must be ruptured.
- CPD must not be present.
- The cervix must be fully dilated.
- The woman's bladder must be empty.

Record FHR before forceps application. Because there is a danger that the cord could be compressed between the forceps blade and the fetal head, assess FHR again immediately after application. The woman's cervix needs to be carefully assessed after forceps birth to be certain that no laceration has occurred. To rule out bladder injury, record the time and amount of the first voiding. In addition, assess the newborn to be certain that no facial palsy or subdural hematoma exists. A forceps birth may leave a transient erythematous mark on the newborn's cheek (see Chapter 18). This mark will fade in 1 to 2 days with no long-term effects.

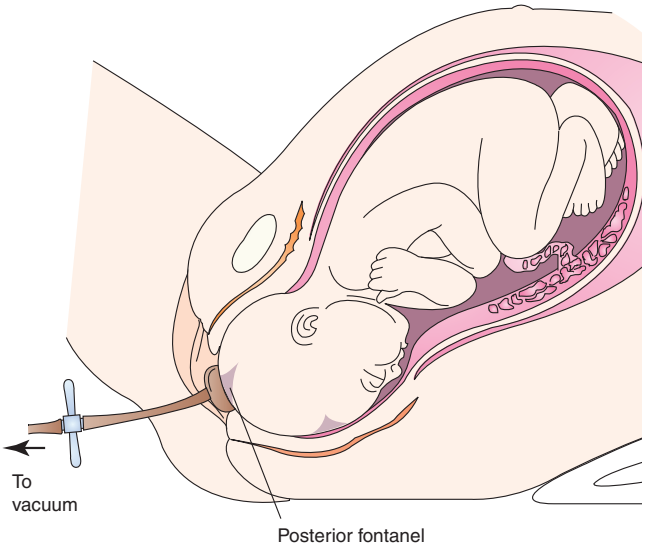

FIGURE 23.14 Vacuum extraction.

Vacuum Extraction

A fetus, if positioned far enough down the birth canal, may be born by **vacuum extraction** (Incerpi, 2007). With the fetal head at the perineum, a disk-shaped cup is pressed against the fetal scalp, over the posterior fontanelle. When vacuum pressure is applied, air beneath the cup is suctioned out and the cup then adheres so tightly to the fetal scalp that traction on the cord leading to the cup extracts the fetus (Fig. 23.14).

Vacuum extraction has advantages over forceps birth in that little anesthesia is necessary (leaving the fetus with less respiratory depression at birth) and fewer lacerations of the birth canal occur (Johanson & Menon, 2009). Its major disadvantage is that it causes a marked caput on the newborn head that may be noticeable as long as 7 days after birth. Tentorial tears from extreme pressure also have occurred. A woman may need reassurance that the caput swelling is harmless to her infant and will decrease rapidly. Vacuum extraction should not be used as a method of birth if fetal scalp blood sampling was used, because the suction pressure can cause severe bleeding at the sampling site. Moreover, vacuum extraction is not advantageous for preterm infants because of the softness of the preterm skull.

ANOMALIES OF THE PLACENTA AND CORD

Anomalies of the Placenta

The placenta and cord are always examined for the presence of anomalies after birth. The normal placenta weighs approximately 500 g and is 15 to 20 cm in diameter and 1.5 to 3.0 cm thick. Its weight is approximately one sixth that of the fetus. A placenta may be unusually enlarged in women with diabetes. In certain diseases, such as syphilis or erythroblastosis, the placenta may be so large that it weighs half as much as the fetus. If the uterus has scars or a septum, the placenta may be wide in diameter because it was forced to spread out to find implantation space.

Placenta Succenturiata

A **placenta succenturiata** (Fig. 23.15A) is a placenta that has one or more accessory lobes connected to the main placenta by blood vessels. No fetal abnormality is associated with this type. However, it is important that it be recognized, because the small lobes may be retained in the uterus after birth, leading to severe maternal hemorrhage. On inspection, the placenta appears torn at the edge, or torn blood vessels extend beyond the edge of the placenta. The remaining lobes are removed from the uterus manually to prevent maternal hemorrhage from poor uterine contraction.

Placenta Circumvallata

Ordinarily, the chorion membrane begins at the edge of the placenta and spreads to envelop the fetus; no chorion covers the fetal side of the placenta. In **placenta circumvallata,** the fetal side of the placenta is covered to some extent with chorion (see Fig. 23.15B). The umbilical cord enters the placenta at the usual midpoint, and large vessels spread out from there. They end abruptly at the point where the chorion folds back onto the surface, however. (In **placenta marginata,** the fold of chorion reaches just to the edge of the placenta.) Although no abnormalities are associated with this type of placenta, its presence should be noted.

Battledore Placenta

In a **battledore placenta,** the cord is inserted marginally rather than centrally (see Fig. 23.15C). This anomaly is rare and has no known clinical significance either.

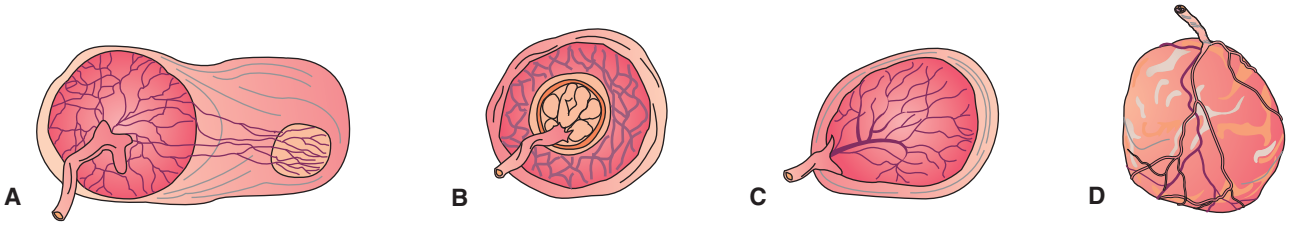

FIGURE 23.15 Abnormal placental formation. (**A**) Placenta succenturiata. (**B**) Placenta circumvallata. (**C**) Battledore placenta. (**D**) Velamentous cord insertion.

Velamentous Insertion of the Cord

Velamentous insertion of the cord is a situation in which the cord, instead of entering the placenta directly, separates into small vessels that reach the placenta by spreading across a fold of amnion (see Fig. 23.15D). This form of cord insertion is most frequently found with multiple gestation. Because it may be associated with fetal anomalies, an infant born with this type of placenta should be examined carefully.

Vasa Previa

In vasa previa, the umbilical vessels of a velamentous cord insertion cross the cervical os and therefore deliver before the fetus (Strehlow & Uzelac, 2007). The vessels may tear with cervical dilatation, just as a placenta previa may tear. Before inserting any instrument such as an internal fetal monitor, be certain to identify structures to prevent accidental tearing of a vasa previa as tearing would result in sudden fetal blood loss. If sudden, painless bleeding occurs with the beginning of cervical dilatation, either placenta previa or vasa previa is suspected. It can be confirmed by ultrasound. If vasa previa is identified, the infant needs to be born by cesarean birth.

Placenta Accreta

Placenta accreta is an unusually deep attachment of the placenta to the uterine myometrium so deeply the placenta will not loosen and deliver (Poggi, 2007). Attempts to remove it manually may lead to extreme hemorrhage because of the deep attachment. Hysterectomy or treatment with methotrexate to destroy the still-attached tissue may be necessary.

Anomalies of the Cord

Two-Vessel Cord

A normal cord contains one vein and two arteries. The absence of one of the umbilical arteries is associated with congenital heart and kidney anomalies, because the insult that caused the loss of the vessel may have affected other mesoderm germ layer structures as well. Inspection of the cord as to how many vessels are present must be made immediately after birth, before the cord begins to dry, because drying distorts the appearance of the vessels. Document the number of vessels present conscientiously. An infant with only two vessels needs to be observed carefully for other anomalies during the newborn period.

Unusual Cord Length

Although the length of the umbilical cord rarely varies, some abnormal lengths may occur. An unusually short umbilical cord can result in premature separation of the placenta or an abnormal fetal lie. An unusually long cord may be easily compromised because of its tendency to twist or knot. Occasionally, a cord actually forms a knot, but the natural pulsations of the blood through the vessels and the muscular vessel walls usually keep the blood flow adequate. It is not unusual for a cord to wrap once around the fetal neck (nuchal cord) but, again, with no interference to fetal circulation (Reed, 2007).

✔ Checkpoint Question 23.3

Oxytocin is administered to Roseann to augment labor. What are the first symptoms of water intoxication to observe for during this procedure?

a. A high, choking voice.
b. Headache and vomiting.
c. A swollen, tender tongue.
d. Abdominal bloating and pain.

Key Points for Review

- Complications of labor can arise from problems with the force of labor, the passage, the passenger, or the woman's reaction to the experience (the psyche). Hypotonic, hypertonic, and uncoordinated contractions all can occur, resulting in ineffective first or second stages of labor.
- Precipitate labor is birth that is completed in less than 3 hours. It can be responsible for subdural hemorrhage in the fetus and cervical lacerations in the woman.
- Uterine rupture, although rare, is usually preceded by a pathologic retraction ring (shown by an indentation across the abdomen over the uterus).
- Uterine inversion is a grave complication. If the situation is not immediately corrected, emergency hysterectomy is necessary to save the woman's life. Almost all occurrences of uterine inversion can be avoided by two axioms of care: (a) *do not put pressure on an uncontracted fundus immediately after birth* (massage it first to cause it to contract); and (b) *do not exert pressure on an umbilical cord to achieve placental delivery.*
- Amniotic fluid embolism occurs when amniotic fluid is forced into an open maternal uterine blood sinus. A woman notices chest pain and dyspnea. Administer oxygen and notify the woman's primary care provider of this emergency.
- Prolapse of the umbilical cord is an emergency situation that requires prompt action. Position a woman quickly into either a Trendelenburg or a knee–chest position to relieve cord compression, or apply manual pressure vaginally to lift the fetal head away from the cord. Notify the woman's primary caregiver of the emergency.
- Multiple gestation can complicate birth. Many infants of multiple gestations are born by cesarean birth.
- Abnormal position, presentation, or size of the fetus (such as occipitoposterior position; breech, face, or brow presentation; transverse lie), as well as problems of the passage such as inlet and outlet contraction, can lead to labor complications.
- Be certain a woman meets the criteria for labor induction before preparing an oxytocin solution. These criteria include engagement of the fetal head, a "ripe" cervix, and absence of CPD. Question an order if these criteria are not met.
- Always prepare oxytocin as a "piggyback" solution, being extremely careful of the dose used. Both a uterine

monitor and an FHR monitor should be used continuously during labor induction. Observe that contractions occur no less than 2 minutes apart and are no longer than 70 seconds in duration.

- Vacuum extraction and forceps are methods to assist birth. The woman as well as the infant needs special observation after these procedures to detect head trauma or cervical or vaginal tearing.
- Anomalies of the placenta and cord (such as placenta succenturiata, velamentous cord insertion, vasi a previa, and two-vessel cord) can lead to birth complications.

CRITICAL THINKING EXERCISES

1. Roseann Bigalow is the woman you met at the beginning of the chapter. Her fetus is in a posterior position, and she has severe back pain. What actions could her husband take to help relieve his wife's pain caused by this posterior fetal position?
2. Suppose that, after rupture of Roseann's membranes, the fetal monitor shows variable decelerations. On inspection, you are able to see the umbilical cord at the vaginal opening. You are aware that this is a fetal emergency. In order of priority, what would be your best actions?
3. Roseann is scheduled for augmentation of labor with oxytocin. What factors would you ensure are in place before augmentation is begun?
4. Examine the National Health Goals related to complications of labor. Most government-sponsored funds for nursing research are allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to the Bigalow family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to nursing care of a family with a complication of labor. Confirm your answers are correct by reading the rationales.

Chapter 24

Nursing Care of a Family During Cesarean Birth

KEY TERMS

- cesarean birth
- classic cesarean incision
- dehiscence
- low segment incision

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe the usual indications for cesarean birth.
2. Identify National Health Goals related to cesarean birth that nurses can help the nation achieve.
3. Use critical thinking to analyze how to keep birth family centered when a cesarean birth is scheduled.
4. Assess a woman scheduled for cesarean birth for effective preoperative, intraoperative, and postoperative needs.
5. Formulate nursing diagnoses related to the family experiencing a cesarean birth.
6. Establish outcomes that meet the needs of a woman requiring a cesarean birth.
7. Plan appropriate nursing care for the family experiencing a cesarean birth.
8. Implement common preoperative and postoperative care measures for cesarean birth.
9. Evaluate expected outcomes for achievement and effectiveness of care.
10. Identify areas related to cesarean birth that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of cesarean birth with the nursing process to achieve quality maternal and child health nursing care.

Moja Hamma is a 29-year-old woman pregnant with her first baby. Her labor began with ruptured membranes and dark green meconium-stained amniotic fluid. Moja called her nurse-midwife, who asked her to come to the hospital immediately. Moja drove herself and arrived in 20 minutes. Fetal heart rate was 100 beats per minute. An obstetrician was consulted, and she scheduled Moja for an immediate cesarean birth. Moja reacted calmly to the news that she needed surgery until she realized her boyfriend would not be able to get to the hospital until her surgery was over. At that point she refused to sign for permission, saying, "I can't. I just can't go through this alone."

Previous chapters described the physiology of labor and the sequence of usual birth. This chapter adds information about cesarean birth for those women who choose to have cesarean birth or must have a cesarean birth to ensure a safe outcome for themselves or their child.

Is Moja's response typical of a woman who is told she needs a surgical procedure for the birth of her baby?

What would be your best action to help her accept this procedure?

Cesarean birth, or birth accomplished through an abdominal incision into the uterus, is one of the oldest types of surgical procedures known. It is always slightly more hazardous than vaginal birth, but compared with other surgical procedures, it is one of the safest types of surgeries and one with few complications (Lavender et al., 2009).

The word "cesarean" is derived from the Latin word *caedore,* which means "to cut." At one time, there was a popular belief that Julius Caesar was born by a cesarean birth and the procedure was named for him. However, because Caesar was born before antibiotics and sterile surgical technique, it seems unlikely that his mother (who is known to have been alive in his adult years) would have survived such a procedure.

The term *cesarean birth,* rather than *cesarean delivery,* is used to accentuate that this is a birth more than a surgical procedure. National Health Goals related to cesarean birth are shown in Box 24.1.

Nursing Process Overview

For a Woman Having a Cesarean Birth

Assessment

Some women elect cesarean rather than vaginal birth. Some women with smaller-than-usual pelvic diameters are told during pregnancy that a cesarean birth may be necessary. Others learn only during labor that a cesarean birth is necessary because a complication is developing. Assessment as to whether a woman will be a good candidate for surgery is sometimes done throughout pregnancy and sometimes done very quickly in an emergency. Either way, assessment must include both physiologic and psychological status and preparedness.

BOX 24.1 ✻ Focus on National Health Goals

Two National Health Goals speak directly to cesarean birth:

- Reduce the rate of cesarean births among low-risk (full-term, singleton, vertex presentation) women having their first child to 15% of live births from a baseline of 18%.
- Reduce the rate of cesarean births among women who have had a prior cesarean birth to 63% of live births from a baseline of 72% (http://www.nih.gov).

Nurses can help the nation achieve these goals by encouraging women who fulfill the criteria for vaginal birth after cesarean (VBAC) to attempt a vaginal birth with a second child.

Additional nursing research in this area could include studies and application of evidence-based practice on the effect of nursing practice and the cesarean birth rate, effective pain management for cesarean birth, and measures to help the family adjust smoothly from the hospital to the home setting after a cesarean birth.

Nursing Diagnosis

Nursing diagnoses specific to cesarean birth are often related to prevention of common complications from surgery or patient/family concerns about surgical birth. Specific examples might include:

- Risk for infection related to a surgical incision
- Fear related to impending surgery
- Pain related to a surgical incision
- Deficient fluid volume related to blood loss from surgery
- Powerlessness related to medical need for cesarean birth

Outcome Identification and Planning

The same important outcome applies to a woman giving birth by cesarean as a woman giving birth vaginally: a healthy mother and a healthy child. Because cesarean birth decisions can be made suddenly, planning can be limited to only a few minutes. This means you have only a very short time to organize presurgical steps such as gastrointestinal or anesthesia preparation (and run through the presurgical checklist when it is an emergency). Plans must include discharge instructions and home care, because a woman will remain in the health care facility only 2 or 3 days. For a woman who knows in advance that she will have a cesarean birth, helpful Web sites to use for referral are the March of Dimes (http://www.marchofdimes.com) and the International Cesarean Awareness Network (http://www.ICAN-ONLINE.org).

Implementation

Every woman is aware that childbirth poses some risk to her health. When major surgery is superimposed on top of this, it is imperative that a woman and her support person feel confidence in the health care personnel who will care for them. Otherwise, they could have difficulty coping with the additional insult of surgery. When giving care to any woman during labor, be certain to establish early on a helping relationship with both the woman and her support person. This relationship becomes especially advantageous should the birth method need to be altered.

An important intervention includes coordination of health care team members such as an anesthesiologist, surgeon, pediatrician or neonatologist, and recovery room or nursery personnel (Box 24.2). This is particularly important if the surgery will be performed in a hospital surgery department rather than in a labor and birthing suite, or if the infant will be transferred to an intensive care nursery or a distant site for intensive care after the birth.

Many interventions focus on teaching and support, because the more a woman understands about what is happening, the more she can accept and cooperate with procedures. During surgery, sterile technique is essential. A postpartal infection can be devastating to a woman who already has made many other physical adaptations. After surgery, be sure to provide adequate "talk time" to allow a woman time to review what has happened and integrate it into what she and her partner expected.

Outcome Evaluation

Evaluation of expected outcomes is important in the care of a woman after cesarean birth to ensure she is not

BOX 24.2 ✻ Focus on Evidence-Based Practice

Is cesarean birth less safe at health care personnel shift changes than at other times?

To answer this question, researchers reviewed the charts of 17,996 women who underwent an unscheduled cesarean birth. They examined the outcomes of their surgery and their newborns' well-being at both the times of physician change of shift (6 AM–8 AM, 5 PM–7 PM) and the time of nursing change of shift (6 AM–8 AM, 2 PM–4 PM, 10 PM–12 AM) and compared surgical outcome at these times to all other times. Results showed that physician change of shift made no measurable effect on maternal and neonatal outcomes. Surprisingly, neonatal facial nerve palsies and hysterectomies were significantly increased in incidence during nursing change of shift times. The researchers were unable to explain why this incidence occurred and suggested further research would be helpful to determine why this happened.

Suppose you were asked to plan an inservice program to help nurses on an obstetrical unit be more thorough in their reports at shift changes. Would the above study influence what you would include in your class?

Source: Bailit, J., et al. (2008). Maternal-Fetal Medicine Units Network cesarean registry: impact of shift change on cesarean complications. *American Journal of Obstetrics and Gynecology, 198*(2),173–177.

developing a complication. It is especially important to consider the overall goals of a healthy baby and a healthy mother and the development of a positive mother–infant (or parent– or family–infant) relationship. The following are examples that would demonstrate successful achievement of outcomes:

- Patient states that she understands the reason for a cesarean birth.
- Patient states that she felt well prepared for cesarean birth even in light of an emergency.
- Couple states that they feel able to cope with newborn care even with mother recovering from surgery.
- Patient remains free of signs and symptoms of infection after cesarean birth.
- Patient states that incisional pain is controlled and tolerable.
- Patient states birth was a fulfilling experience for her even in light of the unplanned cesarean birth.

CESAREAN BIRTH

Currently, cesarean birth is used most often as a prophylactic measure, to alleviate problems of birth such as cephalopelvic disproportion or failure to progress in labor.

A major concern in maternal and child health nursing is the increasing number of cesarean births being performed annually (Clark et al., 2007). In 1970, only 5.5% of women in the United States had infants born by cesarean birth. Currently, the incidence of primary cesarean births is about 30.2% or one-third of births (National Vital Statistics System [NVSS], 2008). This increased rate results from a combination of the increasing safety of cesarean birth, the use of fetal monitors (which provide for early detection of fetal problems), an increased incidence in obese women (Bhattacharva et al., 2007), and elective cesarean births chosen by women for convenience or to prevent potential urinary or anal incontinence later in life (Gourounti & Sandall, 2007; Lavender et al., 2009).

The increase in rate may also be related to physicians' fears of malpractice suits should a fetus be allowed to be born vaginally and then be discovered to have suffered anoxia. Although this present incidence of cesarean births is a concern, this concern must be weighed against the potential for the procedure to reduce the incidence of infants who are born cognitively or physically challenged or who die at birth. Few parents insist that giving birth vaginally is more important than ensuring the birth of a healthy baby by cesarean birth.

Several legal and ethical issues have arisen in recent years when women have refused to undergo cesarean birth after being advised that they need one. Because women do have a right to decide whether they will undergo surgery, the right to refuse the procedure is respected. In some instances, however, a court order for the procedure has been obtained to save a fetus. Most circumstances do not come to this point of conflict with health care providers. Maternal child care nurses should be aware of the opinion of their agency's ethics committee on this issue. As a rule, nurse-midwifery birthing services have a lower incidence of cesarean births than hospital services because of the higher incidence of low-risk women in these settings. Continuous support during labor appears to decrease the incidence (Hodnett et al., 2009).

Scheduled Cesarean Birth

There are two types of cesarean birth: scheduled and emergent. In the first instance, there is time for thorough preparation for the experience throughout the antepartal period. Some women even take a childbirth preparation class specifically for cesarean birth. With the second type of cesarean birth, preparation must be done much more rapidly but with the same concern for fully informing a woman and her support person about what circumstances created the need for a cesarean birth and how the birth will proceed. Cesarean birth is mentioned in most childbirth classes, so any woman who has taken such a class may at least understand that cesarean births are sometimes necessary.

In the 1950s, cesarean birth became a status symbol when Hollywood stars asked to have cesarean births to save themselves the strain of labor and in some instances to schedule the birth conveniently between movie contracts. The average woman came to think of cesarean birth not as a surgical procedure but as an easy method of painless childbirth. Because the risk of injury from cesarean birth is higher than that from vaginal birth, this philosophy put both women and fetuses at greater risk than necessary. Scheduling cesarean births this freely also resulted in preterm births.

Although many cesarean births are done because the woman had a past cesarean birth, with new surgical techniques, particularly the use of a low cervical incision, "once a cesarean, always a cesarean" no longer applies. Most women

who have had a cesarean birth within the past 10 years are eligible to give birth vaginally in subsequent pregnancies if the circumstances otherwise are appropriate for vaginal birth (Dodd et al., 2009). The incidence of women electing a vaginal birth after a previous cesarean birth (VBAC) ranges from about 11% to 13% of women (NVSS, 2008). For more information on VBAC, see Chapter 15.

Cesarean birth is mandatory when there is a physical indication such as a transverse presentation, genital herpes, or cephalopelvic disproportion. Other indications for cesarean birth are shown in Box 24.3. Cesarean birth may reduce the transfer of the human immunodeficiency virus (HIV), hepatitis C, or herpes type 2 from mother to newborn, so it is recommended for women who have these infections (Read & Newell, 2009; McIntyre, Tosh, & McGuire, 2009). It can reduce mortality among infants presenting breech (Hofmeyr & Hannah, 2009). It may be advantageous for a preterm birth to avoid pressure on the fetal head (Robilio et al., 2007) or to avoid postprocedure stress incontinence but whether this last procedure helps is controversial (Dietz, 2007). It is generally contraindicated when there is a documented dead fetus (labor can be induced to avoid a surgical procedure).

Emergent Cesarean Birth

Emergent cesarean births are done for reasons such as placenta previa, premature separation of the placenta, fetal distress, or failure to progress in labor. An emergent cesarean birth carries with it the risk of any emergent surgery: the woman may not be a prime candidate for anesthesia and is psychologically unprepared for the experience. In addition, the woman may have a fluid and electrolyte imbalance and be both physically and emotionally exhausted from a long labor.

BOX 24.3 ✻ Selected Indications for Cesarean Birth

Maternal Factors
- Active genital herpes or perhaps human papillomavirus
- AIDS or HIV-positive status
- Cephalopelvic disproportion
- Cervical cerclage
- Disabling conditions, such as severe hypertension of pregnancy, that prevent pushing to accomplish the pelvic division of labor
- Failed induction or failure to progress in labor
- Obstructive benign or malignant tumor
- Previous cesarean birth by classic incision
- Elective—no indicated risks

Placenta Factors
- Placenta previa
- Premature separation of the placenta
- Umbilical cord prolapse

Fetal Factors
- Compound conditions such as macrosomic fetus in a breech lie
- Extreme low birth weight
- Fetal distress
- Major fetal anomalies, such as hydrocephalus
- Multigestation or conjoined twins
- Transverse fetal lie

Effects of Surgery on a Woman

Like any surgical procedure, cesarean birth has systemic effects.

Stress Response

Whenever the body is subjected to stress, either physical or psychosocial, it responds with measures to preserve the function of major body systems. This results in release of epinephrine and norepinephrine from the adrenal medulla. Epinephrine causes an increased heart rate, bronchial dilatation, and elevation of the blood glucose level. It also leads to peripheral vasoconstriction, which forces blood to the central circulation and increases blood pressure. These normally positive responses (the person is tensed or ready for action with good heart and lung function and glucose for energy) may antagonize anesthetic action, which is aimed at minimizing body activity. In the pregnant woman, such responses may minimize blood supply to the lower extremities. The woman is already prone to thrombophlebitis from stasis of blood flow, so these responses compound or greatly increase the risk of thrombophlebitis. Combined with interferences to major body systems, these effects can add to the risks of surgery.

Interference With Body Defenses

The skin serves as the primary line of defense against bacterial invasion. When skin is incised for a surgical procedure, this important line of defense is lost. Strict adherence to aseptic technique during surgery and in the days following the procedure are necessary to compensate for this impaired defense. If cesarean birth is performed hours after the membranes ruptured, a woman's risk for infection will be higher than if the membranes were intact. Many women receive prophylactic antibiotics, such as ampicillin (Omnipen), or a cephalosporin such as Ancef to ensure protection against postsurgical endometritis, even if the membranes were intact (Hopkins & Smaill, 2009).

Interference With Circulatory Function

Although vessels that must be cut for surgery are immediately clamped and ligated, some blood loss always occurs with surgery. Extensive blood loss can lead to hypovolemia and lowered blood pressure. This could lead to ineffective perfusion of all body tissues if the problem is not quickly recognized and corrected. The amount of blood lost in cesarean birth is comparatively high, because pelvic vessels are congested with blood waiting to supply the placenta. During a vaginal birth, a woman loses 300 to 500 mL of blood. This loss increases to 500 to 1000 mL with a cesarean birth.

Interference With Body Organ Function

When any body organ is handled, cut, or repaired in surgery, it may respond with a temporary disruption in function. Pressure from edema or inflammation as fluid moves into the

injured area further impairs function of the primary organ involved, as well as that of surrounding organs. If blood vessels become compressed as a result of edema, distant organs may be deprived of blood flow, leading to reduced function in those organs. Postoperatively, close assessment, not only of the primary organ involved but of total body function, is necessary, therefore, to determine the total degree of disruption.

Because the uterus is handled during cesarean birth, it may not contract well afterward, which can lead to postpartum hemorrhage. For a surgeon to reach the uterus, the bladder must be displaced anteriorly. As a result of this handling, the bladder may not sense filling as well as usual after the procedure (Datta & Gutman, 2007). During surgery, pressure is also felt by the intestine, so a paralytic ileus or halting of intestinal function may occur (Gates, Brocklehurst, & Davis, 2009). Thrombopheblitis from impaired lower extremity blood flow is yet another possibility. After a cesarean birth, therefore, uterine, bladder, intestinal, and lower extremity circulatory function must all be carefully assessed.

Interference With Self-Image or Self-Esteem

Surgery always leaves an incisional scar that will be noticeable to some extent afterward. Fortunately, the scar resulting from cesarean birth (a horizontal one across the lower abdomen) is not overly noticeable, but its appearance may cause a woman to feel self-conscious later. Although most women accept cesarean birth well, a woman may feel a loss of self-esteem if she believes it marks her as a woman less than others because she was unable to give vaginal birth (Wiklund et al., 2008).

✔ Checkpoint Question 24.1

Moja Hamma is concerned she may lose an excessive amount of blood with cesarean surgery. What is the usual amount of blood lost with cesarean birth?

a. 100–220 mL
b. 250–350 mL
c. 300–500 mL
d. 500–1000 mL

NURSING CARE OF A WOMAN ANTICIPATING A CESAREAN BIRTH

A woman who is admitted to the hospital for an anticipated cesarean birth may be more worried about the procedure, because she has had more time to worry, than a woman who is told during labor that an emergent cesarean is necessary. After the woman is admitted to the health care facility, allow her time to talk about any fears she has. Encourage her to do as much as possible for herself preoperatively, to help her feel in control and diminish her fear (Lobel & DeLuca, 2007).

A woman undergoing surgery cannot begin to relax as long as her support person is nervous and worried. Make a point of including this person in all explanations and admission routines, to keep his or her anxiety under control as well.

Preoperative Interview

Both the physician and the anesthesiologist or nurse-anesthetist will interview a woman preoperatively to obtain a health history and make an assessment and decision for safe use of anesthesia. A nursing assessment is also essential. Be sure to ask about any past surgeries, secondary illnesses, allergies to foods or drugs, reactions to anesthesia, bleeding problems, and current medications to help establish surgical risk and if a woman has any piercing that needs to be removed because of the use of the bovie or arterial cauterizing machine. In addition, include questions to discover:

- The woman's knowledge about the procedure
- The length of hospitalization anticipated
- If she knows about any postsurgical equipment to be used, such as an indwelling catheter or intravenous fluid line
- Any special precautions that will be necessary for her infant

Operative Risk for a Woman

For any surgery to be performed safely, a woman must be in the best possible physical and psychological state. Women who are in less than optimal physical or psychological health are at risk for a complicated surgical outcome unless the risk factor is identified and special precautions are taken.

Poor Nutritional Status

A woman who is obese because of poor nutrition is at risk because such a condition interferes with wound healing. Tissue that contains an abundance of fatty cells is difficult to suture, so the incision may take longer to heal. A prolonged healing period increases the risk for infection and rupture of the incision (**dehiscence**). The woman's heart may also have an increased workload. Therefore, the physiologic shock of surgery may place greater stress on the already overworked organ. In addition, an obese woman often has more difficulty turning and ambulating postoperatively than does a woman of normal weight and therefore has an increased risk for development of respiratory or circulatory complications such as pneumonia or thrombophlebitis (Datta & Gutman, 2007).

A woman with a protein or vitamin deficiency is also at risk for poorer healing, because protein and vitamins C and D are necessary for new cell formation at the incision site. In addition, vitamin K is necessary for blood clotting after surgery. Although most pregnant women follow sound nutritional practices and take iron supplements, some may still be iron deficient (particularly women with a multiple gestation or women who have not taken supplements). This places them at high risk for extreme fatigue after surgery, which could interfere with parent–child bonding.

Age Variations

Age affects surgical risk because it can cause decreased circulatory and renal function. Fortunately, most pregnant women fall within the young adult age group, so they are excellent candidates for surgery. A woman older than 40 years falls into a category of slightly higher risk.

Altered General Health

A woman who has a secondary illness such as cardiac disease, diabetes mellitus, anemia, or kidney or liver disease is at greater than usual surgical risk, depending on the extent of disease, because the pathology from the secondary illness may interfere with her ability to adjust physically to the demands

TABLE 24.1 ✻ Drugs That May Result in Complications of Surgery

Type of Drug	Action
Antibiotics	Specific antibiotics may predispose to renal insufficiency or increase neuromuscular blockage; can lead to opportunistic infections
Anticoagulants	May cause hemorrhage due to lack of hemostasis during surgery
Anticonvulsants	May increase liver action and metabolism of anesthetic agent
Antihypertensives	May result in hypotension after anesthesia
Corticosteroids	May block body's response to shock and lead to lack of adrenal function
Insulin	May lead to hypoglycemia during labor or hyperglycemia if a dextrose solution is administered
Antianxiety agents	May cause hypotension after anesthesia

of surgery. A woman with a secondary illness may also have an accompanying nutritional or electrolyte imbalance caused by her primary illness.

Therefore, asking about any secondary illnesses is an essential component of a preoperative nursing history. While waiting for surgery, people are under stress, a condition that can limit their reasoning and decision-making abilities. For example, it is not unusual for people admitted for any type of surgery to state that they are generally healthy and, minutes later, ask if they should take insulin on the day of surgery because they are diabetic.

A general medication history also is important, because some drugs increase surgical risk by interfering with the effect of an anesthetic or with healing of tissue. Examples of drugs that pregnant women might be taking and their potential complications are shown in Table 24.1.

Fluid and Electrolyte Imbalance

A woman who enters surgery with a lower than normal blood volume will feel the effect of surgical blood loss more than a woman who has a normal blood volume. A woman who began labor and later was told that she is to have a cesarean birth may fall into this category, because she may have had nothing to eat or drink for almost 24 hours. Recent vomiting, diarrhea, or a chronic poor fluid intake can compound her risk. Intravenous fluid replacement usually is initiated preoperatively and continued postoperatively to prevent fluid and electrolyte imbalances.

Fear

Women who are extremely worried need a very detailed explanation of the procedure before they can enter surgery without intense fear. Most cesarean births currently are performed under epidural anesthesia, so they are less frightening for women than when general anesthesia was used. With all anesthesia, a woman who is frightened is at a greater risk for cardiac arrest during anesthesia administration than a woman who is calm and relaxed.

In many instances, just helping a woman acknowledge that her fear of surgery is normal can be helpful. This does not make the procedure any less traumatic, but the woman can view her feelings as "normal" and expected, which helps to enhance her self-esteem and lower anxiety (Barnes, 2007).

Operative Risk to the Newborn

Cesarean birth places a newborn at a greater risk than does a vaginal birth for a number of reasons. When a fetus is pushed through the birth canal, pressure on the chest helps to rid the newborn's lungs of fluid. This makes respirations more likely to be adequate at birth than if a fetus had not been subjected to this pressure. For this reason, more infants born by cesarean birth develop some degree of respiratory difficulty for a day or two after birth than those born vaginally (Hansen et al., 2008). See Chapter 26 for a discussion of this condition, which is often referred to as transient tachypnea of the newborn.

Preoperative Diagnostic Procedures

Preoperative diagnostic procedures for a woman who is to have a cesarean birth include assessments of circulatory and renal function and fetal heart rate including:

- Vital sign determination
- Urinalysis
- Complete blood count
- Coagulation profile (prothrombin time [PT], partial thromboplastin time [PTT])
- Serum electrolytes and pH
- Blood typing and cross-matching
- Ultrasound to determine fetal presentation and maturity

During pregnancy, a woman, and particularly one who was in prolonged labor, may have an elevated leukocyte count (up to 20,000/mm^3), so this finding is not as helpful an indicator for the presence of infection in the pregnant woman as it is in others.

Preoperative Teaching

Fear of the unknown is one of the hardest fears to conquer. Preoperative teaching is aimed at acquainting a woman with cesarean procedure and any special equipment to be used, to make her as informed as possible. Activities that help maintain respiratory and skeletal muscle function, to prevent postsurgical complications, should also be included in teaching.

Before beginning teaching, assess how much a woman already knows about the surgery. A woman who has had a cesarean birth for her first child and now is being admitted for a second procedure already knows many details. Even so, she will undoubtedly appreciate having her memory refreshed and recall confirmed. Answer all specific questions, and fill in gaps in knowledge. Ensure that all information offered is accurate. It is confusing and potentially frightening for a woman to be told, for instance, that she will not have intravenous fluid after the surgery and then discover that an intravenous line will be

placed. Be certain not to use hospital jargon such as "NPO." People under stress do not process new information well. They cannot process information at all if they do not understand the terminology. Ask a woman to return-demonstrate activities, such as deep breathing, to show that she understands the information and can do this well.

Be certain to explain the preoperative measures that will be necessary, such as surgical skin preparation, eating nothing before the time of surgery, premedication (if this will be used), and method of transport to surgery. Review the necessity for an indwelling catheter, intravenous fluid administration, placement of an epidural catheter (if used for postprocedural pain relief), and the advantage of early ambulation afterward.

Throughout teaching, use visual aids as necessary. Draw pictures or show illustrations of anatomy, if necessary. Be careful not to leave textbooks about cesarean procedure techniques with a woman. Typically, these books also describe complications, and, although knowledge of possible complications is necessary for informed consent, reading about complications complete with color illustrations can be overwhelming.

Teaching to Prevent Complications

Women who practice exercises to maintain good respiratory and circulatory function postoperatively will tend to experience fewer postoperative respiratory and circulatory complications than those who do not. These preventive exercises are best taught during the preoperative period, when the woman is free of pain and can concentrate on learning. Such teaching also gives a woman a positive outlook about surgery and a sense of control over her situation. By teaching about postoperative care, you are saying, "I'll see you and your new child safely back here in your room afterward"—a communication with a comforting subliminal message for a woman who has serious doubts that there will be an afterward, or at least not one with a healthy newborn.

Deep Breathing. Periodic deep breathing exercises fully aerate the lungs and help to prevent the stasis of lung mucus from the prolonged time spent in the supine position during surgery. Because stasis always has the potential to cause infection, preventing this helps prevent lung infection such as pneumonia.

A typical exercise is to take 5 to 10 deep breaths every hour. Teach a woman to do this simply by inhaling as deeply as possible, holding her breath for a second or two, and then exhaling as deeply as possible. Be certain she inhales and exhales fully. Otherwise, she might experience lightheadedness from hyperventilation.

Incentive Spirometry. A common device used postoperatively to encourage deep breathing is an incentive spirometer. These devices which cause a small ping-pong-like ball to rise in a narrow tube or cause lights to flash, are not only easy and fun to operate but give a woman a sense of reward for her effort. The initial impression of most people is that the device works by blowing into it. Because its purpose is to fully aerate lung spaces, though, most models are triggered by *inhalation,* not exhalation. There is a gauge to monitor levels and tabs to set goals.

Turning. Women do not need to practice turning side to side before surgery, because this activity is tiring for them to do while pregnant. They should understand, however, that turning postoperatively is important to prevent both respiratory and circulatory stasis.

Ambulation. The most effective way to stimulate lower-extremity circulation after a cesarean birth is by early ambulation. For this reason, most surgeons prefer a woman to be out of bed and walking by 4 hours after surgery (as soon as the effect of the epidural anesthesia has worn off). Helping a woman ambulate this early can be difficult, because she is both fatigued and in pain. Help her to understand that ambulation is extremely important after cesarean birth, because the edema of the low pelvic surgery compresses circulation to the lower extremities, increasing the risk for lower-extremity circulatory stasis. Some women may be prescribed antiembolic stockings (TEDS) to support and encourage venous return in addition to ambulation.

Immediate Preoperative Care Measures

A number of measures must be taken immediately before surgery to ensure a safe outcome.

Informed Consent

Obtaining operative consent is the surgeon's responsibility, but seeing that it is obtained is everyone's responsibility. You may be asked to witness a woman's signature on such a form. Before signing as a witness, be certain that it was *informed* consent, or one in which the risks and benefits of the procedure were explained in terms the woman could easily understand.

The law differs from state to state regarding emancipated minors or mature minors (girls under legal age who are pregnant or already the mother of a previous child). Emancipated minors can sign their own surgical permission, even though they are legally underage.

Overall Hygiene

Most women who are having a planned cesarean birth are admitted to the facility on the morning of surgery and have showered or bathed at home. On admission, provide a clean hospital gown. If a woman's hair is long, encourage her to braid it or put it into a ponytail so that it will more easily fit under the surgical cap she will wear. Hair contained by a cap that way is less likely to spread microorganisms during surgery. Follow institutional procedure about removing nail polish, jewelry, contact lenses, piercings, or hair ornaments before surgery. A growing number of women wear acrylic fingernails and are reluctant to remove them for surgery. If this is so, ensure that the woman's toenails are free of polish so toenails can be used to assess capillary refill if this is needed.

What if... Moja Hamma, who is going to have epidural anesthesia, refuses to remove her contact lenses for surgery even though it is hospital policy for anyone receiving anesthesia? She says, "Without them, I won't be able to see my baby being born." Would you ask the nurse anesthetist whether removing them is absolutely necessary, or would you insist that she follow procedure without question?

Gastrointestinal Tract Preparation

A gastric emptying agent such as metoclopramide (Reglan) to speed stomach emptying or a histamine blocker such as ranitidine (Zantac) to decrease stomach secretions may be prescribed prior to surgery. Yet another possibility is an oral antacid such as sodium citrate (Bicitra), which acts to neutralize acid stomach secretions. These precautions are necessary because the woman will be lying on her back during the procedure, making esophageal reflux and aspiration highly possible.

Baseline Intake and Output Determinations

To reduce bladder size and keep the bladder away from the surgical field, an indwelling urinary catheter may be prescribed before transport for surgery or after arrival in the surgical suite. Catheterizing a pregnant woman is more difficult than catheterizing a nonpregnant woman, because the pressure of the fetal head puts pressure on the urethra and distorts anatomic landmarks. In addition, the vulva may be swollen and distorted from vulval varicosities or edema. Use good lighting so that the perineum is clearly revealed and save a sample for culture to rule out a urinary tract infection. After catheter insertion, be certain that urine is draining freely, because fetal pressure on the urethra may reduce the flow of urine considerably. During transport, keep the drainage bag below the level of the woman's bladder, to prevent urine backflow and the possible introduction of microorganisms into the bladder.

If catheterization is difficult before surgery, do not traumatize the urethra by repeated attempts. Catheterization can be done in the birthing or delivery room after the anesthetic agent is given. If there is a delay between the catheter insertion time and surgery, mark the drainage bag just before surgery with the amount in the bag, or empty it, so that presurgery urine output can be differentiated from postsurgery urine output. One of the gravest dangers of any surgical procedure is kidney failure from the physiologic stress of surgery or lack of blood flow to the kidneys due to decreased blood pressure. All reproductive tract surgery puts ureter flow as well as kidney function at risk, because edema that collects in the surgery area can press on the ureters.

Hydration

Most women have an intravenous fluid line begun before surgery with a fluid such as lactated Ringer's solution. Doing so helps to ensure that a woman is fully hydrated and will not experience hypotension from epidural anesthesia administration, temporary use of a supine position, or blood loss at birth. Be certain that this line is started in the woman's nondominant hand, so that she can hold her newborn after surgery without interference. Use a large-size catheter or needle (18 or 20 gauge), so that blood replacement therapy can be administered, if needed, by the same line.

Preoperative Medication

A minimum of preoperative medication is used with a woman having a cesarean birth, to prevent compromising the fetal blood supply and to ensure that the newborn is wide awake at birth and can initiate respirations spontaneously.

Patient Chart and Presurgery Checklist

Documentation of nursing care up until the time a woman leaves the nursing care unit or labor room must be completed before a woman leaves for the surgical suite. Many hospitals use a preoperative checklist, such as that shown in Figure 24.1, as a reminder of all necessary measures to be taken. Checking and signing such a form indicates that the specific measures were completed.

	Completed

FIGURE 24.1 Preoperative checklist for cesarean birth. Checklists vary from hospital to hospital.

Transport to Surgery

A woman may be transferred to surgery in her bed, or she may be helped to move to a stretcher. If a stretcher is used, be certain to hold it tightly against the side of the woman's bed or use a slide board for safe transfer. A woman is awkward in her movements at term and could easily slip and fall if the stretcher moved. Urge her to lie on her left side during transport, to prevent supine hypotension syndrome. Ensure additional safety by raising the side rails on the bed or stretcher. Cover her with a blanket or sheet to avoid her feeling chilled. Check that her identification is secure before she leaves the patient unit. Make sure that her chart with the surgical checklist accompanies her.

Role of the Support Person

In most instances, a woman's family can be as involved in a cesarean birth as they would be for a vaginal birth. A support person may need more encouragement to watch a cesarean birth than a vaginal one, because he or she may believe that the surgery will be much bloodier than it actually is. Helping family members realize that cesarean birth is little different from vaginal birth not only allows them to watch the procedure but helps them progress to bonding with the infant and incorporating a new member into the family more easily.

✔ Checkpoint Question 24.2

What is an important measure to reduce the size of the bladder and keep it away from the surgical field during a cesarean birth?

a. Restrict fluids in the woman for 4 hours before surgery.
b. Insert a urinary catheter to drain the bladder and decrease its size.
c. Administer an oxytocic to contract the bladder.
d. Give a diuretic to reduce the bladder to its smallest size.

NURSING CARE OF A WOMAN HAVING AN EMERGENT CESAREAN BIRTH

Many women who will have a cesarean birth have no warning during pregnancy that this will be necessary. Suddenly, during labor, they develop a complication such as prolapsed cord or fetal distress, and it becomes necessary.

A woman who was having severe pain with labor and is told an emergent procedure is necessary actually may be relieved that surgery has been suggested, because the surgery will alleviate the pain. In contrast, another woman might feel great disappointment when told her baby must be born by cesarean birth. In many women, both emotions are present.

Surgical risk in an emergent situation is determined from the baseline history and physical examination information previously obtained at the beginning of labor. Preoperative preparation measures such as vital signs, urinalysis, and blood work have also been obtained. Immediate preparation concerns such as informed consent, application of elastic stockings (if appropriate), gastrointestinal tract preparation, bladder catheterization, and establishment of an intravenous line will be the same. Because most cesarean births are completed within 30 minutes of the time one is documented to be necessary, teaching about postoperative measures needs to be delayed until after surgery (Simpson, 2007).

Available time must be spent explaining the immediate procedures to the woman such as transfer, abdominal preparation, and anesthesia. Document carefully what was taught, so that the nurse caring for the woman postoperatively will be aware of the need for additional teaching. At birth, at least one person whose sole responsibility is neonatal resuscitation should be present to care for the baby. Approximately 10% of babies born by cesarean birth need assistance to begin breathing at birth; about 1% of babies need extensive resuscitation to survive (Simpson, 2007).

INTRAOPERATIVE CARE MEASURES

Cesarean birth is most similar to vaginal birth if the woman is awake during the surgery; therefore, after discussion with a woman, the anesthesia of choice is usually a regional block (Box 24.4).

BOX 24.4 ✻ Focus on Communication

Moja Hamma has been told she will need a cesarean birth because of fetal distress that has led to meconium staining.

Less Effective Communication

Nurse: Moja. Can I answer any questions for you?
Moja: I want something to put me to sleep so I won't know what's happening.
Nurse: Most women want an epidural.
Moja: I have to be so sound asleep I won't know what's happening.
Nurse: Most people . . .
Moja: . . . don't have cesarean births, so what applies to them doesn't apply to me.
Nurse: I'll tell the anesthesiologist you want general anesthesia.

More Effective Communication

Nurse: Moja. Can I answer any questions for you?
Moja: I want something to put me to sleep so I won't know what's happening.
Nurse: Most women want an epidural.
Moja: I have to be so sound asleep I won't know what's happening.
Nurse: You're not interested in seeing your baby born?
Moja: I'm not interested in seeing him born dead.
Nurse: Let me find your doctor to explain to you again that you need surgery to prevent something going wrong, not because something is wrong.

Most women appreciate that cesarean births are done to prevent their infant from being harmed. Others interpret a cesarean birth as being done because the harm has already occurred. Some women interpret a cesarean birth as an announcement they are somehow not as competent as other women. Still others are relieved that labor is being interrupted. Be certain to ask enough questions so that you can learn the importance or meaning of the event to an individual woman.

Administration of Anesthesia

A surgical nurse will assist a woman to move from the transport stretcher or bed to the operating room table and will remain with her while anesthesia is administered. If the woman has an epidural catheter in place from labor, be careful not to dislodge it while she is being moved. During transport or in surgery, encourage the woman to remain on her side, or insert a pillow under her right hip to keep her body slightly tilted to the side, to prevent supine hypotension syndrome. If a spinal anesthetic (which may be used in an emergency) is to be administered, the anesthesiologist usually will do this with the woman sitting up. The anesthesiologist may ask you to help the woman curve her back to separate the vertebrae and facilitate entry of the spinal needle. It is difficult for a woman having uterine contractions to remain in this position for long. Talking to her while gently restraining her and letting her lean against you is the most effective means of helping her maintain this position. Epidural anesthesia is usually administered with the woman lying on her side. Duramorph is a form of morphine commonly used in epidurals. Its effect lasts up to 24 hours but because it can cause late occurring respiratory depression, continuous pulse oximetry must be used for 24 hours postsurgery (Ng et al., 2009).

Skin Preparation

Reducing the number of bacteria on the skin before surgery automatically reduces the possibility of bacteria entering the incision at the time of surgery. Shaving away abdominal hair, if indicated, and washing the skin area over the incision site with soap and water accomplishes this.

The skin preparation area for a cesarean birth varies among agencies. Some require extensive skin preparation, from above the umbilicus to below the pubic hair, whereas others require only a limited preparation of the immediate incisional area.

Surgical Incision

After anesthetic administration, a woman is positioned with a towel under her right hip to move abdominal contents away from the surgical field and to lift her uterus off the vena cava. A screen may be placed at her shoulder level and covered with a sterile drape to block the flow of bacteria from her respiratory tract to the incision site. This also helps block the woman's and support person's lines of vision, preventing additional anxiety caused by the sight of the incision. Be sure the support person is positioned at the woman's head to provide support.

The incision area on the woman's abdomen is then scrubbed with an antiseptic such as iodine, and appropriate drapes are placed around the area of incision, so that only a small area of skin is left exposed. Watching a cesarean birth is usually the first time a father or support person has ever witnessed surgery. Because of this, the person may be too overwhelmed by and interested in the procedure to be of optimum support. He or she may become concerned about the amount of manipulation and cutting that occurs before the uterus itself is cut (assuming fetal distress is not extreme). Prepare the woman and support person for the sights they might see, or help talk them through them as they occur. Sponge and instrument counts are simplified by the use of prepackaged cesarean birth components.

Types of Cesarean Incision

There are two types of cesarean incision. The type chosen depends on the presentation of the fetus and the speed with which the procedure will be performed (Fig. 24.2).

In a **classic cesarean incision,** the incision is made vertically through both the abdominal skin and the uterus. It is made high on the uterus so that it can be used with a placenta previa, to avoid cutting the placenta. A disadvantage of this type of incision is that it leaves a wide skin scar and also runs through the active contractile portion of the uterus. Because this type of scar could rupture during labor, it is likely, if this type of incision is used, that a woman will not be able to have a subsequent vaginal birth.

A **low segment incision** (commonly referred to as a low transverse incision) is one made horizontally across the abdomen just over the symphysis pubis and also horizontally across the uterus just over the cervix. This is the most common type of cesarean incision. It is also referred to as a Pfannenstiel incision or a "bikini" incision, because even a low-cut bathing suit will cover the scar. Because this type of incision is through the nonactive portion of the uterus (the part that contracts minimally with labor), it is less likely to rupture in subsequent labors, making it possible for a woman to have a VBAC with a future pregnancy (Lawson &

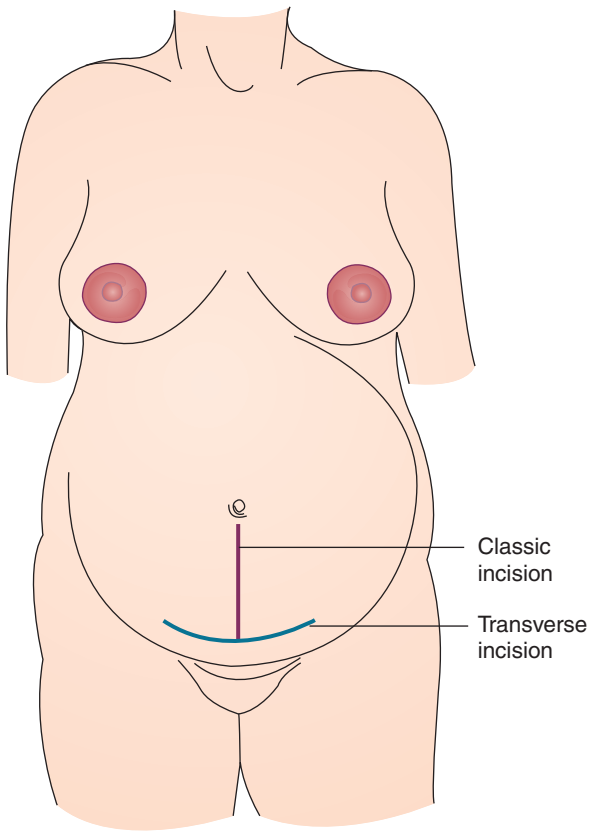

FIGURE 24.2 Types of cesarean incisions.

Bienstock, 2007). It also results in less blood loss, is easier to suture, decreases postpartal uterine infections, and is less likely to cause postpartum gastrointestinal complications (Incerpi, 2007). The major disadvantage of this incision is that it takes longer to perform, possibly making it impractical for an emergent cesarean birth. In a few instances, the skin incision is made horizontally and then the uterine incision is made vertically, or vice versa. For this reason, during a future pregnancy, do not assume that a woman who has a small skin incision also has had a small uterine incision.

Birth of the Infant

Once the surgical incision is complete, retractors (long, curved, metal instruments) are slipped into the incision. Gentle traction on the handles by an assistant keeps the incision spread apart, allowing good visualization of the uterus and the internal incision. Sterile towels may be placed in the incision to separate the uterus from other organs. The uterus is then cut, and the child's head is born manually or by the application of forceps (Fig. 24.3). The mouth and nose of the baby are suctioned by a bulb syringe, the same as in a vaginal birth, before the remainder of the child is born. Oxytocin is administered intravenously by the anesthesiologist as the child or placenta is delivered, to increase uterine contraction and reduce blood loss. In many instances, a woman's partner may be allowed to cut the umbilical cord. After full birth, the uterus is pulled forward onto the abdomen and covered with moist gauze. The internal cavity of the uterus is then inspected, and the membranes and placenta are manually removed. If the woman wishes to have a tubal ligation, it can be done at this time. The uterus, subcutaneous tissues, and skin incisions are then closed. Be sure to remind a woman and her support person that closing the incision can be a long process, so they do not become concerned that something is going wrong. Metal staples are usually used on the exterior skin, because they leave the least amount of scarring (Anderson & Gates, 2009).

Observing the amount of abdominal manipulation that is accomplished during surgery increases understanding of how tender a woman's abdomen will be afterward. This also helps to explain why a woman who has undergone cesarean birth often has an overall "aching" feeling after surgery.

Introduction of the Newborn

Once it is determined that the newborn is breathing spontaneously, he or she is shown to the mother and support person, just as is done after a vaginal birth. The support person may hold the baby immediately. The mother may have difficulty doing this if she has intravenous fluid infusing into one hand and the surgical drapes are still in place. Assist her as necessary. Visiting with the newborn lays a foundation for bonding and also distracts a couple from the tedious process of incision closure. Women are able to breastfeed after cesarean births the same as after vaginal births, but initial breastfeeding is usually delayed until the woman has been moved to a recovery room, because breastfeeding initiates uterine contractions and that may interfere with suture placement. Breastfeeding also may be awkward with the anesthesia screen in place and because of the lack of privacy.

✔ Checkpoint Question 24.3

Moja Hamma asks you how big her scar will be after cesarean birth. Your best answer would be:

a. The incision is big and runs vertically across your abdomen.
b. The incision is made through the vagina so it does not leave a scar.
c. Most cesarean-birth incisions are so low they do not show over a bikini.
d. It is so large that it will always show, but think of it as a mark of pride.

POSTPARTAL CARE MEASURES

Women who have infants by cesarean birth develop an additional care concern in the immediate postpartal period because they are not only postpartal patients but postsurgical ones as well. Due to the strain of the unexpected procedure, they may have increased difficulty bonding with their new infant. They have postsurgical pain in additional to afterpains. As with all postpartal women, the postpartal phase for a woman who has her child by cesarean birth can be divided into an immediate recovery period (the so-called fourth stage of labor) and an extended postpartal period.

Nursing Diagnoses and Related Interventions During the Immediate Postpartal Period

Immediately after surgery, a woman is transferred by stretcher from the operating room table to the postanesthesia care unit (PACU) or postpartal room. If spinal anesthesia was used, remember that her legs are fully anesthetized and she will not be able to help move them.

Nursing Diagnosis: Pain related to surgical incision

Outcome Evaluation: Patient verbalizes extent of pain (from 1 to 10) and need for relief; states that level of pain is tolerable.

In the past, pain control was a major problem after cesarean birth. Pain was so intense from the uterine or abdominal incision that it interfered with a woman's ability to move and deep breathe. This led to surgical complications such as pneumonia or thrombophlebitis. It also impaired a woman's ability to bond with her newborn, because holding her infant was so painful. Today, a number of effective types of pain management are available. Use a pain rating scale to allow a woman to rate her pain. Without the use of a specific tool, assessment can be unreliable, because a woman's overall excitement at having a new child may interfere with the accuracy of the assessment.

A woman who is concerned about her infant may experience more pain than a woman who feels confident that her infant is doing well, because anxiety and fear heighten a pain response, and a tense body posture causes pressure on sutures. Be certain a woman understands that her infant has survived the surgical

FIGURE 24.3 Cesarean birth. (**A**) Preparation for anesthesia. (**B**) Abdominal skin preparation. (**C**) Draping of operative site. (**D**) Preparation for initial incision. (**E**) Initial incision. (**F**) Opening of the peritoneum. *(continued)*

birth well (assuming this is true) or what steps are being taken to make the infant well.

Women who had a long-action morphine epidural for labor have good pain relief up to 24 hours. Others, who give birth without analgesia or received a shorter acting drug for birth, need analgesia to be comfortable. Patient-controlled analgesia (PCA) or continued epidural injections give maximum pain relief. No matter what system of pain relief is used, when administering analgesics after surgery, be sure to supplement them with other comfort measures, such as change of position or straightening of bed linen. Always ask a woman what type of pain she is experiencing before administering a new dose of analgesia, to be certain that she is describing incisional or uterine pain and not pain in a leg or some other body part that would suggest a complication of surgery. Check for abdominal distention, which suggests the pain may be

FIGURE 24.3 *(continued)* (**G**) Retractors in place. (**H**) Birth of head and posterior shoulder. (**I**) Infant born. (**J**) Suturing of uterus complete. (**K**) Suturing of abdominal layers. caused by intestinal gas rather than incision pain. If so, ambulation is often the most effective method to relieve this type of pain.

Urge a woman to continue to take adequate analgesia to effectively manage her pain after she returns home, so she is not so distressed that she cannot nurse her infant. Be certain she understands not to use acetylsalicylic acid (aspirin), because this can interfere with blood clotting and healing. Many women who are breastfeeding are reluctant to accept any type of analgesic, especially just before breastfeeding, for fear that it will pass in breast milk to the infant. Although it is true that most analgesics do pass in breast milk, the infant takes such a small amount of breast milk (mainly colostrum) during the first days after surgery that the amount of analgesia received would be negligible. Also, without the analgesic, the woman may be so uncomfortable that she is unable to hold her infant comfortably and enjoy having the infant with her. Placing a pillow over her lap while she feeds can deflect the weight of the infant from her suture line and lessen pain. Encourage the football hold for breastfeeding as another way to keep the infant's weight off the mother's incision.

Patient-Controlled Analgesia. PCA is a method of pain control in which women administer doses of intravenous narcotic analgesia such as morphine to themselves as needed. Although the technique may be used during labor, it is most frequently used to control postsurgical pain. With a solution such as Ringer's lactate infusing intravenously, a PCA pump containing a locked syringe of narcotic (meperidine or morphine) is attached to the intravenous line at a port close to the woman. To receive a dose of analgesia, the woman pushes a button similar to a call bell. This alerts the automatic pump to deliver a set amount of narcotic into the intravenous line. The pump has a "lock-out" setting that prevents a woman from administering a larger dose or doses more frequently than would be safe such as every 8 minutes (Fig. 24.4).

With PCA, a fairly constant level of pain relief can be maintained, and the pain and fear of injections are eliminated. PCA works well with postcesarean women because they feel well enough to be interested in self-care and self-administration of analgesia. Overall, women tend to use less analgesia with a PCA system than they would with intramuscular injections.

Epidural Analgesia. Today, women who have epidural anesthesia for cesarean birth can have morphine (Duramorph) or fentanyl added to the epidural catheter immediately after surgery, a technique that keeps them pain free for the next 24 hours (see Chapter 16). Although epidural analgesia provides effective pain relief after cesarean birth, side effects of epidural morphine administration, such as intense itching and nausea and vomiting, can occur. An antihistamine such as diphenhydramine (Benadryl) may be given to reduce pruritus; an antiemetic such as metoclopramide (Reglan) may be administered to counteract nausea. The use of fentanyl reduces the risk for these side effects. Even with these annoying side effects, however, epidural analgesia with morphine can be a very effective means of pain control after cesarean birth (Marshall & Baker, 2007).

FIGURE 24.4 Patient-controlled analgesia (PCA) pump. By pushing the button, a client delivers a bolus of narcotic to herself. (© Caroline Brown, RNC, MS, DEd.)

On the postpartal unit, an infusion pump is connected to the woman's epidural catheter and the woman can infuse a bolus of narcotic as additional pain relief is needed. This patient-controlled epidural anesthesia (PCEA) not only is an effective means of relieving pain but omits the problem of infiltration of an intravenous infusion, which can occur with intravenous PCA (Cho & Penning, 2007).

Transcutaneous Electrical Nerve Stimulation. Transcutaneous electrical nerve stimulation (TENS) is, as the name implies, the transmission of an electrical current across the skin. Small electrodes are attached to the woman's skin near her incision; when she feels pain, she pushes a transformer button. Irritation or stimulation of large afferent nerve fibers by the electrical stimulation block the ability of the smaller, pain-carrying nerve fibers to transmit impulses (as predicted by gating control theory). This is the same phenomenon that rubbing or scratching skin at the point of pain achieves (see also Chapter 16). The use of TENS can provide important pain relief after a cesarean birth, because it gives a woman a sense of control over her situation, as does PCA or PCEA (Halls, 2008).

What if... Moja Hamma refuses to allow you to assess her fundal height after her cesarean birth because she has so much pain? How would you approach this situation?

Nursing Diagnosis: Risk for deficient fluid volume related to blood loss during surgery

Outcome Evaluation: Patient's blood pressure is 100/60 mm Hg or higher; pulse remains between 60 and 100 beats per minute; scant to no bleeding on surgical dressing is apparent.

The potential always exists for deficient fluid volume because of blood loss from surgery until all blood

vessels that were cut and ligated during surgery have thrombosed, sclerosed, and permanently sealed closed. The risk of heavy bleeding doubles for the postpartum woman, because she may hemorrhage vaginally from an uncontracted uterus as well as internally from blood vessels that were not securely ligated. This danger is most acute during the first hour after surgery, but it remains an acute problem for the first 24 hours.

To detect the earliest signs of bleeding, monitor blood pressure, pulse, and respiratory rate approximately every 15 minutes for the first hour after surgery, every 30 minutes for the next 2 hours, every hour for the next 4 hours, or as specifically ordered. Signs indicative of possible hemorrhage include:

- Falling blood pressure (more than 20 mm Hg), or a systolic blood pressure less than 80 mm Hg, or a drop of 5 to 10 mm Hg over several readings
- A change in pulse rate (greater than 110 beats per minute or less than 60 beats per minute)
- Rapid respirations
- Restlessness and a sense of thirst

Inspect the dressing over the surgical incision for blood staining each time vital signs are assessed. Observe the perineal pad for lochia flow, and palpate the fundal height each time as well. Lochial discharge may be decreased in a woman after a cesarean birth because the uterus was cleaned during surgery, but some lochia will always be present, and it follows a typical rubra, serosa, alba pattern. Be certain to help a woman turn so you can look under her body for bleeding. Blood oozing from a surgical wound or vaginally can pool considerably under a woman before it is visible.

Oxytocin may be ordered to be added to the first 1 or 2 L of intravenous fluid after surgery to ensure firm uterine contraction. If the rate of fluid administration gets behind, be careful about "catch-up" administration. Oxytocin can elevate blood pressure by causing vasoconstriction. It may be safer to allow the fluid to remain behind for a time, rather than risk causing blood pressure to elevate. Be aware that a woman is very prone to hemorrhage at the point the oxytocin is discontinued, because this is the first time her uterus is being asked to maintain contraction on its own. Notify her care provider of any changes in vital signs that might indicate hemorrhage, so that prompt action can be taken. Remember that a minimal but continued change in vital signs (pulse steadily increasing, blood pressure steadily declining) is as ominous a sign of hemorrhage as is a sudden alteration in these measurements.

A woman who has had either spinal or epidural anesthesia usually will not experience pain on uterine palpation until the anesthesia has worn off, approximately 4 to 24 hours. Therefore, uterine palpation should not increase her pain. Once the effect of the anesthesia or analgesia has decreased, palpate gently to not cause increased pain but thoroughly enough to determine uterine consistency.

At the same time you assess a woman's uterus for firmness, assess the remainder of her abdomen for softness. A hard, "guarded" abdomen is one of the first signs of peritonitis (peritoneal infection), a complication that may occur with any abdominal surgical procedure.

Nursing Diagnoses and Related Interventions During the Extended Postpartal Period

The average woman whose child is born by cesarean birth remains in the hospital from 48 hours to 4 days, depending on her preferences and the regulations of her insurance carrier. During this period and until she returns to have her sutures or staples removed, several interventions are necessary to promote healing, prevent postoperative complications, and help the woman and her family establish bonding with the new child. Common concerns of women include pain, fatigue, interference with gastrointestinal function, and reduced activity level.

Nursing Diagnosis: Risk for deficient fluid volume related to postsurgical fluid restriction

Outcome Evaluation: Patient's urine specific gravity remains between 1.003 and 1.030; weight loss is not more than 5 to 10 lb; fluid intake equals 2 to 3 L/day.

Adequate fluid intake is important after surgery, to replace blood loss from surgery and to maintain blood pressure and renal function. Because the intestine is handled during surgery, it takes approximately 24 to 48 hours before full peristaltic function is restored and oral intake is possible. It is important that intravenous fluids be infused during this time, at a rate that is not too rapid (which could lead to cardiac overload) or too slow (which could lead to inadequate circulatory compensation). Keep an accurate intake and output record for at least the first 24 hours, to be certain an adequate fluid balance has been achieved.

Teach a woman to "guard" her intravenous fluid line, because she needs a high proportion of fluid during this time (all postpartal women undergo diuresis as a physiologic postpartal change). At the same time, do not urge such caution that she is afraid to turn or ambulate. Her risk for thrombophlebitis is high, so she must turn frequently when in bed and ambulate early in the postpartal period to reduce this risk.

Women are kept NPO for a time after surgery to avoid paralytic ileum that occurs from bowel handling during surgery. Because the bowel is not actually handled, however, there is probably little reason to withhold food and fluid as long as common protocols require (Mangesi & Hofmeyr, 2009; Izbizky et al., 2008).

To establish that bowel function has returned, assess a woman's abdomen at least once every 8 hours for bowel sounds, small "pinging" sounds heard on auscultation at a rate of 5 to 10 per minute, which demonstrate that air and fluid are moving through the intestines. Passage of flatus is another indication that intestinal function is again active. As soon as these signs

are present, intravenous fluid therapy is usually discontinued and the woman is allowed sips of fluid. After she begins oral intake, wait 1 hour before removing the intravenous line. Doing so ensures that a woman is not experiencing nausea and vomiting, which might require restarting intravenous therapy. Introduce oral fluid slowly—for example, ice chips for the first hour, then sips of clear fluid such as ginger ale, Jello, tea, or flavored frozen ice. Gradually advance her diet to a soft and then a regular diet as prescribed. Some women assume that they will not be allowed to eat for a long time and are surprised (and suspicious) to learn that they can have ice chips only hours after surgery. This is possible because ice chips dissolve so slowly that the woman receives little fluid from them; they feel cool, however, and quickly take away the dry, "cottony" feeling in her mouth caused by lack of fluid.

Teach women to continue to drink large quantities of fluid after they return home (at least six glasses daily), so that they have adequate body fluid to make breastfeeding successful.

Nursing Diagnosis: Constipation related to effects of abdominal surgery and anesthesia

Outcome Evaluation: Woman voices she has a bowel movement every 2 to 3 days or her usual pattern.

Note carefully the time of a woman's first bowel movement after surgery. If there has been no bowel movement by the time of hospital discharge, her physician may order a stool softener, a suppository, or an enema to facilitate stool evacuation. Reassure a woman who is not receiving much food yet that it is normal not to have bowel movements for 3 or 4 days postoperatively, especially if an enema was administered before surgery.

Teach women to eat a diet high in roughage and fluid and to attempt to move their bowels at least every other day to avoid constipation after they return home. Some women need a stool softener prescribed, because incisional pain interferes with their ability to use their abdominal muscles effectively. Caution them not to strain to pass stools, because this puts pressure on their incision. Keep their water pitcher full to remind them to drink fluids.

Nursing Diagnosis: Risk for impaired urinary elimination related to surgical procedure

Outcome Evaluation: Urinary output is more than 30 mL/h; patient reports no pain, frequency, burning, or hesitancy on voiding.

Voiding after surgery provides evidence of adequate renal and circulatory function, because the kidneys must have adequate blood flow through them to function. Because the bladder was handled and displaced during surgery, its tone or ability to sense filling may be inadequate to initiate voiding. For this reason, the indwelling catheter placed before surgery is usually left in place for 4 to 24 hours to ensure good urine drainage. Assess that the catheter is draining (a postpartal woman has a urine output of 3000 to 5000 mL per 24 hours). Bladder distention will occur rapidly if the catheter becomes blocked.

Before catheter removal, a urine culture may be ordered to check for the possibility of a urinary tract infection. After removal of the catheter, the average woman voids in 4 to 8 hours. Assess for bladder filling at the end of this time by palpation, pressing lightly over the symphysis pubis to assess fullness (Fig. 24.5A), and by percussion. On percussion, an empty bladder sounds dull; a full bladder, resonant; and an extended bladder, hyperresonant (Fig. 24.5B). If a bladder has filled to capacity but cannot empty properly, the woman may have "retention with overflow," or

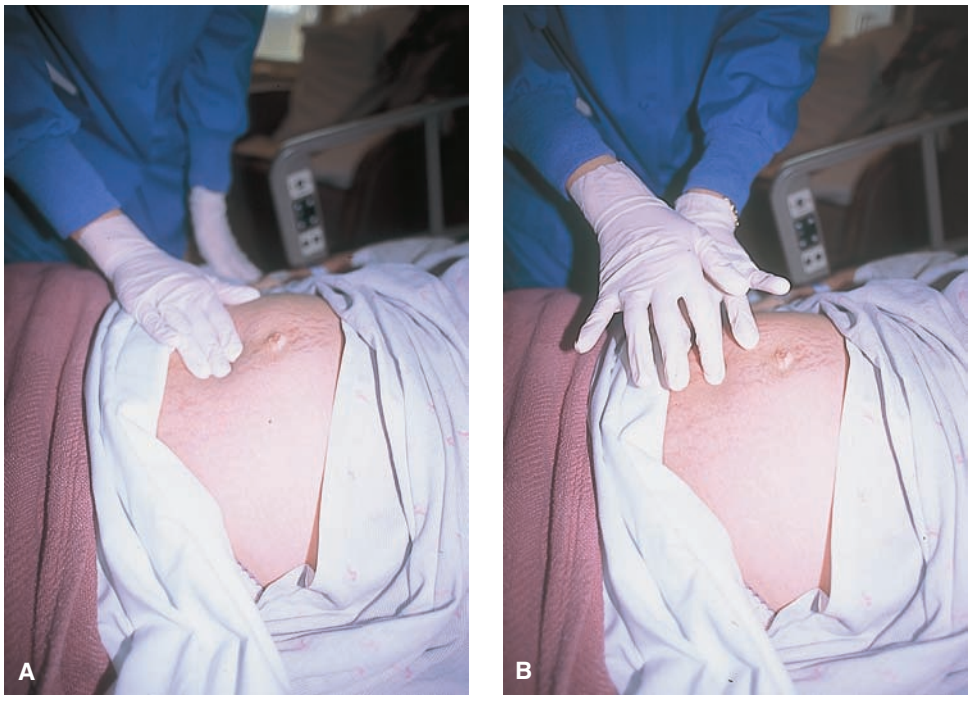

FIGURE 24.5 (**A**) Assessing bladder filling by palpation. (**B**) Assessing bladder filling by percussion. (© Caroline Brown, RNC, MS, DEd.)

voiding 30 to 60 mL of urine every 15 to 20 minutes. This voiding pattern is potentially dangerous because it means that the woman's bladder is held continuously under tension. This can result in permanent bladder damage if the condition goes undetected. In addition, the constantly full bladder may prevent the uterus from contracting, possibly increasing the risk of postpartal hemorrhage.

To help a woman void, suggest she take her prescribed analgesic to help relax abdominal musculature. In addition, provide privacy for voiding, and assist the woman to walk to the bathroom at least every 2 hours. Other measures that might be effective include pouring warm water over her vulva (measure the amount of water used, so that it can be differentiated from urine) or running water from a tap within hearing distance.

Teach women to continue to drink adequate fluid (at least five to six glasses daily) to ensure an adequate fluid output and help prevent urinary tract infection after they return home. Be certain they know to telephone their primary care provider if they should develop symptoms of a urinary tract infection, such as pain or frequency with voiding or blood in urine.

Nursing Diagnosis: Risk for ineffective peripheral tissue perfusion related to immobility during and after surgery

Outcome Evaluation: Capillary refill is less than 5 seconds; there is absence of calf pain, redness, edema, or areas of warmth on lower extremities.

Because a woman's abdominal muscles are lax from the stretching that occurred during pregnancy, abdominal contents tend to shift forward and put pressure on the suture line when she is sitting or standing, causing pain and an uncomfortable feeling often described as "everything falling out." A woman may feel more comfortable turning and sitting up if she supports her abdomen with one hand or splints the incision with a pillow.

Leg exercises such as flexing and extending her knees and early ambulation are a woman's best safeguards against lower-extremity circulatory problems. Thrombohemolytic stockings may be prescribed to help promote venous return and prevent venous stasis. Teach a woman to apply these before arising, while she is supine and venous distention is minimal. Always allow her to sit on the edge of the bed for a few minutes before helping her to a standing position, to prevent orthostatic hypotension (sudden low blood pressure that occurs with sudden position changes). Assessing blood pressure before a woman gets out of bed for the first time is an additional safeguard. Before ambulation, also assess the lower extremities for pain in the calf on dorsiflexion of the foot (Homans' sign—which may or may not be reliable) or for pain, edema, warmth, or redness in the calf, to detect the possibility of a thrombus. It is dangerous for a woman to ambulate if signs of a thrombus are present. A thrombus could shift, becoming an embolus, a potentially lethal situation.

Often, it is difficult for women to understand the importance of turning and ambulating as soon as possible after surgery (Fig. 24.6). Still experiencing the "taking in" postpartal phase, a woman may prefer to spend the first days after surgery just resting quietly in bed. Encourage her to use adequate analgesia during this time, to enable her to move and ambulate with the least amount of pain. Reinforce the need for continued activity balanced with rest after discharge. Be certain she understands the signs and symptoms of complications, such as thrombophlebitis.

FIGURE 24.6 Encouraging women to be out of bed will help prevent complications from a cesarean birth. It is important to splint the incision area while getting up and ambulating. (© Barbara Proud.)

Nursing Diagnosis: Risk for impaired parenting related to the emergent nature of birth or discomfort from surgery

Outcome Evaluation: Parents hold and feed child and voice positive comments about the infant.

When a cesarean birth is unscheduled, a woman does not have much time preoperatively to think about how she will feel after surgery. Most women are surprised to realize how well they feel overall but also how quickly they become fatigued and how painful a simple surgical incision can be. Being reassured they are recovering well but that surgery is a physiologic shock to their system helps them to accept temporary discomforts. It can help them bond with their newborn after a cesarean birth, just as women who give birth vaginally. Encourage women to breastfeed even if this causes temporary uterine pain as the uterus contracts with breastfeeding.

If the woman's baby was born with a complication or has been placed in an intensive care nursery or transferred to a distant hospital for tertiary care, a woman's postpartal course can be difficult because she experiences a sense of loss in addition to the pain and fatigue of surgery. Depression, which can slow all body functions and certainly her ability to "take hold" in the postpartal period, can occur.

Unless her baby was transferred to another site, be certain to provide her with ample time to hold and feed her child if possible. Most women can breastfeed satisfactorily after cesarean birth. If intravenous lines or other devices are present, assist her with holding

FIGURE 24.7 A nurse assists with holding the newborn and positioning the equipment so that the intravenous line does not interfere with mother–child interactions. (© Caroline Brown, RNC, MS, DEd.)

her newborn, so that equipment does not interfere with her time spent with her infant. She may have some reason to think her baby is not quite perfect—after all, the baby was not born "perfectly"—so she may need additional time to inspect her baby and feel comfortable with him or her (Fig. 24.7).

Nursing Diagnosis: Fatigue related to effects of surgery

Outcome Evaluation: Patient states she is pleased with level of self-care; ambulates well by 24 hours, and sleeps restfully at night.

Although a woman needs activity and movement after surgery, she also needs adequate rest. Many women attempt to handle their own and their newborn's needs immediately after surgery, because their excitement over their baby and their new role makes them unaware of their underlying fatigue. Extreme fatigue interferes with healing and possibly increases the risk for infection, however. It also can eventually interfere with bonding. Help a woman plan a day that includes care of her new child as well as periods of rest for herself. Be certain she has adequate analgesic medication at bedtime to allow her to be pain free for the night. Provide a time in the middle of the morning and again in the afternoon for uninterrupted rest. Explore her plans for care at home to be certain that her plans for rest seem realistic for a postsurgical-postpartal woman (Box 24.5).

Once a woman returns home, rest is often best accomplished if it is scheduled for every time her newborn sleeps. Without adequate rest this way, she can notice increased uterine bleeding, which has the potential to lead to excessive loss of fluid and iron stores.

Nursing Diagnosis: Impaired skin integrity related to surgical incision

Outcome Evaluation: Incision line is clean, dry, and intact without erythema; oral temperature is less than 38° C.

Surgical incisions heal by primary intention, or by the gradual removal and replacement of dead or damaged cells at the wound site with new cells produced by the surrounding tissue. Assess the surgical incision once during each nursing shift while a woman is hospitalized, to ensure that the wound edges are approximated and there are no signs of infection, such as erythema. As soon as she can walk steadily, a woman can take a shower (after first removing the dressing), because warm, clean water on the incision is soothing. After this point, she can make a decision about whether to continue to wear a dressing. Lack of a dressing prevents moisture accumulation at the incision site and decreases the possibility of infection.

Teach women to continue to observe their incision daily at home. Instruct them in signs and symptoms of possible infection, including redness or the presence of a discharge, and to report any of these signs to their primary care provider. With a cesarean birth, healing will be adequate enough by day 3 that skin sutures or clamps can be removed, although many are left in place until the woman returns for a follow-up appointment in 2 weeks.

Discharge Planning

A woman being discharged after cesarean birth takes home not only her new baby but a fair amount of pain and discomfort. Be certain to discuss home care arrangements, emphasizing the need for adequate help with her newborn and other responsibilities at home, before discharge. Be sure a woman is aware of any restrictions on exercise or activity

BOX 24.5 ✻ Focus on Family Teaching

Measures to Regain Energy After a Cesarean Birth

Q. Moja Hamma tells you, "I feel so tired after my cesarean. What can I do to feel stronger again?"

A. After a cesarean birth, women usually regain energy rapidly. This is because, unlike most people who have had surgery, you did not have it because you were ill, but because it was an alternative method to have a healthy baby. Good suggestions to help regain your energy rapidly are:

- Drink adequate fluid daily (at least six glasses). This helps prevent a urinary tract infection and also helps supply all the cells in your body with adequate fluid.
- Rest twice a day for at least one-half hour each time. This helps because your baby will probably wake you at least once during the night.
- Do not hesitate to accept help from family and friends for tasks such as house cleaning or grocery shopping.
- Limit the number of stairs that you climb daily to one flight once a day. Also limit the amount of weight you lift to the weight of your new baby.
- Do not attempt to be the "perfect" new mom. Relax and enjoy your new baby.

that she needs to follow (common restrictions are not to lift any object heavier than 10 lb or walk upstairs more than once a day for the first 2 weeks). Also teach her to recognize signs of possible complications directly related to the surgery, such as:

- Redness or drainage at the incision line
- Lochia heavier than a normal menstrual period
- Abdominal pain (other than suture line or afterpain discomfort)
- Temperature greater than 38° C (100.4° F)
- Frequency or burning on urination

A woman can plan on resuming coitus as soon as the act is comfortable for her, possibly as early as 1 week after discharge. Cesarean birth does not interfere with future fertility so be sure that she has contraceptive information, if desired (Oral & Elter, 2007). Also ensure that she has an appointment for a return visit with her health care provider (usually in 2 weeks), for both herself and her newborn.

Unless the reason for the cesarean birth was cephalopelvic disproportion, a woman can probably have her next child vaginally (see Chapter 15). Being certain the woman is aware of this not only makes her an informed consumer of health care but also can influence whether she plans an additional pregnancy (see Focus on Nursing Care Planning Box 24.6).

✔ Checkpoint Question 24.4

Moja Hamma wonders if she can breastfeed following a cesarean birth. Your best answer would be:

a. You do not recommend she try to breastfeed because she will feel so ill.
b. It is difficult for a woman with an abdominal incision to hold a newborn.
c. She will need too much analgesia postoperatively to make breastfeeding safe.
d. Women can breastfeed without difficulty following a cesarean birth.

BOX 24.6 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Woman Following an Emergent Cesarean Birth

Moja Hamma is a 29-year-old primigravida who underwent an emergent cesarean birth with combined spinal-epidural anesthesia for fetal distress. Moja gave birth to a healthy 8-lb 2-oz baby girl. She tells you, "I'm thirsty, and it hurts so much I can't move. Take the baby away. I can't hold her right now."

Family Assessment ✻ Client lives with boyfriend in west-side apartment. Works as a clerk in a bridal salon. Boyfriend is currently unemployed. Borrowed money from a friend for hospital bill.

Client Assessment ✻ Post-cesarean birth 4 hours ago. Estimated blood loss of 700 mL. Abdomen soft but tender with low transverse incision. No bowel sounds present. Incisional dressing clean, dry, and intact. Uterus firm, 1 fingerbreadth below umbilicus. Minimal lochia rubra vaginal drainage. Urine output 100 mL in last hour. Skin pink, warm, and dry. Skin turgor good. Ringer's lactate infusing at 100 mL/hr. Intravenous site clean, dry, without signs of infiltration. Vital signs: temperature, 98.4° F; pulse, 78 beats per minute; respirations, 23 per minute; blood pressure, 130/76 mm Hg. Pulse, respirations, and blood pressure slightly elevated above baseline. Respirations shallow. States she has abdominal pain, especially at incisional area. Holding hands over abdomen; barely moving in bed. Client's mother at bedside holding her hand and stroking her forehead. PCEA pump in place but not being used by client. When asked why she wasn't using the PCEA pump, she answered, "I don't want to take the chance of being paralyzed forever."

Nursing Diagnosis ✻ Pain related to tissue trauma from abdominal incision of cesarean birth

Outcome Criteria ✻ Client identifies pain management measure of choice; reports a decrease in pain with analgesic administration; pulse, respirations, and blood pressure return to baseline.
Client holds infant warmly; maintains eye contact with infant; makes positive statements about the newborn prior to discharge.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Assess client's ability to move in bed and breastfeed infant.	Stress the importance of getting out of bed and caring for infant.	Early ambulation helps prevent thrombophlebitis; early breastfeeding helps establish adequate milk supply.	Client feels well enough to be out of bed and feeding infant by 4 hours' time due to chosen pain relief method.

		Consultations		
Nurse	Investigate whether pain management team is available for consultation.	Ask pain management team to consult on more appropriate pain relief measures.	Client states she is afraid to use PCEA for pain relief.	Pain management team discusses options for pain relief with client and they agree on a suitable procedure by 2 hours.
		Procedures/Medications		
Nurse	Assess what measures client feels would make her most comfortable.	Institute additional comfort measures, such as changing position, splinting incision, using pillows and blankets for support. Institute different pain management system if one is employed or assist with present system if client agrees with system.	Comfort measures reduce stress and anxiety, elevate mood, and raise the pain threshold, enhancing the therapeutic effectiveness of analgesics and the client's control over and ability to tolerate pain.	Client reports additional comfort measures aid pain relief. Client reports pain management system is operating effectively.
Nurse	Assess what measures client thinks would help her be more successful with breastfeeding.	Assist client with handling newborn. Support breastfeeding efforts.	Breastfeeding is a new skill for a first time mother.	Client breastfeeds the infant successfully with support from health care providers.
		Nutrition		
Nurse	Assess bowel sounds to determine when oral fluid can be offered.	Offer ice cubes for dry mouth as soon as bowel sounds are present.	Client cannot drink full liquids until bowel sounds return.	Client states mouth discomfort is reduced by 1 hour after first fluid.
		Patient/Family Education		
Pain management Team/ nurse	Assess client's expectations of pain relief measures.	Review PCEA pump and technique with client.	Client cannot have realistic expectations unless she understands technique.	Client states that she will use PCEA pump on trial basis for 4 hours or choose an alternative method of pain management.
		Psychosocial/Spiritual/Emotional Needs		
Nurse	Assess what additional measures client feels she needs to feel secure after frightening experience of emergent cesarean birth.	Provide reinforcement for positive coping mechanisms that client demonstrates.	Positive reinforcement enhances self-esteem and control. Praise promotes self-esteem and confidence to manage new situations.	Client states she feels her coping measures are reinforced by health care providers. Client states she feels health care providers provide her support equal to her level of pain and fatigue.
Nurse	Assess client's expectations of a newborn.	Praise client for positive behaviors and interactions with the child in light of pain and fatigue level. Encourage client to keep newborn in the room with her for extended periods as she is able.	Extended contact within the client's ability to tolerate the activity encourages bonding while minimizing the risk for additional fatigue.	Client keeps newborn with her in room for the majority of daylight hours. Interacts actively with child.

(continued)

BOX 24.6 ✻ Focus on Nursing Care Planning (continued)

Discharge Planning

Nurse	Assess the level of support client will have after she returns home.	Review with client importance of maintaining a level of pain relief at home so she can ambulate and care for new child.	Ambulation and child care are important for both maternal and child health. Keeping pain to a minimum helps the client achieve these activities.	Client states she will take enough pain relief at home to allow her to be active and care for newborn. She names at least one person to serve as support person.
Nurse	Assess whether client understands signs and symptoms such as pain on urination she will need to report after discharge.	Teach signs of complications she should report to her health care provider.	Knowing signs and symptoms of complications adds to client's base of knowledge.	Client repeats danger signs that she will report to her health care provider.

Key Points for Review

- The term *cesarean birth* is preferred to *cesarean section* or *delivery,* because it puts the focus on the childbirth rather than surgical elements of the procedure.
- Cesarean birth may be either a scheduled or an emergent procedure. Because it carries more risk for the woman and infant than does vaginal birth, it is usually undertaken only when medically necessary, although a current trend allows for elective procedures.
- Establishing surgical risk includes assessment of nutritional status, age, general health, fluid and electrolyte balance, and psychological condition.
- Assessment measures before surgery usually include vital sign determination; urinalysis; blood studies such as complete blood count, electrolytes, blood typing, and cross-matching; and ultrasound.
- The skin incision may be vertical (a classic incision), although it is usually a horizontal one just above the pubic hair. The internal incision into the uterus is also usually a horizontal incision into the lower uterine segment.
- The old saying, "Once a cesarean, always a cesarean," is no longer true, as long as cephalopelvic disproportion does not exist and the previous incision was a low transverse one.
- Support people can lose a great deal of their ability to support if they feel intimidated and out of place in an operating room; offer them support as needed to make this a positive experience for them as well.
- Cesarean birth is one of the safest types of surgery performed. To keep a woman safe after the procedure, remember that she is both a postsurgical and a postpartum patient. Make assessments to ensure that neither postpartum nor postsurgical complications occur.
- Adequate pain management is important to allow a woman a sense of control and comfort and bonding with her newborn.
- Women are physically exhausted after cesarean birth and may be psychologically exhausted because of the emergent nature of the experience. Provide rest time to relieve the physical strain and a chance to verbalize the experience to help relieve the psychological strain.
- A major intervention after cesarean birth is early ambulation to prevent complications. Incisional pain may make this difficult, so strong nursing support and adequate pain management are necessary.

CRITICAL THINKING EXERCISES

1. Moja, the woman you met at the beginning of this chapter, was afraid to have a cesarean birth because she did not want to be alone. What actions could you take to make her situation easier to accept?
2. Suppose Moja is receiving PCEA after her cesarean birth. She tells you that she is not interested in PCEA and would rather have injections for pain. Describe and explain the action you might take. Would you advocate for use of PCEA or advocate with her physician for a changed order?
3. Moja's boyfriend tells you that he cannot possibly stay with her in the operating room while she has a cesarean birth. He's sure he'll feel nauseated and probably faint. How would you intervene to promote family-centered care and meet the couple's needs?
4. Examine the National Health Goals related to cesarean birth. Most government-sponsored funds for nursing research are allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to the Hamma family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to cesarean birth. Confirm your answers are correct by reading the rationales.

Chapter

25 Nursing Care of a Family Experiencing a Postpartal Complication

KEY TERMS

- endometritis
- mastitis
- peritonitis
- postpartal depression
- postpartal psychosis
- thrombophlebitis
- uterine inversion

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe common deviations from the normal that can occur during the puerperium.
2. Identify National Health Goals related to postpartal complications that nurses can help the nation achieve.
3. Use critical thinking to analyze ways that promote family-centered nursing care when a postpartal complication occurs.
4. Assess a woman and her family for deviations from the normal during the puerperium.
5. Formulate nursing diagnoses related to deviations from the normal during the puerperium.
6. Identify expected outcomes for a postpartal woman experiencing a complication.
7. Plan nursing interventions that meet the special needs of a family with a postpartal complication, such as planning for an extended hospitalization.
8. Implement nursing care when a postpartal complication such as hemorrhage, infection, pregnancy-induced hypertension, or postpartal psychosis develops.
9. Evaluate expected outcomes for achievement and effectiveness of care.
10. Identify areas related to care of women with postpartal complications that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of postpartal complications with the nursing process to achieve quality maternal and child health nursing care.

Mary Blackhawk is a 30-year-old woman who had a "textbook-perfect" pregnancy. You enter her room 4 hours after she gave birth to an 8-lb girl, but, because she is sleeping and appears comfortable, you hesitate to awaken her. When you observe her more closely, however, you realize she appears abnormally pale. You obtain her vital signs and document her pulse as 90 beats per minute and her blood pressure as 96/50 mm Hg. When you fold back her bedclothes, you discover her bed is soaked with blood. You suspect she is experiencing one of the most serious complications of pregnancy: postpartum hemorrhage. Yet because she was sleeping, she was totally unaware of it.

In an earlier chapter, you learned about caring for a woman during the usual postpartal period. This chapter adds information about how to care for a woman and her family when there is a complication during this time. Conscientious nursing care is important when a postpartal complication develops because it plays a major role in protecting the health of both women and their families.

What immediate measures does Ms. Blackhawk need? What would be your first action?

Although the puerperium is usually a period of health, complications can occur. When they do, immediate intervention is essential to prevent long-term disability and interference with parent–child relationships. Box 25.1 describes National Health Goals related to this period.

A woman with a postpartal complication is at risk from three points of view: her own health, her future childbearing potential, and her ability to bond with her new infant. Her family may be disrupted because of an extended hospital stay that removes her from other family members. Financial difficulties may arise because of the need for additional child and health care. Fortunately, most postpartal complications are preventable, and if they do occur, the majority can be treated effectively without long-term complications.

Nursing Process Overview

For a Woman Experiencing a Postpartal Complication

Assessment

Women who assume that they will immediately return to an active lifestyle after birth of their child may view hospitalization for a postpartal complication as more upsetting than do women who view the postpartal period as one in which they are expected to rest. Assessing each woman individually is necessary to establish the personal impact of a postpartal complication.

Assessment findings associated with a postpartal complication may be extremely subtle, such as tenderness in the calf of a leg, a slight increase in uterine or perineal pain, a slight elevation in temperature, or a slight increase in the amount of lochia flow (Box 25.2). Because the average woman usually has no postpartal complications and the length of stay in a hospital is short, it is easy to overlook these subtle signs. It is important to be alert to any findings that are "different from usual," because they may be the beginning of a problem. To be certain, do not rely solely on a woman's report of perineal healing or amount of lochia. Always inspect her perineum yourself, because the report of "I feel fine" may be deceptive because she expected to have pain and so reports extreme pain as nothing out of the norm; she has no knowledge of "normal" lochia or fundal height against which to accurately compare her own condition.

An increased temperature during the first 24 hours after birth is an extremely serious finding. Women may try to "explain away" an increased temperature, because they know that if they have an elevated temperature they

BOX 25.1 ✻ Focus on National Health Goals

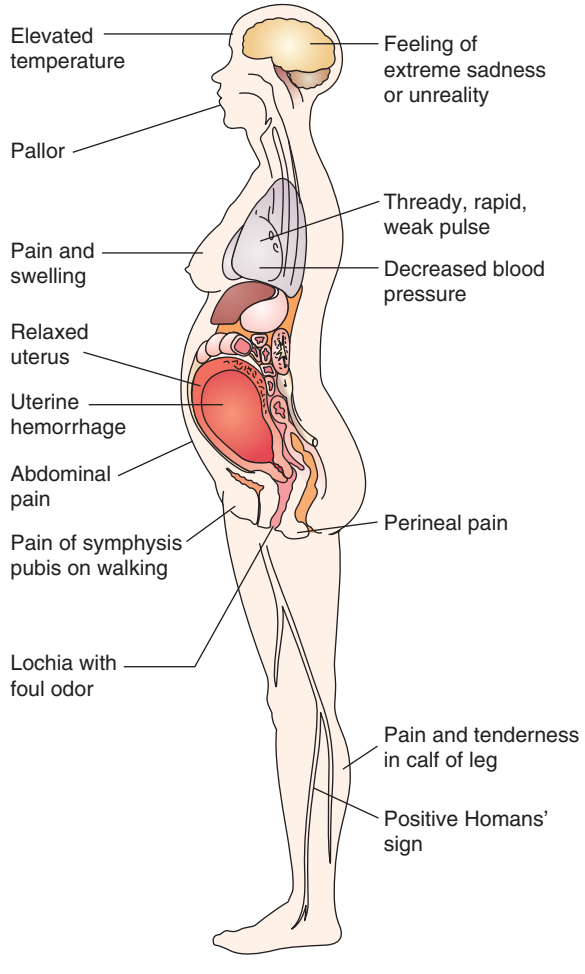
The postpartal period is a time when women are very susceptible to hemorrhage and thrombophlebitis, and with a complication women after childbirth may choose not to breastfeed. Three National Health Goals directly relate to this period:

- Reduce the maternal mortality rate to no more than 3.3 per 100,000 live births from a baseline of 7.1 per 100,000.
- Increase to at least 75% the proportion of mothers who breastfeed their babies in the early postpartal period from a baseline of 64%.
- Increase to at least 60% the proportion of mothers who breastfeed exclusively through 3 months from a baseline of 43% (http://www.nih.gov).

Nurses can help the nation achieve these goals by careful monitoring of uterine involution in the postpartal period and by encouraging women to breastfeed even in the face of a postpartal complication.

Areas related to complications of the postpartal period that could benefit from additional nursing research include methods to better identify risk factors for mastitis and endometritis; identifiable differences between women who stop breastfeeding and those who continue when a complication is present; and health teaching that is effective in preventing mastitis.

Box 25.2 Assessment
Assessing the Postpartal Woman With Complications



may not be allowed to go home or feed their infant. Do not be tempted to rationalize such a finding with explanations such as, "The room was warm," or "She just drank some hot coffee." Although these factors may make a slight difference (part of 1°) in temperature level, they do not affect it enough to account for an oral temperature greater than 100.4° F (38.0° C).

Nursing Diagnosis

Nursing diagnoses during this time vary depending on the postpartal complication. Some examples are:

- Deficient fluid volume related to increased lochia flow
- Risk for infection related to microorganism invasion of episiotomy
- Ineffective peripheral tissue perfusion related to interference with circulation from thrombophlebitis
- Situational low self-esteem related to postpartal infection and inability to feed infant
- Social isolation related to precautions necessary to protect infant and others from infection transmission
- Risk for impaired parenting related to postpartal depression
- Ineffective breastfeeding related to development of mastitis

Outcome Identification and Planning

Outcome identification for a woman with a postpartal complication may be particularly difficult because, although a woman wants to do everything necessary to return to health, she also does not want to allow anything to interfere with her ability to bond with her new child. During the stage of postpartal "taking-in," she may not be interested in doing things for herself; during the second stage of "taking-hold," she may not be interested in having you do procedures for her (see Chapter 17). As a rule, however, never underestimate how much a woman will endure to prepare herself to care for a new child. That quality is the essence of motherhood.

When planning for a postpartal family, provide for measures that will restore the woman most quickly to health and promote contact among her, her child, and her primary support person. If physical contact between a mother and her newborn is not possible, give the mother frequent reports of her infant's health and preferences. During her taking-in phase, have the nursery contact the mother at least once every nursing shift to update her on the infant's status; during her taking-hold phase, encourage her to contact the nursery. If the infant is being cared for in another facility, ask them to fax or e-mail photographs of the infant. This provides something concrete to which a new mother can relate. Many women respond well to notes written as if they were from the child, for example, "Hi, Mom. Just a note to say hello. I'm drinking well but I miss you and can't wait for you to get better and be allowed to come take care of me. Love, Kelsey Marie." Such a note serves to relieve a woman's concern for her child (she is doing well) and also helps to increase the woman's self-esteem, which can promote bonding. As many as 1 woman in every 500 develops severe depression or even psychosis after childbirth (McGarry et al., 2009). This risk increases when a complication develops. A helpful national volunteer support group for women who are depressed after childbirth is Depression After Delivery (http://www.depressionafterdelivery.com).

Implementation

Interventions for a woman with a postpartal complication should include instruction for both self-care and child care (if appropriate), emphasizing the transitory nature of the complication. Continuing to review well-child care in this way helps a woman accept her situation as temporary, reinforcing the idea she will be able to care for her infant when she is healthy again.

Outcome Evaluation

Evaluation of a woman with a postpartal complication should address both her and her family's health as well as her family's ability to bond with the new child. Evaluation may suggest the need for home care follow-up to assist a woman in coping with the responsibility of child care and integrating a new child into the family in the face of reduced energy from illness.

Examples of expected outcomes might include:

- Oral temperature decreases to less than 100.4° F (38.0° C).
- Lochia is free of foul odor.
- Client maintains blood pressure higher than 110/60 mm Hg.
- Client demonstrates bonding behaviors with infant despite separation.
- Client demonstrates warm contact with her child while maintaining required bed rest.

POSTPARTAL HEMORRHAGE

Hemorrhage, one of the most important causes of maternal mortality associated with childbearing, poses a possible threat throughout pregnancy and is also a major potential danger in the immediate postpartal period. Significant hemorrhage occurs in 5% to 8% of women postpartally (Poggi, 2007). Traditionally, postpartal hemorrhage has been defined as any blood loss from the uterus greater than 500 mL within a 24-hour period (Pavone, Purinton, & Petersen, 2007). In specific agencies, the loss may not be considered hemorrhage until it reaches 1000 mL. Hemorrhage may occur either early (within the first 24 hours) or late (anytime after the first 24 hours during the remaining days of the 6-week puerperium). The greatest danger of hemorrhage is in the first 24 hours because of the grossly denuded and unprotected uterine area left after detachment of the placenta.

There are five main causes for postpartal hemorrhage: uterine atony, lacerations, retained placental fragments, uterine inversion, and disseminated intravascular coagulation (Fig. 25.1).

Uterine Atony

Uterine atony, or relaxation of the uterus, is the most frequent cause of postpartal hemorrhage (Poggi, 2007). The uterus must remain in a contracted state after birth to keep the open vessels at the placental site from bleeding. Factors that predis-

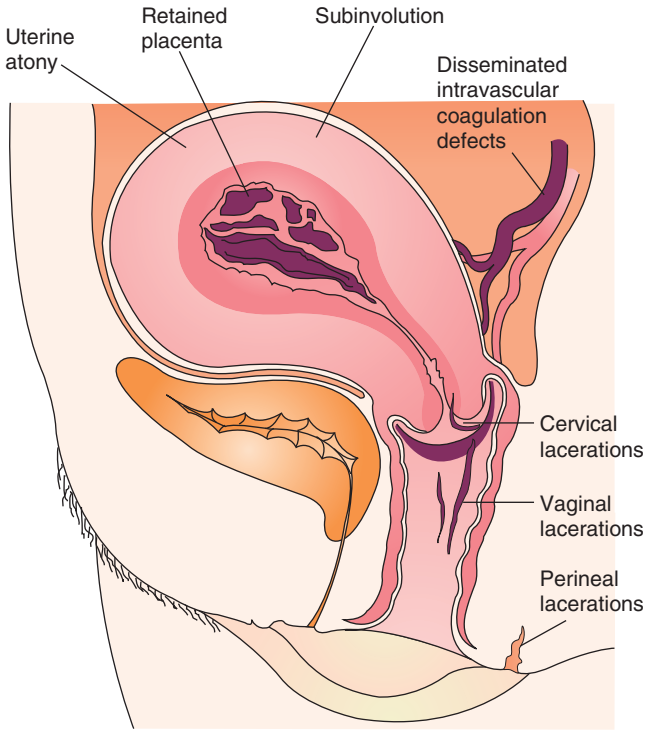


FIGURE 25.1 Common causes of postpartal hemorrhage.

pose to poor uterine tone or any inability to maintain a contracted state are summarized in Box 25.3. When caring for a woman in whom any of these conditions are present, be especially cautious in your observations and be on guard for signs of uterine bleeding. This is especially important because many postpartal women are discharged within 48 hours after birth.

Nursing Diagnosis and Related Interventions

Nursing Diagnosis: Deficient fluid volume related to excessive blood loss after birth.

Outcome Evaluation: Client's blood pressure remains higher than 100/60 mm Hg; pulse remains between 70 and 90 beats per minute; lochia flow is less than one saturated perineal pad per hour.

If the uterus suddenly relaxes, there will be an abrupt gush of blood vaginally from the placental site. If the vaginal bleeding is extremely copious, a woman will exhibit symptoms of shock and blood loss. This can occur immediately after birth or more gradually, over the first postpartum hour, as the uterus slowly becomes uncontracted. When the vaginal bleeding occurs gradually, it results in seepage, not a gush of blood. Over a period of hours, however, continued seepage can be as lethal as a sudden release of blood.

It is difficult to estimate the amount of blood a postpartal woman has lost, because it is difficult to estimate the amount of blood it takes to saturate a perineal pad. The amount is between 25 and 50 mL. By counting the number of perineal pads saturated in given lengths of time such as half-hour intervals, you can form a rough estimate of blood loss. Five pads saturated in half an hour is obviously a different situation from five pads saturated in 8 hours. In either situation, however, a woman will have lost approximately 250 mL of blood, and if either scenario is allowed to continue unattended, she will be in grave danger. Be sure you differentiate between *saturated* and *used* when counting pads. Weighing perineal pads before and after use and then subtracting the difference is an accurate way to measure vaginal discharge: 1 g of weight is comparable to 1 mL of blood volume. Always be sure to turn a woman on her side when inspecting for blood loss, to

BOX 25.3 ✻ Conditions That Increase a Woman's Risk for Postpartal Hemorrhage

Conditions That Distend the Uterus Beyond Average Capacity
Multiple gestation
Hydramnios (excessive amount of amniotic fluid)
Large baby (>9 lb)
Presence of uterine myomas (fibroid tumors)

Conditions That Could Have Caused Cervical or Uterine Lacerations
Operative birth
Rapid birth

Conditions With Varied Placental Site or Attachment
Placenta previa
Placenta accreta
Premature separation of the placenta
Retained placental fragments

Conditions That Leave the Uterus Unable to Contract Readily
Deep anesthesia or analgesia
Labor initiated or assisted with an oxytocin agent
Maternal age greater than 35 years
High parity
Previous uterine surgery
Prolonged and difficult labor
Possible chorioamnionitis
Secondary maternal illness (e.g., anemia)
Prior history of postpartum hemorrhage
Endometritis
Prolonged use of magnesium sulfate or other tocolytic therapy

Conditions That Lead to Inadequate Blood Coagulation
Fetal death
Disseminated intravascular coagulation

be certain that a large amount of blood is not pooling undetected beneath her.

Palpate a woman's fundus at frequent intervals postpartally to be certain that her uterus is remaining in a state of contraction. This is the best measure for preventing early hemorrhage. When palpating a uterine fundus, if you are unsure whether you have located it, the uterus is probably in a state of relaxation. Under normal circumstances, a well-contracted uterus is firm and easily recognized because it feels like no other abdominal organ. Frequent assessments of lochia (to be certain that the amount of the flow is under a saturated pad per hour, and that any clots are small), as well as vital signs, particularly pulse and blood pressure, are equally important.

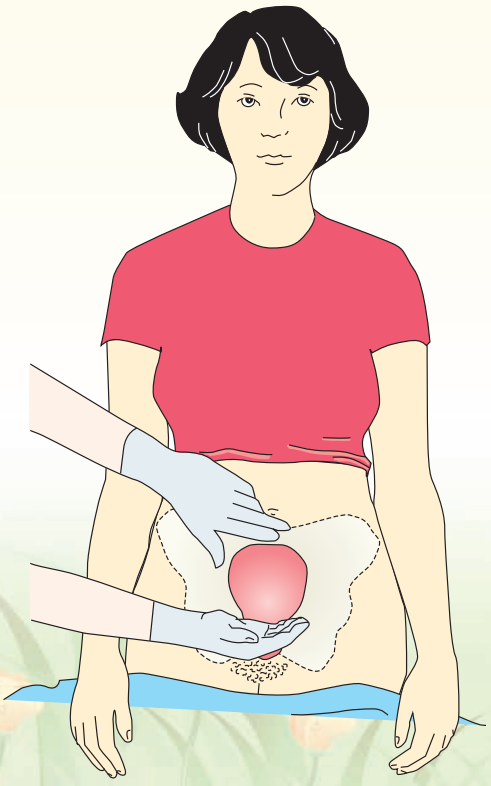
Therapeutic Management

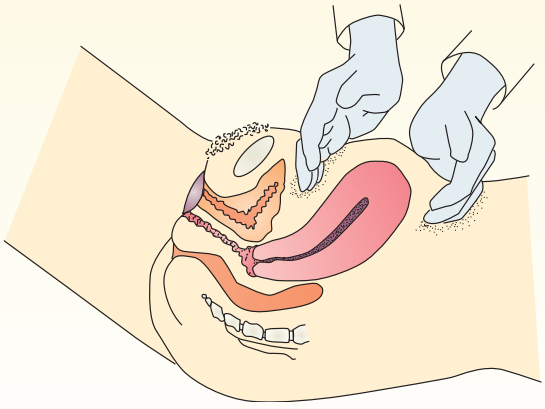
In the event of uterine atony, the first step in controlling hemorrhage is to attempt uterine massage to encourage contraction (Box 25.4). Unless the uterus is extremely lacking in tone, this procedure is usually effective in causing contraction, and, after a few seconds, the uterus assumes its healthy, grapefruit-like feel.

Box 25.4 Nursing Procedure ✻ Fundal Massage

Purpose: To stimulate uterine contraction, promote uterine tone and consistency, and minimize the risk of hemorrhage.

Procedure	Principle
1. Explain the procedure to the client and provide privacy.	**1.** Explanations help to decrease anxiety; providing privacy enhances self-esteem.
2. Ask the client to void (unless bleeding is extensive and more rapid action seems necessary).	**2.** An empty bladder prevents displacement of the uterus and ensures accurate assessment of uterine tone.
3. Place the client supine with her knees flexed and feet together.	**3.** Proper positioning enhances visualization and effectiveness of procedure.
4. a. Put on gloves. Place one hand on the abdomen just above the symphysis pubis.	**4. a.** This location anchors the lower uterine segment.
b. Place the other hand around the top of the fundus.	**b.** This location helps to assess and locate the fundus and determine height.



Procedure	Principle
5. Rotate the upper hand to massage the uterus until it is firm, being careful not to overmassage the uterus.	**5.** Massage should be done only when uterus is not firm; otherwise muscle fatigue and uterine relaxation may occur. Aggressive massage may lead to partial or complete uterine prolapse.
	


6. When the uterus is firm, gently press the fundus between the hands using slight downward pressure against the lower hand.	**6.** Gently squeezing with downward pressure helps to expel blood or clots collected in the uterine cavity.
7. Remove the perineal pad. Observe the perineum for passage of clots and amount of bleeding.	**7.** This helps to assess the degree of bleeding.
8. When the uterus is again firm, cleanse the perineum and apply a clean perineal pad. Discard gloves and soiled pads according to agency policy.	**8.** This helps to promote comfort and hygiene while reducing the risk for infection.
9. Document results of procedure. Continue to assess fundus and lochia according to agency policy. Notify physician or nurse-midwife if fundus does not remain firm or bleeding continues.	**9.** Documentation provides a means for evaluation. Continued assessment allows for early identification and prompt intervention with additional measures, such as oxytocin, to prevent hemorrhage.

With uterine atony, even if the uterus responds well to massage, the problem may not be completely resolved. After you remove your hand from the fundus, the uterus may relax and the lethal seepage may begin again. Therefore, remain with the woman after massaging her fundus, to be certain the uterus is not relaxing again. Observe carefully, including fundal height and consistency and lochia, for the next 4 hours.

If a uterus cannot remain contracted, her physician or nurse-midwife probably will order a dilute intravenous infusion of oxytocin (Pitocin) to help the uterus maintain tone (see Box 15.10 in Chapter 15). Carboprost tromethamine (Hemabate), a prostaglandin F_{2a} derivative, or methylergonovine maleate (Methergine), an ergot compound, given intramuscularly, are second possibilities. Rectal misoprostol, a prostaglandin E_1 analogue, may be administered rectally. Hemabate may be repeated every 15 to 90 minutes up to 8 doses; methylergonovine may be repeated every 2 to 4 hours up to 5 doses. All these drugs should be readily available for use on a hospital unit in the event of postpartal hemorrhage. Because prostaglandins tend to cause diarrhea as a side effect, assess for this frequently.

The usual dosage of oxytocin is 10 to 40 U per 1000 mL of a Ringer's lactate solution. When oxytocin is given intravenously, its action is immediate. However, be aware that oxytocin has a short duration of action, approximately 1 hour, so symptoms of uterine atony can recur quickly after administration of only a single dose. Methylergonovine causes increased blood pressure so it is contraindicated with a woman with hypertension (generally a blood pressure over 140 mm Hg systolic).

Additional measures that can be helpful:

- Offer a bedpan or assist the woman with ambulating to the bathroom at least every 4 hours to be certain her bladder is empty. A full bladder pushes an uncontracted uterus into an even more uncontracted state. To reduce bladder pressure, insertion of a urinary catheter may be ordered.
- If a woman is experiencing respiratory distress from decreasing blood volume, administer oxygen by face mask at a rate of about 4 L/min. Position her supine to allow adequate blood flow to her brain and kidneys.
- Obtain vital signs frequently and make sure to interpret them accurately, looking for trends. For example, a continuously rising pulse rate is an ominous pattern.

If a woman is losing enough blood to affect her systemic circulation, she will develop signs of shock, such as an increased, thready, and weak pulse; decreased blood pressure; increased and shallow respirations; pale, clammy skin; and increasing anxiety.

In the event of slow bleeding, there is little change in pulse and blood pressure at first because of circulatory compensation. Suddenly, however, the system can compensate no more, and then the pulse rate rises rapidly. The pulse becomes weak and thready, and the blood pressure drops abruptly. The woman's skin becomes cold and clammy, and she shows obvious signs of shock. Consistent frequent assessments of uterine tone and vital signs and laboratory assessments such as hemoglobin and hematocrit levels help to detect blood loss before this point is ever reached.

When planning continuing care after sudden blood loss, understand that a woman may be so exhausted that she resents frequent uterine and blood pressure assessments. Explain that these measures, although disturbing, are important for her welfare. Obtain vital signs as quickly and gently as possible, so that a woman feels a minimum of discomfort and disruption, allowing her time to rest.

Bimanual Massage. If fundal massage and administration of oxytocin or methylergonovine are not effective in stopping uterine bleeding, a sonogram may be done to detect possible retained placental fragments. The woman's physician or nurse-midwife may attempt bimanual compression. With this procedure, the physician or nurse-midwife inserts one hand into a woman's vagina while pushing against the fundus through the abdominal wall with the other hand. The woman may be returned to the delivery or birthing room so that her uterine cavity can be explored manually. Uterine packing may be inserted during this procedure to help halt bleeding. Uterine manipulation is painful; anticipate the need for analgesia or anesthesia to provide comfort. If uterine packing is used, be certain this is documented in a woman's chart so it can be removed before agency discharge. Retained packing serves as a growth medium for microorganism invasion that could lead to a postpartal infection (Begley & Barnes, 2007).

Prostaglandin Administration. Prostaglandins promote strong, sustained uterine contractions. Intramuscular injection of prostaglandin F_{22} is another way to initiate uterine contractions. Observe for nausea, diarrhea, tachycardia, and hypertension, all of which are possible adverse effects of prostaglandin administration (Karch, 2009).

Blood Replacement. Blood transfusion to replace blood loss with postpartal hemorrhage may be necessary. Make certain that blood typing and cross-matching were done when the woman was admitted and that blood is available. Some women donate blood during pregnancy so that they can be autotransfused if hemorrhage should occur postpartally.

The average woman takes the full postpartal period to regain her strength. Women who experience postpartal hemorrhage tend to have a longer than average recovery period, because the physiologic exhaustion of body systems can interfere with their recovery. Iron therapy may be prescribed to ensure good hemoglobin formation. Activity level, exertion, and postpartal exercise may be restricted somewhat. Discuss with a woman the possibility of having someone stay with her at home, at least for the first week, to help with the care of her new baby and to prevent exhaustion from turning childbearing into a less-than-satisfying event.

Extensive blood loss is one of the precursors of postpartal infection because of the general debilitation that results. For any woman who has experienced more than a normal loss of blood, observe for changes in lochia discharge. Also, monitor her temperature closely in the postpartal period, to detect the earliest signs of developing infection. Make certain the patient knows how to check for normal lochia and temperature once she is discharged.

Hysterectomy or Suturing. Usually, therapeutic management is effective in halting bleeding. In the rare instance of extreme uterine atony, sutures or balloon compression may be used to halt bleeding (Nelson & O'Brien, 2007). Embolization of pelvic and uterine vessels by angiographic techniques may be successful. As a last resort, ligation of the uterine arteries or a hysterectomy may be necessary. In this total unexpected outcome of childbearing, provide comfort and support to both a woman and her support person.

After hysterectomy, a woman may want to talk about what happened, why surgery was necessary, or how she feels now that she can no longer bear children. She needs to discuss her feelings with a person who will listen quietly and help her sort through her feelings of "Why me?" She may have ambiguous feelings: she wanted to have more children (or at least have the ability to have more), but she also wants to live. She is thankful that her life was saved, but she may feel resentful that she has been left incapable of future childbearing. She may grieve for children who will not be born. If this child was born outside the hospital and the woman was brought there under emergency circumstances, she may have a need to talk about her choice of location for childbirth. She may feel guilty that she did not choose a more controlled place for childbirth.

Open lines of communication between the couple and health care providers that allow a family to vent its feelings are most helpful to a couple in this crisis. Referral to a grief counselor may be necessary as grieving for future children who will not be born can interfere with bonding with the present child.

Lacerations

Small lacerations or tears of the birth canal are common and may be considered a normal consequence of childbearing. Large lacerations, however, can cause complications. They occur most often:

- With difficult or precipitate births
- In primigravidas
- With the birth of a large infant (>9 lb)
- With the use of a lithotomy position and instruments

Either cervical, vaginal, or perineal lacerations may occur. After birth, any time a uterus feels firm but bleeding persists, suspect a laceration of one of these three sites.

Cervical Lacerations

Lacerations of the cervix are usually found on the sides of the cervix, near the branches of the uterine artery. If the artery is torn, the blood loss may be so great that blood gushes from the vaginal opening. Because this is arterial bleeding, it is brighter red than the venous blood lost with uterine atony. Fortunately, this bleeding ordinarily occurs immediately

after delivery of the placenta, when the physician or nurse-midwife is still in attendance.

Therapeutic Management. Repair of a cervical laceration is difficult, because the bleeding can be so intense that it obstructs visualization of the area. Be certain that a physician or nurse-midwife has adequate space to work, adequate sponges and suture supplies, and a good light source. The woman is not always aware of what is happening at this point, but she senses quickly that something is seriously wrong. Try to maintain an air of calm and, if possible, stand beside the woman, at the head of the table. She may be worried that the extra activity in the room has something to do with her baby. Assure her about her baby's condition and inform her about the need to stay in the birthing room a little longer than expected while the physician or nurse-midwife places additional sutures. Remember that the protective attitude a woman has felt toward her body all during pregnancy is now turned toward her baby, so she usually is relieved to learn that any problem that may be occurring is hers, not her infant's.

If the cervical laceration appears to be extensive or difficult to repair, it may be necessary for the woman to be given a regional anesthetic to relax the uterine muscle and to prevent pain. Explain the need for an anesthetic and the procedures being carried out.

Vaginal Lacerations

Although they are rare, lacerations can also occur in the vagina. They are easier to assess than cervical lacerations, because they are easier to view.

Therapeutic Management. Because vaginal tissue is friable, vaginal lacerations are also hard to repair. Some oozing often occurs after a repair, so the vagina may be packed to maintain pressure on the suture line. An indwelling urinary catheter (Foley catheter) may be placed at the same time, because the packing causes pressure on the urethra and can interfere with voiding. If packing is inserted, document in a woman's nursing care plan when and where it was placed, so you can be certain it will be removed after 24 to 48 hours or before discharge. Packing that is left in place too long leads to stasis and infection similar to toxic shock syndrome, a form of septic shock (Begley & Barnes, 2007).

Perineal Lacerations

Lacerations of the perineum usually occur when a woman is placed in a lithotomy position for birth, because this position increases tension on the perineum. Perineal lacerations are classified by four categories, depending on the extent and depth of the tissue involved. These categories are shown in Table 25.1.

Therapeutic Management. Perineal lacerations are sutured and treated as an episiotomy repair. Make certain that the degree of the laceration is documented, because women with fourth-degree lacerations need extra precautions to avoid having repair sutures loosened or infected. Both lacerations and episiotomy incisions tend to heal in the same length of time. A diet high in fluid and a stool softener may be prescribed for the first week after birth to prevent constipation and hard stools, which could break the sutures.

TABLE 25.1 ✻ Classification of Perineal Lacerations

Classification	Description of Involvement
First degree	Vaginal mucous membrane and skin of the perineum to the fourchette
Second degree	Vagina, perineal skin, fascia, levator ani muscle, and perineal body
Third degree	Entire perineum, extending to reach the external sphincter of the rectum
Fourth degree	Entire perineum, rectal sphincter, and some of the mucous membrane of the rectum

Any woman who has a third- or fourth-degree laceration should not have an enema or a rectal suppository prescribed or have her temperature taken rectally, because the hard tips of equipment could open sutures near to or including those of the rectal sphincter. Be sure that ancillary caregivers such as nurses' aides are informed of this, so that they understand these measures. Although fourth-degree lacerations can lead to long-term dyspareunia, rectal incontinence, or sexual dissatisfaction, they usually heal without further complications.

Retained Placental Fragments

Occasionally, a placenta does not deliver in its entirety; fragments of it separate and are left behind. Because the portion retained keeps the uterus from contracting fully, uterine bleeding occurs. Although this is most likely to happen with a succenturiate placenta—a placenta with an accessory lobe (see Chapter 23)—it can happen in any instance. Placenta accreta—a placenta that fuses with the myometrium because of an abnormal decidua basalis layer—may also be retained. This occurs at an incidence of about 1 in 3000 births (Poggi, 2007). To detect the complication of retained placenta, every placenta should be inspected carefully after birth to see that it is complete. Retained placental fragments may also be detected by ultrasound. A blood serum sample that contains human chorionic gonadotropin hormone (hCG) also reveals that part of a placenta is still present.

Assessment

If an undetected retained fragment is large, bleeding will be apparent in the immediate postpartal period, because the uterus cannot contract with the fragment in place. If the fragment is small, bleeding may not be detected until postpartum day 6 to 10, when the woman notices an abrupt discharge and a large amount of blood. On examination, usually the uterus is not fully contracted.

Therapeutic Management

Removal of the retained placental fragment is necessary to stop the bleeding. Usually, a dilatation and curettage (D&C) is performed to remove the placental fragment. In some

instances, placenta accreta is so deeply attached that it cannot be surgically removed. Balloon occlusion and embolization of the internal iliac arteries may minimize blood loss. Methotrexate may be prescribed to destroy the retained placental tissue (Szymanski & Bienstock, 2007). Because the hemorrhage from retained fragments may be delayed until after a woman is at home, be certain a woman knows to continue to observe the color of lochia discharge and to report any tendency for the discharge to change from lochia serosa or alba back to rubra.

✔ Checkpoint Question 25.1

Suppose Mary Blackhawk has a retained placental fragment that is causing extensive postpartal bleeding. What hormone test would you anticipate being ordered to detect whether placenta is still present?

a. Placental and cord blood estrogen.
b. Progesterone from the placenta.
c. Human chorionic gonadotropin hormone.
d. Systemic prolactin (a pituitary hormone).

Uterine Inversion

Uterine inversion is prolapse of the fundus of the uterus through the cervix so that the uterus turns inside out. This usually occurs immediately after birth so is discussed in Chapter 23.

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) is a deficiency in clotting ability caused by vascular injury. It may occur in any woman in the postpartal period, but it is usually associated with premature separation of the placenta, a missed early miscarriage, or fetal death in utero. DIC is discussed in Chapter 21 along with these disorders.

Subinvolution

Subinvolution is incomplete return of the uterus to its prepregnant size and shape. With subinvolution, at a 4- or 6-week postpartal visit, the uterus is still enlarged and soft. Lochial discharge usually is still present. Subinvolution may result from a small retained placental fragment, a mild **endometritis** (infection of the endometrium), or an accompanying problem such as a uterine myoma that is interfering with complete contraction.

Therapeutic Management

Oral administration of methylergonovine, 0.2 mg four times daily, usually is prescribed to improve uterine tone and complete involution. If the uterus is tender to palpation, suggesting endometritis, an oral antibiotic also will be prescribed. Being certain that women are able to recognize the normal process of involution and lochial discharge before hospital discharge helps women to be able to identify subinvolution and seek early health care if it occurs. A chronic loss of blood from subinvolution will result in infection or anemia and lack of energy, conditions that possibly could interfere with infant bonding.

Perineal Hematomas

A perineal hematoma is a collection of blood in the subcutaneous layer of tissue of the perineum. The overlying skin, as a rule, is intact with no noticeable trauma. Such blood collections can be caused by injury to blood vessels in the perineum during birth. They are most likely to occur after rapid, spontaneous births and in women who have perineal varicosities. They may occur at the site of an episiotomy or laceration repair if a vein was punctured during repair. Although they can cause a woman acute discomfort and concern, they usually represent only minor bleeding.

Assessment

Perineal sutures almost always give a postpartal woman some discomfort. If a woman reports severe pain in the perineal area or a feeling of pressure between her legs, inspect the perineal area for a hematoma. If one is present, it appears as an area of purplish discoloration with obvious swelling. It may be as small as 2 cm or as large as 8 cm in diameter (Fig. 25.2). The area is tender to palpation. At first it may feel fluctuant, but as seepage into the area continues and tissue is drawn taut, it palpates as a firm globe.

Therapeutic Management

Report the presence of a hematoma, its size, and the degree of the woman's discomfort to her primary care provider. Assess the size by measuring it in centimeters with each inspection. Describing a hematoma as "large" or "small" gives little information about the actual size. Describing a lesion as 5 cm across or the size of a quarter or a half dollar is more meaningful because it establishes a basis for comparison.

Administer a mild analgesic as ordered for pain relief. Applying an ice pack (covered with a towel to prevent thermal injury to the skin) may prevent further bleeding. Usually the hematoma is absorbed over the next 3 or 4 days. If the hematoma is large when discovered or continues to increase in size, the woman may have to be returned to the delivery or birthing room to have the site incised and the bleeding vessel ligated under local anesthesia.

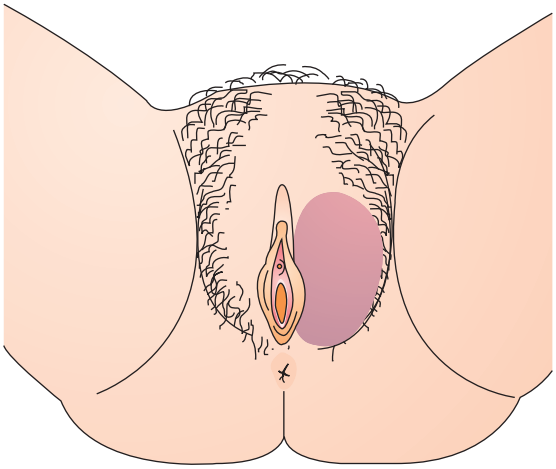


FIGURE 25.2 Appearance of a perineal hematoma from a bleeding subcutaneous vessel.

You can reassure a woman that, even though the hematoma is causing her considerable discomfort, her hospital stay probably will not be lengthened by its occurrence (unless it is extremely extensive). In most women, hematomas absorb over the next 6 weeks, causing no further difficulty. If an episiotomy incision line is opened to drain a hematoma, it may be left open and packed with gauze rather than resutured. Packing is usually removed within 24 to 48 hours. Be certain to record that this packing was placed, so it can be removed before discharge or when the woman returns to an ambulatory setting. A suture line opened in this way heals by tertiary intention, more slowly than a first-degree intention suture line. Be certain the woman has clear instructions before discharge regarding necessary suture line care that she needs to do at home such as keeping it clean and dry and perhaps using a sitz bath once or twice a day.

PUERPERAL INFECTION

Infection of the reproductive tract is another leading cause of maternal mortality (Pavone, Purinton, & Petersen, 2007). Factors that predispose women to infection in the postpartal period are shown in Box 25.5. When caring for a woman who has any of these circumstances, be aware that the risk for postpartal infection is greatly increased.

Theoretically, the uterus is sterile during pregnancy and until the membranes rupture. After rupture, pathogens can invade. The risk of infection is even greater if tissue edema and trauma are present. If infection occurs, the prognosis for complete recovery depends on:

- Virulence of the invading organism
- The woman's general health
- Portal of entry
- Degree of uterine involution at the time of the microorganism invasion
- Presence of lacerations in the reproductive tract

A puerperal infection is always potentially serious, because, although it usually begins as only a local infection, it can spread to involve the peritoneum (peritonitis) or the circulatory system (septicemia). These conditions can be fatal in a woman whose body is already stressed from childbirth.

Management for puerperal infection focuses on the use of an appropriate antibiotic after culture and sensitivity testing of the isolated organism. Organisms commonly cultured postpartally include group B streptococci and aerobic gram-negative bacilli such as *Escherichia coli.* Staphylococcal infections also are becoming more common. Staphylococcal infections are the cause of toxic shock syndrome, an infection similar to puerperal infection in its ability to cause death and morbidity (see Chapter 47).

BOX 25.5 ✻ Conditions That Increase a Woman's Risk for Postpartal Infection

1. Rupture of the membranes more than 24 hours before birth (bacteria may have started to invade the uterus while the fetus was still in utero)
2. Placental fragments retained within the uterus (the tissue necroses and serves as an excellent bed for bacterial growth)
3. Postpartal hemorrhage (the woman's general condition is weakened)
4. Pre-existing anemia (the body's defense against infection is lowered)
5. Prolonged and difficult labor, particularly instrument births (trauma to the tissue may leave lacerations or fissures for easy portals of entry for infection)
6. Internal fetal heart monitoring (contamination may have been introduced with placement of the scalp electrode)
7. Local vaginal infection was present at the time of birth (direct spread of infection has occurred)
8. The uterus was explored after birth for a retained placenta or abnormal bleeding site (infection was introduced with exploration)

Nursing Diagnoses and Related Interventions ✻

Nursing Diagnosis: Risk for infection related to loss of uterine sterility with childbirth

Outcome Evaluation: Client's temperature remains below 100.4° F or 38° C orally, excluding the first 24 hours after birth; lochia is present without foul odor.

To help prevent infection, any articles such as gloves or instruments that are introduced into the birth canal during labor, birth, and the postpartal period should be sterile. In addition, adherence to standard infection precautions is essential.

Instruct a postpartal woman in proper perineal care, including wiping from front to back so that she does not bring *E. coli* organisms forward from the rectum. Use good handwashing technique before, during, and after any client care, to prevent cross-contamination. When giving perineal care, both wash your hands and wear gloves. Each postpartal woman should have her own bedpan and perineal supplies and should not share them, to prevent transfer of pathogens from one woman to another.

Intravenous antibiotics usually are prescribed for a postpartal infection. Frequently used antibiotics include ampicillin, gentamicin, and third-generation cephalosporins such as cefixime (Suprax). If the woman will be continuing drug therapy at home, stress that she must take the full course to prevent the infection from recurring. Be certain that women who are breastfeeding are not prescribed antibiotics incompatible with breastfeeding. Alert them to observe for problems in their infant, such as white plaques or thrush (oral *Candida*) in their infant's mouth. This occurs because a portion of the maternal antibiotic passes into breast milk and can cause an overgrowth of fungal organisms (opportunistic infection) in the infant. The infant also should be assessed for easy bruising. A decrease of microorganisms in the bowel caused by an antibiotic passed in breast milk may lead to insufficient

vitamin K formation and, consequently, decreased blood-clotting ability.

Nursing Diagnosis: Social isolation related to precautions necessary to protect baby and others from exposure to infectious microorganisms

Outcome Evaluation: Client describes agency policy regarding precautions and states plans for diversional activities to pass time; demonstrates bonding behaviors, such as asking about newborn and expressing desire to see infant.

Most hospitals have well-defined guidelines on whether a woman who has an infection should be separated from other women or allowed to feed and care for her baby (Box 25.6). It is difficult for many women to accomplish their new role change even when things are going well. If a woman is segregated from others, frightened by her condition, and denied the pleasure of holding and feeding her baby, her situation may seem overwhelming. Women who are isolated this way need friendly, understanding support from hospital personnel who give them care. Fortunately, because modern antibiotics work quickly to reduce the possibility of contagion, the required period of separation may be as short as 24 hours. Encourage women who are breastfeeding to pump their breasts to maintain their milk supply during this time.

Often, the choice to breastfeed is culturally influenced. If a postpartal complication interferes with breastfeeding, a woman who feels that breastfeeding is very important can be expected to react less favorably than a woman from a culture in which formula feeding is preferred.

Endometritis

Endometritis is an infection of the endometrium, the lining of the uterus. Bacteria gain access to the uterus through the vagina and enter the uterus either at the time of birth or during the postpartal period. This may occur with any birth, but the infection is usually associated with chorioamnionitis and cesarean birth (Szymanski & Bienstock, 2007).

Assessment

A benign temperature elevation may occur on the first postpartal day, particularly if a woman is not drinking enough fluid. The fever of endometritis usually manifests on the third

BOX 25.6 ❇ Common Guidelines for the Woman With a Postpartal Infection

1. As a rule, the baby of a mother with an increased temperature (100.4° F [38° C]) for two consecutive 24-hour periods exclusive of the first 24 hours is kept in an isolation nursery until the cause of the infection is determined. The mother may have an upper respiratory tract or gastrointestinal infection that is unrelated to childbearing but transmittable to a newborn.
2. If the cause of the fever is found to be related to childbirth but involves a closed infection, such as thrombophlebitis, with no danger of the baby contracting the disease, the woman may care for her child as long as she maintains bed rest in the prescribed position while doing so.
3. If the infection involves drainage such as can occur with endometritis or a perineal abscess, newborn visiting may be contraindicated. If rooming-in is continued, the mother should wash her hands thoroughly before holding her infant. She should never place her baby on the bottom bed sheet, where there may be some infected drainage from her perineal pad (furnish a clean sheet to spread over the covers).
4. Most hospitals are reluctant to return a baby to a central nursery after a baby has visited in a room where there is an infection. The hospital should provide a small nursery that may be used as an isolation nursery for these situations, or the baby can be placed in a closed Isolette in a central nursery or continue to be cared for in the woman's room.
5. If the woman has a high fever, breast milk may be deficient. With modern antimicrobial therapy, puerperal infections are limited, and the period of high fever usually is transient. If the mother is too ill to nurse her baby during this time or if she is receiving an anticoagulant or antibiotic that is passed in breast milk and would be harmful to the baby, the infant should be fed by a supplementary milk formula. The woman's breast milk can be manually expressed or pumped to maintain the production of milk so it will be available when she is again able to nurse. You may need to assist her with this, because she fatigues easily and her energy level may not be enough to support her good intentions. If it appears that the course of the infection will be long, a woman may choose to discontinue breastfeeding.
6. If it is necessary for a woman to discontinue breastfeeding, she needs to be assured that she can meet the needs of the child through bottle feeding.
7. If a woman is going to be hospitalized beyond the usual time, she may have to make arrangements for the discharge and care of her baby. She may be interested in a homemaker service or temporary foster care if she has no close friends or family. If she has older children at home, she needs to keep in close contact with them, calling them on the telephone or writing them short notes if possible. If the infant is housed in a high-risk nursery, she needs to see a photograph of the newborn (a Polaroid or digital camera should be a piece of equipment on every postpartal unit) and hear daily reports of his or her progress and well-being.

or fourth postpartal day, suggesting that much of the invasion occurred during labor or birth (consistent with the time it takes for infectious organisms to grow).

Normally, the white blood cell count of a postpartal woman is increased to 20,000 to 30,000 cells/mm^3. Because of this increase, the conventional method of detecting infection (elevated white blood cell count) is not of great value in the puerperium. An increase in oral temperature to more than 100.4° F (38° C) for two consecutive 24-hour periods, excluding the first 24-hour period after birth, is defined by the Joint Committee on Maternal Welfare as a febrile condition suggesting infection (Crombleholme, 2009). Infection should be suspected in all postpartal women with temperatures in this range, until proved otherwise. Because many women are at home when this elevated temperature occurs, any woman who feels as if she has an increased temperature should measure her temperature to be certain.

A rise in temperature that occurs on the third or fourth day postpartum occurs at the same time during which breast filling occurs. Do not be led astray by attributing an elevated temperature at this time to breast filling. Suspect fever on the third or fourth day postpartum as possible endometritis until proved otherwise.

Depending on the severity of the infection, a woman may have accompanying chills, loss of appetite, and general malaise. Her uterus usually is not well contracted and is painful to the touch. She may feel strong afterpains. Lochia usually is dark brown and has a foul odor. It may be increased in amount because of poor uterine involution, but if the infection is accompanied by high fever, lochia may be scant or absent. Ultrasound may be ordered to confirm the presence of placental fragments that are a possible cause of the infection.

Therapeutic Management

Treatment of endometritis consists of the administration of an appropriate antibiotic, such as clindamycin (Cleocin), as determined by a culture of the lochia. Be sure to obtain the culture from the vagina, using a sterile swab, rather than from a perineal pad, to ensure that you are culturing the endometrial infectious organism and not an unrelated one from the pad. An oxytocic agent such as methylergonovine, may be prescribed to encourage uterine contraction. The woman requires additional fluid to combat the fever. If strong afterpains and abdominal discomfort are present, she needs an analgesic for pain relief.

Sitting in a Fowler's position or walking encourages lochia drainage by gravity and helps prevent pooling of infected secretions. Because this drainage is contaminated, be certain to wear gloves when helping a woman change her perineal pads. In addition, both you and the woman must use good handwashing techniques before and after handling these pads.

As with any infection, endometritis can be controlled best if it is discovered early. If you can interpret the normal color, quantity, and odor of lochia discharge and the size, consistency, and tenderness of a normal postpartal uterus, you may be the first person to recognize that infection is present. Because a woman may be at home when signs of infection occur, teaching about the signs and symptoms of endometritis is essential. In addition, follow-up by a home care nurse can help with early detection.

If the infection is limited to the endometrium, the course of infection is about 7 to 10 days. If this occurs while a woman is hospitalized, she may have to make arrangements for her baby's discharge before her own, or for help with newborn care, if her hospital stay is extended for a few days. Or, she may be discharged home on intravenous antibiotic therapy with follow-up by a home care nurse.

An added danger of endometritis is that it can lead to tubal scarring and interference with future fertility. At a future time, if the woman desires more children, she may need a fertility assessment (including a hysterosalpingogram) to determine tubal patency. With mild endometritis this is usually not a problem, but a woman should be forewarned that it could occur.

What if... Mary Blackhawk tells you she has developed chills and a fever of 101.5° F (41.6° C) on her second postpartal day? Her lochia is dark brown and foul smelling. On palpation, you notice her abdomen is very tender. What should you do next?

Infection of the Perineum

If a woman has a suture line on her perineum from an episiotomy or a laceration repair, a portal of entry exists for bacterial invasion.

Assessment

Infections of the perineum usually remain localized. They are revealed by symptoms similar to those of any suture-line infection, such as pain, heat, and a feeling of pressure. The woman may or may not have an elevated temperature, depending on the systemic effect and spread of the infection.

Inspection of the suture line reveals the inflammation. One or two stitches may be sloughed away, or an area of the suture line may be open with purulent drainage present (Fig. 25.3). Notify the woman's physician or nurse-midwife of the localized symptoms, and culture the discharge using a sterile cotton-tipped applicator touched to the secretions.

Therapeutic Management

A woman's physician or nurse-midwife may choose to remove perineal sutures, to open the area and allow for drainage. Packing, such as iodoform gauze, may be placed in the open lesion to keep it open and allow drainage. Be sure the woman is aware that the packing is in place, so she knows not to dislodge it as she changes her perineal pad.

Typically, a systemic or topical antibiotic is ordered even before the culture report is returned. An analgesic may be prescribed to alleviate discomfort. Sitz baths, moist warm compresses, or Hubbard tank treatments may be ordered to hasten drainage and cleanse the area. Remind the woman to change perineal pads frequently, because they are contaminated by drainage. If they are left in place too long, they might cause vaginal contamination or reinfection. Be certain a woman wipes front to back after a bowel movement, to prevent bringing feces forward onto the healing area.

With a local infection of this nature, a woman is usually discharged with a referral for home care follow-up, because

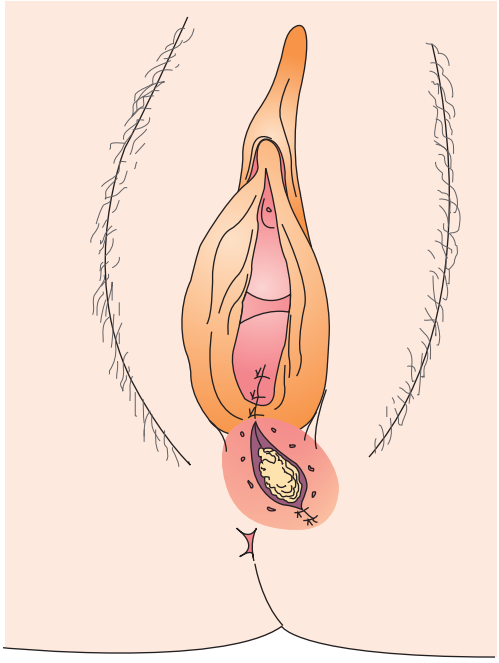

FIGURE 25.3 An infected suture line appears reddened and edematous and often contains infected secretions.

the incision site, once opened, must heal by tertiary rather than primary intention. Infections of this nature are annoying and painful, but fortunately, with improved techniques during parturition and the puerperium, perineal infections occur only rarely. Because they are localized, there is no need to restrict the woman from caring for her infant, as long as she washes her hands well before holding her newborn. Be certain not to place the infant on the bottom bed sheet of the woman's bed, where the baby could contact pathogenic bacteria. Encourage the woman to ambulate and ask for analgesia as needed. Often the pain from an infected suture line is severe, and the woman may decrease ambulation unless she is urged to continue.

Peritonitis

Peritonitis, or infection of the peritoneal cavity, usually occurs as an extension of endometritis. It is one of the gravest complications of childbearing and is a major cause of death from puerperal infection. The infection spreads through the lymphatic system or directly through the fallopian tubes or uterine wall to the peritoneal cavity. An abscess may form in the cul-de-sac of Douglas, because this is the lowest point of the peritoneal cavity and gravity causes infected material to localize there.

Assessment

Symptoms are the same as those of a surgical patient in whom a peritoneal infection develops: rigid abdomen, abdominal pain, high fever, rapid pulse, vomiting, and the appearance of being acutely ill. When assessing the abdomen of a postpartal woman, be sure to note not only that her uterus is well contracted but also that the remainder of her abdomen is soft. The occurrence of a rigid abdomen (guarding) is one of the first symptoms of peritonitis.

Therapeutic Management

Peritonitis is often accompanied by paralytic ileus (blockage of inflamed intestines). This requires insertion of a nasogastric tube to prevent vomiting and rest the bowel. Intravenous fluid or total parenteral nutrition may be necessary. A woman will need analgesics for pain relief. She will be administered large doses of antibiotics to treat the infection. Her hospital stay will be extended, but with effective antibiotic therapy, the outcome usually is good. Peritonitis can interfere with future fertility, because it leaves scarring and adhesions in the peritoneum. Adhesions formed this way may separate the fallopian tubes from the ovaries to the extent that ova can no longer easily enter the tubes.

✔ Checkpoint Question 25.2

Mary Blackhawk develops endometritis. What would be the best activity for her?

a. Lying in bed with a cold cloth on her forehead.
b. Walking around her room listening to music.
c. Reading while resting in a Trendelenburg position.
d. Sitting with her feet elevated while playing cards.

THROMBOPHLEBITIS

Phlebitis is inflammation of the lining of a blood vessel. **Thrombophlebitis** is inflammation with the formation of blood clots. When thrombophlebitis occurs in the postpartal period, it is usually an extension of an endometrial infection. It tends to occur because:

- A woman's fibrinogen level is still elevated from pregnancy, leading to increased blood clotting.
- Dilatation of lower extremity veins is still present as a result of pressure of the fetal head during pregnancy and birth.
- The relative inactivity of the period or a prolonged time spent in delivery or birthing room stirrups leads to pooling, stasis, and clotting of blood in the lower extremities.
- Obesity from increased weight before pregnany and pregnancy weight gain can lead to relative inactivity and lack of exercise.
- The woman smokes cigarettes.

Thrombophlebitis is classified as superficial vein disease (SVD) or deep vein thrombosis (DVT). Women most prone to thrombophlebitis are those who are obese, have varicose veins, have had a previous thrombophlebitis, are older than 35 years of age with increased parity, or have a high incidence of thrombophlebitis in their family (Gates, Brocklehurst, & Davis, 2009).

Prevention of endometritis by the use of good aseptic technique during birth helps to prevent thrombophlebitis. Ambulation and limiting the time a woman remains in obstetric stirrups encourages circulation in the lower extremities, promotes venous return, and decreases the possibility of clot formation, also helping to prevent thrombophlebitis. If stirrups of examining or delivery tables are used, be certain

they are well padded, to prevent any sharp pressure against the calves of the legs. If a woman had varicose veins during pregnancy, wearing support stockings for the first 2 weeks after birth can help increase venous circulation and prevent stasis. If these are prescribed, be certain a woman knows to put them on before she rises in the morning. If she waits until she is already up and walking, venous congestion has already occurred and the stockings are less effective. Urge her to remove the support stockings twice daily and assess her skin underneath for mottling or inflammation that would suggest inflammation of her veins. Beginning such activities as walking can also be important. An exercise program will also be important in helping women lose their pregnancy weight (Keller et al., 2008). Additional measures for preventing thrombophlebitis are summarized in Box 25.7.

Femoral Thrombophlebitis

With femoral thrombophlebitis, the femoral, saphenous, or popliteal veins are involved. Although the inflammation site in thrombophlebitis is a vein, an accompanying arterial spasm often occurs, diminishing arterial circulation to a leg as well. This decreased circulation, along with edema, gives the leg a white or drained appearance. It was formerly believed that breast milk drained into the leg, giving it its white appearance. The condition was, therefore, formerly called *milk leg* or *phlegmasia alba dolens* ("white inflammation").

BOX 25.7 ❊ Focus on Family Teaching

Preventing Thrombophlebitis

Q. Mary Blackhawk tells you, "My sister got thrombophlebitis after the birth of her first baby. How can I prevent that from happening to me?"

A. Here are a few helpful hints for preventing thrombophlebitis:

- Ask your primary care provider if you can use a side-lying or back-lying (supine recumbent) position for birth, rather than a lithotomy position (lithotomy position can increase the tendency for pooling of blood in the lower extremities).
- If you will be using a lithotomy position, ask for padding on the stirrups to prevent calf pressure.
- Drink adequate fluids to be certain you're not dehydrated (6–8 glasses of fluid/day).
- Do not sit with your knees bent sharply, and avoid wearing constricting clothing such as knee-high stockings.
- Ambulate as soon after birth as you are able. Early ambulation is the best preventive measure. When resting in bed, wiggle your toes or do leg lifts to improve venous return.
- Ask your primary care provider if he or she recommends support stockings in the immediate postpartal period. Be certain to put these on before ambulating in the morning, before leg veins fill.
- Quit smoking as this is associated with the development of thrombophlebitis.

Assessment

If femoral thrombophlebitis develops, a woman notices an elevated temperature, chills, pain, and redness in the affected leg about 10 days after birth. Her leg begins to swell below the lesion at the point at which venous circulation is blocked. Her skin becomes so stretched from swelling that it appears shiny and white. Homans' sign (pain in the calf of the leg on dorsiflexion of the foot) may be positive; however, a negative Homans' sign does not rule out obstruction. The diameter of the leg at thigh or calf level may be increased compared with the other leg. Doppler ultrasound or contrast venography usually is ordered to confirm the diagnosis.

Therapeutic Management

Treatment consists of bed rest with the affected leg elevated, administration of anticoagulants, and application of moist heat. Women who have been discharged from the hospital may be cared for at home or may return to the hospital so that strict bed rest can be enforced. A bed cradle keeps pressure of the bedclothes off the affected leg, both to decrease the sensitivity of the leg and to improve circulation. Provide good back, buttocks, and heel care. Check for bed wrinkles so that a woman does not develop the secondary problem of a pressure ulcer while on bed rest.

Never massage the skin over the clot; this could loosen the clot, causing a pulmonary or cerebral embolism. Heat supplied by a moist, warm compress can help decrease inflammation. Although simple in theory, unfortunately, this is one of the most technically difficult treatments to carry out, because dressings invariably dry or become cold after only a short time. Compresses and water used in this way do not have to be sterile because, with thrombophlebitis, there is no break in the skin. Be certain to test water temperature by dipping your inner wrist in it before soaking a dressing, to be sure it is not too warm (because edema decreases sensation in a woman's leg, she can burn easily). Always cover wet, warm dressings with a plastic pad to hold in heat and moisture. In addition, a commercial pad with circulating heating coils or chemical hot packs may be positioned over the plastic to ensure that soaks stay warm. Be certain the weight of a hot pack or pad does not rest on the leg, causing an obstruction to flow of blood.

Check a woman's bed frequently when moist compresses are used, to be certain the mattress does not become wet from seeping water. For soaks to stay in place, a woman must keep her leg fairly immobile. However, be certain she does not interpret this as meaning that she cannot turn or move about. Provide her with appropriate activities to exercise the other parts of her body and stimulate her mind. One way of helping a woman use her time on bed rest is to offer reading material about newborns. This activity helps her maintain bed rest and also educates her about infant care.

The pain of thrombophlebitis is usually severe enough to require administration of an analgesic. An appropriate antibiotic to reduce the initial infection is prescribed. Often, an anticoagulant (coumarin derivative or heparin) or a thrombolytic agent such as streptokinase or urokinase is prescribed to dissolve the clot through the activation of fibrinolytic precursors and prevent further clot formation. Blood coagulation levels to determine the effectiveness of the drug therapy are measured daily before administration of the

anticoagulant. Depending on the drug prescribed, a baseline activated partial thromboplastin time (aPTT) or prothrombin time (PT) is obtained.

Heparin, an anticoagulant, can be administered by continuous intravenous infusion or intermittently by intravenous or subcutaneous injection (Box 25.8). If a woman will be discharged on subcutaneous therapy, be certain she has demonstrated good injection technique before discharge and understands the importance of required blood work (coagulation studies) so that she schedules these appropriately. Protamine sulfate, the antagonist for heparin, should be readily available any time heparin is administered.

A woman can continue to breastfeed while receiving heparin. If she does not wish to breastfeed, she can be switched to warfarin (an oral coumarin derivative) before hospital discharge. The antidote to warfarin is vitamin K. A woman has to discontinue breastfeeding during therapy with coumarin, because coumarin-derived anticoagulants are passed in breast milk. If the thrombophlebitis does not seem to be severe and the woman wants to restart breastfeeding after the course of anticoagulant (about 10 days), encourage her to manually express breast milk at the time of normal feedings, to maintain a good milk supply.

Lochia usually increases in amount in a woman who is receiving an anticoagulant. Be sure to keep a meaningful record of the amount of this discharge so that it can be estimated. "Lochia serosa with scattered pinpoint clots; three perineal pads saturated in 8 hours" is far more meaningful than "large amount of lochia." Also assess for other possible signs of bleeding, such as bleeding gums, ecchymotic spots on the skin, or oozing from an episiotomy suture line.

Women taking anticoagulants are not normally prescribed salicylic acid (aspirin) for pain, because salicylic acid prevents blood clotting by preventing platelet aggregation and clot formation. However, some women may be prescribed aspirin every 4 hours as a preventive measure if they are at high risk for recurrent thrombophlebitis. If this is so, be certain you do not interpret aspirin used this way as a PRN analgesic order and withhold it depending on the woman's level of pain.

With proper treatment, the acute symptoms of femoral thrombophlebitis last only a few days, but the full course of the disease takes 4 to 6 weeks before it is resolved. Anticoagulant therapy may need to be continued for 3 to 6 months. The affected leg may never return to its former size and may always cause discomfort after long periods of standing.

BOX 25.8 * Focus on Pharmacology

Heparin Calcium Injection (Hepalean, Liquamin Sodium) or Dalteparin (low-molecular-weight heparin)

Classification: Heparin is an anticoagulant.

Action: Heparin blocks the conversion of prothrombin to thrombin and of fibrinogen to fibrin, decreasing clotting ability and resulting in the inhibition of thrombus and clot formation. It is used to prevent and treat thrombosis and pulmonary embolism (Karch, 2009).

Pregnancy risk category: B

Dosage: Dosage is dependent on coagulation studies. Dosage is considered therapeutic when the activated partial thromboplastin time (aPTT) is 1.5 to 3 times the control value. The drug can be given by continuous intravenous (IV) infusion or by intermittent direct IV or subcutaneous injection.

Possible adverse effects: Hemorrhage, bruising, thrombocytopenia, urticaria

Nursing Implications

- Obtain baseline coagulation studies as ordered.
- Continue to monitor aPTT results and adjust dosage as ordered. Obtain aPTT results 30 minutes before intermittent dosage administration or every 4 hours for continuous IV infusion.
- Anticipate use of an intermittent infusion device to minimize the number of intravenous injections.
- Avoid any intramuscular injection of other medications, because a hematoma may form at injection site.
- When administering an IV infusion, do not add heparin to existing IV solutions or piggyback other drugs into a heparin infusion. Use an infusion pump.
- When administering heparin subcutaneously, inject deeply, and rotate injection sites. Do not aspirate for blood return or massage the injection site afterward. Apply direct pressure to the injection site after administration. Inspect the injection site for signs of hematoma formation.
- Assess a woman for signs and symptoms of bleeding, such as oozing from the gums, nosebleeds, hematuria, or frank or occult blood in stool.
- Closely monitor client's lochia, including amount and color. Assess pad count to determine extent of vaginal bleeding.
- Keep protamine sulfate, the antidote, readily available in case of overdose.
- Instruct a woman about antibleeding precautions such as using a soft toothbrush to minimize the risk of bleeding.

Pelvic Thrombophlebitis

Pelvic thrombophlebitis involves the ovarian, uterine, or hypogastric veins. It usually follows a mild endometritis and occurs later than femoral thrombophlebitis, often around the 14th or 15th day of the puerperium.. Risk factors are the same as for femoral thrombophlebitis.

Assessment

With pelvic thrombophlebitis, a woman suddenly becomes extremely ill, with high fever, chills, and general malaise. Her infection can be so severe it necroses the vein and results in a pelvic abscess. It can become systemic and result in a lung, kidney, or heart valve abscess.

Therapeutic Management

As with femoral thrombophlebitis, therapy involves total bed rest and administration of antibiotics and anticoagulants.

The disease runs a long course of 6 to 8 weeks. If an abscess forms, it can be located by sonogram and incised by laparotomy, if necessary. Formation of an abscess is associated

with a high mortality rate. An inflammation of this extent may leave tubal scarring and interfere with future fertility. A woman may need surgery to remove the affected vessel before she attempts to become pregnant again.

Regardless of the type of thrombophlebitis, teach women preventive measures to reduce the risk of recurrence with future pregnancies. These measures include not wearing constricting clothing such as garters or tight stockings on the lower extremities, resting with the feet elevated, and ambulating daily during pregnancy. Caution a woman to tell her physician or nurse-midwife before her next pregnancy of the difficulty she experienced this time, so that extra prophylactic precautions can be taken to prevent thrombophlebitis.

Pulmonary Embolus

A pulmonary embolus is obstruction of the pulmonary artery by a blood clot; it usually occurs as a complication of thrombophlebitis. The signs of pulmonary embolus are sudden, sharp chest pain; tachypnea; tachycardia; orthopnea (inability to breathe except in an upright position); and cyanosis (the blood clot is obstructing the pulmonary artery, blocking blood flow to the lungs and return to the heart). It is an emergency. A woman needs oxygen administered immediately and is at high risk for cardiopulmonary arrest. Her condition is extremely guarded until the clot is lysed or adheres to the pulmonary artery wall and is reabsorbed. Because of the seriousness of this condition, a woman with a pulmonary embolism commonly is transferred to an intensive care unit for continuing care (Cansino & Lipsett, 2007).

MASTITIS

Mastitis (infection of the breast) may occur as early as the seventh postpartal day or not until the baby is weeks or months old (Reddy et al., 2007).

The organism causing the infection usually enters through cracked and fissured nipples. Therefore, measures that prevent cracked and fissured nipples also help prevent mastitis. These measures include:

- Making certain the baby is positioned correctly and grasps the nipple properly, including both nipple and areola
- Releasing a baby's grasp on the nipple before removing the baby from the breast
- Washing hands between handling perineal pads and touching the breasts
- Exposing nipples to air for at least part of every day
- Using a vitamin E ointment to soften nipples daily
- If a woman has one cracked and one well nipple, encourage her to begin breastfeeding (when the infant sucks most forcefully) on the unaffected nipple.

Occasionally, the organism that causes mastitis comes from the nasal–oral cavity of the infant. In these instances, the infant has usually acquired a *Staphylococcus aureus* infection while in the hospital. Candidiasis can also be spread this way. By sucking on a nipple, the infant introduces the organisms into the milk ducts, where they proliferate (breast milk is an excellent medium for bacterial growth). This is an epidemic breast abscess. When it occurs, it is usually discovered that several women discharged from the hospital at the same time have similar infections.

Assessment

Mastitis is usually unilateral, although epidemic mastitis, because it originates with the infant, may be bilateral. The affected breast is painful, swollen, and reddened. Fever accompanies these first symptoms within hours, and breast milk becomes scant.

Therapeutic Management

Treatment consists of antibiotics effective against penicillin-resistant staphylococci such as dicloxacillin or a cephalosporin (Crombleholme, 2009). Breastfeeding is continued, because keeping the breast emptied of milk helps to prevent growth of bacteria. Some women find an infected breast too painful to allow their infant to suck and prefer to express milk manually from the affected breast until their antibiotic has taken effect and the mastitis has diminished (about 3 days). Cold or ice compresses and a good supportive bra help with pain relief until the process improves. Warm, wet compresses may be ordered to reduce inflammation and edema.

If therapy is started as soon as symptoms are apparent, the condition runs a short course of about 2 or 3 days. If left untreated, a breast infection can become a localized abscess. This may involve a large portion of the breast and rupture through the skin, with thick, purulent drainage, necessitating incision and drainage of the abscess. If an abscess forms, breastfeeding on that breast is discontinued. However, a woman is encouraged to continue to pump breast milk until the abscess has resolved, to preserve breastfeeding. Some women find that the infected breast is too tender to do this. They can be reassured that formula feeding will be an acceptable alternative for their child.

Neither mastitis nor breast abscess leaves any permanent breast disease. A woman can be assured that such an incident is not associated with development of breast cancer and does not interfere with future breastfeeding potential (see Focus on Nursing Care Planning Box 25.9).

URINARY SYSTEM DISORDERS

Because a woman's bladder is compressed by the infant's head during birth, several urinary tract disorders can occur.

Urinary Retention

Urinary retention occurs as a result of inadequate bladder emptying. After childbirth, bladder sensation for voiding is decreased because of bladder edema caused by the pressure of birth. Unable to empty, the bladder fills to overdistention. When the woman does void, instead of emptying completely, the bladder empties only a small portion of its contents (retention with overflow). As a result, it becomes overdistended again. Bladder overdistention is potentially serious. If it is allowed to continue, permanent damage may occur from loss of bladder tone, leading to permanent incontinence (Chelmow, Aronson, & Wosu, 2007).

Assessment

Urinary retention is associated with the use of anesthesia, especially epidural anesthesia (Musselwhite et al., 2007). In a postpartal woman, urinary retention with overflow

BOX 25.9 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Woman With Mastitis

Mary Blackhawk calls your clinic 3 weeks after childbirth because she has a fever and swelling and pain in her right breast. She comes to the clinic for an evaluation.

Family Assessment ✻ Client lives in three-bedroom apartment with boyfriend. Worked as a card dealer in casino before birth; has not returned to work. Describes finances as "good—I'm on maternity leave." Boyfriend is a short-order cook but is currently unemployed. Wants her to stop breastfeeding because of her infection.

Client Assessment ✻ A 30-year-old primipara woman who gave birth vaginally 3 weeks ago and is breastfeeding. Temperature 101.1° F (38.4° C). Other vital signs within acceptable parameters. Right breast reddened and edematous, tender and warm to touch. Slight fissure noted on right nipple. States, "I hurt too much to breastfeed any longer. How can I be a good mother if I don't breastfeed my baby?"

Nursing Diagnosis ✻ Pain related to development of mastitis

Outcome Criteria ✻ Client states that pain is decreasing with treatment; demonstrates measures to promote comfort. Breast swelling, redness, fever, and tenderness decrease.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Physician/ nurse	Assess whether client could continue breastfeeding with additional support.	Encourage client to continue breastfeeding on left breast to keep breast empty of milk. Pump right breast if too tender for nursing.	Milk provides a good medium for bacterial growth. Complete emptying of breasts prevents stasis of milk and engorgement and aids in reducing the risk of further infection and pain.	Client states she will try to continue breastfeeding even though infection is present.
		Consultations		
Nurse	Assess whether client has a support person she uses for breastfeeding advice or would like one.	Suggest client contact local La Leche League chapter hot line for consultation and support.	Support from experts in the technique of breastfeeding can offer helpful tips to ensure success.	Client states she will contact a support service for additional information within 2 days.
		Procedures/Medications		
Nurse/ physician	Assess what actions client feels will help relieve her pain best.	Apply warm compresses to right breast at visit. Instruct in ways to apply warm moist heat, such as with a shower or warm packs, at home.	Moist heat promotes comfort and increases circulation to the area, decreasing inflammation and edema.	Client states she understands purpose and techniques of warm moist heat.
Nurse	Review good breastfeeding strategies with client.	Encourage client to nurse every 2–3 hr, to wear a support bra, and to start each infant feeding on the unaffected breast.	Beginning a feeding on the unaffected breast reduces discomfort, because infant will not suck as hard on affected breast. Breast care promotes integrity of breasts, reducing risk of cracked or fissured nipples and future mastitis.	Client states she will try suggested techniques.

		Procedures/Medications		
Nurse	Assess whether client has health insurance and can afford antibiotic prescribed.	Review necessity of taking antibiotic for full 7-day course.	The antibiotic must be taken for a full course or the infective organisms could regrow.	Client states she has means to purchase medicine and will take it conscientiously.
		Nutrition		
Nurse	Assess whether client understands importance of a good fluid intake for breastfeeding success.	Advise client to be certain to drink at least 8 glasses of fluid daily.	Fluid is important for breast milk formation and to prevent dehydration with fever.	Client states she has access to fluid and understands the importance of fluid intake.
		Patient/Family Education		
Nurse/nurse-midwife	Assess client's knowledge of mastitis and how microorganisms enter and infect a breast.	Clarify any misconceptions client may have about mastitis. Inform client that mastitis does not result in permanent breast disease or interfere with continued breastfeeding.	Misconceptions can negatively affect self-esteem. Providing information helps to alleviate possible anxiety related to any misconceptions and lack of knowledge.	Client states she realizes the infection is not her fault; she is not a "bad mother" because of it.
		Psychosocial/Spiritual/Emotional Needs		
Nurse	Attempt to identify the meaning of breastfeeding to client.	Encourage client to express feelings and thoughts about herself, breastfeeding, and mastitis. Review and reinforce with client positive attributes about herself.	Identifying the meaning of breastfeeding assists in determining the effect that a diagnosis of mastitis may have on client.	Client states that she views this event as only a minor setback to her childrearing plans.
		Discharge Planning		
Nurse	Determine whether client has appointment for follow-up care.	Encourage active participation in decision making to foster self-esteem. Urge boyfriend to provide breastfeeding support.	Adequate self-esteem is important to make effective childrearing decisions.	Client will discuss apparent lack of breastfeeding support with boyfriend. Will keep follow-up appointment.

may be more difficult to detect than primary or simple overdistention.

With primary overdistention, a woman does not void at all. A longer-than-usual time (>8 hours) passes after the birth or between voids. Assessment by percussion or palpation of the bladder reveals the bladder distention.

With urinary retention and overflow, a woman is able to void. Voiding is very frequent, however, and in small amounts; her overall output is inadequate. Always measure the amount of a woman's first voiding after birth. As a rule, if this voiding is less than 100 mL, suspect urinary retention.

Urinary retention is confirmed by catheterizing a woman immediately after she voids. If the amount of urine left in the bladder after voiding (termed *residual*) is greater than 100 mL, the woman has retention of more than the normal amount. Typically, her physician or nurse-midwife writes an order such as, "Catheterize for residual urine. If this is greater than 100 mL, leave indwelling catheter in place." Always use strict antiseptic technique to prevent introducing pathogenic bacteria into the sterile urinary tract and causing a urinary tract infection. Always use an indwelling (Foley) catheter rather than a temporary one (straight catheter) to catheterize

for residual urine. This helps to minimize the risk of introducing pathogens with a second catheterization, should an indwelling catheter be needed.

Catheterizing a woman during the early postpartal period can be difficult. Vulvar edema often distorts the position and appearance of the urinary meatus. Use a gentle technique, remembering that a woman's perineum is apt to feel tender to touch.

Therapeutic Management

The amount of urine to remove from an overdistended bladder is controversial. There is a suggestion that removing more than 750 to 1000 mL of urine at any one time may create extreme pressure changes in the bladder and lower abdomen. Decreased pressure may cause blood to flow into the area, creating supine hypotension. There are few documented occurrences of this happening, however. Particularly in the postpartal period, when a bladder is easily distended and the uterus is larger than normal, this shift in pressure may not be as important as usual. Follow your health care agency's policy concerning how much urine to remove from a full bladder at catheterization.

If an indwelling catheter will be left in place, be certain to explain the rationale for its insertion and how it works. Explain how the balloon is inflated to hold it in place. This prevents a woman from limiting her activity to try and keep it in place. Activity and ambulation help to prevent other complications, such as thrombophlebitis.

Catheterization is a procedure that has a reputation as being extremely painful. Assure a woman that, as a rule, it involves only a momentary discomfort, such as a pinprick, as the catheter is inserted. Because the pain sensation of edematous tissue is decreased, a woman with extreme vulvar edema may experience only slight discomfort.

After 24 hours, the physician or nurse-midwife may order the indwelling catheter to be clamped for a short time and then removed. Encourage the woman to void by the end of 6 hours after removal of the catheter by offering fluid, administering an analgesic so she can relax, assisting her to the bathroom as necessary, and trying time-tested solutions such as running water at the sink or letting her hold her hand under warm running water. In most women, bladder and vulvar edema have decreased significantly by this time, so they are able to void without further difficulty. You may be asked to assess for residual urine again. If a woman has not voided by 8 hours after catheter removal, the physician or nurse-midwife may order reinsertion of the indwelling catheter for an additional 24 hours.

Difficulty with bladder function after childbirth is becoming less of a problem as less anesthesia and fewer forceps are used at birth, decreasing bladder and vulvar pressure. If problems do arise, they may be difficult for a woman to accept, because bladder elimination is a basic step of self-care. Bladder problems can be disappointing and discouraging to a woman who wants not only to be able to care for herself but also to care for a new infant. Reassure a woman that bladder complications are not uncommon after childbirth. Usually they are present for no longer than 48 hours, and most likely they will not recur.

Urinary Tract Infection

A woman who is catheterized at the time of childbirth or during the postpartal period is prone to development of a urinary tract infection, because bacteria may be introduced into the bladder at the time of catheterization.

Assessment

If a urinary tract infection develops, a woman notices symptoms of burning on urination, possibly blood in the urine (hematuria), and a feeling of frequency or that she always has to void. The pain is so sharp on voiding that she may resist voiding, further compounding the problem of urinary stasis. She may also have a low-grade fever and discomfort from lower abdominal pain.

Obtain a clean-catch urine specimen from any woman with symptoms of urinary tract infection (see Nursing Procedure Box 11.6 in Chapter 11). This can be done as an independent nursing action. So that lochial discharge does not contaminate the specimen, provide a sterile cotton ball for the woman to tuck into her vagina after perineal cleansing. Be certain to ask if she removed the cotton ball after the procedure; otherwise, it could cause stasis of vaginal secretions and increase the possibility of endometritis. Mark the specimen "possibly contaminated by lochia," so that any blood in the specimen will not be overly interpreted by the laboratory technician.

Therapeutic Management

Although sulfa drugs are normally prescribed for urinary tract infection, they are contraindicated for breastfeeding women because they can cause neonatal jaundice. Typically, therefore, a broad-spectrum antibiotic such as amoxicillin or ampicillin will be prescribed to treat a postpartal urinary tract infection. If an antibiotic contraindicated by breastfeeding is prescribed, check with a woman's physician about possibly changing the antibiotic to one that is safe for breastfeeding. Otherwise, once she is home, the woman may decide to breastfeed and not take the prescribed antibiotic.

Encourage a woman to drink large amounts of fluid (a glass every hour) to help flush the infection from her bladder. She may need an oral analgesic, such as acetaminophen (Tylenol), to reduce the pain of urination for the next few times she voids until the antibiotic begins to have an effect and the burning sensation disappears. Otherwise, because voiding is painful, she may not drink the fluid you suggest, knowing that it will increase the number of times she needs to void.

Although symptoms of urinary tract infection decrease quickly, be certain a woman understands the importance of continuing to take the prescribed antibiotic for the full 5 to 7 days to eradicate the infection completely. Women often stop taking medicine after the symptoms disappear, especially if they are busy—and women at home with new babies are busy. Make a chart for a woman to post on her refrigerator door as a reminder to continue to take the medication. If she stops the antibiotic, bacteria in the urine will begin to multiply again, and in another week symptoms and the active infection will recur. Be certain a woman is aware of common methods all women should use to prevent urinary tract infections (see Chapter 46).

What if... It has been approximately 7 hours since Mary Blackhawk gave birth and she still has not voided? What should you do next?

CARDIOVASCULAR SYSTEM DISORDERS

Because pregnancy requires major changes in the volume of blood and blood pressure, some excess volume and pressure can still be present in the postpartal period.

Postpartal Pregnancy-Induced Hypertension

Because pregnancy-induced hypertension (PIH) usually develops during pregnancy, it is discussed in Chapter 21. Mild pre-existing hypertension may increase in severity during the first few hours or days after birth. Rarely, PIH develops for the first time in a woman who has had no prenatal or intranatal symptoms. When this happens, the cardinal symptoms are the same as those of prenatal PIH: proteinuria, edema, and hypertension (Bailis & Witter, 2007).

The treatment measures for postpartal PIH are also the same as for antepartal PIH: bed rest, a quiet atmosphere, frequent monitoring of vital signs and urine output, and administration of magnesium sulfate or an antihypertensive agent. Antihypertensive therapy can be administered in higher doses than during pregnancy, because there is no longer any risk of injury to a fetus. The reason the condition occurs is usually retention of some placental material. The woman may be taken to surgery to have a D&C to be certain that all placental fragments have been removed from her uterus. After the D&C, blood pressure often falls dramatically to normal.

Seizures, if they occur postpartally as a symptom of PIH, typically develop 6 to 24 hours after birth. Seizures occurring more than 72 hours after birth are probably not the result of PIH but the result of some cause unrelated to childbearing.

Women in whom postpartal PIH develops are bewildered by what is happening to them. If seizures occur, they are frightened to discover how little control they have over their body. They worry that they will have a seizure after they are at home, while holding their baby. You can assure them that PIH, although it appears late, is a condition of pregnancy, so the symptoms will now fade quickly. Women with chronic hypertension need frequent monitoring during a future pregnancy to prevent PIH symptoms from occurring again (Miller, 2007).

REPRODUCTIVE SYSTEM DISORDERS

Pregnancy may leave reproductive system organs weakened or displaced.

Reproductive Tract Displacement

If the support systems of the uterus are weakened because of pregnancy, the ligaments may no longer be able to maintain the uterus in its usual position or level after pregnancy. Problems of retroflexion, anteflexion, retroversion, and anteversion or prolapse of the uterus may occur. These uterine displacement disorders may interfere with future childbearing and fertility and may cause continued pain or a feeling of lower abdominal heaviness or discomfort.

If the walls of the vagina are weakened, a cystocele (outpouching of the bladder into the vaginal wall) or a rectocele (outpouching of the rectum into the vaginal wall) may occur. These problems tend to develop most frequently in women with a high parity and after a forceps birth (see Figure 5.8 in Chapter 5). Surgery to repair such conditions may be necessary. If stress incontinence (involuntary voiding on exertion) occurs, Kegel exercises to strengthen perineal muscles may be helpful (Hay-Smith & Dumoulin, 2009).

Separation of the Symphysis Pubis

During pregnancy, many women feel some discomfort at the symphysis pubis because of relaxation of the joint preparatory to birth. If a fetus is unusually large or fetal position is not optimal, the ligaments of the symphysis pubis may be so stretched by birth that they actually tear. After birth, the woman experiences acute pain on turning or walking; her legs tend to rotate externally, giving her a waddling gait. A defect over the symphysis pubis can be palpated; the area is swollen and tender to touch.

Bed rest and the application of a snug pelvic binder to immobilize the joint are necessary to relieve pain and allow healing. As with all ligament injuries, a 4- to 6-week period is necessary for healing to take place. During this time, a woman may need to arrange for a person to help her with child care at home. She should avoid heavy lifting for an extended period, until healing in the pubic ligaments is complete. She may be advised to consider cesarean birth for any future pregnancy.

EMOTIONAL AND PSYCHOLOGICAL COMPLICATIONS OF THE PUERPERIUM

Any woman who is extremely stressed or who gives birth to an infant who in any way does not meet her expectations such as being the wrong sex, being physically or cognitively challenged, or being ill may have difficulty bonding with her infant. Inability to bond is a postpartal complication with far-reaching implications, possibly affecting the future health of the entire family.

A Woman Whose Child Is Born With an Illness or Is Physically Challenged

The average woman often has difficulty immediately after birth believing that her pregnancy is over and her child has been born. This difficulty is further compounded for a woman whose child is challenged in some way. She must not only grasp the fact that her baby has been born but also understand that her actual baby is different from her wished-for one.

Most women say during pregnancy they do not care about the sex of their child so long as the child is born healthy. This can make them feel cheated when this one requirement is not met. They can feel angry, hurt, and disappointed. They may feel a loss of self-esteem: they have given birth to an imperfect child, and so they see themselves as imperfect. A woman sometimes responds with a grief reaction, as if her child had died. The image of the "perfect" child she thought she was carrying *has* died.

In most instances, parents are shown their child moments after birth, so if a condition or problem exists, it can be immediately explained to them. Although this is a shock to couples, it allows them to face the problem with support people readily available. The physician or nurse-midwife usually makes it her or his responsibility to tell the parents about the

defect. Be prepared to reinforce this information or review the problem. People who are under stress are not good listeners and may need repeated explanations before they completely understand the problem.

If possible, it is important for the parents to care for the child during the postpartal period, so that they can touch, relate to, and "claim" the infant in as nearly normal a manner as possible. Many women wait until their support person is present to visit an intensive care nursery, so that visiting with their newborn is a family activity.

Open lines of communication between the parents and the hospital staff that allow for free discussion of feelings and fears will do much to strengthen parent–child relationships and prepare for future hospitalizations or care of the child.

A Woman Whose Newborn Has Died

A woman whose newborn dies at birth always has questions about what happened. She is likely to feel bewildered, perhaps bitter, and perhaps resentful that the hospital staff could not save her child. "Why me? Of all the women here, why did my baby die?" She needs concerned support from health care personnel to help her cope with such a devastating loss.

Most women are interested in seeing the baby. This is generally therapeutic because it helps them begin grieving. Clean the baby, wrap the baby in an infant blanket, and bring him or her to the parents. Remain with them, but give them time to handle and inspect the child as they wish. Parents may want to take a photograph of the baby for a memory book. Be familiar with the forms the mother or father have to sign when a baby dies or is born dead. Know whether your state requires stillborn infants to be given a name and a funeral.

Other women on the unit tend to stay away from a woman whose child has died, as if what happened to her baby was contagious. Friends and relatives may be equally unable to talk about the situation. Most women, therefore, want a nurse to approach them and say, "Do you want to talk about what's happened?" or "How do you feel?" Be careful not to use trite sympathy phrases such as, "One door closes, another one opens" or "God must have another purpose for you." These may be your beliefs but they may not be the woman's.

Do not place a woman whose child has died in a hospital room with a woman who has a healthy baby. Provide a private room, to allow the woman an opportunity to grieve. Allow her family to visit freely. She needs them with her to fill a portion of the void left by her loss. The process of grieving and the support a woman requires at this time is further discussed in Chapter 56.

Postpartal Depression

Almost every woman notices some immediate (1 to 10 days postpartum) feelings of sadness (postpartal "blues") after childbirth. This probably occurs as a response to the anticlimactic feeling after birth and also probably is related to hormonal shifts as the levels of estrogen, progesterone, and gonadotropin-releasing hormone in her body decline or rise (Baker, 2008).

In as many as 20% of women, these normal feelings continue beyond the immediate postpartal period and may even be present for longer than 1 year (Box 25.10). The sensations of overwhelming sadness can interfere with breastfeeding, child care, and returning to work (Box 25.11). In addition to an overall feeling of sadness, a woman may notice extreme fatigue, an inability to stop crying, increased anxiety about her own or her infant's health, insecurity (unwillingness to be left alone or inability to make decisions), psychosomatic symptoms (nausea and vomiting, diarrhea), and either depressive or manic mood fluctuations. Depression of this kind is termed **postpartal depression** and reflects a more serious problem than normal "baby blues" (Schatzberg, Cole, & DeBattista, 2007) (Table 25.2). Risk factors for postpartal depression include a history of depression, a troubled childhood, low self-esteem, stress in the home or at work, and lack of effective support people. Different expectations between partners (if a woman wants a child and her partner does not,

BOX 25.10 ✻ Focus on Communication

Mary Blackhawk is about to be discharged from the hospital, 72 hours after childbirth. You notice that, although her boyfriend visited with her, left some baby clothes, and then went downstairs to complete the discharge papers, Mary has made no attempt to change to street clothes or dress her new baby girl. The baby clothes her boyfriend left include a baseball-type shirt.

Less Effective Communication

Nurse: Mary? Do you need some help with the baby?
Mary: Are you sure I can't stay? I feel too tired to go home.
Nurse: Your insurance won't pay if you stay. [Mary starts to cry.]
Mary: This isn't right. I am just too tired to go home.
Nurse: It's the baby blues. If you change your mind and do need help with the baby, let me know. I'll be glad to dress her for you.

More Effective Communication

Nurse: Mary? Do you need some help with the baby?
Mary: Are you sure I can't stay? I feel just too tired to go home.
Nurse: Tell me more about that. [Mary starts to cry.]
Mary: I'm tired all over. It would be easier for me to kill myself than go home, try and take care of this baby myself, work full-time, and still finish school.
Nurse: Is that different from how you thought things would be after you had the baby?
Mary: I thought he'd ask me to marry him. I bet he would have if I'd had a boy instead of a girl.
Nurse: I'm worried about you going home, too.

Almost all women experience some fatigue after childbirth. As many as 70% experience a temporary feeling of sadness (baby blues). About 10%, however, develop depression severe enough to need therapy. Be sure to ask enough questions to be certain that a woman's crying is not something more serious than simple "baby blues" before she is discharged from the health care facility. In this way, a woman who has more serious problems can be referred to the proper professionals for help and support.

BOX 25.11 ✻ Focus on Evidence-Based Practice

What is the effect of postpartum depression on breastfeeding success?

To investigate this concern, researchers asked 163 women to complete an Edinburgh Postnatal Depression Scale questionnaire and to submit hand-expressed breast milk for sodium and potassium analysis between the 2nd and 12th weeks after birth. Of these women, 40 (24.5%) were rated as having a high risk for a depressive episode; 63 (41%) did not feel confident about breastfeeding. Women who have symptoms of depression or lack of confidence in their ability to breastfeed tend to supplement breastfeeding more than women without depression or lack of confidence. It is well documented that sodium levels rise in the breast milk of women who produce a limited supply of breast milk. Women who supplement breastfeeding with formula feeding produce less breast milk and so have higher sodium levels in milk. In this study, supplementation increased the risk of high sodium in relation to potassium in breast milk by as much as 209%. The researchers suggest that any measures to help women avoid postpartal depression and to feel confident in their ability to breastfeed can be instrumental in ensuring healthy breast milk for newborns.

What interventions could you use with postpartal women to help them feel confident at breastfeeding?

Source: Flores-Quijano, M. E., et al. (2008). Risk for postpartum depression, breastfeeding practices, and mammary gland permeability. *Journal of Human Lactation, 24*(1), 50–57.

BOX 25.12 ✻ Focus on Family Teaching

Q. Mary asks you, "How can I avoid becoming depressed after I return home with my new baby?"

A. Some helpful guidelines are:

- Plan a balanced program of nutrition, exercise, and sleep. Plan meals that are easy to prepare; sleep whenever your baby sleeps; begin a program of walking daily with your baby.
- Share your feelings with a support person. Many communities have postpartum support groups to help with this.
- Take some time every day to do something for yourself (work on a scrapbook, go shopping, for example) so you have a break from baby care.
- Do not try to be perfect. Analyze what are the important things to do and get them done. Let unimportant things go for another day.
- Do not let yourself be isolated by baby care. Use the Internet or telephone to keep in contact with your friends so you are not lonely.

for example) or disappointment in the child (a boy instead of a girl, for example) could play major roles.

It is difficult to predict which women will develop postpartal depression before birth, because childbirth can result in so many varied reactions; if factors could be identified, pregnancy counseling might be able to prevent symptoms (Haessler & Rosenthal, 2007). In the postpartal period, discovery of the problem as soon as symptoms develop is a nursing priority. A number of depression scales to help detect postpartum depression are available but conscientious observation and discussion with women can reveal symptoms just as well. A woman may need counseling and possibly antidepressant therapy to integrate the experience of childbirth into her life (Leahy-Warren & McCarthy, 2007). This is crucial to development of a healthy maternal–infant bond, to the health of any other children in the family, and to overall family functioning. Ask at postpartal return visits and well-child visits about symptoms that would suggest depression, and recommend an appropriate referral. Measures to help prevent depression are shown in Box 25.12.

Postpartal Psychosis

As many as 1 woman in 500 has enough symptoms during the year after the birth of a child to be considered psychiatrically ill. This statistic represents the current rate of overall mental

TABLE 25.2 ✻ Comparing Postpartal Blues, Depression, and Psychosis

	Postpartal Blues	Postpartal Depression	Postpartal Psychosis
Onset	1–10 days after birth	1–12 months after birth	Within first year after birth
Symptoms	Sadness, tears	Anxiety, feeling of loss, sadness	Delusions or hallucinations of harming infant or self
Incidence	70% of all births	10% of all births	1%–2% of all births
Etiology (possible)	Probable hormonal changes, stress of life changes	History of previous depression, hormonal response, lack of social support	Possible activation of previous mental illness, hormonal changes, family history of bipolar disorder
Therapy	Support, empathy	Counseling, drug therapy	Psychotherapy, drug therapy
Nursing role	Offer compassion and understanding	Refer to counseling	Refer to psychiatric care, safeguarding mother from injury to self or to newborn

illness (American Psychiatric Association [APA], 2000). When the illness coincides with the postpartal period, it is called **postpartal psychosis** (Haessler & Rosenthal, 2007). Rather than being a response to the physical aspects of childbearing, however, it is probably a response to the crisis of childbearing. The majority of these women have had symptoms of mental illness before pregnancy. If the pregnancy had not precipitated the illness, a death in the family, loss of a job or income, divorce, or some other major life crisis would probably have precipitated the same recurrence.

A woman with postpartal psychosis usually appears exceptionally sad. By definition, psychosis exists when a person has lost contact with reality. A woman with a postpartal psychosis may deny that she has had a child and, when the child is brought to her, insist that she was never pregnant. She may voice thoughts of infanticide or that her infant is possessed. If observation tells you that a woman is not functioning in reality, you cannot improve her concept of reality by a simple measure such as explaining what a correct perception is. Her sensory input is too disturbed to comprehend this. In addition, she may interpret your attempt as threatening. She may respond with anger or become equally threatening. A psychosis is a severe mental illness that requires referral to a professional psychiatric counselor and antipsychotic medication.

While waiting for such a skilled professional to arrive, do not leave the woman alone, because her distorted perception might lead her to harm herself. Nor should you leave her alone with her infant.

Always keep in mind that postpartum psychosis does exist, although it is rare. Remembering that childbearing can lead to this degree of mental illness helps you to put childbearing into perspective. For some people, childbearing is such a crisis in their lives that it triggers mental illness. Certainly, it cannot be considered an everyday incident in anyone's life.

✔ Checkpoint Question 25.3

Which statement by Mary Blackhawk is most suggestive of a woman developing postpartal psychosis?

a. "I wish my baby had more hair."
b. "My baby has the devil's eyes."
c. "I feel exhausted since birth."
d. "Breastfeeding is harder than I thought."

Key Points for Review

- Establishing a firm family–newborn relationship may be difficult when a woman has a postpartal complication. Investigate ways that will allow a woman to care for her baby, or offer necessary support to family members so that they can fulfill this role.
- Hemorrhage (defined as a loss of blood greater than 500 mL within a 24-hour period) is a major potential danger in the immediate postpartal period. The most frequent cause of postpartal hemorrhage is uterine atony. Continuous limited blood loss can be as important over time as sudden, intense bleeding. With hemorrhage, administration of oxytocin may be necessary to initiate uterine tone and halt the bleeding.
- Other causes of hemorrhage include lacerations (vaginal, cervical, or perineal) and retained placental fragments. Lacerations are most apt to occur with forceps birth or with the birth of a large infant. Disseminated intravascular coagulation can also cause postpartum hemorrhage.
- Puerperal infection (a temperature greater than 100.4° F or 38.0° C) is a potential complication after any birth until the denuded placental surface has healed. Retained placental fragments and the use of internal fetal heart monitoring leads are potential sources of infection.
- Thrombophlebitis, an inflammation of the lining of a blood vessel, occurs most often as an extension of an endometrial infection. Therapy includes bed rest with moist heat applications and anticoagulant therapy. *Never massage the leg of a woman with thrombophlebitis;* doing so can cause the clot to move and become a pulmonary embolus, a possibly fatal complication.
- Mastitis is infection of the breast. The symptoms include pain, swelling, and redness. Antibiotic therapy is necessary.
- A woman whose child is born with a physical or cognitive challenge needs special consideration after birth. This is obviously a time of stress, and a woman needs supportive nursing care.
- Postpartal "blues" are a normal accompaniment to birth. Postpartal depression (a feeling of extreme sadness) and postpartal psychosis (an actual separation from reality) are not normal and need accurate assessment so a woman can receive adequate therapy for these conditions.

CRITICAL THINKING EXERCISES

1. Mary Blackhawk, whom you met at the beginning of the chapter, was having heavy vaginal bleeding at 4 hours after birth. Because she was sleeping, however, she was totally unaware of it. What action on your part would have prevented so much blood loss? What action would be most appropriate now?
2. Eight hours after birth, Mary Blackhawk tells you that she has frequency and burning on urination. She had a urinary tract infection during pregnancy, so she recognizes the symptoms. She has some medicine left from pregnancy and tells you that she will take it to cure the infection. What advice would you give her?
3. When Mary returns for a postpartal checkup, you notice red streaks on both legs along the course of her veins, and she has pain on dorsiflexion of her foot. You are concerned that she is developing thrombophlebitis. Describe a plan of care that could have reduced this risk during labor and in the immediate postpartal period.
4. Examine the National Health Goals related to complications of the puerperium. Most government-sponsored funds for nursing research are allotted based on these goals. What would be a possible research topic to ex-

plore pertinent to these goals that would be applicable to the Blackhawk family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to postpartal complications. Confirm your answers are correct by reading the rationales.

Chapter 26

Nursing Care of a Family With a High-Risk Newborn

KEY TERMS

- apnea
- apparent life-threatening event
- appropriate for gestational age (AGA)
- brown fat
- caudal regression syndrome
- developmental care
- dysmature
- extracorporeal membrane oxygenation (ECMO)
- fetal alcohol syndrome
- gestational age
- hemorrhagic disease of the newborn
- hydrops fetalis
- hyperbilirubinemia
- intrauterine growth restriction
- large for gestational age (LGA)
- low-birth-weight infant
- macrosomia
- ophthalmia neonatorum
- periodic respirations
- periventricular leukomalacia
- postterm syndrome
- preterm infants
- retinopathy of prematurity
- shoulder dystocia
- small for gestational age (SGA)

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Define the following terms—*small-for-gestational-age infant, term infant, large-for-gestational-age infant, preterm infant,* and *postterm infant*—and describe common illnesses that occur in these and other high-risk newborns.
2. Identify National Health Goals related to high-risk newborns nurses can be instrumental in helping the nation achieve.
3. Use critical thinking to analyze the special crisis imposed on families when alterations of newborn development or neonatal illness occur to make nursing family centered.
4. Assess a high-risk newborn to determine whether safe transition to extrauterine life has occurred.
5. Formulate nursing diagnoses related to a high-risk newborn.
6. Identify expected outcomes for a high-risk newborn and family.
7. Plan nursing care focused on priorities to stabilize a high-risk newborn's body systems.
8. Implement nursing care for a high-risk newborn such as monitoring body temperature.
9. Evaluate expected outcomes for achievement and effectiveness of care.
10. Identify areas related to the care of high-risk newborns that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of the needs of a high-risk newborn with nursing process to achieve quality maternal and child health nursing care.

Mr. and Mrs. Atkins are the parents of a 34-week-gestation, 2-lb baby boy born last night after a short, 4-hour labor. Their baby took a few gasping respirations at birth but then stopped breathing. He was resuscitated by the neonatal nurse practitioner and respiratory therapist and then transported to the intensive care nursery. Mr. Atkins was not present for the birth because he was out of town on business. You notice Mrs. Atkins has not visited the intensive care nursery to see her son. She also refused to sign the birth certificate because she could not decide on a name. She said, "I don't want to give him our favorite name because he might die." Mr. Atkins called early this morning and acted more upset the baby was born than relieved the baby was receiving intensive care. You hear him ask his wife, "What did you do to cause this?" Previous chapters described the birth of well newborns and care of newborns who are well at birth. This chapter adds information on care of newborns who are ill or have a significant variation in gestational age or weight. Learning to recognize these infants at birth and organizing care for them can be instrumental in helping protect both their present and future health.

What type of help do the Atkinses need to better accept what has happened to them?

During pregnancy, screening women for risk factors that could lead to illness in a newborn such as younger or older than average maternal age, concurrent disease conditions such as diabetes or human immunodeficiency virus (HIV) infection, pregnancy complications such as placenta previa, or an unhealthy maternal lifestyle such as drug abuse is essential to identify infants who may need greater-than-usual care at birth (Pinheiro, 2007). Unfortunately, not all instances of high risk can be predicted. Even a newborn from a "perfect" pregnancy may require specialized care or develop a problem over the first few days of life necessitating special interventions. Any infant who is born **dysmature** (before term or postterm, or who is underweight or overweight for gestational age) is also at risk for complications at birth or in the first few days of life. Parents need thorough education about their baby's health because these problems may require rehospitalization or additional follow-up at home. National Health Goals related to the high-risk newborn are shown in Box 26.1.

Being able to predict an infant is at high risk allows for advanced preparation so that specialized, skilled health care personnel can be present at the child's birth to perform necessary interventions, such as resuscitating a newborn who has difficulty establishing respirations. Immediate, skilled handling of any problems that occur may help to save the newborn's life and also prevent future problems, such as neurologic disorders (Saigal & Doyle, 2008).

BOX 26.1 ❊ Focus on National Health Goals

Preterm birth has the potential for leading to so many complications in newborns that National Health Goals were written specifically concerning preterm birth:

- Reduce low birth weight (LBW) to an incidence of no more than 5% of live births and very low birth weight (VLBW) to an incidence of no more than 0.9% of live births from baselines of 7.6% and 1.4%, respectively.
- Increase the proportion of very low birth weight (VLBW) infants born at level III hospitals or subspecialty perinatal centers from a baseline of 73% to a target level of 90%.
- Reduce the rate of fetal and infant deaths during the perinatal period (28 weeks of gestation to 7 days or more after birth) to 4.4 per 1000 live births from a baseline of 7.3 per 1000 live births.
- Reduce the rate of deaths from sudden infant death syndrome (SIDS) to 0.23 per 1000 live births from a baseline of 0.67 per 1000 live births (http://www.nih.gov).

Nurses can help the nation achieve these goals by teaching women the symptoms of preterm labor so that, ideally, birth can be delayed until infants reach term. Nurses also need to be prepared for resuscitation at birth of preterm infants and to plan developmental care that can help prevent conditions such as apnea, intraventricular hemorrhage, and periventricular leukomalacia.

Further research is needed regarding how best to position infants to promote development and prevent fatigue, what measures can best prevent conditions such as intraventricular hemorrhage, and what measures can make parents feel most comfortable and allow them to best interact with their infants in neonatal intensive care units.

Nursing Process Overview

For the Family of a High-Risk Newborn

Assessment

All infants need to be assessed at birth for obvious congenital anomalies and **gestational age** (number of weeks they remained in utero). Both determinations can be done by the nurse who first examines an infant. Be certain these assessments are made with an infant under a prewarmed radiant heat warmer to guard against heat loss.

Continuing assessment of high-risk infants involves the use of instrumentation such as cardiac, apnea, and blood pressure monitoring. However, no matter how many monitors are used, they never replace the role of frequent, close, common-sense observation. Carefully evaluate comments from fellow nurses that an infant "isn't himself" or "breathes oddly." These comments, although not scientific, are the same observations that parents who know their baby well report at health visits. A nurse who knows an infant well from having cared for a baby consistently over time often senses changes before a monitor or other equipment begins to put a quantitative measurement on the factor.

Nursing Diagnosis

To establish nursing diagnoses for high-risk infants, it is important to be aware of the normal assessment parameters of newborns. Nursing diagnoses generally center on the nine priority areas of care for any newborn:

- Ineffective airway clearance related to presence of mucus or amniotic fluid in airway
- Ineffective cardiovascular tissue perfusion related to breathing difficulty
- Risk for deficient fluid volume related to insensible water loss
- Ineffective thermoregulation related to newborn status and stress from birth weight variation
- Risk for imbalanced nutrition, less than body requirements related to lack of energy for sucking
- Risk for infection related to lowered immune response in newborn
- Risk for impaired parenting related to illness in newborn at birth
- Deficient diversional activity (lack of stimulation) related to illness at birth
- Readiness for developmental care to decrease overstimulation easily caused by necessary life-saving procedures

Outcome Identification and Planning

Be certain when establishing expected outcomes that they are consistent with a newborn's potential. A goal that implies complete recovery from a major illness, for example, may be unrealistic for one newborn but completely appropriate for another. Plan care that is individualized

considering a newborn's developmental as well as physiologic strengths, weaknesses, and needs. This helps to ensure that parents as well as the health care team understand the newborn's particular care priorities and potential. Many families of high-risk newborns will need continued support to care for their infants at home. They may need referral to a home health care or other agency. Helpful Internet sites to use for referring parents are the Web sites of the March of Dimes (http://www.marchofdimes.com), American Sudden Infant Death Syndrome Institute (http://www.sids.org), and Newborn Individualized Developmental Care and Assistance Program (http://www.nidcap.org).

Implementation

Interventions for any high-risk newborn are best carried out by a consistent caregiver and should focus on conserving the baby's energy and providing a thermoneutral environment to prevent exhaustion and chilling. Painful procedures should be kept to a minimum to help the infant achieve a sense of comfort and balance. Assisting parents to participate in care such as bathing or feeding their infant may help make the child real to them for the first time and start the bonding process.

Outcome Evaluation

High-risk newborns need long-term follow-up so any consequences of their birth status, such as minimal neurologic injury, can be identified and arrangements for special schooling or counseling can be made. Examples of expected outcomes include:

- Infant maintains a patent airway.
- Infant tolerates all procedures without accompanying apnea.
- Infant demonstrates growth and development appropriate for gestational age, birth weight, and condition.
- Infant maintains body temperature at 98.6° F (37.0° C) in open crib with one added blanket.
- Parents visit at least once and make three telephone calls to neonatal nursery weekly.
- Parents demonstrate positive coping skills and behaviors in response to newborn's condition.

NEWBORN PRIORITIES IN FIRST DAYS OF LIFE

All newborns have eight priority needs in the first few days of life:

1. Initiation and maintenance of respirations
2. Establishment of extrauterine circulation
3. Control of body temperature
4. Intake of adequate nourishment
5. Establishment of waste elimination
6. Prevention of infection
7. Establishment of an infant–parent relationship
8. Developmental care, or care that balances physiologic needs and stimulation for best development

These are also the priority needs of high-risk newborns. Because of small size or immaturity or illness, fulfilling these needs, however, may require special equipment or care measures. Not all newborns will be able to achieve full wellness because of extreme insults to their health at birth or difficulty adjusting to extrauterine life. Indications that a newborn is having difficulty making the transition from intrauterine to extrauterine life may be apparent during the intrapartum period, at birth, or at initial assessment because of a low Apgar score (see Chapter 18).

Initiating and Maintaining Respirations

Ultimately, the prognosis of a high-risk newborn depends primarily on how the first moments of life are managed. Most deaths occurring during the first 48 hours after birth result from the newborn's inability to establish or maintain adequate respirations (National Vital Statistics System [NVSS], 2009). An infant who has difficulty accomplishing effective respiratory action in the first hours of life and yet survives may experience residual neurologic difficulties because of cerebral hypoxia. Prompt, thorough care is necessary for effective intervention.

Most infants are born with some degree of respiratory acidosis. However, this is rapidly corrected by the spontaneous onset of respirations. If respiratory activity does not begin immediately, respiratory acidosis will increase. The blood pH and bicarbonate buffer system will fail. Newborn defense mechanisms are inadequate to reverse the process. Therefore, the effort to establish respirations must be started immediately after birth. By 2 minutes, the development of severe acidosis is already well under way (Thilo & Rosenberg, 2008).

Any infant who sustains some degree of asphyxia in utero, such as could occur from cord compression, maternal anesthesia, placenta previa, or preterm separation of the placenta, may already be experiencing acidosis at birth and may have difficulty before the first 2 minutes of life.

Resuscitation

Factors that commonly predispose infants to respiratory difficulty and so may require resuscitation are shown in Box 26.2. If breathing is ineffective, circulatory shunts, particularly the

BOX 26.2 ✻ Factors Predisposing Infants to Respiratory Difficulty in the First Few Days of Life

Low birth weight
Maternal history of diabetes
Premature rupture of membranes
Maternal use of barbiturates or narcotics close to birth
Meconium staining
Irregularities detected by fetal heart monitor during labor
Cord prolapse
Lowered Apgar score (<7) at 1 or 5 minutes
Postmaturity
Small for gestational age
Breech birth
Multiple birth
Chest, heart, or respiratory tract anomalies

ductus arteriosus, can fail to close. Because left-side heart pressure is stronger than right-side pressure, blood circulates through a patent ductus arteriosus left to right or from the aorta to the pulmonary artery, creating ineffective pump action in the heart. Struggling to breathe and circulate blood, an infant uses available serum glucose quickly and may become hypoglycemic, compounding the initial problem.

For all these reasons, resuscitation becomes important for infants who fail to take a first breath or have difficulty maintaining adequate respiratory movements on their own.

Resuscitation follows an organized process: (a) establish and maintain an airway, (b) expand the lungs, and (c) initiate and maintain effective ventilation. If respiratory depression becomes severe, a newborn's heart will fail. Resuscitation then must also include cardiac massage (American Heart Association [AHA], 2008).

Airway

For a well term newborn, usually bulb syringe suction, which removes mucus and prevents aspiration of any mucus and amniotic fluid present in the mouth or nose with the first breath, is all that is necessary to help establish a clear airway (see Chapter 18).

If a newborn does not draw in a first breath spontaneously, suction the infant's mouth and nose with a bulb syringe again and rub the back to see if skin stimulation initiates respirations. Be certain an infant is dry, including the hair and head, to prevent chilling. If a newborn has to attempt to raise body temperature because of chilling, this will increase the need for oxygen, which the baby cannot supply because breathing has not yet been initiated. Warmed, blow-by oxygen by face mask or positive-pressure mask may be administered.

If a newborn's amniotic fluid was meconium stained, do not stimulate an infant to breathe by rubbing the back or administering air or oxygen under pressure as doing so could push meconium down into an infant's airway, further compromising respirations. Give oxygen by mask without pressure. Wait for a laryngoscope to be passed and the trachea to be deep suctioned before giving oxygen under pressure.

If deeper suctioning than by a bulb syringe is required, place an infant on the back and slide a folded towel or pad under the shoulders to raise them slightly so the head is in a neutral position. Slide a catheter (8F to 12F) over the infant's tongue to the back of the throat (Fig. 26.1). Do not suction for longer than 10 seconds at a time (count seconds as you suction) to avoid removing excessive air from an infant's lungs. Use a gentle touch. Bradycardia or cardiac arrhythmias can occur because of vagus stimulation (at the posterior oropharynx) from vigorous suctioning. In most newborns, this degree of resuscitation will initiate responsive respirations and a strong heartbeat. Color, muscle response, and reflexes will improve.

An infant who still makes no effort at spontaneous respirations requires immediate laryngoscopy to open the airway. Once a laryngoscope has been inserted, deep tracheal suctioning can be performed. After deep suctioning, an endotracheal tube can be inserted and oxygen administered by a positive-pressure bag and mask with 100% oxygen at 40 to 60 breaths per minute.

In the first few seconds of life, a newborn this severely depressed may take several weak gasps of air and then almost immediately stop breathing; the heart rate begins to fall.

FIGURE 26.1 Suctioning a newborn with mechanical suction controlled by a finger valve. Suction is applied as the catheter is withdrawn. If the catheter is rotated as it is withdrawn, the risk of traumatizing membrane is reduced.

This period of halted respirations is termed *primary apnea*. After 1 or 2 minutes of apnea (a pause in respirations longer than 20 seconds with accompanying bradycardia), an infant again tries to initiate respirations with a few strong gasps. However, a newborn cannot maintain this effort longer than 4 or 5 minutes. After this, the respiratory effort will become weaker again and the heart rate will fall further until the newborn stops the gasping effort altogether. The infant then enters a period of *secondary apnea*. Although usually a phenomenon that occurs after birth, both types of apnea may occur in utero.

During the period of first gasps, resuscitation attempts are generally successful. Once a newborn is allowed to enter a secondary apnea period, however, resuscitation measures become difficult and may be ineffective. Because it is impossible to distinguish between the two periods simply by observation, resuscitation must always be started as if secondary apnea were occurring.

An obstetrician, pediatrician, neonatologist, anesthesiologist, or neonatal nurse practitioner skilled in laryngoscope and endotracheal tube insertion should be present at the birth of all infants identified as high risk so a laryngoscope can be quickly passed (Raab, 2007). Laryngoscope insertion is easy in theory; in practice, the wide variation in the size of infants' posterior pharynx and trachea and the emergency conditions present make it difficult (Fig. 26.2).

Laryngoscopes are equipped with different-size blades. Size 0 or 1 is used with newborns. The endotracheal tube fits inside the laryngoscope. Infants under 1000 g need a 2.5-mm endotracheal tube; those over 3000 g need a 4.0-mm tube. Because preterm infants are prone to hemorrhage because of capillary fragility, gentle care during insertion is crucial.

Lung Expansion

Once an airway has been established, a newborn's lungs need to be expanded. Well newborns inflate their lungs adequately

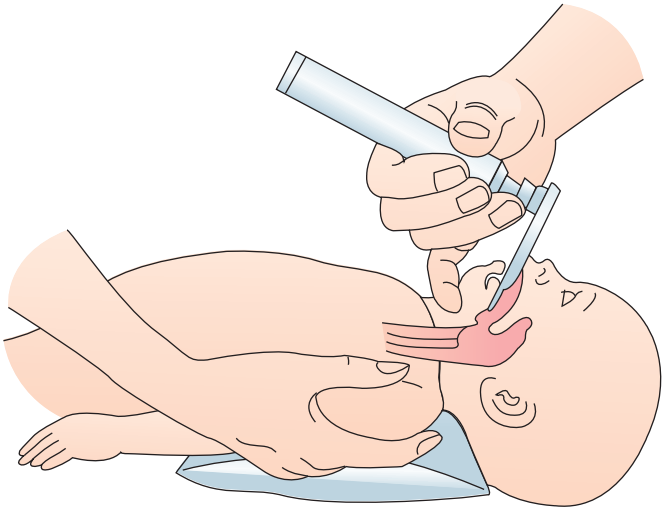

FIGURE 26.2 Intubation. Place the head in a neutral position with a towel under the shoulders. The blade of the laryngoscope is inserted to reveal the vocal cords. An endotracheal tube for ventilation is then passed into the trachea, past the laryngoscope.

with a first breath. The sound of the baby crying is proof that lung expansion is good because the vocal sounds are produced by a free flow of air over the vocal cords.

An infant who breathes spontaneously but then cannot sustain effective respirations may need oxygen by bag and mask to aid lung expansion. The mask should cover both the mouth and the nose to be effective. It should not cover the eyes, because it can cause eye injury mechanically from the mask or drying of the cornea from oxygen administration. Administer 100% oxygen by face mask and pressure bag at a rate of 40 to 60 compressions per minute. To prevent cooling, oxygen should be administered both warmed (between 89.6° and 93.2° F, or 32° and 34° C) and humidified (60%–80%).

The pressure needed to open lung alveoli for the first time is approximately 40 cm H_2O. After that, pressures of 15 to 20 cm H_2O are generally adequate to continue inflating alveoli (Thilo & Rosenberg, 2008). The pressure from anesthesia bags is controlled solely by the pressure of a hand against the bag. Other types of bags such as the Ambu-bag can be set with a blow-off valve that limits the pressure in the apparatus (Fig. 26.3).

It is important not to let oxygen levels in a newborn fluctuate, as fluctuation can cause bleeding from immature cranial vessels. In addition, no pressure above what is necessary should be used because excessive force can rupture lung alveoli. On the other hand, if adequate insufflation is not achieved, a newborn stands little chance of survival. To be certain oxygen is reaching the lungs with resuscitation, monitor the newborn's oxygen level with pulse oximetry in addition to auscultating the chest for the sound of breathing (Shiao & Ou, 2007).

Be certain to listen to both lungs to be sure both lungs are being aerated. If air can be heard on only one side or sounds are not symmetric, the endotracheal tube is probably at the bifurcation of the trachea and blocking one of the main-stem bronchi. Drawing it back half a centimeter will usually free it and allow oxygen to flow to both lungs.

When oxygen is given under pressure to a newborn this way, the stomach also quickly fills with oxygen. If the resuscitation continues for over 2 minutes, inserting an orogastric tube and leaving the distal end open will help deflate the stomach and decrease the possibility that vomiting and aspiration of stomach contents from overdistention will occur.

Drug Therapy

Stimulants have little place in newborn resuscitation unless an infant's respiratory depression appears to be related to the

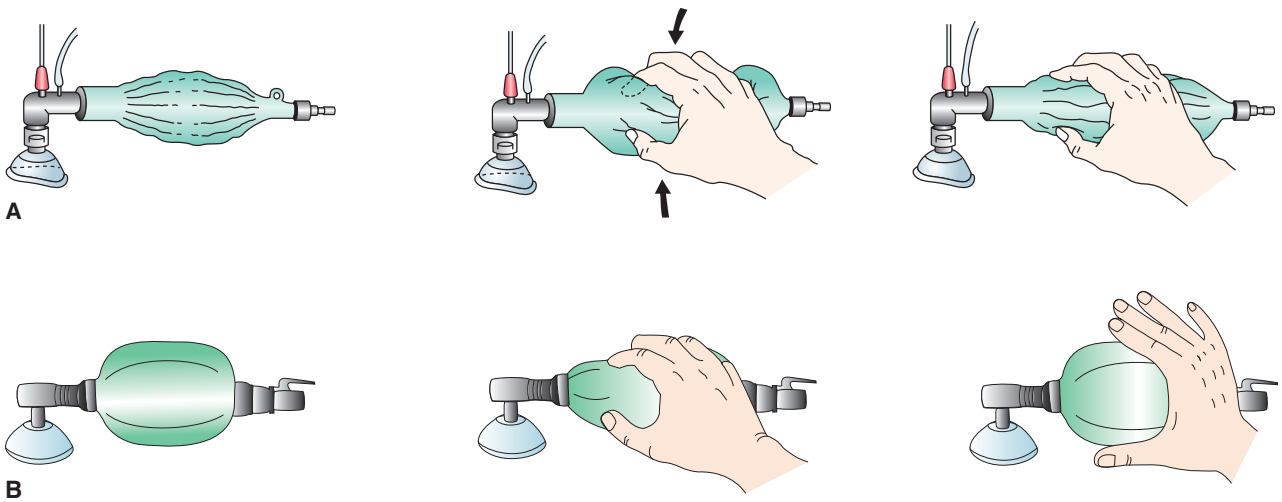

FIGURE 26.3 Types of ventilation bags used in neonatal resuscitation. (**A**) The flow-inflating (anesthesia) bag requires a compressed gas source for inflation but is able to deliver 100% oxygen. (**B**) The self-inflating (Ambu) bag remains inflated at all times and is not dependent on a compressed gas source. It is limited to delivering oxygen concentration of 40%, which may be inadequate for resuscitation at birth.

BOX 26.3 ✻ Focus on Pharmacology

Naloxone (Narcan)

Classification: Naloxone is a pure narcotic antagonist.
Action: Administered parenterally to reverse the effects, such as respiratory depression, that may occur with opioid narcotic agents (Karch, 2009).
Pregnancy risk category: B
Dosage: Initially 0.01 mg/kg IV. Dosage may be repeated at 2- to 3-minute intervals.
Possible adverse effects: Hypertension, irritability, tachycardia

Nursing Implications

- Assess respiratory status carefully, including rate, depth, and character of respirations.
- Anticipate the need for repeat doses.
- Maintain a patent airway at all times.
- Have emergency resuscitation equipment readily available and prepare to resuscitate if necessary.

administration of a narcotic such as morphine or meperidine (Demerol) to the mother during labor. In these instances, a narcotic antagonist such as naloxone (Narcan) injected into an umbilical vessel or intramuscularly into a thigh will relieve the depression (Box 26.3). The dose of naloxone is determined by institutional policy but is usually 0.01 to 0.1 mg/kg body weight (Karch, 2009). If there is suspicion of maternal drug abuse, naloxone is used cautiously because it might cause acute withdrawal in the neonate. Other drug therapies in addition to naloxone are shown in Boxes 26.4 and 26.5.

BOX 26.5 ✻ Focus on Pharmacology

Surfactant (Survanta)

Action: Surfactant restores naturally occurring lung surfactant to improve lung compliance.
Pregnancy risk category: X
Dosage: 4 mL/kg intratracheally; four doses in first 48 hours of life
Possible adverse effects: Transient bradycardia, rales

Nursing Implications

- Suction infant before administration.
- Assess infant's respiratory rate, rhythm, arterial blood gases, and color before administration.
- Ensure proper endotracheal tube placement before dosing.
- Change infant's position during administration to encourage drug to flow to both lungs.
- Assess infant's respiratory rate, color, and arterial blood gases after administration.
- Do not suction endotracheal tube for 1 hour after administration, to avoid removing drug.

Ventilation Maintenance

To allow a newborn to adjust to and maintain cardiovascular changes, effective ventilation (continued respirations) must be maintained. Healthy newborns accomplish this task on their own. All infants, especially those who had difficulty establishing respirations at birth, should be carefully observed in the next few hours to be certain respirations are maintained.

BOX 26.4 ✻ Focus on Pharmacology

Drugs Used in Resuscitation

Drugs commonly used in newborn resuscitation include:

Atropine: Reduces bronchial secretions, keeping the airway clear during resuscitation. Reduces vagus nerve effects, relieving bradycardia.
Calcium chloride: Increases heart contractility.
Dopamine: Increases systemic blood perfusion by increasing blood pressure through beta-agonist action.
Epinephrine: Strengthens or initiates cardiac contractions; increases heart rate and blood pressure.
Lidocaine: Counteracts ventricular arrhythmias by decreasing automaticity of ventricular cells.
Sodium bicarbonate ($NaHCO_3$) or tromethamine: Corrects metabolic acidosis. **Caution:** Do not give these agents unless ventilation is adequate or acidosis can be increased by retained CO_2.

Many preterm infants have such respiratory distress at birth that they need continued therapy, including:

Surfactant: All preterm infants weighing less than 1500 g receive surfactant administered by endotracheal tube at birth (see Box 26.5). Some newborns need administration of additional surfactant to prevent symptoms of respiratory distress syndrome.
Nitric oxide: Nitric oxide is a potent vascular dilator. Because it dilates the capillaries next to alveoli, it reduces the pulmonary resistance and therefore increases oxygenation and lung function (Barrington & Finer, 2009).
Liquid ventilation: Liquid ventilation is the instillation of liquid fluorocarbon (Perflubron) into the lungs. It fills and clings to alveoli. Perflubron is not absorbed by the body but instead leaves the lungs by evaporation. Although studies in young infants are few in number, liquid ventilation has the potential to reduce lung disease (Davies & Sargent, 2009). It acts as an anti-inflammatory and reduces oxygen toxicity and perhaps infection because bacteria cannot live in the medium. Adverse effects may be pneumothorax and mucus plugging.

An increasing respiratory rate in a newborn is often the first sign of obstruction or respiratory compromise. If the respiratory rate is increased, undress the baby's chest and look for retractions (inward sucking of the anterior chest wall on inspiration). Retractions of this type reflect the difficulty the newborn is having in drawing in air (tugging so hard to inflate the lungs that the anterior chest muscles are drawn inward).

A newborn who is having difficulty with maintaining respirations should be placed under an infant warmer and have the weight of clothing removed from the chest. Keeping the infant warm is important to prevent acidosis. Positioning an infant on the back with the head of the mattress elevated approximately 15 degrees allows the abdominal contents to fall away from the diaphragm, offering additional breathing space.

If secretions are accumulating in the respiratory tract, they must be suctioned. If the newborn has an endotracheal tube in place, perform tracheal suctioning. "Bagging" an infant for a minute before suctioning can improve the infant's oxygen level and prevent it from dropping to dangerous levels during suctioning. Use pulse oximetry or transcutaneous oxygen monitoring to monitor oxygen level if available (see Chapter 40). The cause of the respiratory distress must be determined and appropriate interventions undertaken to correct the difficulty (see Chapter 40).

Establishing Extrauterine Circulation

Although establishing respirations is the usual priority at a high-risk infant's birth, lack of cardiac function may be present concurrently or may develop if respiratory function cannot be quickly initiated and maintained. If an infant has no audible heartbeat, or if the cardiac rate is below 80 beats per minute, closed-chest massage should be started. Hold an infant with fingers supporting the back and depress the sternum with two fingers (see Chapter 41). Depress the sternum approximately one third of its depth (1 or 2 cm) at a rate of 100 times per minute (AHA, 2008). Lung ventilation at a rate of 30 times per minute should be continued and interspersed with the cardiac massage at a ratio of 1:3.

Continue to monitor transcutaneous oxygen or pulse oximetry to evaluate respiratory function and cardiac efficiency. If the pressure and the rate of massage are adequate, it should be possible, in addition, to palpate a femoral pulse. If heart sounds are not resumed above 80 beats per minute after 30 seconds of combined positive-pressure ventilation and cardiac compressions, 0.1 to 0.3 mL/kg epinephrine (1:10,000) may be sprayed into the endotracheal tube to stimulate cardiac function (AHA, 2008). Newborns who have difficulty maintaining cardiac function need to be transferred to a transitional or high-risk nursery for continuous cardiac surveillance.

Maintaining Fluid and Electrolyte Balance

After an initial resuscitation attempt, hypoglycemia (decreased blood glucose) may result from the effort the newborn expended to begin breathing. Dehydration may result from increased insensible water loss from rapid respirations. Infants with hypoglycemia are treated initially with 10% dextrose in water to restore their blood glucose level. Fluids such as Ringer's lactate or 5% dextrose in water are commonly used to maintain fluid and electrolyte levels. Electrolytes (particularly sodium and potassium) and glucose are added as necessary, depending on electrolyte analysis.

The rate of fluid administration must be carefully monitored because a high fluid intake can lead to patent ductus arteriosus or heart failure. When using a radiant warmer, there is an increase in water loss from convection and radiation. A newborn on a warmer, therefore, will require more fluid than if he or she were placed in a double-walled incubator.

Dehydration may be monitored by urine output and urine specific gravity measures. An output less than 2 mL/kg/hr or a specific gravity greater than 1.015 to 1.020 suggests inadequate fluid intake. Elevated specific gravity may also be caused by inappropriate antidiuretic hormone secretion or kidney failure because of a primary illness.

If an infant has hypotension without hypovolemia, a vasopressor such as dopamine may be given to increase blood pressure and improve cell perfusion. If hypovolemia is present, the cause is usually fetal blood loss from a condition such as placenta previa (see Chapter 21) or twin-to-twin transfusion. With hypovolemia, typically tachypnea, pallor, tachycardia, decreased arterial blood pressure, decreased central venous pressure, and decreased tissue perfusion of peripheral tissue, with a progressively developing metabolic acidosis, will be present. The hematocrit may be normal for some time after acute blood loss because blood cells present are in proportion to plasma. Normal saline or Ringer's lactate may be administered to increase blood volume. Control the rate carefully to prevent heart failure, patent ductus arteriosus, or intracranial hemorrhage from fluid pressure overload.

✔ Checkpoint Question 26.1

Baby Atkins was given a drug at birth to reverse the effects of a narcotic given to his mother in labor. What drug is commonly used for this?

a. Sodium chloride
b. Morphine sulfate
c. Penicillin G
d. Naloxone (Narcan)

Regulating Temperature

All high-risk infants may have difficulty maintaining a normal temperature. This is because, in addition to stress from an illness or immaturity, the infant's body is often exposed during procedures such as resuscitation and blood drawing.

It is important to keep newborns in a neutral-temperature environment, one that is neither too hot nor too cold, as doing so places less demand on them to maintain a minimal metabolic rate necessary for effective body functioning. If the environment is too hot, they must decrease metabolism to cool their body. If it is too cold, they must increase metabolism to warm body cells. The increased metabolism required calls for increased oxygen; without this oxygen available, body cells become hypoxic. To save oxygen for essential body functions, vasoconstriction of blood vessels occurs. If this process continues for too long, pulmonary vessels become affected and pulmonary perfusion becomes decreased. An infant's P_{O_2} level falls and P_{CO_2} increases. The decreased P_{O_2} level may open fetal right-to-left shunts again. Surfactant production may halt, which may further interfere with lung function. To supply glucose to maintain increased metabolism, an infant begins anaerobic glycolysis, which pours acid into the bloodstream. An infant becomes acidotic, and with acidosis comes the increased risk of kernicterus (invasion of

brain cells with unconjugated bilirubin) as more bilirubin-binding sites are lost and more bilirubin is free to pass out of the bloodstream into brain cells. In short, because of becoming chilled, heart action, breathing, and electrolytic balance are all affected.

To prevent a newborn from becoming chilled after birth, wipe an infant dry, cover the head with a cap, and place the baby immediately under a prewarmed radiant warmer or in a warmed incubator (Fig. 26.4) or skin-to-skin against the mother. Additional measures are the use of plastic wrap, plastic shields, or warmed mattresses. Air, incubator, or radiant warmer temperatures should be kept regulated to maintain an infant's axillary temperature at 97.8° F (36.5° C). Be certain that during procedures an infant is placed on a radiant heat warmer or a chemical warming pad, not placed directly on cool x-ray tables, scales, or an unheated radiant warmer to prevent heat loss (Box 26.6).

Radiant Heat Sources

Radiant heat warmers are open beds that have an overhead radiant heat source. Such units have servocontrol probes, which when placed on an infant's skin continually monitor his or her temperature. Abdominal skin temperature, when measured this way, should be 95.9° to 97.7° F (35.5° to 36.5° C). If an infant's temperature falls below this level, an alarm will sound. Be certain to tape the probe or disk onto the infant's abdomen between the umbilicus and the xiphoid process. Do

BOX 26.6 ✻ Focus on Evidence-Based Practice

Does placing a cap on a low-birth-weight infant guard against hypothermia?

It is critical to guard against hypothermia in low-birth-weight infants because they are unable to increase their metabolism rate to warm themselves again. To investigate whether the simple act of covering the infant's head with a cap prevents enough evaporation and heat loss to prevent hypothermia, researchers reviewed six studies with a total of 304 infants comparing different methods of guarding against newborn cooling. Conclusions of this meta-analysis revealed that plastic wraps or bags, skin-to-skin care, and warmed mattresses all keep preterm infants warmer, leading to higher temperatures on admission to neonatal units. Stockinette caps alone do not provide this same protection.

Based on this study, at the birth of a low-birth-weight infant, would you omit a cap or use it in addition to other measures?

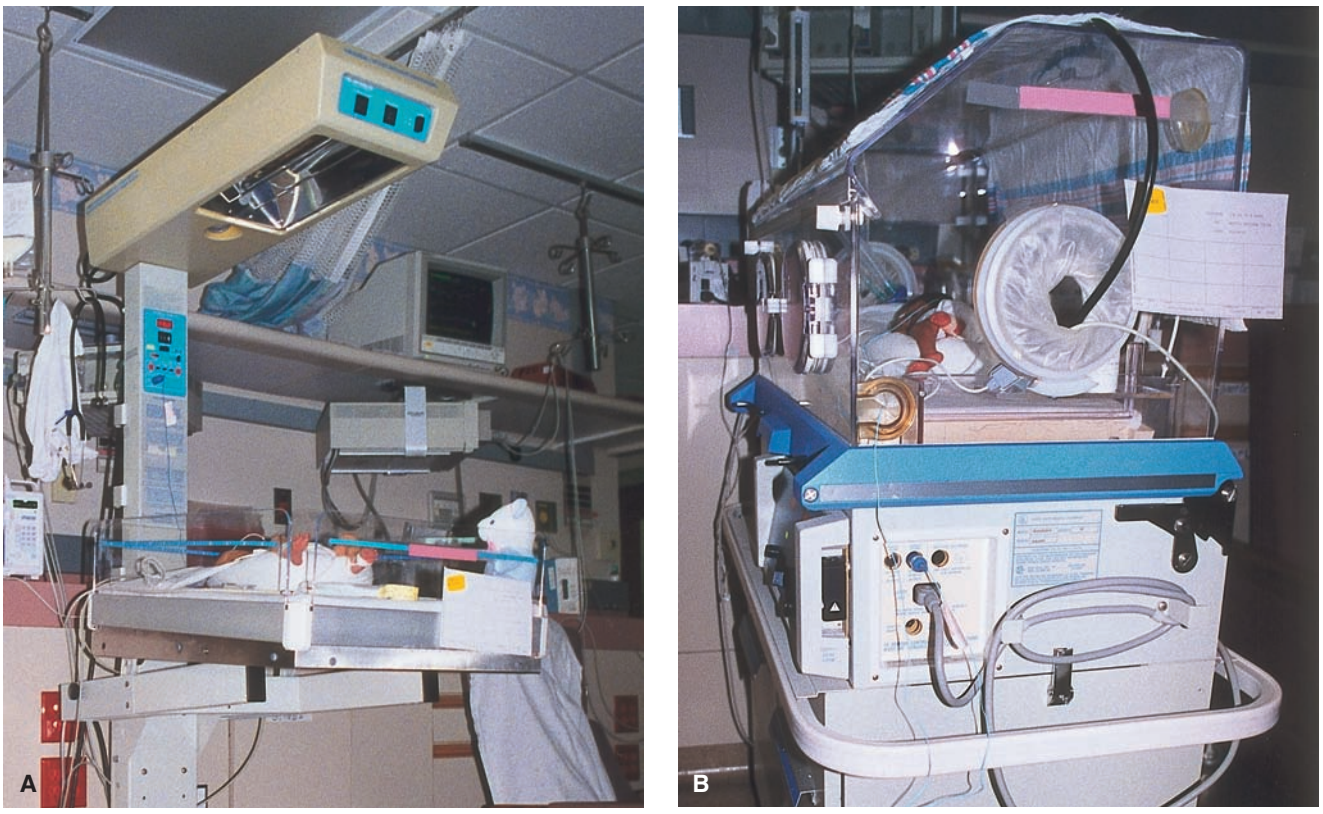

FIGURE 26.4 Neutral thermal environment. (**A**) A neonate in the intensive care bed with overhead radiant warmer can be examined periodically with ease. (**B**) Use of an incubator allows maintenance of a neutral thermal environment for neonates not requiring minute-to-minute intervention.

not tape it under an infant or it will register a falsely high reading. Be sure it is not over the rib cage, where the thin subcutaneous tissue will not allow an accurate reading. Also do not place it over the liver, because increased metabolism may lead to falsely high readings. A plastic bridge or shield placed over the child will better preserve heat by reducing convection and radiation losses; plastic wrap placed over an infant will produce this same effect. When performing care or leaning over an infant, be careful your head does not block the heat from an overhead source and keep it from reaching the baby. An additional warming pad placed under an infant may be necessary for very preterm infants or for lengthy procedures to maintain body heat.

Incubators

After an initial resuscitation attempt, newborns may be cared for in incubators. The temperature of incubators varies with the amount of time portholes remain open and the temperature of the area in which the incubator is placed. Placing it in direct sunlight or near a warm radiator can increase the internal temperature markedly. For this reason, a newborn's temperature must be checked at frequent intervals when in an incubator to be certain the temperature level designated is being maintained. Use of an additional acrylic shield inside the incubator helps prevent radiation and convection heat loss when portholes are opened for care.

Similar to radiant warmers, some incubators have servocontrol mechanism units that monitor the infant's temperature and automatically change the temperature of the incubator as needed. Portholes must remain closed to keep the servocontrol operating efficiently.

As infants' conditions improve, they can be weaned from an incubator. Dress the infant as if he or she were going to be in a bassinet, then set the incubator about 2° F (1.2° C) below the infant's temperature. After a half-hour, assess whether the infant is able to maintain body temperature. If so, lower the incubator temperature another 2° F and continue until room temperature is reached. If an infant cannot maintain adequate temperature as the incubator temperature level is lowered, the infant is not yet ready for room-temperature air, and the weaning process needs to be slowed or stopped until the baby is more mature or better able to self-regulate temperature.

Skin-to-Skin Care

Originally referred to as kangaroo care, skin-to-skin care is the use of skin-to-skin contact to maintain body heat. Provide a quiet setting with lights dimmed. Undress the infant except for a diaper and perhaps a cap. Assist the parent to sit comfortably in a chair and hold the infant snugly against his or her chest, skin to skin (Moore, Anderson, & Bergman, 2009). Place a blanket over the infant for added warmth. This method of care not only supplies heat but also encourages parent–child bonding.

Establishing Adequate Nutritional Intake

Infants who experienced severe asphyxia at birth usually receive intravenous fluids so they do not become exhausted from sucking or until necrotizing enterocolitis (NEC) has been ruled out, as this could result from the temporary reduction in oxygen to the bowel (see Chapter 45 for a discussion of NEC). If an infant's respiratory rate remains rapid and NEC has been ruled out, gavage feeding may be introduced (Fig. 26.5). Preterm infants should be breastfed if possible because of the immune protection this offers. If breastfeeding is not possible because the infant is too immature to suck effectively, a mother can manually express breast milk or use a breast pump to initiate and continue her milk supply until the time the infant is mature enough or otherwise ready for effective sucking. Her expressed breast milk can be used in the infant's gavage feeding (Jones & Spencer, 2007). Be sure when bottled breast milk is supplied by parents that it is well marked with the infant's name or breast milk errors can occur the same as medication errors (Drenckpohl, Bowers, & Cooper, 2007). It should be stored in nonshiny plastic bags or bottles to avoid the infant being exposed to polycarbonate, which can leech into stored milk and possibly cause chromosomal aberrations (Raloff, 2007).

FIGURE 26.5 Infants who are ill at birth often need supplemental feedings by nasogastric or gastrostomy tube.

Preterm infants reveal hunger by the same signs as term infants, such as rooting and crying and sucking motions. All babies who are gavage fed and need oral stimulation from nonnutritive sucking seem to enjoy a pacifier at feeding times and, in immature infants, this may help them develop an effective sucking reflex. Exceptions are infants too immature to have a sucking reflex and infants who must not swallow air, such as those with a tracheoesophageal fistula awaiting surgery. The techniques of gavage feeding, intravenous feeding, and gastrostomy feeding are discussed in Chapter 37.

Establishing Waste Elimination

Although most immature infants void within 24 hours of birth, they may void later than term newborns because, as a result of all the procedures that may be necessary for resuscitation, their blood pressure may not be adequate to optimally supply their kidneys. Carefully document any voidings that occur during resuscitation. This is proof that hypotension is improving and the kidneys are being perfused. Immature infants also may pass stool later than the term infant because meconium has not yet reached the end of the intestine at birth.

Preventing Infection

Contracting an infection could drastically complicate a high-risk newborn's ability to adjust to extrauterine life. Infection, like chilling, increases metabolic oxygen demands, which the

stressed newborn may not be able to meet. In addition, infection stresses the immature immune system and already stressed defense mechanisms of a high-risk newborn. Infections may have prenatal, perinatal, or postnatal causes. In some instances, such as preterm rupture of the membranes, it is an infection such as pneumonia or skin lesions that place the infant in a high-risk category (Herbst & Kallen, 2007).

Common viruses that affect infants in utero are cytomegalovirus and toxoplasmosis virus. An infant with either of these infections may be born with congenital anomalies from the virus invasion (see Chapter 12). The most prevalent perinatal infections are those contracted from the vagina during birth. Early-onset sepsis is most commonly caused by group B streptococcus, *E. coli, Kelbsiella*, and *Listeria monocytogenes*. Late-onset, or nosocomial, infections are more commonly caused by *Staphylococcus aureus, Enterobacter*, and *Candida*. These late-onset infections are probably most commonly spread to newborns from health care personnel. For this reason, all persons coming in contact with or caring for infants must observe good handwashing technique and standard precautions to reduce the risk of infection transmission. Health care personnel with infections have a professional and moral obligation to refrain from caring for newborns.

Establishing Parent–Infant Bonding

It is helpful if all women who are diagnosed as having a high-risk pregnancy are offered a tour of a neonatal intensive care unit (NICU) during pregnancy so if their infant should be admitted to a NICU, they will be more comfortable in the high-tech environment.

Be certain that the parents of a high-risk newborn are kept informed of what is happening during resuscitation at birth. They should be able to visit the special nursing unit to which the child is admitted as often as they choose, and, after washing and gowning, hold and touch their child. This helps to make the child's birth real to them. Should a child not survive an initial illness, these interactions can help make the death more real. Only when both birth and death seem real can parents begin to work through their feelings and accept these events.

All parents handle newborn babies tentatively until they have "claimed" them or have become better acquainted. It may be months before the parents of a child who has been ill since birth can handle their baby comfortably and confidently. Urge parents to spend time with their infant in the intensive care nursery as the infant improves. Be certain that parents have access to health care personnel after discharge to help them care confidently for the child at home.

If an infant dies despite newborn resuscitation attempts, parents need to see the infant without being covered by a myriad of equipment. This is a time for parents to reassure themselves their newborn was a perfect baby in every other way except lung function or whatever was the infant's fatal disorder. Thinking this way can give them confidence to plan for other children or simply to continue their lives after such a stressful experience.

Anticipating Developmental Needs

High-risk newborns need special care to ensure that the amount of pain they experience during procedures is limited to the least amount possible and that they receive adequate stimulation for growth. Most high-risk infants enjoy "catch-up" growth once they stabilize from the trauma of birth or whatever caused them to be classified as high risk. They quickly move to playing with age-appropriate toys. Some parents may need support before and after their infants are discharged home to begin to view them as well and capable of doing all the things they are now capable of doing. Anticipatory guidance helps them to be ready for the next developmental step.

Follow-up of High-Risk Infants at Home

Each time parents visit a high-risk nursery, assess their level of knowledge about their child's condition and development. Thorough education and referral to a home care agency may be necessary to help parents continue with the level of care that is required when their infant is discharged home (see Chapter 4). Before discharge, the safety of their home for the care of such a small infant needs to be evaluated. Transporting a preterm infant in a car requires special care, including a blanket or commercial head support, because a very small infant does not fit securely in a standard infant car seat.

Although not well documented regarding when or why it occurs, some preterm infants experience episodes of oxygen desaturation, apnea, or bradycardia when seated in standard car safety seats (DeGrazia, 2007). To detect if this will occur, the American Academy of Pediatrics (AAP, 2009) recommends that all preterm infants be assessed for cardiorespiratory stability in their car seat prior to discharge—the "car seat challenge."

High-Risk Infants and Child Abuse

When a child is ill or born preterm, the expected reaction of the parents would be to protect the child even more than the average child so no further harm can result. In reality, particularly in reference to preterm children, the opposite may occur. Preterm children are at high risk for abuse (Sirotnak & Krugman, 2008). This is probably because of the separation of the child from the family at birth, which interferes with bonding. Child abuse is discussed in Chapter 55.

What if... Mrs. Atkins is about to visit her preterm newborn for the first time and states, "I'm so scared. He's so tiny and frail. How can I even hold him?" How should you respond to this new mother to make her visit easier?

THE NEWBORN AT RISK BECAUSE OF ALTERED GESTATIONAL AGE OR BIRTH WEIGHT

Infants need to be evaluated as soon as possible after birth to determine their weight and gestational age as classification by growth charts and gestational history is important to determine immediate health care needs and to help anticipate possible problems. Birth weight is normally plotted on a growth chart such as the Colorado (Lubchenco) Intrauterine Growth Chart (see Appendix E). Infants born after the beginning of week 38 and before week 42 of pregnancy (calculated from the first day of the last menstrual period) are classified as *term*

infants. Approximately 90% of all live births are term. Infants born before term (less than the full 37th week of pregnancy) account for approximately 7% to 19% of all births and are classified as **preterm infants,** regardless of their birth weight. Infants born after the onset of week 43 of pregnancy are classified as postterm, dysmature, or postmature (Fortner, Althaus, & Gurewitsch, 2007).

Normally, birth weight varies for each gestational week of age. Infants who fall between the 10th and 90th percentiles of weight for their age regardless of gestational age are considered **appropriate for gestational age (AGA).** Infants who fall below the 10th percentile of weight for their age are considered **small for gestational age (SGA).** Those who fall above the 90th percentile in weight are considered **large for gestational age (LGA).** Infants weighing under 2500 g are **low-birth-weight infants.** Those weighing 1000 to 1500 g are *very-low-birth-weight infants* (VLB). Those born weighing 500 to 1000 g are considered *extremely very-low-birth-weight infants* (EVLB). Preterm infants may be AGA, SGA, LGA, low birth weight, VLB, or EVLB.

All such infants have immediate needs that are different from or more pronounced than the needs of term newborns. Each of these categories carries its own set of potential risks.

The Small-for-Gestational-Age Infant

An infant is SGA if the birth weight is below the 10th percentile on an intrauterine growth curve for that age. SGA infants may be born preterm (before week 38 of gestation), term (between weeks 38 and 42), or postterm (past 42 weeks). SGA infants are small for their age because they have experienced **intrauterine growth restriction (IUGR)** or failed to grow at the expected rate in utero (Rahimian & Varner, 2007). This characteristic makes them distinctly different from infants whose weight is low but who are average for gestational age.

Etiology

A woman's nutrition during pregnancy plays a major role in fetal growth, so lack of adequate nutrition may be a major contributor to IUGR. Pregnant adolescents have a high incidence of SGA infants. Because adolescents must meet their own nutritional and growth needs, needs of a growing fetus can be compromised. However, the most common cause of IUGR is a placental anomaly: either the placenta did not obtain sufficient nutrients from the uterine arteries or it was inefficient at transporting nutrients to the fetus. Placental damage, such as partial placental separation with bleeding, limits placental function because the area of placenta that separated becomes infarcted and fibrosed, reducing the placental surface available for nutrient exchange. A developmental defect in the placenta can also prevent it from functioning properly. Women with systemic diseases that decrease blood flow to the placenta, such as severe diabetes mellitus or pregnancy-induced hypertension (both are diseases in which blood vessel lumens are narrowed), are at higher risk for delivering SGA babies than others. Women who smoke heavily or use narcotics also tend to have SGA infants (Rahimian & Varner, 2007).

In other instances, the placental supply of nutrients is adequate but an infant cannot use them because the infant has contracted an intrauterine infection such as rubella or toxoplasmosis or has a chromosomal abnormality.

Assessment

The SGA infant may be detected in utero when fundal height during pregnancy becomes progressively less than expected. However, if a woman is unsure of the date of her last menstrual period, this discrepancy can be hard to substantiate. A sonogram can then demonstrate the decreased size. A biophysical profile including a nonstress test, placental grading, amniotic fluid amount, and ultrasound examination can provide additional information on placental function. If poor placental function is apparent from such determinations, it can be predicted the infant will do poorly during labor because of periods of relative hypoxia during contractions may result. Cesarean birth is the birth method of choice in such circumstances.

Appearance. Generally, an infant who suffers nutritional deprivation early in pregnancy, when fetal growth consists primarily of an increase in the number of body cells, is below average in weight, length, and head circumference. An infant who suffers deprivation late in pregnancy, when growth consists primarily of an increase in cell size, may have only a reduction in weight. Regardless of when deprivation occurs, an infant tends to have an overall wasted appearance. The child may have a small liver, which can cause difficulty regulating glucose, protein, and bilirubin levels after birth. The infant also may have poor skin turgor and generally appear to have a large head because the rest of the body is so small. Skull sutures may be widely separated from lack of normal bone growth. Hair is dull and lusterless. The abdomen may be sunken. The umbilical cord often appears dry and may be stained yellow.

In contrast, because an infant's age is more advanced than the weight implies, a child may have better-developed neurologic responses, sole creases, and ear cartilage than expected for a baby of that weight. The skull may be firmer, and the infant may seem unusually alert and active for that weight. The SGA infant needs careful assessment for possible congenital anomalies occurring as a result of the poor nutritional intrauterine environment.

Laboratory Findings. Blood studies at birth usually show a high hematocrit level (less than normal amounts of plasma in proportion to red blood cells are present because of a lack of fluid in utero) and an increase in the total number of red blood cells (polycythemia). The increase in red blood cells occurs because anoxia during intrauterine life stimulates the development of red blood cells. The polycythemia that results causes increased blood viscosity, a condition that puts extra work on the infant's heart because it is more difficult to effectively circulate thick blood. As a consequence, acrocyanosis (blueness of the hands and feet) may be prolonged and persistently more marked than usual. If the polycythemia is extreme, vessels may actually become blocked and thrombus formation can result. If the hematocrit level is more than 65% to 70%, an exchange transfusion to dilute the blood may be necessary.

Because SGA infants have decreased glycogen stores, one of the most common problems is hypoglycemia (decreased blood glucose, or a level below 45 mg/dL). Such infants may need intravenous glucose to sustain blood sugar until they are able to suck vigorously enough to take sufficient oral feedings.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Ineffective breathing pattern related to underdeveloped body systems at birth

Outcome Evaluation: Newborn maintains respirations at a rate of 30 to 60 breaths per minute after resuscitation at birth.

Birth asphyxia is a common problem for SGA infants, both because they have underdeveloped chest muscles and because they are at risk for developing meconium aspiration syndrome as a result of anoxia during labor. Fetal hypoxia causes a reflex relaxation of the anal sphincter and increased intestinal movement. When gasping for breath in utero, the fetus draws meconium that was discharged from the intestine into the amniotic fluid down into the trachea and bronchi. Acting as a foreign substance, this blocks airflow into the alveoli, leading to hypoxemia, acidosis, and hypercapnia. For this reason, many SGA infants require resuscitation at birth. Closely observe both respiratory rate and character in the first few hours of life. Underdeveloped chest muscles can make SGA infants unable to sustain the rapid respiratory rate of a normal newborn.

Nursing Diagnosis: Risk for ineffective thermoregulation related to lack of subcutaneous fat

Outcome Evaluation: Infant's temperature is maintained at 36.5° C (97.8° F) axillary.

SGA infants are less able to control body temperature than other newborns because they lack subcutaneous fat. A carefully controlled environment is essential to keep the infant's body temperature in a neutral zone (see Chapter 18).

Nursing Diagnosis: Risk for impaired parenting related to child's high-risk status and possible cognitive or neurologic impairment from lack of nutrients in utero

Outcome Evaluation: Parents express interest in infant and ask questions about what the child's care needs will be at home.

Although SGA infants may gain weight and appear to thrive in the first few days of life, their cognitive development may have been impaired because of lack of oxygen and nourishment in utero. Babies who were growing normally in utero but whose gestation was interrupted preterm (true preterm babies) usually gain weight and height so rapidly that by the end of the first year of life they are near the 50th percentile on growth charts. SGA infants, in contrast, may always be below usual on standard growth charts. This inability to reach normal levels of growth and development may interfere with bonding because a child does not meet the parents' expectations. Eventually, it can interfere with the child's self-esteem if the child is never able to meet parental expectations or reach full height.

An SGA infant needs adequate stimulation during the infant period to reach normal growth and developmental milestones. Encourage parents to provide toys suitable for their child's chronologic age, not physical size. Because an infant tires easily in the first few weeks of life, urge them to space play periods with rest periods or hypoglycemia or apnea can occur. All infants with IUGR need continued follow-up after hospital discharge as they may have neurologic deficits that will interfere with learning at school age (Leitner et al., 2007).

✔ Checkpoint Question 26.2

Why are small-for-gestational-age newborns at risk for difficulty maintaining body temperature?

a. They are preterm so they are born relatively small in size.
b. They are more active than usual so they throw off covers.
c. They do not have as much fat stores as do other infants.
d. Their skin is more susceptible to conduction of cold.

The Large-for-Gestational-Age Infant

An infant is LGA (also termed **macrosomia)** if the birth weight is above the 90th percentile on an intrauterine growth chart for that gestational age. Such a baby appears deceptively healthy at birth because of the weight, but a gestational age examination will reveal immature development. It is important that LGA infants be identified immediately so that they can be given care appropriate to their gestational age rather than being treated as term newborns (Lawrence, 2007).

Etiology

Infants who are LGA have been subjected to an overproduction of growth hormone in utero. This happens most often to infants of women with diabetes mellitus or women who are obese (Strehlow et al., 2007). Extreme macrosomia occurs in fetuses of diabetic women whose symptoms are poorly controlled, because these fetuses are exposed to high glucose levels. Multiparous women are also prone to have large babies because with each succeeding pregnancy, babies tend to grow larger. Other conditions associated with LGA infants include transposition of the great vessels, Beckwith syndrome (a rare condition characterized by overgrowth), and congenital anomalies such as omphalocele.

Assessment

A fetus is suspected of being LGA when a woman's uterus is unusually large for the date of pregnancy. Abdominal size can be deceptive, however—because a fetus lies in a flexed fetal position, he or she does not occupy significantly more space at 10 lb than at 7 lb. If a fetus does seem to be growing at an abnormally rapid rate, a sonogram can confirm the suspicion. A nonstress test to assess the placenta's ability to sustain a large fetus during labor may be performed. To see if an LGA fetus is mature, lung maturity may be assessed by amniocentesis.

If an infant's large size was not detected during pregnancy, it may be first recognized during labor when the baby cannot descend through the pelvic rim. If this happens, cesarean birth may be necessary to avoid **shoulder dystocia** (the wide fetal shoulders cannot pass through the outlet of the pelvis).

Appearance. At birth, LGA infants may show immature reflexes and low scores on gestational age examinations in relation to their size. They may have extensive bruising or a birth injury such as a broken clavicle or Erb-Duchenne

paralysis from trauma to the cervical nerves if they were born vaginally (see Chapter 51). Because the head is large, it may have been exposed to more than the usual amount of pressure during birth, causing a prominent caput succedaneum, cephalhematoma, or molding.

An LGA newborn requires the same cautious care necessary for a preterm infant. Specific criteria for initial or continuing assessment are shown in Table 26.1.

Cardiovascular Dysfunction. Observe LGA infants closely for signs of hyperbilirubinemia (increased serum bilirubin level), which may result from absorption of blood from bruising and polycythemia. Polycythemia has been caused by an infant's system attempting to fully oxygenate all body tissues. This effort puts extra stress on the heart, so the heart rate of LGA infants should be carefully observed. If cyanosis is present, it may be a sign of transposition of the great vessels, a serious heart anomaly associated with macrosomia (see Chapter 41).

Hypoglycemia. LGA infants also need to be carefully assessed for hypoglycemia in the early hours of life because infants require large amounts of nutritional stores to sustain their weight. If the mother had diabetes that was poorly controlled, the infant will have had an increased blood glucose level in utero causing the infant to produce elevated levels of insulin. After birth, these increased insulin levels will continue for up to 24 hours of life, possibly causing rebound hypoglycemia.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Ineffective breathing pattern related to possible birth trauma in LGA newborn

Outcome Evaluation: Newborn initiates breathing at birth; maintains normal newborn respiratory rate of 30 to 60 breaths per minute.

Some LGA infants have difficulty establishing respirations at birth because of birth trauma. Increased intracranial pressure from birth of the larger-than-usual head could have led to pressure on the respiratory center. This, in turn, can cause a decrease in respiratory function. A diaphragmatic paralysis may occur because of cervical nerve trauma as the head is bent sideways to allow for birth of the large shoulders. This prevents active lung motion on the affected side. If an infant was born by cesarean birth, transient fluid can remain in the lungs and interfere with effective gas exchange. Careful observation is needed to detect these conditions. Care of an infant with transient lung fluid is discussed later in this chapter.

Nursing Diagnosis: Risk for imbalanced nutrition, less than body requirements, related to additional nutrients needed to maintain weight and prevent hypoglycemia

Outcome Evaluation: Infant's weight follows percentile growth curve; skin turgor is good; specific gravity of urine is 1.003 to 1.030; serum glucose is above 45 mg/dL.

As a rule, an LGA infant needs to be breastfed immediately to prevent hypoglycemia. The infant may need supplemental formula feedings after breastfeeding to supply enough fluid and glucose for the larger-than-normal size for the first few days. Newborns who are offered bottles often have more difficulty than do others learning to breastfeed. Offer both the mother and baby support to overcome this hurdle.

Do not overestimate LGA infants' ability to suck effectively at birth. Such infants may seem as if they should be able to suck well because they are already the size of a 2-month-old. However, the infant is an inexperienced newborn, so sucking may not be effective enough to obtain the larger-than-usual amount of milk needed.

Nursing Diagnosis: Risk for impaired parenting related to high-risk status of large-for-gestational-age infant

TABLE 26.1 Important Assessment Criteria for a Large-for-Gestational-Age Infant

Assessment	Rationale
Skin color for ecchymosis, jaundice, and erythema	Bruising occurs with vaginal birth; jaundice may occur from breakdown of ecchymotic collections of blood; polycythemia causes ruddiness of skin.
Motion of extremities on spontaneous movement and in response to a Moro's reflex to detect clavicle fracture (crepitus or swelling may then be palpated at the fracture site) or Erb's palsy because of edema of the cervical nerve plexus	Clavicle or cervical nerve injuries may occur because of problem at birth of wider-than-normal shoulders.
Asymmetry of the anterior chest or unilateral lack of movement to detect diaphragmatic paralysis from edema of the phrenic nerve	This cervical nerve may be stretched by birth of wide shoulders.
Eyes for evidence of unresponsive or dilated pupils; vomiting, bulging fontanelles, and a high-pitched cry suggestive of increased intracranial pressure	Compression of third, fourth, and sixth cranial nerves by increased pressure limits eye response; other signs of increased intracranial pressure may occur.
Activities such as jitteriness, lethargy, and uncoordinated eye movements that suggest seizure activity	Seizures may be caused by increased intracranial pressure; hypoglycemia seizures in newborns often produce only vague symptoms.

Outcome Evaluation: Parents hold infant; speak of the child in positive terms; state accurately why their infant needs to be closely observed in postnatal period.

Parents may underestimate this infant's needs because of the child's large size. He or she seems so big and healthy; parents may be confused about why their infant needs careful watching. They may read more into the child's condition than is present (he or she must be sick in some way they are not being told about), and so bonding does not happen as instinctively as it might. If a woman sustained a cervical or perineal tear or required a cesarean birth, she may need some time to air any resentment she may feel toward the infant for causing her extra pain. Otherwise, her perception that her infant is the cause of her additional distress may interfere with her ability to bond with the child.

An LGA infant needs the same developmental care as all infants. Singing or talking to the baby, stroking the child's back, and rocking the baby are all important for the large infant's development. Encourage parents to treat their baby as a fragile newborn who needs warm nurturing of this type, not as a tough big infant who has grown past that stage. Also remind parents an infant's birth weight is not a correlation of the child's projected adult size. Otherwise, parents may fear their infant may grow to be a larger-than-usual adult.

A Preterm Infant

A preterm infant is traditionally defined as a live-born infant born before the end of week 37 of gestation; another criterion used is a weight of less than 2500 g (5 lb 8 oz) at birth. Preterm birth occurs in approximately 7% of live births of white infants. In African American infants, the rate is doubled to approximately 14% (Thilo & Rosenberg, 2008). When a preterm infant is recognized by a gestational age assessment, observe closely for the specific problems of prematurity, such as respiratory distress syndrome, hypoglycemia, and intracranial hemorrhage.

All preterm infants need intensive care from the moment of birth to give them their best chance of survival without neurologic after-effects. A lack of lung surfactant makes them extremely vulnerable to respiratory distress syndrome (Thilo & Rosenberg, 2008).

The maturity of a newborn is determined by physical findings such as sole creases, skull firmness, ear cartilage, and neurologic findings that reveal gestational age, as well as the mother's report of the date of her last menstrual period and sonographic estimations of gestational age.

Preterm babies, regardless of their weight, need to be differentiated at birth from SGA babies (who also may have a low birth weight). The two conditions result from different situations and therefore will cause different problems in adjustment to extrauterine life. A preterm infant is immature and small but well proportioned for age. Unlike the SGA infant, this baby appears to have been doing well in utero. For an unexplained reason, however, the trigger that initiates labor was activated too early and birth resulted, even though the baby is immature. Preterm infants are invariably low-birth-weight infants. Characteristics of SGA and preterm infants are compared in Table 26.2.

Etiology

Preterm infant deaths account for 80% to 90% of infant mortality in the first year of life (NVSS, 2009). Infant mortality could be reduced dramatically if the causes of preterm birth could be discovered and corrected and all pregnancies brought to term. However, the exact cause of premature labor and early birth is rarely known.

There is a high correlation between low socioeconomic level and early termination of pregnancy. In women from middle and upper socioeconomic groups, only 4% to 8% of pregnancies are terminated early. However, in women from low socioeconomic levels, as many as 10% to 20% end before term. The major influencing factor in these instances appears to be inadequate nutrition before and during pregnancy, as a result of either lack of money for or lack of knowledge about good nutrition. Additional factors that seem to be related to preterm birth are shown in Box 26.7. Iatrogenic (health care–caused) issues, such as elective cesarean birth and inducing labor according to dates rather

TABLE 26.2 ✻ Differences Between Small-for-Gestational-Age and Preterm Infants

Characteristic	Small-for-Gestational-Age Infant	Preterm Infant
Gestational age	24–44 wk	<37 wk
Birth weight	<10th percentile	Normal for age
Congenital malformations	Strong possibility	Possibility
Pulmonary problems	Meconium aspiration, pulmonary hemorrhage, pneumothorax	Respiratory distress syndrome
Hyperbilirubinemia	Possibility	Very strong possibility
Hypoglycemia	Very strong possibility	Possibility
Intracranial hemorrhage	Strong possibility	Possibility
Apnea episodes	Possibility	Very strong possibility
Feeding problems	Most likely because of accompanying problem such as hypoglycemia	Small stomach capacity; immature sucking reflex
Weight gain in nursery	Rapid	Slow
Future restricted growth	Possibly always be <10th percentile because of poor organ development	Not likely to be restricted in growth as "catch-up" growth occurs

BOX 26.7 ✻ Common Factors Associated With Preterm Birth

- Low socioeconomic level
- Poor nutritional status
- Lack of prenatal care
- Multiple pregnancy
- Previous early birth
- Race (nonwhites have a higher incidence of prematurity than whites)
- Cigarette smoking
- Age of the mother (highest incidence is in mothers younger than age 20)
- Order of birth (early termination is highest in first pregnancies and in those beyond the fourth pregnancy)
- Closely spaced pregnancies
- Abnormalities of the mother's reproductive system, such as intrauterine septum
- Infections (especially urinary tract infection)
- Obstetric complications, such as premature rupture of membranes or premature separation of the placenta
- Early induction of labor
- Elective cesarean birth

than fetal maturity, also result in preterm births. Testing fetal maturity by amniocentesis or ultrasound is used to avoid these problems. The increasing use of assisted fertility methods such as in vitro fertilization that results in multiple births leads to an increased preterm rate as more multiple pregnancies result in preterm birth than term pregnancies (Goldenberg et al., 2008).

Assessment

Although a detailed pregnancy history may sometimes reveal the reason for a preterm birth, the pregnancy history is often normal up to the beginning of labor.

When interviewing parents of a preterm infant, be careful not to convey disapproval of reported pregnancy behaviors such as cigarette smoking or working a 12-hour shift that may have contributed to preterm birth. Once an infant is born, a new mother needs a high level of self-esteem and all of her inner resources to sustain her through the crisis. Being overburdened by guilt may be detrimental to her attempts to bond with her infant. A good answer to her direct inquiries about causes is, "No one really knows what causes prematurity." Teaching about better pregnancy practices can wait until she is ready for a second pregnancy.

In many instances, preterm labor might have been halted had a woman been able to recognize she was in true labor and not having Braxton Hicks contractions. In a first labor, this can easily occur because a woman does not know how true labor feels. Television shows often depict women in labor as having agonizingly painful contractions or the opposite, simply announcing, "This is it," and then proceeding to give birth within the 30-minute show. In reality, a first-time

FIGURE 26.6 An immature infant. Notice the lax position of limbs because of immature muscle development.

mother does not realize that labor usually begins with subtle signs and mild contractions, not with a dramatic announcement. With preterm labor, often a woman reports that she thought she was having intestinal cramps. Because each labor proceeds differently, even a multipara may miss the signs of early labor until it is too far advanced to be reversed. Reassure a woman it is understandable she did not realize what was happening until cervical dilatation had occurred and labor could not be reversed.

On gross inspection, a preterm infant appears small and underdeveloped (Fig. 26.6). The head is disproportionately large (≥3 cm greater than chest size). The skin is generally unusually ruddy because there is little subcutaneous fat beneath it; veins are easily noticeable, and a high degree of acrocyanosis may be present. The preterm neonate, 24 to 36 weeks, typically is covered with vernix caseosa. However, in very preterm newborns (less than 25 weeks' gestation), vernix is absent because it is not formed this early in pregnancy. Lanugo is usually extensive, covering the back, forearms, forehead, and sides of the face, because this amount is present until late in pregnancy. Both anterior and posterior fontanelles are small. There are few or no creases on the soles of the feet.

Physical findings and reflex testing are used to differentiate between term and preterm newborns (Fig. 26.7). The eyes of most preterm infants appear small. Although difficult to elicit, pupillary reaction is present. Ophthalmoscopic examination is extremely difficult and often uninformative because the vitreous humor may be hazy. A preterm infant has varying degrees of myopia (nearsightedness) because of lack of eye globe depth.

The ears appear large in relation to the head. The cartilage of the ear is immature and allows the pinna to fall forward. The level of the ears should be carefully inspected to rule out chromosomal abnormalities (see Chapter 7).

Neurologic function in the preterm infant is often difficult to evaluate as the neurologic system is still so immature. The observation of spontaneous or provoked movements may yield findings as important as reflex testing. If tested, reflexes such as sucking and swallowing will be absent if an infant's age is below 33 weeks; deep tendon reflexes such as the Achilles tendon reflex are also markedly diminished. During an examination, a preterm infant is much less active than a mature infant and rarely cries. If the infant does cry, the cry is weak and high-pitched.

Laboratory values for a preterm infant are compared with those of the term infant in Appendix F.

Potential Complications

Because of immaturity, preterm infants are prone to several specific conditions.

Anemia of Prematurity. Many preterm infants develop a normochromic, normocytic anemia (normal cells, just few in number). The reticulocyte count is low because the bone marrow does not increase its production until approximately 32 weeks. The infant will appear pale and may be lethargic and anorectic. The fault appears to be immaturity of the hematopoietic system combined with destruction of red blood cells because of low levels of vitamin E, which normally protects red blood cells against oxidation. Excessive blood drawing for electrolyte or blood gas analysis can potentiate the problem. For this reason, keep a record of the amount of blood drawn for analysis.

Red blood cell production can be stimulated by the administration of DNA recombinant erythropoietin. In addition, an infant may need blood transfusions to supply needed red blood cells and vitamin E and iron, which can be supplemented (Thilo & Rosenberg, 2008).

Kernicterus. Kernicterus is destruction of brain cells by invasion of indirect bilirubin (Symons & Mahoney, 2008). This invasion results from the high concentrations of indirect bilirubin in the blood from excessive breakdown of red blood cells. Preterm infants are more prone to the condition than term infants because with the acidosis that occurs from poor respiratory exchange, brain cells are more susceptible to the effect of indirect bilirubin than usually. Preterm infants also have less serum albumin available to bind indirect bilirubin and inactivate its effect. Because of this, kernicterus may occur at lower levels (as low as

A

Premature Infant

Full-term Infant

RESTING POSTURE *The premature infant is characterized by very little, if any, flexion in the upper extremities and only partial flexion of the lower extremities. The full-term infant exhibits flexion in all four extremities.*

B

Premature Infant, 28–32 Weeks

Full-term Infant

WRIST FLEXION *The wrist is flexed, applying enough pressure to get the hand as close to the forearm as possible. The angle between the hypothenar eminence and the ventral aspect of the forearm is measured. (Care must be taken not to rotate an infant's wrist.) The premature infant at 28–32 weeks' gestation will exhibit a 90-degree angle. With the full-term infant it is possible to flex the hand onto the arm.*

FIGURE 26.7 Examples of physical examination findings and reflex tests used to judge gestational age. (**A**) Resting posture. (**B**) Wrist flexion. *(continued)*

C

Premature Infant

Full-term Infant

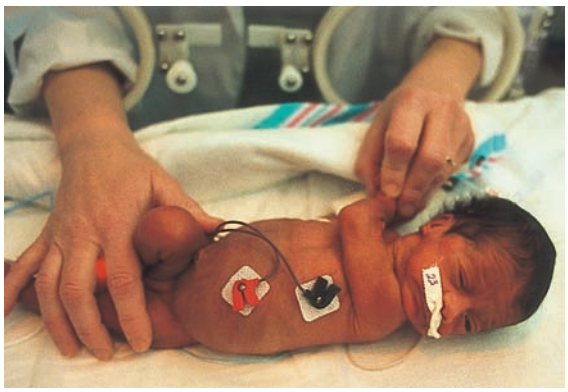
Response in Premature Infant

Response in Full-term Infant

RECOIL OF EXTREMITIES *Place an infant supine. To test recoil of the legs (1) flex the legs and knees fully and hold for 5 seconds (shown in top photographs), (2) extend the legs fully by pulling on the feet, (3) release. To test the arms, flex forearms and follow same procedure. In the premature infant response is minimal or absent* (bottom left); *in the full-term infant extremities return briskly to full flexion* (bottom right).

D

Premature Infant



Full-term Infant

SCARF SIGN *Hold the baby supine, take the hand, and try to place it around the neck and above the opposite shoulder as far posteriorly as possible. Assist this maneuver by lifting the elbow across the body. See how far across the chest the elbow will go. In the premature infant the elbow will reach near or across the midline. In the full-term infant the elbow will not reach the midline.*

FIGURE 26.7 *(continued)* (**C**) Recoil of extremities (legs). (**D**) Scarf sign. *(continued)*

Premature Infant **Full-term Infant**

E

HEEL TO EAR *With the baby supine and the hips positioned flat on the bed, draw the baby's foot as near to the ear as it will go without forcing it. Observe the distance between the foot and head as well as the degree of extension at the knee. In the premature infant very little resistance will be met. In the full-term infant there will be marked resistance; it will be impossible to draw the baby's foot to the ear.*

Premature Infant **Full-term Infant**

F

SOLE (PLANTAR) CREASES *The sole of the premature infant has very few or no creases. With the increasing gestation age, the number and depth of sole creases multiply, so that the full-term baby has creases involving the heel. (Wrinkles that occur after 24 hours of age can sometimes be confused with true creases.)*

Premature Infant **Full-term Infant**

G

BREAST TISSUE *In infants younger than 34 weeks' gestation the areola and nipple are barely visible. After 34 weeks the areola becomes raised. Also, an infant of less than 36 weeks' gestation has no breast tissue. Breast tissue arises with increasing gestational age because of maternal hormonal stimulation. Thus, an infant of 39–40 weeks will have 5–6 mm of breast tissue, and this amount will increase with age.*

FIGURE 26.7 *(continued)* (**E**) Heel to ear. (**F**) Plantar creases. (**G**) Breast tissue. *(continued)*

Premature Infant, 34–36 Weeks | **Full-term Infant**

H

EARS *At fewer than 34 weeks' gestation infants have very flat, relatively shapeless ears. Shape develops over time so that an infant between 34 and 36 weeks has a slight incurving of the superior part of the ear; the term infant is characterized by incurving of two thirds of the pinna; and in an infant older than 39 weeks the incurving continues to the lobe. If the extremely premature infant's ear is folded over, it will stay folded. Cartilage begins to appear at approximately 32 weeks so that the ear returns slowly to its original position. In an infant of more than 40 weeks' gestation, there is enough ear cartilage so that the ear stands erect away from the head and returns quickly when folded. (When folding the ear over during examination, be certain that the surrounding area is wiped clean or the ear may adhere to the vernix.)*

Premature Male | **Full-term Male**

I

MALE GENITALIA *In the premature male the testes are very high in the inguinal canal and there are very few rugae on the scrotum. The full-term infant's testes are lower in the scrotum and many rugae have developed.*

Premature Female | **Full-term Female**

J

FEMALE GENITALIA *When the premature female is positioned on her back with hips abducted, the clitoris is very prominent and the labia majora are very small and widely separated. The labia minora and the clitoris are covered by the labia majora in the full-term infant.*

FIGURE 26.7 *(continued)* (**H**) Ears. (**I**) Male genitalia. (**J**) Female genitalia. (© Caroline Brown, RNC, MS, DEd.)

12 mg per 100 mL of indirect bilirubin) in these infants. If jaundice occurs, phototherapy or exchange transfusion can be initiated to prevent excessively high indirect bilirubin levels.

Persistent Patent Ductus Arteriosus. Because preterm infants lack surfactant, their lungs are noncompliant, so it is more difficult for them to move blood from the pulmonary artery into the lungs. This condition leads to pulmonary artery hypertension, which may interfere with closure of the ductus arteriosus. Administer intravenous therapy cautiously to preterm infants to avoid increasing blood pressure and further compounding this problem. Either indomethacin or ibuprofen may be administered to close the patent ductus arteriosus (Donze, Smith, & Bryowsky, 2007). A side effect of indomethacin is oliguria, so urine output needs to be monitored closely if this is used.

Periventricular/Intraventricular Hemorrhage. Preterm infants are prone to periventricular hemorrhage (bleeding into the tissue surrounding the ventricles) or intraventricular hemorrhage (bleeding into the ventricles); these conditions occur in as many as 50% of infants of very low birth weight (Thilo & Rosenberg, 2008). This occurs because preterm infants have both fragile capillaries and immature cerebral vascular development. When there is a rapid change in cerebral blood pressure, such as with hypoxia, intravenous infusion, ventilation, or pneumothorax, capillaries rupture. An infant experiences brain anoxia distal to the rupture. Hydrocephalus may occur from bleeding into the aqueduct of Sylvius with resulting clotting and obstruction of the aqueduct. Preterm infants often have a cranial ultrasound performed after the first few days of life to detect if a hemorrhage has occurred. An infant's prognosis is guarded until it can be shown that development in an infant is progressing normally after an intracranial bleed.

Other Potential Complications. Preterm infants are particularly susceptible to several illnesses in the early postnatal period, including respiratory distress syndrome, apnea, retinopathy of prematurity (all discussed later in this chapter), and necrotizing enterocolitis (discussed in Chapter 45).

Nursing Diagnoses and Related Interventions

Because a preterm infant has few body resources, both physiologic and psychological stress must be reduced as much as possible and interventions initiated gently to prevent depletion of resources. Close observation and analysis of findings are essential to managing problems quickly.

Nursing Diagnosis: Impaired gas exchange related to immature pulmonary functioning

Outcome Evaluation: Newborn initiates breathing at birth after resuscitation; maintains normal newborn respirations of 30 to 60 breaths per minute free of assisted ventilation; exhibits oxygen saturation levels of at least 90% as evidenced by arterial blood gases (ABGs).

Many preterm babies, particularly those under 32 weeks of age, have an irregular respiratory pattern (a few quick breaths, a period of 5 to 10 seconds without respiratory effort, a few quick breaths again, and so on). There is no bradycardia with this irregular pattern (sometimes termed **periodic respirations**). Although the pattern is seen in term infants as well, it seems to be intensified by immaturity. With true apnea, the pause in respirations is more than 20 seconds and bradycardia does occur. True apnea is discussed in more detail later in this chapter.

Preterm infants have great difficulty initiating respirations at birth because pulmonary capillaries are still so immature. Lung surfactant does not form in adequate amounts until about the 34th to 35th week of pregnancy. Inadequate lung surfactant leads to alveolar collapse with each expiration. This condition forces an infant to use maximum strength to inflate lung alveoli each time. It is very difficult for infants to maintain effective expirations under these conditions. In addition, because a fetus usually turns to a vertex presentation late in pregnancy, a preterm infant may still be in a breech position at birth. Breech-born infants are apt to expel meconium into the amniotic fluid. If the fetus aspirates either vaginal secretions or meconium, the respiratory problem can be aggravated by inflammation or pneumonia.

Cesarean birth, although it has the advantage of reducing pressure on the immature head, may lead to additional respiratory complications because of retained lung fluid. Giving the mother oxygen by mask during the birth can help provide a preterm infant with optimal oxygen saturation at birth (85%–90%). Keeping maternal analgesia and anesthesia to a minimum also offers an infant the best chance of initiating effective respirations.

Even term infants experience temporary respiratory acidosis until they take a first breath. Once respirations are established, however, this condition quickly clears. Because preterm infants cannot initiate effective respirations as quickly as mature infants, they are susceptible to irreversible acidosis. Birthing room teams need to be prepared with preterm-size laryngoscopes, endotracheal tubes, suction catheters, and synthetic surfactant to be administered by the endotracheal tube so resuscitation can be accomplished within 2 minutes. Infants must be kept warm during resuscitation procedures so they are not expending extra energy to increase metabolic rate to maintain body temperature. All procedures must be carried out gently; a preterm infant's tissues are extremely sensitive to trauma and can be damaged or bruised easily by an oxygen mask. When blood from bruising is reabsorbed, this could lead to hyperbilirubinemia, yet another problem.

Giving 100% oxygen to preterm infants during resuscitation or to maintain respirations presents two additional dangers: pulmonary edema and retinopathy of prematurity (blindness of prematurity; see dis-

cussion later in this chapter) may develop. The development of both of these conditions depends on saturation of the blood with oxygen (Po_2 of more than 100 mm Hg, which usually occurs when oxygen is administered at a concentration over 70%). Although a newborn's oxygen saturation level should be continually monitored, as long as an infant is cyanotic, the blood saturation level of oxygen is likely to be low or well beneath this level.

The soft rib cartilage of a preterm infant tends to create respiratory problems because it collapses on expiration. The accessory muscles of respiration may be underdeveloped as well, leaving preterm infants with no backup muscles to use when they become fatigued from trying to maintain respirations. Because of this, preterm infants may need continued oxygen administration after resuscitation to allow them to effectively maintain respirations.

Nursing Diagnosis: Risk for deficient fluid volume related to insensible water loss at birth and small stomach capacity

Outcome Evaluation: Plasma glucose is between 40 and 60 mg per 100 mL; specific gravity of urine is maintained at 1.003 to 1.030; urine output is maintained at a minimum of 1 mL/kg/hr; electrolyte levels are within normal limits.

A preterm newborn experiences a high insensible water loss because of a large body surface relative to total body weight. Preterm infants also cannot concentrate urine well because of immature kidney function. Because of this, a high proportion of body fluid is excreted. All these factors make it important for a preterm baby to receive up to 160 to 200 mL of fluid per kilogram of body weight daily (higher than the term infant).

Intravenous fluid administration typically begins within hours after birth to fulfill this fluid requirement and provide glucose to prevent hypoglycemia. Intravenous fluid should be given via a continuous infusion pump to ensure a constant infusion rate and prevent accidental overload. Intravenous sites must be checked conscientiously because if infiltration should occur, the lack of subcutaneous tissue places a preterm newborn at risk for damaged tissue. Specially designed 27-gauge needles are available for use on small veins. However, many preterm infants lack adequately sized peripheral veins for even this small a needle. Therefore, they need to receive intravenous fluid by an umbilical venous catheter.

Monitor the baby's weight, urine output and specific gravity, and serum electrolytes to ensure adequate fluid intake. Too little fluid and calories can lead to dehydration and starvation, acidosis, and weight loss. Overhydration may lead to nonnutritional weight gain, pulmonary edema, and heart failure.

Most preterm infants void and pass meconium within 24 hours after birth, although this is delayed in very small infants. Measure urine output by weighing diapers rather than using urine collection bags, as disposable collection bags can lead to skin irritation and breakdown from frequent changing and leaking.

The amount of urine output for the first few days of life in preterm babies is high in comparison with that of the term baby because of poor urine concentration: 40 to 100 mL per kg per 24 hours, compared with 10 to 20 mL per kg per 24 hours. The specific gravity is low, rarely more than 1.012 (normal term babies may concentrate urine up to 1.030). Also, test urine for glucose and ketones. Hyperglycemia caused by the glucose infusion may lead to glucose spillage into the urine and an accompanying diuresis. If too little glucose is being supplied and body cells are using protein for metabolism, ketone bodies will appear in urine.

Blood glucose determinations every 4 to 6 hours help to determine hypoglycemia or hyperglycemia (increased serum glucose). Blood glucose should range between 40 and 60 mg/dL. Because of the numerous blood tests performed, be certain to keep a record of all blood drawn so an infant does not become hypovolemic from the amount removed. Check for blood in stools to evaluate possible bleeding from the intestinal tract. This is helpful in determining the possible cause of hypovolemia if it occurs.

Nursing Diagnosis: Risk for imbalanced nutrition, less than body requirements, related to additional nutrients needed for maintenance of rapid growth, possible sucking difficulty, and small stomach

Outcome Evaluation: Infant's weight follows percentile growth curve; skin turgor is good; specific gravity of urine is maintained between 1.003 and 1.030; infant has no more than 15% weight loss in first 3 days of life and continues to gain weight after this point.

Nutrition problems can arise with a preterm infant because the infant's body is attempting to continue to maintain the rapid rate of intrauterine growth. Because of this, a preterm newborn requires a larger amount of nutrients than the mature infant. If these nutrients are not supplied, an infant can develop hypocalcemia (decreased serum calcium) or azotemia (low protein level in blood). Delayed feeding and a resultant decrease in intestinal motility may also add to hyperbilirubinemia, a problem an infant already is at high risk of developing when fetal red blood cells begin to be destroyed.

Digestion and absorption of nutrients in a preterm infant's stomach and intestine may be immature. Nutrition problems are further compounded by a preterm infant's immature reflexes, which make swallowing and sucking difficult. Increased activity that occurs from ineffective sucking may increase the metabolic rate and oxygen requirements. This increases the caloric requirements even more. In addition, the preterm infant's stomach capacity is small, possibly limiting adequate intake. If a small stomach is distended from a full feeding, this puts pressure on the diaphragm and can lead to respiratory distress. An immature cardiac sphincter (between the stomach and esophagus) allows regurgitation to occur readily. The lack of a cough reflex may lead an infant to aspirate regurgitated formula.

Feeding Schedule. With the early administration of intravenous fluid to prevent hypoglycemia and supply

fluid, feedings may be safely delayed until an infant has stabilized his or her respiratory effort from birth. Preterm infants may be fed by total parenteral nutrition until they are stable enough for other means. Breast, gavage, or bottle feedings are begun as soon as an infant is able to tolerate them to prevent deterioration of the intestinal villi. Most preterm infants have a chest radiograph taken before a first feeding. The presence of air in the stomach shows that the route to the stomach is clear.

A preterm infant needs 115 to 140 calories per kilogram of body weight per day, compared with 100 to 110 needed by a term infant. Protein requirements are 3 to 3.5 g per kilogram of body weight, compared with 2.0 to 2.5 for a term newborn. Because preterm infants have a smaller stomach capacity than term neonates, they cannot take large feedings and so must be fed more frequently with smaller amounts. Feedings may be as small as 1 or 2 mL every 2 to 3 hours.

Gavage Feeding. A gag reflex is not intact until 32 weeks' gestation. Although a sucking reflex is present earlier, the ability to coordinate sucking and swallowing is inconsistent until approximately 34 weeks' gestation. Infants who are born before 32 to 34 weeks' gestation and those who are ill or experiencing respiratory distress are usually started on gavage feedings. Bottle feeding or breastfeeding is gradually introduced as an infant matures and begins to demonstrate feeding behaviors such as being awake, moving or fussing as if hungry (Fig. 26.8). To avoid tiring, preterm nipples that are softer than regular nipples are used.

Observe preterm infants closely after both oral and gavage feeding to be certain their filled stomach is not causing respiratory distress. Offering a pacifier during gavage feeding can help strengthen the sucking reflex, better prepare an infant for bottle feeding or breastfeeding, and provide oral satisfaction. In addition, initiating and maintaining nonnutritive sucking can help a newborn remember how to suck.

Gavage feedings may be given intermittently every few hours or continuously via tubes passed into the stomach or intestine through the mouth or nose. Infants may be fed by continuous drip feedings at about 1 mL/hr. This can be helpful for infants on ventilators or those who experience oxygen deprivation with handling. If feedings are given intermittently, stomach secretions are usually aspirated, measured, and replaced before each feeding. An infant who has a stomach content of more than 2 mL just before a feeding is receiving more formula than he or she can digest in the time allowed. Feedings should not be increased and possibly even cut back to ensure better digestion and to decrease the possibility of regurgitation and aspiration. Inability to digest this way is also a sign that necrotizing enterocolitis, a destructive intestinal disorder that often occurs in preterm babies, may be developing (Raab, 2007) (see Chapter 45).

FIGURE 26.8 Feeding a preterm infant. Notice the small bottle used. (© Caroline Brown, RNC, MS, DEd.)

Formula. The caloric concentration of formulas used for preterm infants is usually 24 cal/oz, compared with 20 cal/oz for a term baby. Supplementing additional minerals such as iron, calcium, and phosphorus and electrolytes such as sodium, potassium, and chloride may be necessary, depending on the newborn's blood studies. As with a term neonate, vitamin K should be administered at birth. However, the amount administered is more often 0.5 mL instead of 1 mL because of the infant's small size. Vitamin A is important in improving healing and possibly reducing the incidence of lung disease (Wiswell, Tin, & Ohler, 2007). Vitamin E seems to be important in preventing hemolytic anemia in preterm infants.

Breast Milk. There is increasing evidence that although preterm infants grow well on the increased caloric distribution of commercial formulas, the best milk for them, the same as with term infants, is breast milk (Sisk et al., 2007). The immunologic properties of breast milk apparently play a major role in preventing neonatal necrotizing enterocolitis, as well as increase immune defenses (Conti, 2007).

The mother who wants to breastfeed can manually express breast milk for her infant's gavage feedings. If she cannot bring this in daily, expressed breast milk can be frozen for safe transport and storage. The sodium content of breast milk in a mother whose infant has been born preterm is higher than that of milk in a mother whose infant has been born at term. Therefore, it is better for infants to receive their own mother's breast milk rather than banked milk. This high level of sodium is necessary for fluid retention in the preterm infant. Breast milk is 20 cal/oz, so parents may be advised to add a human milk fortifier to supplemental bottles of breast milk to supply additional calories, protein, vitamins, and minerals (Conti, 2007). Mothers should continue to breastfeed their preterm infants after hospital discharge (Greer, 2007).

Nursing Diagnosis: Ineffective thermoregulation related to immaturity

Outcome Evaluation: Infant's temperature is maintained at 97.6° F (36.5° C) axillary.

Preterm newborns have a great deal of difficulty maintaining body temperature because they have a rela-

tively large surface area per kilogram of body weight. In addition, because they do not flex their body well but remain in an extended position, rapid cooling from evaporation is more likely to occur (Knobel & Holditch-Davis, 2007).

A preterm infant has little subcutaneous fat for insulation and poor muscular development and so cannot move as actively as an older infant to produce body heat. A preterm infant also has a limited amount of **brown fat,** the special tissue present in newborns to maintain body temperature. Preterm infants also cannot shiver, a useful mechanism to increase body temperature; at the same time, they cannot sweat and thereby reduce body temperature because of an immature central nervous system and hypothalamic control. This makes preterm infants dependent on the environmental temperature provided to keep warm. In a birthing room, typically kept at 62° to 68° F (16.6° to 20° C), preterm infants should be kept under radiant heat warmers or warmed by skin-to-skin contact. A 1500-g infant exposed to this low a temperature loses 1° C of body heat every 3 minutes if left unprotected.

Be certain that a radiant heat warmer is warmed before the infant is born. Unless there are obvious abnormalities noted when the child is born, physical assessment of a preterm infant, even weighing, can be delayed until the infant can be placed in the warmth of an incubator or under a radiant warmer with a servocontrol.

If an infant is going to be transported to a department within the hospital, such as the x-ray department, or to a regional center for specialized care, keeping the newborn warm during transport is crucial. Remember infants lose heat by radiation as well as conduction. If a warmed incubator is placed near a cold window or air conditioner or in a cold transport ambulance, the infant will lose heat to the distant source. An additional heat shield or plastic wrap may be placed over an infant on a radiant warmer to help conserve heat during transport.

Nursing Diagnosis: Risk for infection related to immature immune defenses in preterm infant

Outcome Evaluation: Temperature is maintained at 97.6° F (36.5° C) axillary; further signs and symptoms of infection such as poor growth or a reduced temperature are absent.

The skin of a preterm baby is easily traumatized and therefore offers less resistance to infection than the skin and mucous membrane of a mature baby. In addition, preterm infants have a lowered resistance to infection. They have difficulty producing phagocytes to localize infection and have a deficiency of IgM antibodies because of insufficient production. To help prevent infection, linen and equipment used with preterm infants must not be shared with other infants. Staff members must be free of infection, and handwashing and gowning regulations should be strictly enforced.

Nursing Diagnosis: Risk for impaired parenting related to interference with parent–infant attachment resulting from hospitalization of infant at birth

Outcome Evaluation: Parents visit frequently and hold infant; speak of him or her in positive terms.

In a preterm infant, the first and second periods of reactivity normally observed in newborns at 1 hour and 4 hours of life (see Chapter 18) may be delayed. In some infants, no period of increased activity or tachycardia may appear until 12 to 18 hours of age. If the purpose of a period of reactivity is to stimulate respiratory function, this places a preterm infant at an even greater threat of respiratory failure, because respiratory efforts may not be stimulated. A second consequence of a delayed period of reactivity is the loss of an opportunity for interaction between parents and the newborn in the early postpartum period.

At one time, a preterm infant was handled as little as possible by hospital staff to conserve the infant's energy. Parents were strictly isolated from the nursery to prevent the introduction of infection. When the child reached a "magic" weight of 4.5 or 5.5 lb, the parents were called and told their child was ready to be discharged. Some nursery personnel offered to allow the mother to feed her infant once under supervision before the day of discharge. In other nurseries, the mother was simply handed the smallest infant she had ever seen and told to take the child home and "mother" this stranger.

Although it is extremely important to conserve a preterm infant's strength by reducing sensory stimulation as much as possible and handling an infant gently, it is now recognized that preterm infants need as much loving attention as term newborns. Rocking, singing, and talking to them and gentle holding are measures to help preterm infants develop a sense of trust in people, which will enable them to relate satisfactorily to people in the future. Encourage parents to begin interacting with their infant in as normal a manner as possible as soon as possible to strengthen bonding (Box 26.8). Holding an infant with skin-to-skin contact is an effective way to begin this (Moore, Anderson, & Bergman, 2009).

Before effective bonding can be established, parents may need time to come to terms with their feelings of disappointment that the infant is so small or guilt that they were not able to stop the preterm birth. A nurse can be instrumental in helping them air these feelings and develop a more positive attitude toward their preterm infant.

If an infant cannot be removed from an incubator or a radiant heat warmer, parents can still handle and stroke the infant in the incubator or warmer. Because parents may not be psychologically ready for birth when a preterm baby is born, it may be more difficult for them to believe they have a child than if the baby were born at term. Encourage a woman to express breast milk for her infant if the child is too young to nurse. If a woman decides not to breastfeed, encourage her to come to the hospital and hold the baby before and after gavage feedings or to give bottle feedings. By feeding her baby or expressing milk for the feedings, she is directly participating in the care and taking on responsibility for the infant's welfare.

BOX 26.8 ✻ Focus on Family Teaching

Guidelines for Parents of a Newborn in Intensive Care

Q. Mrs. Atkins tells you, "I'm always afraid I'll touch the wrong thing when I visit our son in the neonatal intensive care unit. What can I do to feel more comfortable there?"

A. Here are some guidelines that should be helpful:

- Learn the name of your child's primary nurse or care manager and physician. Make a point of talking to them when you visit, so the information you receive is consistent, and these people can get to know you.
- Discuss with your child's care manager or primary nurse the time you will usually visit, so she or he can reserve this time for you. It helps them to schedule the baby's procedures and rest times so there is time during your visits for you to hold your child and interact with him.
- Ask for explanations of any equipment or medications being used with your child, so you understand the plan of care. Insist on being included in care decisions.
- If you cannot visit on any day, call the nursery and ask to talk to your child's primary care nurse or physician. Such telephone calls are not viewed as a bother but are welcomed as the mark of a concerned parent.
- If you planned to breastfeed, ask if you can supply expressed breast milk for your infant as soon as feedings are started. This contribution may help to give you a feeling of having a greater part in your baby's care.
- Supply a tape recording of your voice, so your baby can learn to recognize it, and a small toy for your baby's bed. These actions not only supply auditory and visual stimulation for your child but also help to give you a more "normal" feeling toward infant care.
- Use your baby's name when you talk about him (not "the baby") to help you gain a firm feeling that this is your baby, not the nursery's.
- If your child is hospitalized a distance from home, ask if transfer to a local hospital in a less technical environment will be possible at a later date.

If the baby is transferred to a regional center, make sure the parents have an opportunity to see the baby before the transfer. A photograph of the baby for them to keep is helpful in making the birth more real. Encourage them to visit the distant site as often as possible. Notes to convey messages from the baby to them can be taped to the incubator or warmer.

On the days they cannot visit, parents can still stay in touch by telephone or nursery e-mail. By the time a baby is ready for discharge, the parents should be able to feel they are taking home "their" baby, one whom they know and have already begun to love.

Parents visiting a high-risk nursery often need a great deal of support from nursing personnel (Box 26.9). Remember that although radiant warmers, incubators, ventilators, and monitors become familiar equipment to nurses, they are unusual and frightening to parents. A parent may want very much to touch an infant but be so

BOX 26.9 ✻ Focus on Communication

Mrs. Atkins gave birth to a 2-lb boy at 34 weeks of pregnancy, 2 days ago. The infant has been classified as a small-for-gestational-age preterm infant. Although you have told Mrs. Atkins twice that she is welcome to visit the neonatal intensive care unit (NICU), you notice that her chart indicates that she has not yet done so.

Less Effective Communication

Nurse: Mrs. Atkins, I've noticed you haven't been to the nursery to see your son yet.
Mrs. Atkins: I'm waiting for my husband to come in.
Nurse: Will that be today?
Mrs. Atkins: Tomorrow. He's out of town on business.
Nurse: Have you called the nursery to ask about your son?
Mrs. Atkins: No. I'm waiting for my husband. We'll do it together.
Nurse: Okay. Let me know if there is anything else you need.

More Effective Communication

Nurse: Mrs. Atkins, I've noticed you haven't been to the nursery to see your son yet.
Mrs. Atkins: I'm waiting for my husband to come in.
Nurse: Will that be today?
Mrs. Atkins: Tomorrow. He's out of town on business.
Nurse: Have you called the nursery to ask about your son?
Mrs. Atkins: No. I'm waiting for my husband. We'll do it together.
Nurse: Often it's intimidating to visit or telephone a high-risk nursery. I know it's important to you to go as a family, but I hate to see you miss these first few days with your son. What if I go with you?
Mrs. Atkins: Could you? I don't want to go alone.

Visiting an NICU is intimidating for parents, not only because of the high-tech equipment that surrounds their baby but also because their baby often appears much smaller or sicker than they imagined. In the first scenario, the nurse assumed that waiting for the husband to come to the hospital was what was important to the mother. In the second scenario, the nurse asked enough questions to realize that having another person accompany her to the nursery was the mother's need, a need the nurse could meet.

FIGURE 26.9 Encourage families to visit with immature infants to establish bonding. (© Caroline Brown, RNC, MS, DEd.)

afraid touching might set off an alarm that he or she stands back with arms folded instead (Fig. 26.9).

Because preterm infants are hospitalized for long periods, parents can be baffled by receiving information from a parade of different health care professionals or a different person every time they visit. Primary nursing or case management with one nurse as the consistent caregiver helps to reduce the number of people who contact the parents and who communicate the baby's nursing needs to the rest of the staff.

Making the baby's siblings as welcome in a high-risk nursery as the baby's parents is yet another major role for a nurse of high-risk infants. Check to be certain that siblings do not have an upper respiratory infection or fever. Their immunizations should be up to date and they should not have been recently exposed to a communicable disease, such as chickenpox.

Nursing Diagnosis: Deficient diversional activity (lack of stimulation) related to preterm infant's rest needs

Outcome Evaluation: Infant demonstrates interaction with caregivers by attuning to faces or voices.

Preterm infants need rest to conserve energy for growth and respiratory function, to combat hypoglycemia and infection, to stabilize temperature, and to develop inner balance and attentiveness. To allow for this, procedures should be organized to maximize the amount of rest available to an infant. If this is not a coordinated effort, an infant may be awakened constantly for procedures. Preterm infants may have more difficulty blocking out stimuli than term infants do because their nervous systems are immature. They may react negatively by such behaviors as gagging, crying, splaying fingers and toes, or going limp when exposed to bright lights, noise, or overly strenuous handling. Because these infants have little strength to move away from an unwanted stimulus, it is a caregiver's responsibility to be sensitive to these cues and move the object or noise away from the infant (Thomas & Uran, 2007). Until ready to take in stimuli, the infant may need to be shielded from noise and light as much as possible. Likewise, pain should be kept to a minimum.

At the same time as a preterm infant needs rest, he or she needs planned periods of pleasing sensory stimulation. Like all newborns, preterm infants respond best to stimulation that appeals to their senses—sight, sound, and touch. A passive face, picture, or decal may be appealing for only short periods.

The view from inside an incubator can be distorted by the acrylic dome. Most people view an infant in an incubator from the side. This means an infant's face is rarely in the same line of vision as the adult's (an en face position). It is important to look directly at an infant in the straightforward position so the infant is provided with the stimulation of a human face. As infants mature, they should have mobiles (perhaps black and white) or bright objects placed in view. As an infant's position is changed from side to stomach to opposite side, the object should be moved to be in line with the child's vision.

Infants in closed incubators may be able to hear nothing but the sound of the incubator motor. They may see people looking or nodding at them and may see their mouths moving, but they cannot benefit from the sound of their voices because this is obscured by the continuous hum of the motor. Provide some "talk time"—words spoken softly but clearly to an infant's ear—during each nursing shift to offer normal contact.

Even an infant who cannot be removed from an incubator should not suffer from lack of touch. Gently stroking an infant's back or smoothing the back of the head should not be tiring. Transcutaneous oxygen determinations allow you to recognize when an infant is comforted by handling (oxygen saturation remains steady or increases) and when the child is growing tired (oxygen saturation falls). There should be time during every nursing shift for this interaction, particularly if clinical interventions with an infant include uncomfortable procedures such as suctioning or blood drawing. As soon as infants can be out of incubators or removed from warmers, they need special time just to be rocked and held.

Nursing Diagnosis: Risk for disorganized infant behavior related to prematurity and environmental overstimulation

Outcome Evaluation: Newborn's vital signs remain within normal limits; infant demonstrates increasing ability to adapt to stimuli; demonstrates decreasing levels of irritability, crying, respiratory pauses, tachypnea, and color changes.

The amount of rest and stimulation required by preterm infants for healthy development is best individualized. **Developmental care** (care designed to meet the specific needs of each infant) can lead to increased weight gain and decreased crying and apnea spells in preterm infants (Symington & Pinelli, 2009) (Box 26.10). Because preterm infants have immature central nervous systems, their reactions or adjustments to stimuli may be different from those of term infants. The environment of an intensive care unit is also totally different from what infants would have experienced if they had remained in utero until term. Based on these two premises, nursing care must be geared toward making the environment of infants as

BOX 26.10 ✻ Developmental Care

Developmental care is individually designed care based on a preterm infant's behavioral cues to meet the special needs of a preterm infant. Common measures included are:

Parent Welcoming Procedures

- Welcoming parents to the intensive care environment by both words and actions.
- Providing room around incubators or warmers for rocking chairs so parents can hold their baby comfortably.
- Encouraging parent participation in feeding or supplying nonnutritive sucking experiences.
- Demonstrating the infant's capabilities and how, although immature, these are correct for the age or weight.
- Keeping parents informed of the baby's progress and rationale for therapies.
- Asking parents for input into the baby's rhythm of care that will best suit them and the infant after they return home.

Infant Developmental Procedures

- Providing a consistent routine to help infant develop sleep/wake cycles.
- Timing infant care and feeding based on the sleep/wake cycle of the infant.
- Clustering aspects of care so the infant enjoys the longest possible sleep intervals to conserve energy.
- Providing a "nest" with blankets to offer a sense of boundaries or security.
- Providing "quiet or rest times" by covering an incubator and limiting sound.
- Providing tactile stimulation by back stroking or massage.
- Providing audio and visual stimulation by the use of mobiles or music or a parent's voice.
- Halting procedures when the infant evidences stress.

atraumatic as possible while helping them adjust to new experiences within their limited ability.

The usual sound level of nurseries has been documented to be about 40 to 50 dB; a radio playing raises this to 60 to 65 dB. The closing of portholes or tapping on the sides of incubators raises the sound level inside them to 80 dB or more, or a sound level that can be painful. Other abnormal stimuli are bright lights for 24 hours a day, frequent handling, and painful procedures.

When a preterm infant is stressed, behaviors such as respiratory pauses, tachypnea, color changes, tremors, sighing, flaccidity, finger splaying, and gaze averting occur. Such behaviors are alerts that the environment has become too stimulating and needs to be modified. Activities such as dimming the lights or covering an incubator, turning an infant to the side and containing his body with rolled towels, offering nonnutritive sucking, and maintaining a "quiet hour" to reduce sound are all ways to reduce stimuli (Symington & Pinelli, 2009).

Nursing Diagnosis: Parental health-seeking behaviors related to preterm infant's needs for health maintenance

Outcome Evaluation: Parents describe schedule for basic immunizations and health assessments and state who will provide ongoing health care.

Discharge from an NICU is a major transition for parents as well as their infant. Before discharge, the parents of a preterm infant need to learn and practice any special methods of care necessary for their infant and interventions to help maximize their child's development. Some parents tend to overprotect preterm infants, such as not allowing visitors or not taking an infant outside. Let parents know their concern is normal, but overprotection is not necessary.

Ongoing health maintenance of a preterm infant follows the usual pattern of well-child care. Basic immunizations are given according to the chronologic age of an infant. In many communities, NICUs maintain their own well-child settings for infants who were hospitalized there. This allows for long-term follow-up studies on the effect of oxygen or drug therapy and continuity of care. Many parents prefer bringing their infant back to such a facility rather than establishing a new network of health care because they have already established trust and confidence in that health care team. This often also increases their self-esteem because they hear the staff's delight in the progress made by their child. However, preterm infants can be followed by any health care provider for well-child care.

When plotting the height and weight of preterm infants at well-child visits, remember to account for early birth on the growth chart by double charting—that is, plotting the child's weight and height according to the chronologic age (a pattern that probably in the early months places the child below the 10th percentile). Then, in another color, plot the height and weight according to an infant's "setback" or adjusted age, or the age an infant would be if he or she had been born at term. A preterm baby typically gains "catch-up" weight in the first 6 months of life, so by 1 year of age a baby plots over the 10th percentile on a growth chart without accounting for a setback age.

Evaluate growth and development of a preterm infant by the same manner. A preterm infant can be expected to meet first-year milestones not at the chronologic age but at the setback age.

To evaluate the parents' transition to having so small an infant at home, ask at health promotion visits if the parents are:

- Beginning to feel more comfortable with their infant
- Able to allow the child to stay with a babysitter or another family member
- Beginning to incorporate their infant normally into their family life
- Making plans for the infant beyond the immediate newborn period

The Postterm Infant

A postterm infant is one born after the 42nd week of a pregnancy (Fortner, Althaus, & Gurewitsch, 2007). Most nurse-midwives and obstetricians recommend inducing labor at 2 weeks postterm to avoid postmature births. However, when gestational age has been miscalculated or if for some other reason labor is not induced until week 43 of pregnancy or after, the pregnancy may result in a postterm infant.

An infant who stays in utero past week 42 of pregnancy is at special risk because a placenta appears to function effectively for only 40 weeks. After that time, it seems to lose its ability to carry nutrients effectively to the fetus. A fetus who remains in utero with a failing placenta may die or develop **postterm syndrome.** Infants with this syndrome have many of the characteristics of the SGA infant: dry, cracked, almost leather-like skin from lack of fluid, and absence of vernix. They may be lightweight from a recent weight loss that occurred because of the poor placental function. The amount of amniotic fluid may be less at birth than normal, and it may be meconium stained. Fingernails will have grown well beyond the end of the fingertips. Such infants may demonstrate an alertness much more like a 2-week-old baby than a newborn.

When a pregnancy becomes postterm, a sonogram is usually obtained to measure the biparietal diameter of the fetus. A nonstress test or complete biophysical profile (see Chapter 9) may be done to establish whether the placenta is still functioning adequately. Cesarean birth may be indicated if a nonstress test reveals that compromised placental functioning may occur during labor.

At birth, the postterm baby is likely to have difficulty establishing respirations, especially if meconium aspiration occurred. In the first hours of life, hypoglycemia may develop because the fetus had to use stores of glycogen for nourishment in the last weeks of intrauterine life. Subcutaneous fat levels may also be low, having been used in utero. This can make temperature regulation difficult, making it important to prevent a postterm infant from becoming chilled at birth or during transport. Polycythemia may have developed from decreased oxygenation in the final weeks. The hematocrit may be elevated because the polycythemia and dehydration have lowered the circulating plasma level.

Any woman is anxious when she does not have her baby on her due date. She is apt to become extremely anxious and perhaps angry when it is determined her baby is postterm or should have been born earlier. It may seem that if a baby stayed so long in utero, the baby should be extra healthy and strong. Why, then, she asks, is her baby being transferred for special care? A mother may also feel guilty for not providing well for her infant in the last few weeks of pregnancy.

Make sure a woman spends enough time with her newborn to assure herself that although birth did not occur at the predicted time, the baby should do well with appropriate interventions to control possible hypoglycemia or meconium aspiration. All postterm infants need follow-up care until at least school age to track their developmental abilities. The lack of nutrients and oxygen in utero may have left them with neurologic symptoms that will not become apparent until they attempt fine-motor tasks.

ILLNESS IN THE NEWBORN

A number of illnesses occur specifically in newborns. These automatically cause the infant to become high risk.

Respiratory Distress Syndrome

Respiratory distress syndrome (RDS) of the newborn, formerly termed *hyaline membrane disease,* most often occurs in preterm infants, infants of diabetic mothers, infants born by cesarean birth, or those who for any reason have decreased blood perfusion of the lungs, such as occurs with meconium aspiration (Raab, 2007). The pathologic feature of RDS is a hyaline-like (fibrous) membrane formed from an exudate of an infant's blood that begins to line the terminal bronchioles, alveolar ducts, and alveoli. This membrane prevents exchange of oxygen and carbon dioxide at the alveolar–capillary membrane. The cause of RDS is a low level or absence of surfactant, the phospholipid that normally lines the alveoli and reduces surface tension to keep the alveoli from collapsing on expiration.

Because surfactant does not form until the 34th week of gestation, as many as 30% of low-birth-weight infants and as many as 50% of very-low-birth-weight infants are susceptible to this complication.

Pathophysiology

High pressure is required to fill the lungs with air for the first time and overcome the pressure of lung fluid. For example, it takes a pressure between 40 and 70 cm H_2O to inspire a first breath but only 15 to 20 cm H_2O to maintain quiet, continued breathing. If alveoli collapse with each expiration, as happens when surfactant is deficient, forceful inspirations requiring optimum pressure are still required to inflate them.

Even very immature infants release a bolus of surfactant at birth into their lungs from the stress of birth. However, with deficient surfactant, areas of hypoinflation begin to occur and pulmonary resistance increases. Blood then shunts through the foramen ovale and the ductus arteriosus as it did during fetal life. The lungs are poorly perfused, affecting gas exchange. As a result, the production of surfactant decreases even further.

The poor oxygen exchange that results leads to tissue hypoxia, which causes the release of lactic acid. This, combined with the increasing carbon dioxide level resulting from the formation of the hyaline membrane on the alveolar surface, leads to severe acidosis. Acidosis causes vasoconstriction, and decreased pulmonary perfusion from vasoconstriction further limits surfactant production. With decreased surfactant production, the ability to stop alveoli from collapsing with each expiration becomes impaired. This vicious cycle continues until the oxygen–carbon dioxide exchange in the alveoli is no longer adequate to sustain life without ventilator support.

Assessment

Most infants who develop RDS have difficulty initiating respirations at birth. After resuscitation, they appear to have a period of hours or a day when they are free of symptoms because of an initial release of surfactant. During this time, however, subtle signs may appear:

- Low body temperature
- Nasal flaring

- Sternal and subcostal retractions
- Tachypnea (more than 60 respirations per minute)
- Cyanotic mucous membranes

Within several hours, expiratory grunting, caused by closure of the glottis to create a prolonged expiratory time, can be heard. A partially closed glottis this way is helpful as it increases the pressure in the alveoli on expiration, helps to keep the alveoli from collapsing, and makes oxygen exchange more complete. Even with this attempt at better oxygen exchange, however, as the disease progresses, infants become cyanotic and their P_{O_2} and oxygen saturation levels fall in room air. On auscultation, there may be fine rales and diminished breath sounds because of poor air entry. As distress increases, an infant may exhibit:

- Seesaw respirations (on inspiration, the anterior chest wall retracts and the abdomen protrudes; on expiration, the sternum rises)
- Heart failure, evidenced by decreased urine output and edema of the extremities
- Pale gray skin
- Periods of apnea
- Bradycardia
- Pneumothorax

The diagnosis of RDS is made on the clinical signs of grunting, central cyanosis in room air, tachypnea, nasal flaring, retractions, and shock. A chest radiograph will reveal a diffuse pattern of radiopaque areas that look like ground glass (haziness). Blood gas studies (taken from an umbilical vessel catheter) will reveal respiratory acidosis. A β-hemolytic, group B streptococcal infection may mimic RDS, as this infection is so severe in newborns that the insult to the lungs is enough to stop surfactant production. Cultures of blood, cerebrospinal fluid, and skin may be obtained to rule out this condition. An antibiotic (penicillin or ampicillin) and an aminoglycoside (gentamicin or kanamycin) may be started while culture reports are pending.

Therapeutic Management

RDS can be largely prevented by the administration of surfactant through an endotracheal tube at birth for an infant at risk because of low gestational age.

Surfactant Replacement. As a preventive measure, synthetic surfactant is sprayed into the lungs by a syringe or catheter through an endotracheal tube at birth while an infant is first positioned with the head held upright and then tilted downward. It is important an infant's airway not be suctioned for as long a period as possible after administration of surfactant to avoid suctioning the drug away. Although there are almost no unfavorable reactions to surfactant administration, some, such as mucus plugging from the solution, do occur. An infant who is receiving surfactant and then is placed on a ventilator needs close observation because lung expansion can improve rapidly. Anticipate the need to adjust ventilator settings to prevent excessive lung pressure.

Oxygen Administration. Administration of oxygen is necessary to maintain correct P_{O_2} and pH levels. Continuous positive airway pressure (CPAP) or assisted ventilation with positive end-expiratory pressure (PEEP) will exert pressure on the alveoli at the end of expiration and keep the alveoli from collapsing (Ho et al., 2009). This greatly improves oxygen exchange. A possible complication of oxygen therapy in the very immature or very ill infant is retinopathy of prematurity (see discussion later in chapter) or bronchopulmonary dysplasia (see Chapter 40).

Ventilation. Normally, on a ventilator, inspiration is shorter than expiration, or there is an inspiratory/expiratory ratio (I/E ratio) of 1:2. It is difficult to deliver enough oxygen to stiff, noncompliant lungs in this usual ratio, however, without forcing the air into the lungs at such a high pressure and rapid rate that a pneumothorax becomes a constant concern (Snow & Brandon, 2007). Infant ventilators are therefore available with a reversed I/E ratio (2:1). These are pressure-cycled to control the force with which air is delivered. High-frequency, oscillatory, and jet ventilation are other methods of introducing oxygen to infants with noncompliant lungs. These systems maintain airway pressure and then intermittently "jet" or oscillate at a rapid rate (400–600 times a minute) an additional amount of air to inflate alveoli.

Complications of any type of ventilation are possible, such as pneumothorax and impaired cardiac output because of decreased blood flow through the pulmonary artery from lung pressure. There is also a possible risk of increased intracranial and arterial pressure and hemorrhage from changing blood pressure. Being certain that infants are not overhydrated is important to help prevent increased blood pressure and increased pulmonary artery pressure.

Indomethacin or ibuprofen may be used to cause closure of a patent ductus arteriosus, making ventilation more efficient (Donze, Smith, & Bryowsky, 2007). Indomethacin has been associated with adverse effects such as decreased renal function, decreased platelet count, and gastric irritation. Carefully monitor urine output and observe for bleeding, especially at puncture sites, if this is prescribed.

Additional Therapy. Yet another method of increasing pulmonary blood flow is by using muscle relaxants. Pancuronium (Pavulon) can be administered intravenously to the point of abolishing spontaneous respiratory action. Doing so allows mechanical ventilation to be accomplished at lower pressures because there is no normal muscle resistance to overcome. The possibility of pneumothorax is reduced while P_{O_2} is increased. Obviously infants who have no spontaneous respiratory function because of drug administration need critical observation and frequent ABG analysis because they totally depend on caregivers at this point (Playfor et al., 2007).

The effect of pancuronium decreases as the life of the drug expires; its effect can be interrupted by the administration of atropine or injectable neostigmine methylsulfate (Prostigmin Methylsulfate Injectable). For this reason, when pancuronium is being administered, both atropine and Prostigmin should be immediately available. An infant's plan of care should be specially marked to show that pancuronium therapy is being used so in the event of a power failure, manual ventilatory assistance can be begun immediately.

Some infants are maintained on **extracorporeal membrane oxygenation** (ECMO) to ensure adequate oxygenation (Maclaren & Butt, 2007). Other therapies include liquid ventilation or administration of perfluorocarbons and inhalation of nitric oxide (Stephens & Fawcett, 2007).

Extracorporeal Membrane Oxygenation. ECMO was first developed as a means of oxygenating blood during cardiac surgery. Its current use has expanded to the management of chronic severe hypoxemia in newborns with illnesses such as meconium aspiration, RDS, pneumonia, and diaphragmatic hernia. It is used also for near-drowning victims or infants with severe lung infection. With ECMO, blood is removed from the baby by gravity using a venous catheter advanced into the right atrium of the heart. The blood circulates from the catheter to the ECMO machine, where it is oxygenated and rewarmed. It is then returned to an infant's aortic arch by a catheter advanced through the carotid artery. ECMO is typically used for 4 to 7 days. It has many potential complications, chief of which is intracranial hemorrhage, possibly from the anticoagulation therapy necessary to prevent thromboembolism. Constant nursing care is required for a child receiving ECMO to ensure that the child's blood volume remains adequate, bleeding does not occur, and adequate oxygen is being supplied to body tissues.

Liquid Ventilation. Liquid ventilation involves the use of perfluorocarbons, substances used in industry to assess for leakage in pipes. When oxygen is bubbled through it, perfluorocarbons pick up and carry the oxygen with them. When perfluorocarbons are introduced into lungs that inflate poorly because they are deficient in surfactant, or in lungs damaged by trauma or disease, the weight of the fluid, which is heavy compared with air, helps to distend the lungs. As the liquid moves into a lung, oxygen is carried along with it; as the liquid spreads over all lung surfaces, an exchange of oxygen occurs (Lindemann et al., 2007). The administration of liquid ventilation can also be used to deliver surfactant to a newborn's lungs.

Nitric Oxide. An additional measure that can help to oxygenate a newborn's lungs is the administration of nitric oxide. This causes pulmonary vasodilation, which can be helpful to increase blood flow to the alveoli when persistent pulmonary hypertension is present (Kumar et al., 2007).

What if... While you were caring for Baby Atkins, who is ventilator dependent and receiving pancuronium, a power failure occurred? What would be your first actions?

Supportive Care. An infant with RDS must be kept warm because cooling increases acidosis in all newborns, and for the newborn with RDS it may increase to lethal levels. Keeping an infant warm also reduces the metabolic oxygen demand. Provide hydration and nutrition with intravenous fluids, glucose, or gavage feeding because the respiratory effort makes an infant too exhausted to suck (see Focus on Nursing Care Planning Box 26.11).

Prevention

RDS rarely occurs in mature infants. Dating a pregnancy by sonogram and by documenting that the level of lecithin in surfactant obtained from amniotic fluid exceeds that of sphingomyelin by 2:1 are important ways to be certain an in-

BOX 26.11 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Newborn With Respiratory Distress Syndrome

Mr. and Mrs. Atkins are the parents of a 34-week-old, 2-lb baby boy, born last night after a short, 4-hour labor.

Family Assessment ✻ Family consists of two parents. Mr. Atkins works as a consulting engineer; Mrs. Atkins worked before pregnancy as a home decorator. Mr. Atkins was out of town on business so was not present for the infant's birth. Mrs. Atkins has not visited the intensive care nursery. She refused to sign the birth certificate because she could not decide on a name. She said, "I don't want to give him our favorite name because he might die." Mr. Atkins telephoned early this morning and acted more upset the baby was born than relieved the baby was receiving intensive care. He asked his wife, "What did you do to cause this?"

Client Assessment ✻ Newborn, 5 hours old, delivered vaginally. Difficulty establishing respirations at birth. Resuscitated by the neonatal nurse practitioner and respiratory therapist and then transported to the intensive care nursery. Temperature 97.2° F (36.2° C). Bradycardic and tachypneic with grunting respirations. Sternal and subcostal retractions present. Skin pale and somewhat cyanotic. Chest x-ray with ground-glass appearance. Arterial blood gases (ABGs) reveal respiratory acidosis. Endotracheal (ET) intubation, mechanical ventilation, supplemental oxygen, and intravenous fluid therapy initiated.

Nursing Diagnosis ✻ Impaired gas exchange related to immaturity of newborn's lungs and lack of surfactant

Outcome Criteria ✻ Vital signs within acceptable parameters. Temperature maintained at 97.7° F (36.5° C). Absence of cyanosis; diminished retractions; ABG values within acceptable parameters; no sound of grunting respirations.

		Activities of Daily Living		
Nurse/ neonatal nurse practitioner	Assess respiratory rate, depth, and rhythm; auscultate lung sounds; evaluate ABG results and skin color.	Maintain respiratory program as prescribed, such as oxygen by ET tube or ventilator.	Signs of increasing respiratory distress may denote lessening air exchange.	Infant maintains a stable respiratory rate and depth with assistive respiratory aids in place.
Nurse	Assess infant's axillary temperature every hour.	Maintain a neutral thermal environment so infant's temperature remains stable.	Neutral thermal environment minimizes the risk of cold stress, which increases metabolic demands for oxygen.	Infant's temperature is maintained at 36.5° C (97.7° F) axillary.
		Consultations		
Nurse	Determine what developmental care resources will be available for infant care.	Consult with developmental care coordinator regarding specific developmental care measures for infant.	Developmental care or trying to reduce infant stress can improve infant's outcome.	Developmental care coordinator establishes an individualized program for infant care.
		Procedures/Medications		
Nurse/ neonatal nurse practitioner; physician	Assess infant's response to respiratory support. Assess oxygen saturation levels via pulse oximetry.	Maintain ET tube, mechanical ventilation, and supplemental warm humidified oxygen. Anticipate the need for CPAP or PEEP.	The ET tube protects a patent airway. Mechanical ventilation assists with delivering necessary air to the lungs. Using warm, humidified oxygen prevents cold stress and drying of mucous membranes. Oxygen saturation levels provide information about tissue oxygenation. CPAP and PEEP exert pressure on alveoli at end-expiration, preventing alveolar collapse.	Respiratory support measures are in place, and infant's respiratory rate remains within designated parameters.
Physician/nurse	Assess availability of surfactant for administration.	Administer surfactant via ET tube as per protocol. Refrain from suctioning for 1 hour if possible.	Surfactant restores the naturally occurring lung surfactant to improve lung compliance. Suctioning would remove the drug from its intended site.	Surfactant is administered.
		Nutrition		
Nurse/ nutritionist/ physician	Assess infant's need for nourishment based on gestational age and exhaustion from rapid breathing.	Administer nutrition via enteral feedings: breast milk supplemented with high-calorie formula. Anticipate the need for total parenteral nutrition if weight gain is not sufficient.	Additional nutrients are necessary because stress of RDS requires increased caloric expenditure. Total parenteral nutrition may be necessary to meet these additional needs.	Infant tolerates enteral feedings without difficulty. Mother supplies breast milk for feedings.

(continued)

BOX 26.11 ✻ Focus on Nursing Care Planning (continued)

		Nutrition		
Nurse	Assess blood glucose levels every 4 hours by heel stick.	Report hypoglycemia (blood glucose level <45 mg/dL).	Glucose is a source of energy. Monitoring glucose levels helps to determine if sufficient energy is available to meet the newborn's metabolic needs.	Infant maintains a glucose level >45 mg/dL.
		Patient/Family Education		
Nurse	Assess what parents know about the cause of preterm labor.	Teach parents that the cause of preterm birth often cannot be identified.	Parents will need to work together to arrange for best care for preterm infant.	Parents state they are adjusting to shock of preterm birth based on better knowledge of cause.
		Psychosocial/Spiritual/Emotional Needs		
Nurse	Assess what activities parents think their very small infant can accomplish.	Invite parents to see, touch, and spend as much time as possible with newborn. Guide them in activities such as skin-to-skin contact and basic caregiving.	Seeing, touching, and caring promote attachment. Guidance in activities helps to alleviate anxiety.	Parents visit in nursery or telephone at least every other day; touch and talk to newborn.
		Psychosocial/Spiritual/Emotional Needs		
Nurse	Assess if parents have worked through shock of preterm birth.	Suggest parents bring in a mobile or toy to keep near newborn.	A mobile or toy provides visual stimulation and promotes feelings of participation in the newborn's care.	Parents state they know preterm birth is no one's fault; express interest in parenting.
		Discharge Planning		
Nurse	Assess what community organizations will be available to family for continued support.	Refer parents to Web sites helpful for preterm information; suggest they join local Parents of Preemies organization.	Parents may need continued support after they return home with a small infant.	Parents give examples of how they are making active plans for infant's discharge and care.

fant born by cesarean birth or has labor induced is mature enough that RDS is not likely to occur.

Using a tocolytic agent such as terbutaline can help to prevent preterm birth for a few days. Because steroids appear to quicken the formation of lecithin, it may be possible to prevent RDS in infants by administering two injections of a glucocorticosteroid, such as betamethasone, to the mother at 12 and 24 hours during this time. This is most effective when given between weeks 24 and 34 of pregnancy. Unfortunately, there is often no warning that preterm birth is imminent until hours before birth. Because the steroid does not take effect before 24 to 48 hours, some labors and births will progress too rapidly for this preventive measure to be effective.

✔ Checkpoint Question 26.3

Baby Atkins has surfactant administered at birth. The purpose of surfactant is to:

a. Help raise lung secretions by relaxing the airway.
b. Prevent alveoli from collapsing on expiration.
c. Paralyze respiratory muscles to synchronize breathing.
d. Reduce gastric secretions by action on the pancreas.

Transient Tachypnea of the Newborn (TTN)

At birth, a newborn may have a rapid rate of respirations, up to 80 breaths per minute when crying, caused by retained lung fluid (Raab, 2007). Within 1 hour, however, this rapid rate slows to between 30 and 60 breaths per minute. In about 10 in 1000 live births, the respiratory rate remains at a high level, between 80 and 120 breaths per minute. The infant does not appear to be in a great deal of distress, aside from the tiring effort of breathing so rapidly. Mild retractions but not marked cyanosis, mild hypoxia, and hypercapnia may be present. Feeding is difficult because the child cannot suck and breathe this rapidly at the same time. A chest radiograph will reveal some fluid in the central lung, but aeration is, overall, adequate. An ultrasound may show like findings (Copetti & Cattarossi, 2007).

Transient tachypnea may reflect a slight decrease in production of phosphatidyl glycerol or mature surfactant but is a direct result of retained lung fluid. Retained lung fluid limits the amount of alveolar surface that is available for oxygen exchange. This limitation requires an infant to increase respiratory rate and depth of respirations to better use the surface available. Transient tachypnea occurs more often in infants who are born by cesarean birth, in infants whose mothers received extensive fluid administration during labor, and in preterm infants. Infants born by cesarean birth are probably more prone to develop this form of respiratory distress because the thoracic cavity is not compressed as it is in vaginal birth, so less lung fluid is expelled than normally.

Close observation of such a newborn is a priority. Watch carefully to be certain the increased effort is not tiring. Also watch for beginning signs of a more serious disorder, because a rapid respiratory rate is often the first sign of respiratory obstruction. Oxygen administration may be necessary. Transient tachypnea of the newborn peaks in intensity at approximately 36 hours of life and then begins to fade. Typically, by 72 hours of life, it spontaneously fades as the lung fluid is absorbed and respiratory activity becomes effective.

Meconium Aspiration Syndrome

Meconium is present in the fetal bowel as early as 10 weeks' gestation. If hypoxia occurs, a vagal reflex is stimulated, resulting in relaxation of the rectal sphincter. This releases meconium into the amniotic fluid. Babies born breech may expel meconium into the amniotic fluid from pressure on the buttocks. In both instances, the appearance of the fluid at birth is green to greenish black from the staining. Meconium staining occurs in approximately 10% to 12% of all pregnancies; in 2% to 9% of these pregnancies, infants will aspirate the meconium (Szymanski & Bienstock, 2007). Meconium aspiration does not tend to occur in extremely-low-birth-weight infants because the substance has not passed far enough in the bowel for it to be at the rectum in these infants.

An infant may aspirate meconium either in utero or with the first breath at birth. Meconium can cause severe respiratory distress in three ways: it causes inflammation of bronchioles because it is a foreign substance; it can block small bronchioles by mechanical plugging; and it can cause a decrease in surfactant production through lung trauma. Hypoxemia, carbon dioxide retention, and intrapulmonary and extrapulmonary shunting occur. A secondary infection of injured tissue may lead to pneumonia.

Assessment

Infants with meconium-stained amniotic fluid can have difficulty establishing respirations at birth (those who were not born breech have had a hypoxic episode in utero to cause the meconium to be in the amniotic fluid). The Apgar score is apt to be low. Almost immediately, tachypnea, retractions, and cyanosis occur.

With meconium-stained amniotic fluid, an infant should be suctioned with a bulb syringe or catheter while at the perineum, before the birth of the shoulders, to avoid meconium aspiration. Although there is some dispute regarding whether all infants with meconium staining need intubation, those with severe staining are intubated and meconium is suctioned from their trachea and bronchi (Halliday & Sweet, 2009). Do not administer oxygen under pressure (bag and mask) until an infant has been intubated and suctioned, so that the pressure of the oxygen does not drive small plugs of meconium farther down into the lungs, worsening the irritation and obstruction.

After the initiation of respirations, an infant's respiratory rate may remain elevated (tachypnea) and coarse bronchial sounds may be heard on auscultation. An infant may continue to have retractions because the inflammation of bronchi tends to trap air in the alveoli, limiting the entrance of oxygen. This air trapping may also cause enlargement of the anteroposterior diameter of the chest (barrel chest). Blood gases will reveal a poor gas exchange, evidenced by a decreased P_{O_2} and an increased P_{CO_2}. A chest radiograph will show bilateral coarse infiltrates in the lungs, with spaces of hyperaeration (a peculiar honeycomb effect). The diaphragm will be pushed downward by the overexpanded lungs.

Therapeutic Management

Amnioinfusion can be used to dilute the amount of meconium in amniotic fluid and reduce the risk of aspiration although this is usually reserved for instances where the fetus shows distress (Szymanski & Bienstock, 2007). Some infants are scheduled to be born by cesarean birth after deeply meconium-stained amniotic fluid becomes evident during labor. After birth and tracheal suction, infants may need to be treated with oxygen administration and assisted ventilation. Antibiotic therapy may be used to forestall the development of pneumonia as a secondary problem. Surfactant may be administered to increase lung compliance (El Shahed et al., 2009). Lung tissue is fairly noncompliant after meconium aspiration, which may necessitate high inspiratory pressure. This can cause pneumothorax or pneumomediastinum. Infants must be observed closely for signs of trapping air in the alveoli, because the alveoli can expand only so far and then will rupture, sending air into the pleural space (pneumothorax).

Because of increased pulmonary resistance, the ductus arteriosus may remain open, causing blood to shunt from the pulmonary artery into the aorta, compromising cardiac efficiency and increasing hypoxia. Observe an infant closely for signs of heart failure such as increased heart rate or respiratory distress. Maintain a temperature-neutral environment to prevent

increasing metabolic oxygen demands. Chest physiotherapy with clapping and vibration may be helpful to encourage removal of remnants of meconium from the lungs (see Chapter 40). Some infants will be maintained on ECMO to ensure adequate oxygenation (Radhakrishnan et al., 2007).

Although meconium aspiration is a serious insult to a newborn, with therapeutic interventions, the symptoms of this will begin to fade by a week's time with no long-term results.

Apnea

Apnea is a pause in respirations longer than 20 seconds with accompanying bradycardia. Beginning cyanosis also may be present. Many preterm infants have periods of apnea as a result of fatigue or the immaturity of their respiratory mechanisms. Babies with secondary stresses, such as infection, hyperbilirubinemia, hypoglycemia, or hypothermia, tend to have a high incidence of apnea (Thilo & Rosenberg, 2008).

Gently shaking an infant or flicking the sole of the foot often stimulates the baby to breathe again, almost as if the child needed to be reminded to maintain this function. If an infant does not respond to these simple measures, resuscitation is necessary.

Closely observe all newborns, but especially preterm ones, to detect these apneic episodes. Apnea monitors that record respiratory movements are invaluable tools to detect failing respiration and sound a warning an infant needs attention. Infants with frequent or difficult-to-correct episodes may be placed on ventilators to provide respiratory coordination until they are more mature.

To help prevent episodes of apnea, maintain a neutral thermal environment and use gentle handling to avoid excessive fatigue. Always suction gently to minimize nasopharyngeal irritation, which can cause bradycardia because of vagal stimulation. Using indwelling nasogastric tubes rather than intermittent ones can also reduce the amount of vagal stimulation. After feeding, observe an infant carefully because a full stomach can put pressure on the diaphragm and potentially compromise respirations. Careful burping also helps to reduce this effect. Never take rectal temperatures in infants prone to apnea; the resulting vagal stimulation can reduce the heart rate (bradycardia), which can lead to apnea. Theophylline or caffeine sodium benzoate may be administered to stimulate respirations. The mechanism by which these drugs reduce the incidence of apneic episodes is unclear, but they appear to increase an infant's sensitivity to carbon dioxide, ensuring better respiratory function. Infants who have had an apneic episode severe enough to require resuscitation are at a high risk for sudden infant death syndrome (SIDS). Such infants may be discharged home with a monitoring device to be used for 2 to 6 months.

Sudden Infant Death Syndrome (SIDS)

SIDS is sudden unexplained death in infancy. It tends to occur at a higher-than-usual rate in infants of adolescent mothers, infants of closely spaced pregnancies, and underweight and preterm infants. Also prone to SIDS are infants with bronchopulmonary dysplasia, twins, Native American infants, Alaskan Native infants, economically disadvantaged black infants, and infants of narcotic-dependent mothers. The peak age of incidence is 2 to 4 months of age (Barkin & James, 2007).

Although the cause of SIDS is unknown, in addition to prolonged but unexplained apnea, other possible contributing factors include:

- Viral respiratory or botulism infection
- Pulmonary edema
- Brain stem abnormalities
- Neurotransmitter deficiencies
- Heart rate abnormalities
- Distorted familial breathing patterns
- Decreased arousal responses
- Possible lack of surfactant in alveoli
- Sleeping in a room without moving air currents (the infant rebreathes expired carbon dioxide)

Typically, affected infants are well nourished. Parents report that an infant may have had a slight head cold. After being put to bed at night or for a nap, the infant is found dead a few hours later. Infants who die this way do not appear to make any sound as they die, which indicates they die with laryngospasm. Although many infants are found with blood-flecked sputum or vomitus in their mouths or on the bedclothes, this seems to occur as the result of death, not as its cause. An autopsy often reveals petechiae in the lungs and mild inflammation and congestion in the respiratory tract. However, these symptoms are not severe enough to cause sudden death. It is clear these children do not suffocate from bedclothes or choke from overfeeding, underfeeding, or crying. Since the American Academy of Pediatrics made its recommendation to put newborns to sleep on their back and with a pacifier, the incidence of SIDS has declined almost 50% (Damato, 2007). With the recommendation that infants sleep with a fan in their room to keep air moving, the incidence is expected to decrease further (Coleman-Phox, Odouli, & Li, 2008).

Parents have a difficult time accepting the death of any child. This can be especially difficult when it happens so suddenly. In discussing the child, they often use both the past and present tense as if they are not yet aware of the death. Many parents experience a period of somatic symptoms that occur with acute grief, such as nausea, stomach pain, or vertigo. Parents should be counseled by a nurse or someone else trained in counseling at the time of the infant's death; it helps if they can talk to this same person periodically for however long it takes to resolve their grief. The American Sudden Infant Death Institute, listed at the beginning of the chapter, offers suggestions for counseling.

Autopsy reports should be given to parents as soon as they are available (if toxicology tests are included in the autopsy, results will not be available for weeks). Reading that their child's death was unexplained can help to reassure parents the death was not their fault. They need this assurance if they are to plan for other children. If there are older children in the family, they also need assurance that SIDS is a disease of infants and that the strange phenomenon that invaded their home and killed a younger brother or sister will not also kill them. If they wished the infant dead, as all children wish siblings were dead on some days, they need reassurance that their wishes did not cause the baby's death.

When another child is born, parents can be expected to become extremely frightened at any sign of illness in their child. They need support to see them through the first few months of the second child's life, particularly past the point

at which the first child died. Some parents may need support to view a second child as an individual child and not as a replacement for the one who died.

Often a new baby born to a family in which a SIDS infant died is screened using a sleep assessment as a precaution within the first 2 weeks of life. Depending on the parents' level of anxiety, the new baby may receive this screening before hospital discharge. The baby may then be placed on continuous apnea monitoring pending the results of the sleep assessment.

Apparent Life-Threatening Event

Some infants have been discovered cyanotic and limp in their beds but have survived after mouth-to-mouth resuscitation by parents. An episode of this kind is called an **apparent life-threatening event** (Shah & Sharieff, 2007). For these infants as well as for preterm infants with a tendency toward apnea or new babies born to a family whose child died from SIDS, apnea monitoring is available. With apnea monitoring in place, an alarm sounds when the neonate experiences a period of apnea of 20 seconds or longer or a decreased heart rate below 80 beats per minute (Fig. 26.10). If parents are going to use an apnea monitor at home, make certain they will be able to hear it in all parts of the house or apartment. Usually the alarm is not loud enough to be heard in the basement from an upstairs bedroom. Caution them about household noises such as a loud television, radio, vacuum cleaner, or hair dryer that may interfere with hearing the alarm. Be certain they know how to apply and reposition the apnea leads and that they are comfortable enough with the monitor to see past it to the child. In addition, parents should be taught cardiopulmonary resuscitation before their infant is discharged from the hospital (Fig. 26.11).

Caring for a child at home on an apnea monitor may be extremely stressful for the parents and their relationship. They often have difficulty finding a competent babysitter.

FIGURE 26.10 An apnea monitor for home monitoring. (Photograph courtesy of Respironics/Healthdyne Technologies, Marietta, GA.)

FIGURE 26.11 Parents of infants with respiratory disorders need to learn cardiac resuscitation before their infant is discharged from the hospital. Here a nurse teaches the technique using a doll.

These parents can benefit from a community or home care referral so they have a second opinion regarding how well they are managing, as well as a listening ear to discuss the strain of having to be constantly alert for a sound that means their infant has stopped breathing. Having someone periodically review with them what steps to take should the alarm sound (jiggle the baby, begin mouth-to-mouth resuscitation, call the emergency response personnel) can be very comforting. Because SIDS is a baffling disease, these parents will live in fear of SIDS until their child reaches at least 1 year of age.

Periventricular Leukomalacia

Periventricular leukomalacia (PVL) is abnormal formation of the white matter of the brain (Tsukimori et al., 2007). It is caused by an ischemic episode that interferes with circulation to a portion of the brain. Phagocytes and macrophages invade the area to clear away necrotic tissue. What is left is an abnormality in the white matter of the brain (revealed on a sonogram as a hollow space). PVL occurs most frequently in preterm infants who experience cerebral ischemia. Once the condition has occurred, there is no therapy. Infants may die of the original insult; they may be left with long-term effects such as learning disabilities. Any action to reduce environmental stimuli or sudden shifts in cerebral blood flow, such as avoiding rapid fluid infusions or sudden noises, is important in preventing PVL and limiting the long-term effects of prematurity (Brunssen & Harry, 2007).

Hemolytic Disease of the Newborn

The term "hemolytic" is derived from the Latin word for "destruction" (lysis) of red blood cells. Lysis of red blood cells in the newborn leads to **hyperbilirubinemia** (an elevated level of bilirubin in the blood). This can result from destruction of red blood cells by a normal physiologic process (see Chapter 18). When abnormal destruction of red blood cells occurs, it is termed hemolytic disease. In the past, hemolytic disease of the newborn was most often caused by an Rh blood type incompatibility. Because prevention of Rh

antibody formation has been available for almost 40 years, the disorder is now most often caused by an ABO incompatibility. In both instances, the mother builds antibodies against an infant's red blood cells, leading to hemolysis (destruction) of the cells. The destruction of red blood cells causes severe anemia and hyperbilirubinemia from the bilirubin released from red cells. Prevention of the condition begins in pregnancy, as discussed in Chapter 21.

Rh Incompatibility

Theoretically, no direct connection exists between the fetal and maternal circulation, so no fetal blood cells should enter the maternal circulation. In actuality, occasional placental villi break and a drop or two of fetal blood does enter the maternal circulation. If the mother's blood type is Rh (D) negative and the fetal blood type is Rh positive (contains the D antigen), the introduction of fetal blood causes sensitization to occur, and the woman begins to form antibodies against the D antigen. Few antibodies form this way, however. Most form in the woman's bloodstream in the first 72 hours after birth because there is an active exchange of fetal–maternal blood as placental villi loosen and the placenta is delivered. After this sensitization, in a second pregnancy there will be a high level of antibody D circulating in the woman's bloodstream, which will then act to destroy the fetal red blood cells early in the pregnancy if the new fetus is Rh positive. By the end of pregnancy, a fetus can be severely compromised by the action of these antibodies crossing the placenta and destroying red blood cells. Some infants require intrauterine transfusions to combat red cell destruction. Preterm labor may be induced to remove the fetus from the destructive maternal environment. Administering phenobarbital to women during their last weeks of pregnancy has been tried to reduce symptoms in newborns as it speeds liver maturity so that the infant liver better converts indirect to direct bilirubin. This, unfortunately, also carries the risk of fetal sedation (Thomas, Muller, & Wilkinson, 2009).

ABO Incompatibility

In most instances of ABO incompatibility, the maternal blood type is O and the fetal blood type is A; it may also occur when the fetus has type B or AB blood. A reaction in an infant with type B blood is often the most serious.

Hemolysis can become a problem with a first pregnancy in which there is an ABO incompatibility as the antibodies to A and B cell types are naturally occurring antibodies or are present from birth in individuals whose red cells lack these antigens. Unlike the antibodies formed against the Rh D factor, these antibodies are of the large (IgM) class and do not cross the placenta. An infant of an ABO incompatibility, therefore, is not born anemic, as is the Rh-sensitized child. Hemolysis of the blood begins with birth, when blood and antibodies are exchanged during the mixing of maternal and fetal blood as the placenta is loosened; destruction of red cells may continue for up to 2 weeks of age. Interestingly, preterm infants do not seem to be affected by ABO incompatibility. This may be because the receptor sites for anti-A or anti-B antibodies do not appear on red cells until late in fetal life. Even in the mature newborn, a direct Coombs' test may be only weakly positive because of the few anti-A or anti-B sites present. The reticulocyte count (immature or newly formed red blood cells) is usually elevated as the infant attempts to replace destroyed cells.

Assessment

Rh incompatibility of the newborn can be predicted by finding a rising anti-Rh titer or a rising level of antibodies (indirect Coombs' test) in a woman during pregnancy. It can be confirmed by detecting antibodies on the fetal erythrocytes in cord blood (positive direct Coombs' test) by percutaneous umbilical blood sampling (see Chapter 9) or at birth. The mother in this situation will always have Rh-negative blood (*dd*), and the baby will be Rh positive (*DD* or *Dd*).

With Rh incompatibility, an infant may not appear pale at birth despite the red cell destruction that has occurred in utero. This is because the accelerated production of red cells during the last few months in utero compensates to some degree for the destruction. The liver and spleen may be enlarged from an attempt to destroy damaged blood cells. If the number of red cells has significantly decreased, the blood in the vascular circulation may be hypotonic to interstitial fluid; fluid will shift from the lower to higher isotonic pressure by the law of osmosis, causing extreme edema. Finally, the severe anemia can result in heart failure as the heart has to beat so fast to push the dilute blood forward. **Hydrops fetalis** is an old term for the appearance of a severely involved infant at birth. Hydrops refers to the edema, and fetalis refers to the lethal state.

Most infants do not appear jaundiced at birth because the maternal circulation has evacuated the rising indirect bilirubin level. With birth, progressive jaundice, usually occurring within the first 24 hours of life, will begin, indicating in both Rh and ABO incompatibility that a hemolytic process is at work. The jaundice occurs because as red blood cells are destroyed, indirect bilirubin is released. Indirect bilirubin is fat soluble and cannot be excreted from the body. Under normal circumstances, the liver enzyme glucuronyl transferase converts indirect bilirubin to direct bilirubin. Direct bilirubin is water soluble and combines with bile for excretion from the body with feces. In preterm infants or those with extreme hemolysis, the liver cannot convert indirect to direct bilirubin, so jaundice becomes extreme.

Pregnanediol, the breakdown product of progesterone, can interfere with the conjugation of indirect bilirubin. This is excreted in breast milk until the high levels of progesterone that were present during pregnancy are decreased, usually 24 to 48 hours after birth. Breastfed babies, therefore, may evidence more jaundice than bottle-fed babies.

Normally, cord blood has an indirect bilirubin level of 0 to 3 mg/100 mL. An increasing indirect bilirubin level is dangerous because if the level rises above 20 mg/dL in a term infant or 12 mg/dL in a preterm infant, brain damage from bilirubin-induced neurologic dysfunction (BIND) or a wide spectrum of disorders caused by increasingly severe hyperbilirubinemia that range from mild dysfunction to kernicterus (invasion of bilirubin into brain cells) can occur. An infant needs to use glucose stores to maintain metabolism in the presence of anemia. This can cause a progressive hypoglycemia, compounding the initial problem. A decrease in hemoglobin during the first week of life to a level less than that of cord blood is a later indication of blood loss or hemolysis.

Therapeutic Management

Initiation of early feeding, use of phototherapy, and exchange transfusion all may be immediate measures necessary to reduce indirect bilirubin levels in an infant affected by ABO or Rh incompatibility. In infants with severe hemolytic disease, the hemoglobin concentration may continue to drop during the first 6 months of life, or their bone marrow may fail to increase production of erythrocytes in response to continuing hemolysis. If this occurs, an infant may need an additional blood transfusion to correct this late anemia. Therapy with erythropoietin to stimulate red blood cell production is also possible.

Initiation of Early Feeding. Bilirubin is removed from the body by being incorporated into feces. Therefore, the sooner bowel elimination begins, the sooner bilirubin removal begins. Early feeding (either breast milk or formula), therefore, stimulates bowel peristalsis and accomplishes this.

Phototherapy. An infant's liver processes little bilirubin in utero because the mother's circulation does this for an infant. With birth, exposure to light apparently triggers the liver to assume this function. Additional light supplied by phototherapy appears to speed the conversion potential of the liver. In phototherapy, an infant is continuously exposed to specialized light such as quartz halogen, cool white daylight, or special blue fluorescent light. The lights are placed 12 to 30 inches above the newborn's bassinet or incubator. Specialized fiberoptic light systems incorporated into a fiberoptic blanket also have been developed and are ideal for home care. The infant is undressed except for a diaper so as much skin surface as possible is exposed to the light (Fig. 26.12).

Term newborns are generally scheduled for phototherapy when the total serum bilirubin level rises to 10 to 12 mg/dL at 24 hours of age; preterm infants may have treatment begun at levels lower than this (Symons & Mahoney, 2008).

Continuous exposure to bright lights this way may be harmful to a newborn's retina, so the infant's eyes must always be covered while under bilirubin lights. Eye dressings or cotton balls can be firmly secured in place by an infant mask.

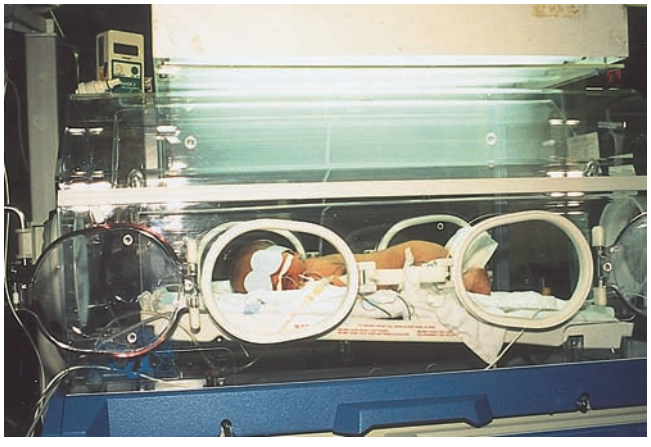


FIGURE 26.12 A newborn receiving phototherapy is undressed except for a diaper so he receives maximum exposure to the lights. His eyes are covered snugly to protect them from the bright light.

Check the dressings frequently to be certain they have not slipped or are causing corneal irritation. A constant concern is that suffocation from eye patches could occur.

The stools of an infant under bilirubin lights are often bright green because of the excessive bilirubin that is excreted as the result of the therapy. They are also frequently loose and may be irritating to skin. Urine may be dark-colored from urobilinogen formation. Monitor axillary temperature to prevent an infant from overheating under the bright lights. Assess skin turgor and intake and output to ensure that dehydration is not occurring from the warm environment.

Infants receiving phototherapy should be removed from under the lights for feeding so that they continue to have interaction with their mother. In addition, supplemental feedings with additional formula may be recommended to prevent dehydration. Remove the eye patches while the infant is with the mother to give an infant a period of visual stimulation. To prevent a lengthy hospital stay, infants may be discharged and continue therapy at home.

Parents need an explanation of the rationale for phototherapy. Incubators are automatically associated with seriously ill infants, but the use of lights does not seem scientific (almost a home remedy). Parents can easily be confused by the two interventions, one seemingly serious and the other seemingly not serious at all. Although the long-term effects have not yet been studied, there appears to be minimal risk to an infant from phototherapy, provided the infant's eyes remain covered and dehydration from increased insensitive water loss does not occur. It is too early to predict if all infants who receive phototherapy need follow-up in coming years to detect skin cancer that possibly could occur from the therapy (Newman & Maisels, 2007).

Home Phototherapy. Home phototherapy is primarily used for decreasing physiologic jaundice rather than that associated with blood incompatibility. It has the advantage of allowing for uninterrupted contact between the parents and a newborn and therefore has the potential to aid bonding. Parents must understand the importance of the therapy; the lights must be a full 12 inches away from an infant to prevent burning; an infant must continuously wear eye patches and a diaper during phototherapy to protect the retinas and the ovaries or testes; and bilirubin levels should be assessed approximately every 12 hours.

An infant should have the eye patches removed when away from the lights for feeding for a period of visual stimulation and interaction. The point at which infants are most apt to dislodge eye patches is when they cry as they wake for a feeding. Urge parents not to allow an infant under bilirubin lights to cry for a sustained period to avoid having this happen.

An infant's progress can be measured daily by a transcutaneous bilirubinometer, a hand-held fiberoptic light placed against an infant's skin. The intensity of the yellow color of the skin is measured by the meter, and a numeric level of bilirubin is calculated.

A newer innovation for hyperbilirubinemia management is the phototherapy blanket, a fiberoptic blanket that is wrapped around the baby. Light generated by the blanket has the same effect on bilirubin levels as banks of overhead lights. The advantages of a blanket are that an infant can be held for

long periods without interrupting the phototherapy, and eye patches are unnecessary (Box 26.12).

Exchange Transfusion. Intensive phototherapy in conjunction with hydration and close monitoring of serum bilirubin levels is the preferred method of treatment of neonatal jaundice. Despite these measures, if bilirubin levels continue to rise, exchange transfusion may be necessary. Before the procedure, the baby's stomach is aspirated to minimize the risk of aspiration from the manipulation involved. The umbilical vein is catheterized as the site for transfusion. The procedure involves alternatively withdrawing small amounts (2–10 mL) of the infant's blood and then replacing it with equal amounts of donor blood. The blood is exchanged slowly this way to prevent alternating hypovolemia and hypervolemia. This can make an exchange transfusion a lengthy procedure of 1 to 3 hours. Automatic pumps are helpful to perform the exhausting repeated ritual. At the end of the procedure, using the last specimen of blood withdrawn, hematocrit, bilirubin, electrolytes (especially calcium), glucose determination, and blood culture are taken. Exchange transfusion may need to be repeated because additional unconjugated bilirubin from tissue moves into the circulation after the exchange.

The therapy may be used for any condition that leads to hyperbilirubinemia or polycythemia. When used as therapy for blood incompatibility, it removes approximately 85% of sensitized red cells. It reduces the serum concentration of indirect bilirubin and often prevents heart failure in infants. Because indirect bilirubin levels rise at relatively predictable levels, standards for performing exchange transfusion depend on the indirect bilirubin concentration, and transfusion is used when this level exceeds:

- 5 mg/100 mL at birth
- 10 mg/100 mL at age 8 hours
- 12 mg/100 mL at age 16 hours
- 15 mg/100 mL at 24 hours

It also may be used if the serum bilirubin level is rising more than 0.5 mg/hr in infants with Rh incompatibility or 1.0 mg/hr in infants with ABO incompatibility.

Keep a newborn warm during the procedure to prevent energy expenditure from having to maintain body temperature. Maintain the blood being given at room temperature, or shock from the cold insult can result. Use only commercial blood warmers to warm blood, not hot towels or a radiant heat warmer, to avoid destroying red cells.

Albumin may be administered 1 to 2 hours before the procedure to increase the number of bilirubin binding sites and to increase the efficiency of the transfusion. Be careful to monitor the rate of flow of the albumin transfusion, because rapid flow of such a viscous fluid can quickly overburden an infant's heart. The type of blood used for transfusion is O Rh-negative blood, even though an infant's blood type is positive; if Rh-positive or type A or B blood were given, the maternal antibodies that entered the infant's circulation would destroy this blood also, and the transfusion would be ineffective. An amount equal to twice the blood volume (average is 86 mL/kg) is used because this quantity will ensure an exchange of erythrocytes that is 85% to 90% effective. If the baby is transported to a regional center for the exchange transfusion, a sample of the mother's blood should accompany the infant, so cross-matching on the mother's serum can be done there.

During the transfusion, carefully monitor the newborn's heart rate, respirations, and blood pressure. Because blood stored for transfusion contains acid-citrate-dextrose (ACD), added to blood as an anticoagulant, which can lower blood calcium levels and cause acidosis, calcium gluconate is given

BOX 26.12 ✻ Focus on Family Teaching

Home Phototherapy Blanket

Q. Mrs. Atkins' doctor has ordered a phototherapy blanket for her to use at home to help reduce her son's jaundice. She asks you, "What are the rules for using the blanket effectively?"

A. Use the guidelines below to ensure the effectiveness of a home phototherapy blanket:

- Be aware that a home care nurse will assist you in setting up and using the equipment. The nurse will also obtain daily blood specimens to check your infant's bilirubin levels.
- Take your infant's temperature every 8 hours throughout the course of therapy. Because the blanket being used does not provide heat, changes in temperature may indicate a problem, such as an infection.
- Monitor your infant's urine output. Keep track of the number of diapers he wets.
- Also monitor your infant's bowel movements. He may have loose, green-tinged bowel movements as the bilirubin begins to break down. Keep the skin clean and dry to prevent irritation.
- Keep track of the amount (if bottle feeding) or duration (if breastfeeding) of feeding and the frequency of feedings. Usually, an infant receiving phototherapy should be fed approximately every 3 hours to prevent dehydration.
- Supplement formula or breast milk with glucose water unless you are told otherwise. An infant needs additional fluids during this time.
- When placing the child in the blanket device, be sure the fabric side goes against the infant's skin, with the lower portion on the outside of the baby's diaper. Be sure to fold the diaper down below the baby's navel in front and as far as possible in back so as much of the skin as possible is exposed to the light.
- Do not wrap the baby too tightly. Leave a space about the size of two fingers between the panel and the baby's skin.
- Do not be afraid to pick up the baby at any time and hold him. You can rock, cuddle, or feed him. Be careful not to walk around with the baby wrapped in the blanket, because you could trip on the cord and fall, injuring yourself or the baby.
- Call your pediatric care provider if you find any of the following: refusal of feedings, persistent temperature control problems, fewer than five wet diapers in 24 hours, pronounced change in the child's level of activity, or vomiting of entire feedings.

through the exchange catheter after each 100 mL of blood. If citrate-phosphate-dextrose was used as a preservative, hyperglycemia may occur during the transfusion from the dextrose in the preservative. This may be followed by overproduction of insulin and hypoglycemia in the infant. If heparinized blood is used, the heparin content may interfere with clotting after the transfusion. In addition, because of its relatively low glucose concentration, heparinized blood may also lead to hypoglycemia. Administering protamine sulfate aids in the metabolism of heparin and restoration of clotting ability.

After the transfusion, closely observe the infant for umbilical vessel bleeding. Redness or inflammation of the cord suggests infection. Report any changes in vital signs. Take and record a blood glucose determination at 1 hour after the procedure. Monitor bilirubin levels for 2 or 3 days after the transfusion to ensure the level of bilirubin is not rising again and that no further transfusion is necessary. Erythropoietin may be administered to increase new blood cell growth and prevent extended anemia.

Hemorrhagic Disease of the Newborn

Hemorrhagic disease of the newborn results from a deficiency of vitamin K (McNinch, Busfield, & Tripp, 2007). Vitamin K is essential for the formation of prothrombin by the liver. Lack of it causes decreased prothrombin function and impaired blood coagulation. Vitamin K is formed by the action of bacteria in the intestine. Because the intestinal tract of a newborn is sterile at birth, an infant forms minimal amounts of vitamin K until normal intestinal tract flora are established at about 24 hours of age. Babies born to women receiving anticonvulsive medication are at high risk for the condition because many of these medications interfere with vitamin K formation. Administering vitamin K intramuscularly to these women before birth can help to protect the newborn.

Newborns with vitamin K deficiency show petechiae from superficial bleeding into the skin. They may have conjunctival, mucous membrane, or retinal hemorrhage. They may vomit fresh blood or pass black, tarry stools because of bleeding into the gastrointestinal tract.

Distinguishing between tarry stools and normal meconium stools can be difficult in the first 1 or 2 days of life by simple observation. However, if an infant's stool does not change as it should from greenish-black (meconium) to the yellow color of a bottle-fed or breastfed baby, or if the stool color changes normally and then becomes black again, gastrointestinal bleeding should be suspected. You can check for the presence of blood in the stool by a dipstick guaiac test.

Vitamin K deficiency bleeding usually occurs on day 2 to day 5 of life, when the available prothrombin is at its lowest level. The prothrombin time will be prolonged; the coagulation time may be normal or prolonged.

Hemorrhagic disease of the newborn can be prevented by the intramuscular administration of 1 mg of vitamin K to all newborns immediately after birth. Make certain infants who were born in unusual circumstances, such as those born outside the hospital, are given vitamin K on their admission to the hospital nursery. Also double-check that infants whose birth involved an emergency, such as maternal hemorrhage or failure of the newborn to breathe spontaneously, have received it.

An infant who develops hemorrhagic disease of the newborn is treated with vitamin K, given intravenously or intramuscularly. If bleeding is severe, an infant may need a transfusion of fresh, whole blood to increase the prothrombin level immediately.

Handle infants with this disease extremely gently to prevent further bleeding, because they bruise easily from heavy pressure. Subdural hemorrhage may occur, making hemorrhagic disease a serious and potentially fatal disorder.

Twin-to-Twin Transfusion

Twin-to-twin transfusion is a phenomenon that can occur if twins are monozygotic (identical; share the same placenta) or if abnormal arteriovenous shunts occur that direct more blood to one twin than the other (Norton, 2007). The process occurs in as many as one third of all identical twin pregnancies. Enough blood is exchanged to be clinically important in only about 15% of such pregnancies. The result of this shift of blood leads to anemia in the donor twin and polycythemia in the receiving twin. The anemic twin may also be SGA because of the lack of nutrients or oxygen for growth. This same SGA twin will be prone to hypoglycemia from lack of glucose stores. The hypovolemic twin will appear pale next to the polycythemic twin; the polycythemic twin is prone to hyperbilirubinemia as the excessive red blood cell level is broken down.

Twin-to-twin transfusion can be identified in utero by a sonogram because one twin is noticeably larger than the other. All identical twins should have hemoglobin determinations done at birth and the results compared. A difference of more than 5.0 g per 100 mL is enough to suggest a transfusion has occurred. Each twin needs therapy as indicated by the extent of the blood distribution. The donor twin may need a transfusion to establish a functioning blood level; the recipient twin may need an exchange transfusion to reduce the polycythemia and viscosity of the blood.

✔ Checkpoint Question 26.4

Baby Atkins develops hyperbilirubinemia. What is a method used to treat hyperbilirubinemia in a newborn?

a. Keeping infants in a warm and dark environment.
b. Early feeding to speed passage of meconium.
c. Gentle exercise to stop muscle breakdown.
d. Administration of a cardiovascular stimulant.

Necrotizing Enterocolitis

Necrotizing enterocolitis (NEC) develops in approximately 5% of all infants in intensive care nurseries (Carter, 2007). The bowel develops necrotic patches, interfering with digestion and possibly leading to a paralytic ileus. Perforation and peritonitis may follow. NEC may occur as a complication of exchange transfusion. The disorder is discussed in Chapter 45.

Retinopathy of Prematurity

Retinopathy of prematurity (ROP), an acquired ocular disease that leads to partial or total blindness in children, is caused by vasoconstriction of immature retinal blood vessels. It was first recognized as an eye disorder in 1942, but only

later was a high concentration of oxygen established as the causative agent (Askie & Henderson-Smart, 2009). Immature retinal blood vessels constrict when exposed to high oxygen concentrations. In addition, endothelial cells in the layer of nerve fibers in the periphery of the retina proliferate, leading to retinal detachment and blindness. Infants who are most immature and most ill (and consequently receive the most oxygen) are at highest risk.

A preterm infant who is receiving oxygen must have blood P_{O_2} levels monitored by pulse oximeter, transcutaneous oxygen saturation, or blood gas monitoring. Keeping blood P_{O_2} levels within normal limits lowers the risk. When blood P_{O_2} levels rise to higher than 100 mm Hg, the risk of the disease increases greatly.

In the past, once ROP occurred, there was no reversing it. Today, cryosurgery or laser therapy may be effective in preserving sight. A person experienced in recognizing ROP should examine the eyes of all low-birth-weight newborns and those who have received oxygen therapy before discharge from a hospital nursery and again at age 4 to 6 weeks of age to detect any occurrence of the syndrome. Nurses can be instrumental in limiting the occurrence of ROP by conscientious oxygen management (Coe, 2007).

THE NEWBORN AT RISK BECAUSE OF MATERNAL INFECTION OR ILLNESS

Maternal Infection

Newborns are susceptible to infection at birth because their ability to produce antibodies is immature. A number of infections in newborns, such as toxoplasmosis, rubella, syphilis, and cytomegalovirus infections, are spread to the fetus across the placenta in utero. The effect on the woman of these disorders is discussed in Chapter 12. Other infections are contracted from exposure to vaginal secretions at birth. Those infections are described next.

β-Hemolytic, Group B Streptococcal Infection

The major cause of infection in newborns is the β-hemolytic, group B streptococcal organism (GBS). This gram-positive bacterium is a natural inhabitant of the female genital tract. Between 50 and 300 infants in every 1000 live births display a positive culture for the organism (Heath & Schuchat, 2007). It may be spread from baby to baby if good handwashing technique is not used in handling newborns. If a woman is found to be positive for GBS during late pregnancy (see Chapter 21), ampicillin administered intravenously at 28 weeks and again during labor helps to reduce the possibility of newborn exposure.

Assessment. Typically, a newborn at risk, such as one born after prolonged rupture of membranes or if the woman's vaginal culture is positive for GBS, will be screened for infection with a blood culture.

Colonization by GBS can result in an early-onset or a late-onset illness. With the early-onset form, signs of pneumonia become apparent within the first day of life, as well as tachypnea, apnea, and signs of shock such as decreased urine output, extreme paleness, or hypotonia. A chest radiograph is almost indistinguishable from that of RDS (a ground-glass appearance). Pneumonia may develop so rapidly that as many as 20% of infants who contract the infection die within 24 hours of birth.

A late-onset type occurs at 2 to 4 weeks of age. With this, instead of pneumonia being the infection focus, meningitis tends to occur. Typical signs include lethargy, fever, loss of appetite, and bulging fontanelles from increased intracranial pressure as meningitis develops. Mortality from the late-onset type is not as high as that from the early-onset form (15% versus 20%), but neurologic consequences can occur in up to 50% of infants who survive.

Therapeutic Management. If a newborn displays signs or a blood screening test is positive, antibiotics are administered. Gentamicin, ampicillin, and penicillin are all effective against GBS infections.

Parents may have difficulty understanding how their infant could suddenly become this ill and may need a great deal of support in caring for their infant. This is even more important if the newborn survives the infection but is left neurologically challenged. In the future, immunization of all women of childbearing age against streptococcal B organisms could decrease the incidence of newborns infected at birth.

Ophthalmia Neonatorum

Ophthalmia neonatorum is an eye infection that occurs at birth or during the first month (MacDonald, Mailman, & Desai, 2008). The most common causative organisms are *Neisseria gonorrhoeae* and *Chlamydia trachomatis.* An infant contracts the organism during birth, from vaginal secretions. *N. gonorrhoeae* infection is an extremely serious form of conjunctivitis because, if left untreated, the infection progresses to corneal ulceration and destruction, resulting in opacity of the cornea and severe vision impairment.

Assessment. Ophthalmia neonatorum is generally bilateral. The conjunctivae become fiery red, with thick pus. The eyelids are edematous. Although this usually occurs on day 1 to day 4 of life, it should be considered as a possibility when conjunctivitis occurs in any infant younger than 30 days.

Prevention. The prophylactic instillation of erythromycin ointment into the eyes of newborns prevents both gonococcal and chlamydial conjunctivitis. In the past, eye prophylaxis was given immediately after birth so it was never forgotten. Now it is customary to delay administration of the ointment until after the first reactivity period so the newborn can clearly see the parents during this important attachment period. This makes it easy for administration to be forgotten, so use some type of a checklist as a reminder of this important prophylaxis. Infants born outside the hospital also need prophylaxis to prevent ophthalmia neonatorum, the same as infants born in a birthing room.

Therapeutic Management. Therapy is individualized depending on the organism cultured from the exudate. If gonococci are identified, intravenous ceftriaxone (Rocephin) and penicillin are effective drugs. If chlamydia is identified, an ophthalmic solution of erythromycin is used.

Use standard and contact infection precautions when caring for this newborn. In addition to systemic antibiotic therapy, the eyes are irrigated with sterile saline solution to clear the copious discharge. When irrigating eyes, use a sterile medicine dropper or bulb syringe, and use barrier protection, including goggles to avoid splashing any solution into your own eye. The solution should be at room temperature. Direct the stream of the irrigation fluid laterally so it does not enter and contaminate the other eye.

The mother of the infected infant needs treatment for gonorrhea or chlamydia, before fallopian tube sterility or pelvic inflammatory disease results. Sexual contacts of the mother should be treated also, so the spread of the disease can be halted. With either infection, parents can be assured that with early diagnosis and treatment the prognosis for normal eyesight in their child is good.

Hepatitis B Virus Infection

Hepatitis B virus (HBV) can be transmitted to the newborn through contact with infected vaginal blood at birth when the mother is positive for the virus (HBsAg+). Hepatitis B is a destructive illness: 70% to 90% of infected infants become chronic carriers of the virus. As many as 15% of these will develop liver cancer later in life (McKinlay & Matheny, 2007).

To reduce the possibility of HBsAg being spread to newborns in the future, infants are now routinely vaccinated at birth (Lee et al., 2009). If the mother is identified as HBsAg+, an infant is also administered immune serum globulin (HBIG) within 12 hours of birth to decrease the possibility of infection. The infant should be bathed as soon as possible after birth to remove HBV-infected blood and secretions. Gentle suctioning is necessary to avoid trauma to the mucous membrane, which could allow HBV invasion. Although the virus is transmitted in breast milk, once immune globulin has been administered, women may breastfeed without risk to an infant. Hepatitis B is further discussed in Chapter 45, because it also occurs in older children.

Generalized Herpesvirus Infection

A herpes simplex virus type 2 (HSV-2) infection, most prevalent among women with multiple sexual partners, can be contracted by a fetus across the placenta if the mother has a primary infection during pregnancy. More often, however, the virus is contracted from the vaginal secretions of a mother who has active herpetic vulvovaginitis at the time of birth. Between 15% and 30% of women of childbearing age demonstrate antibodies to this virus or have the potential to have active lesions during labor (American College of Obstetricians and Gynecologists [ACOG], 2007).

Assessment. If the infection was acquired during pregnancy, an infant may be born with vesicles covering the skin. The long-term prognosis of the child is guarded, because severe neurologic damage may have occurred simultaneously. If infants acquire the infection at birth, at approximately day 4 to day 7 of life they show a loss of appetite, perhaps a low-grade fever, and lethargy. Stomatitis (ulcers of the mouth) or a few vesicles on the skin appear. Herpes vesicles are always clustered, pinpoint in size, and surrounded by a reddened base. After the vesicles appear, infants become extremely ill. They develop dyspnea, jaundice, purpura, convulsions, and shock. Death may occur within hours or days. Between 25% and 70% of newborns who survive generalized herpesvirus infections have permanent central nervous system sequelae.

To confirm the diagnosis, cultures are obtained from representative vesicles as well as the nose, throat, anus, and umbilical cord. Blood serum is analyzed for IgM antibodies.

Therapeutic Management. An antiviral drug such as Acyclovir (Zovirax), a drug that inhibits viral deoxyribonucleic acid synthesis, is effective in combating this overwhelming infection. Prevention, however, is the newborn's best protection. Women with active herpetic vulvar lesions are advised to have cesarean birth rather than vaginal birth to minimize the newborn's exposure. Antenatal antiviral prophylaxis reduces viral shedding and recurrences at birth and reduces the need for cesarean birth (Hollier & Wendel, 2009). Infants with an infection should be separated from other infants. Although transmission from this source is rare, women with herpes lesions on their face (herpes simplex or cold sores) should not feed or hold their newborns until lesions are crusted and no longer contagious. Health care personnel who have herpes simplex infections should not care for newborns until the lesions are crusted. Although facial herpes simplex lesions are probably caused by herpesvirus type 1, limiting contact does not seem excessive in light of the severity of HSV-2 disease. Urge a woman who is separated from her newborn at birth to view her infant from the nursery window and participate in planning care to aid bonding.

Human Immunodeficiency Virus Infection

HIV infection and acquired immunodeficiency syndrome (AIDS) can be caused by placental transfer or direct contact with maternal blood during birth. As older children are also exposed to this, the care of children with this infection is discussed in Chapter 42.

An Infant of a Woman Who Has Diabetes Mellitus

An infant of a woman who has diabetes mellitus whose illness was poorly controlled during pregnancy is typically longer and weighs more than other babies (macrosomia). The baby also has a greater chance of having a congenital anomaly such as a cardiac anomaly, as if hyperglycemia is teratogenic to a rapidly growing fetus. **Caudal regression syndrome** (hypoplasia of the lower extremities) is a syndrome that occurs almost exclusively in such infants (Strehlow et al., 2007).

Most such babies have a cushingoid (fat and puffy) appearance. They tend to be lethargic or limp in the first days of life as a result of hyperglycemia. The macrosomia results from overstimulation of pituitary growth hormone and extra fat deposits created by high levels of insulin during pregnancy. The infant's large size is deceptive, however: such babies are often immature. RDS occurs frequently in these infants because they may be born preterm or, even at term, lecithin pathways may not mature as rapidly in them. High fetal insulin secretion during pregnancy to counteract the hyperglycemia may interfere with cortisol release. This could

block the formation of lecithin and prevent lung maturity. A term frequently used for these infants is "fragile giant."

An infant of a diabetic woman loses a greater proportion of weight in the first few days of life than does the average newborn because of the loss of the extra fluid accumulated. Observe an infant closely to be certain that this large weight loss actually represents a loss of extra fluid and that dehydration is not occurring.

Complications

A macrosomic infant has a greater chance of birth injury, especially shoulder and neck injury. Cesarean birth may be necessary to avoid cephalopelvic disproportion. Immediately after birth, the infant tends to be hyperglycemic because the mother was at least slightly hyperglycemic during pregnancy and excess glucose transfused across the placenta. During pregnancy, the fetal pancreas responds to this high glucose level with islet cell hypertrophy, resulting in matching high insulin levels. After birth, as an infant's glucose level begins to fall because the mother's circulation is no longer supplying glucose, the overproduction of insulin will cause the development of severe hypoglycemia. Hyperbilirubinemia also may occur in these infants because, if immature, they cannot effectively clear bilirubin from their system. Hypocalcemia also frequently develops because parathyroid hormone levels are lower in these infants because of hypomagnesemia from excessive renal losses of magnesium.

Although infants of diabetic women are usually LGA, an infant born to a woman with extensive blood vessel involvement may be SGA because of poor placental perfusion. The problems of hypoglycemia, hypocalcemia, and hyperbilirubinemia remain the same.

Therapeutic Management

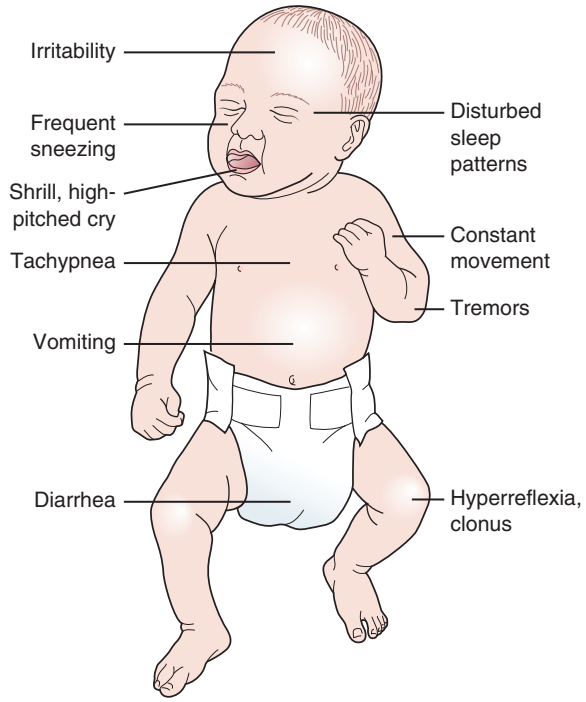
In a newborn, hypoglycemia is defined as a serum glucose level of less than 45 mg/dL. To avoid a serum glucose level from falling this low, infants of diabetic women are fed early with formula or administered a continuous infusion of glucose. It is important the infant not be given only a bolus of glucose; otherwise, rebound hypoglycemia (accentuating the problem) may occur. Some infants of diabetic women have a smaller-than-usual left colon, apparently another effect of intrauterine hyperglycemia, which limits the amount of oral feedings they can take in their first days of life. Signs of an inadequate colon include vomiting or abdominal distention after the first few feedings. Careful monitoring for normal bowel movements is important.

An Infant of a Drug-Dependent Mother

Infants of drug-dependent women tend to be SGA. If the woman is dependent on a drug, an infant will show withdrawal symptoms (neonatal abstinence syndrome) shortly after birth (Box 26.13). These include such signs as:

- Irritability
- Disturbed sleep pattern
- Constant movement, possibly leading to abrasions on the elbows, knees, or nose
- Tremors
- Frequent sneezing
- Shrill, high-pitched cry

Box 26.13 Assessment
Assessing the Newborn of a Drug-Addicted Mother



- Possible hyperreflexia and clonus (neuromuscular irritability)
- Convulsions
- Tachypnea (rapid respirations), possibly so severe that it leads to hyperventilation and alkalosis
- Vomiting and diarrhea, leading to large fluid losses and secondary dehydration

Specific neonatal abstinence scoring tools may be used to quantify and assess an infant's status. In newborns experiencing opiate withdrawal, signs usually begin 24 to 48 hours after birth, but in some infants they may not appear for up to 10 days. Generally signs last approximately 2 weeks, but mild signs may appear for up to 6 months. In heroin-addicted neonates, the signs begin within the first 2 weeks of life, with an average onset of approximately 72 hours. The signs may last 8 to 16 weeks or longer. In methadone-addicted newborns, withdrawal begins later and lasts longer than heroin withdrawal. The onset varies. A newborn may exhibit signs beginning at 24 to 28 hours, or these early signs may improve, then reappear at 2 to 4 weeks of age. Other newborns exhibit no signs until they are 2 to 3 weeks old.

There is no predictable withdrawal sequence noted for the cocaine-addicted neonate. Whether cocaine causes long-term effects varies with different studies, but factors such as maladaptive coping behaviors may be present in such newborns (Bernstein & Weinstein, 2007).

Narcotic metabolites or quinine (heroin is often mixed with quinine) may be obtained from an infant's urine or meconium in the first hour after birth. These products are quickly cleared from the body, however, so by the time

symptoms become severe, detection of narcotic substances may no longer be possible. Cocaine may be detected in infants' hair samples for an extended time.

Infants of drug-dependent women usually seem most comfortable when firmly swaddled. Keep them in an environment free from excessive stimuli (a small isolation nursery, not a large, noisy one). Some quiet best if the room is darkened. Many infants of heroin-addicted women suck vigorously and continuously and seem to find comfort and quiet if given a pacifier. Infants of methadone- and cocaine-addicted women may have extremely poor sucking ability and may have difficulty achieving sufficient fluid intake unless gavage fed.

Specific therapy for an infant is individualized according to the nature and severity of the signs. Maintenance of electrolyte and fluid balance is essential. If an infant has vomiting or diarrhea, intravenous administration of fluid may be indicated. The drugs used to counteract withdrawal symptoms include paregoric, phenobarbital, methadone, chlorpromazine (Thorazine), and diazepam (Valium). These are typically used if the neonatal abstinence scoring system average score is elevated on three successive occasions and nursing interventions do not reduce the score. An infant should not be breastfed to avoid passing narcotics in breast milk to the child.

Once an infant has been identified as having been exposed to drugs in utero, the mother needs treatment for withdrawal symptoms and follow-up care as much as the infant. In addition, evaluation is necessary to determine before discharge whether an environment that allowed for drug abuse will be safe for an infant at home (Sun, Freese, & Fitzgerald, 2007). Infants who are exposed to drugs in utero may have long-term neurologic problems (Pulsifer et al., 2008).

An Infant With Fetal Alcohol Exposure

Alcohol crosses the placenta in the same concentration as is present in the maternal bloodstream. This results in fetal alcohol exposure and **fetal alcohol syndrome** (Elias, Tsai, & Manchester, 2008). The syndrome appears in about 2 per 1000 newborns and is often more difficult to document than recreational drug exposure. Alcohol has deteriorating effects on the placenta (Burd et al., 1007). Because it is unknown if there is a safe threshold of alcohol ingestion during pregnancy, all pregnant women are advised to avoid alcohol intake to prevent any teratogenic effects on their newborn (Welch & Mullins, 2007).

The newborn with fetal alcohol syndrome has several possible problems at birth. Characteristics that mark the syndrome include prenatal and postnatal growth restriction; central nervous system involvement such as cognitive challenge, microcephaly, and cerebral palsy; and a distinctive facial feature of a short palpebral fissure and thin upper lip. During the neonatal period, an infant may be tremulous, fidgety, and irritable and may demonstrate a weak sucking reflex. Sleep disturbances are common, with the baby tending to be either always awake or always asleep, depending on the mother's alcohol level close to birth.

The most serious long-term effect is cognitive challenge. Behavior problems such as hyperactivity may occur in school-age children. Growth deficiencies may remain throughout life. An infant needs follow-up so any future problems can be discovered. The mother needs follow-up to see if she can reduce her alcohol intake for better overall health.

✔ Checkpoint Question 26.5

Why is it important for infants of diabetic women to be fed early?

a. Their stomachs are empty at birth.
b. To help prevent hypoglycemia.
c. Their mothers could not eat during labor.
d. To clear mucus from their intestinal tracts.

Key Points for Review

- Priorities for infants born with special needs, such as preterm or postterm infants, are the same as for term infants: initiation and maintenance of respirations, establishment of extrauterine circulation, control of body temperature, intake of adequate nourishment, establishment of waste elimination, establishment of an infant–parent relationship, prevention of infection, and provision of developmental care for mental and social development.
- Many high-risk infants need resuscitation at birth. Prompt action with such measures as warmth, oxygen, intubation, and suctioning are needed.
- A small-for-gestational-age infant is one whose birth weight is below the 10th percentile on an intrauterine growth curve for that age infant. An infant could be preterm, term, or postterm.
- Small-for-gestational-age infants have difficulty maintaining body warmth because of low fat stores and may develop hypoglycemia from low glucose stores.
- A large-for-gestational-age infant is one whose birth weight is above the 90th percentile on an intrauterine growth chart for that gestational age. The infant could be born preterm, term, or postterm.
- Large-for-gestational-age infants tend to be infants of diabetic women; they are particularly prone to hypoglycemia or birth trauma.
- A preterm infant is one born before 37 weeks of gestation. Preterm infants have particular problems with respiratory function, anemia, jaundice, persistent patent ductus arteriosus, and intracranial hemorrhage. Infants who are born weighing 1500 to 2500 g are also termed low-birth-weight infants; those born weighing 1000 to 1500 g are very-low-birth-weight infants; those born weighing between 500 and 1000 g are extremely very-low-birth-weight infants. All such infants need intensive care from the moment of birth to give them their best chance of survival without neurologic aftereffects caused by their being so close to the age of viability.
- A postterm infant is one who has remained in utero past week 42 of pregnancy. Postterm infants have particular problems with establishing respirations, meconium aspiration, hypoglycemia, temperature regulation, and polycythemia.
- Respiratory distress syndrome commonly occurs in preterm infants from a deficiency or lack of surfactant in the alveoli. Without surfactant, the alveoli collapse on ex-

piration and require extreme force for reinflation. Primary therapy is synthetic surfactant replacement at birth by endotracheal tube insufflation, followed by oxygen and ventilatory support.

- Transient tachypnea of the newborn is a temporary condition caused by slow absorption of lung fluid at birth. Close observation of the infant is necessary until the fluid is absorbed and respirations slow to a normal rate.
- Meconium aspiration syndrome occurs when an infant aspirates meconium-stained amniotic fluid before or during birth. Meconium is irritating to the airway and leads to both airway spasm and pneumonia. Infants need oxygen, ventilatory support, and possibly an antibiotic until the effects of the insult to the airway subside. Infants should be suctioned before oxygen administration under pressure to prevent meconium from being forced further into their lungs.
- Apnea is a pause in respirations longer than 20 seconds, with accompanying bradycardia. It tends to occur in preterm infants who have secondary stresses such as infection, hyperbilirubinemia, hypoglycemia, or hypothermia. Apnea monitors are used to detect this, and infants who are at high risk for apnea may be discharged home on a home monitoring program.
- Sudden infant death syndrome is the sudden, unexplained death of an infant. It is associated with infants sleeping on their stomachs (prone) and preterm birth. An important preventive measure is advising parents to position their infant on the back for sleeping.
- Hyperbilirubinemia results from the destruction of red blood cells, owing either to a normal physiologic response or an abnormal destruction of red blood cells. Hemolytic disease of the newborn is destruction of red blood cells from Rh or ABO incompatibility. The administration of RHIG (Rh antibodies) to Rh-negative mothers during pregnancy and after the birth of an Rh-positive infant to an Rh-negative mother has greatly reduced the incidence of the condition. Affected infants are jaundiced from release of bilirubin from injured red blood cells. Phototherapy and exchange transfusion are used to prevent kernicterus (deposition of bilirubin in brain cells, causing destruction of the cells).
- Hemorrhagic disease of the newborn is a lack of clotting ability resulting from a deficiency of vitamin K at birth. This disorder is prevented by administering vitamin K to infants at birth.
- Retinopathy of prematurity is destruction of the retina caused by exposure of immature retinal capillaries to high levels of oxygen. Monitoring oxygen saturation via arterial blood gases is an important preventive measure.
- Severe infections acquired at birth that may be seen in newborns include streptococcal group B pneumonia, hepatitis B infection, ophthalmia neonatorum (gonococcal and chlamydial conjunctivitis), and herpesvirus infection. Assessing newborns for symptoms of these infections is an important nursing responsibility.
- Infants of women with diabetes and those of drug-abusing women are at high risk at birth for further complications. Both need careful assessment for respiratory distress and hypoglycemia.

CRITICAL THINKING EXERCISES

1. The Atkinses are the family you met at the beginning of the chapter. Mrs. Atkins does not want to visit or "waste her favorite name" on her new baby because the baby might die. How would you advise her?
2. Infants who are cared for in neonatal nurseries may need either reduced stimulation because they fatigue so easily or increased stimulation because their stay in the nursery will be so extended. What are examples of developmental care you might use with Baby Atkins?
3. Retinopathy of prematurity is an example of a disease caused by the therapy given an infant. What measures would you take to safeguard Baby Atkins against this disorder?
4. Examine the National Health Goals related to high-risk newborns. Most government-sponsored funds for nursing research are allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to the Atkins family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to care of a family with a high-risk newborn. Confirm your answers are correct by reading the rationales.

Chapter 27

Nursing Care of the Child Born With a Physical or Developmental Challenge

KEY TERMS

- ankyloglossia
- atresia
- cleft lip
- cleft palate
- developmental hip dysplasia
- fistula
- frenulum
- hydrocephalus
- meconium plug
- omphalocele
- polydactyly
- spina bifida
- stenosis
- syndactyly
- transillumination
- volvulus

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe common physical and developmental birth disorders.
2. Identify National Health Goals related to children born physically or developmentally challenged that nurses can help the nation achieve.
3. Use critical thinking to analyze the effect of a physically or developmentally challenged child on a family and propose ways to make care more family centered.
4. Assess a child who is born physically or developmentally challenged.
5. Formulate nursing diagnoses for children born with a physical or developmental challenge.
6. Establish expected outcomes to meet the needs of a child with a physical or developmental challenge.
7. Plan nursing care to meet the needs of a child born with a physical or developmental challenge such as encouraging mobility.
8. Implement nursing interventions for care of children born with physical or developmental challenges, such as preventing infection in a child with a neural tube disorder.
9. Evaluate expected outcomes to determine achievement and effectiveness of care.
10. Identify areas related to physically or developmentally challenged infants that could benefit by additional nursing research or application of evidence-based practice.
11. Integrate knowledge of congenital physical or developmental challenges with the nursing process to achieve quality maternal and child health nursing care.

Bobby Jo Sparrow, age 16, is a new mother whose child has been admitted to the neonatal intensive care unit because of a neural tube disorder and congenital hip dysplasia. Ms. Sparrow is obviously upset over the diagnosis. She says, "I'm a good person. The only thing I did wrong during pregnancy was to take some cough medicine, so how could this have happened?"

Previous chapters described the importance of assessing all infants at birth. This chapter adds information about common congenital anomalies or structural disturbances that may occur in newborns. This information can serve as a basis for newborn assessment and for health teaching for parents.

How would you answer this mother? What type of advice would be most helpful to her?

Few things can change the usually joyous tone of a birthing room faster than the birth of a baby with a physical or developmental challenge. Physicians or nurse-midwives, who are used to saying "perfect boy" or "beautiful girl" and holding up the infant for the parents' first glance, are suddenly without words. Words of congratulations hang unsaid in the air.

When a child is born with an apparent physical or developmental challenge, nurses must play a major role in supporting and educating the parents to help them move forward from this point. Some congenital disorders require surgery but the prognosis is good, so this is only a temporary concern. Other disorders, however, represent serious, even life-threatening concerns for infants and financially draining long-term responsibilities for parents. This chapter covers the physical congenital disorders that are apparent at birth or soon after. Such disorders primarily involve the gastrointestinal, neurologic, and skeletal systems. Congenital disorders of the cardiovascular system, which also represent life-threatening problems for an infant, are addressed in Chapter 41. National Health Goals related to children with congenital anomalies are shown in Box 27.1.

Nursing Process Overview

For Care of a Physically or Developmentally Challenged Child

Assessment

Nursing assessment of a physically or developmentally challenged newborn focuses on determining an infant's immediate physiologic needs required to sustain life and the parents' immediate emotional needs to promote bonding between the child and parents. Assess how the anomaly affects the infant's eight primary needs:

- Establishment and maintenance of adequate respiration
- Establishment of extrauterine circulation
- Establishment of normal body temperature
- Ability to take in adequate nourishment
- Establishment of waste elimination
- Prevention of infection
- Development of an infant–parent bond
- Exposure to adequate stimulation

The parents' response to the diagnosis of a congenital challenge must also be assessed. Anomalies that affect a child's appearance may have the most immediate effect on the parents' ability to establish a positive feeling about their child. It is important, however, not to jump to conclusions about parents' responses. Assessment of the family's verbal and nonverbal responses may reveal parents ready to meet this infant's special needs.

Nursing Diagnosis

Many nursing diagnoses established for children who are physically or developmentally challenged address the effect of the disorder on body function, including the child's primary needs, and also on family interaction. Examples of possible diagnoses are:

- Imbalanced nutrition, less than body requirements, related to inability to take in adequate nutrition secondary to physical challenge
- Impaired physical mobility related to congenital anomaly
- Risk for impaired parenting related to birth of child with congenital anomaly
- Anticipatory grieving (parental) related to loss of "perfect" child

Outcome Identification and Planning

Nurses play an important role in providing care to high-risk infants at birth and guarding their health until a child care team arrives to transport the infant to a high-risk nursery. When establishing expected outcomes and planning care, be certain to consider both the short- and long-term needs of the newborn and how these needs may affect the family. Also consider the family's resources, both emotional and financial, and devise a plan of care with these in mind. Parents with supportive family members nearby may be able to accept the limits of a child's challenge and turn their attention to the planned treatment regimen or care priorities sooner than those without close friends or relatives to whom they can turn for comfort and support. For the latter, you may need to act not only as a source of information and support but also as a sounding board and advocate until the parents can begin to develop positive coping mechanisms that will help them come to

BOX 27.1 ✻ Focus on National Health Goals

Many congenital anomalies, such as cleft lip, omphalocele, and neural tube disorders, can be detected during intrauterine life. The following National Health Goals address the importance of early identification and therapy:

- Reduce the occurrence of developmental disabilities by 5% (actual rate varies with condition).
- Reduce the occurrence of spina bifida and other neural tube disorders by 50% from a baseline of 6 per 10,000 births to 3 per 10,000 births.
- Increase the proportion of pregnancies begun with an optimal folic acid level from a baseline of 21% to a target level of 80%.
- Increase the proportion of territories and states that have service systems for children with special health care needs to 100% from a baseline of 15% (http://www.nih.gov).

Nurses can help the nation achieve these goals by ensuring that women obtain prenatal care and receive comprehensive advice after diagnosis of a fetal disorder.

Additional nursing research in this area is needed concerning factors that determine which women will continue their pregnancies after a congenital anomaly is discovered in the fetus; how far it is reasonable to ask parents to travel for follow-up care for a newborn; the measures parents feel were most helpful to them at the time that a fetal or newborn anomaly was diagnosed; and the most effective way to inform all women about the importance of folic acid during pregnancy.

terms with this unexpected event. Referrals for support groups may be beneficial, allowing parents to learn they are not alone in this situation. The following organizations can be helpful sources of support for parents: National Easter Seal Society (http://www.easterseals.com), Spina Bifida Association of America (http://www.sbaa.org), March of Dimes Birth Foundation (http://www.marchofdimes.com), and American Cleft Palate Foundation (http://www.cleftline.org).

Implementation

Nursing interventions for a baby born physically challenged include immediate life-sustaining measures such as providing for adequate intake of nutrients when a disorder prevents the infant from sucking. Educating the parents about pretreatment and posttreatment procedures and encouraging them to hold, touch, and talk with their baby are especially important to the future emotional well-being of the child and family.

Parents may suffer a loss of self-esteem with the child's birth, feeling as if the baby is proof that something in the combination of their genes or the prenatal environment they provided was inadequate. They may need to hear positive comments about themselves and need to be given support until they can realize that by caring for the child they are accomplishing more, not less, than other couples.

You can expect parents to move through the same stages of grief as those whose child has died at birth. Chapter 56 describes those stages and helpful nursing interventions in more detail.

Parents are acutely aware of what people think of their child. They watch closely how nurses and other health care providers handle their baby to see if they are giving as much attention to their baby as to other babies. To encourage parents to accept the child, be certain to treat the child in the same manner as any other—for example, rocking the baby after feeding or cooing and talking to the baby as much as with other babies. Otherwise, parents may think that if a professional finds their child distasteful, how will they dare show the child to their family and friends? If you are able to look past the anomaly to the whole child, however, they begin to do so, too. Through positive role modeling, you can set the stage for healthy parent–child interaction every time you handle an infant born with a physical or developmental challenge.

Outcome Evaluation

Evaluation should focus on expected outcomes established for a child's physical health and developmental needs, as well as the family's ability to cope with whatever special care and growth needs the child may have in the future. Be sure parents have numbers to call for questions, follow-up care, and support.

Evidence suggesting achievement of expected outcomes may include:

- Parent describes positive features of child by 2 weeks.
- Parents state they understand talipes anomaly is a correctable condition by 1 month.
- Child is ambulatory with walker by 2 years of age.

IMMEDIATE CARE AT THE BIRTH OF AN INFANT BORN PHYSICALLY OR DEVELOPMENTALLY CHALLENGED

Most physicians and nurse-midwives believe that relating the news of congenital physical or developmental anomalies to parents is their responsibility. However, because the physician or nurse-midwife must deliver the placenta and suture the perineum if an episiotomy was used for birth, if a neonatal specialist is not immediately available, many minutes may pass before this person is ready to make a second inspection of the baby, assess the extent of the disorder from the physical symptoms present, and tell the parents about the baby's condition and prognosis. This delay affects the parents in two ways: It leaves them believing they have just given birth to a perfect child among people who do not share their enthusiasm, or they have just given birth to a child so deformed all the professionals in the room find it too horrible to even talk to them. Because parents are aware of the atmosphere in a birthing room, the second response is by far more likely. In terms of parent–child interaction, this response is unhealthy. Parents may begin anticipatory grieving for what they believe is a severely deformed child. Even when they are told later the disorder is not extensive and is easily correctable, and that as soon as the correction is made the child will be fine, the anticipatory grief reaction may be hard to stop. They may continue to cut themselves off emotionally from their child.

For this reason, nurses need to be familiar with the most frequently encountered physical or developmental anomalies so that as the person who at that moment in the birth process is most available for patient education, they can explain the problem to parents. In other instances, nurses must be ready to serve as back-up informants to answer parents' questions after they have been told by a primary care provider their child has been born less than perfect (Glenny et al., 2009).

The causes of most congenital anomalies are unknown, although they probably arise from a combination of environmental and genetic factors. Still, many people persist in believing that infants with congenital anomalies are born to people less deserving than others or to those who have sinned or have been looked on by someone with envy during pregnancy. That eating raisins during pregnancy causes brown spots, and that strawberries cause hemangiomas, are common beliefs that are still prevalent.

New parents need explanation of their child's disorder and a chance to talk about why they believe their child's disorder occurred, to relieve their guilt that they were the cause and to allow them to regain sufficient self-esteem to be able to raise a child with a congenital disorder.

It is probably best to explain to parents what the disorder consists of and what the usual prognosis is before showing the baby to them. Parents may find it hard to look at an infant with a cleft lip or palate or exposed abdominal contents, for example, and also listen. Their minds are so consumed with the sight, so unlike the child they had imagined, that they cannot hear. A typical explanation would be: "Your baby's upper lip isn't completely formed. That's called a cleft lip. Your doctor will call one of the plastic surgeons here to look at your baby. This is a problem that can be repaired so well surgically you'll barely be able to tell your baby had this problem. I'll bring the baby over so you can see her. Remember when you look at her this can be repaired. She seems perfect in every other way."

These statements define and limit the problem for the parents. They also give them direction about where and how they should proceed in beginning to seek help for their child. As most congenital abnormalities involve surgery, be certain to plan for adequate pain assessment and management postoperatively to make the experience of surgery this early in life not an unbearable procedure for a neonate (American Academy of Pediatrics [AAP], 2007).

PHYSICAL AND DEVELOPMENTAL DISORDERS OF THE GASTROINTESTINAL SYSTEM

Many of the most common congenital anomalies involve the gastrointestinal system because the gastrointestinal tract forms first as a solid tube, then undergoes canalization. If this canalization does not occur, a partial or complete blockage or obstruction can occur. Other disorders of the tract, such as cleft lip and cleft palate, are the result of midline closure failure extremely early in intrauterine life. All of these disorders can interfere with an infant's ability to take in nourishment at birth. You may need to reinforce a mother's resolve to breastfeed as appropriate to aid in her success with this method of feeding.

Ankyloglossia (Tongue-Tie)

Ankyloglossia is an abnormal restriction of the tongue caused by an abnormally tight **frenulum,** the membrane attached to the lower anterior tip of the tongue (Kelley et al., 2008). Normally, in newborns, the frenulum appears short and is positioned near the tip of the tongue. As the anterior portion of the infant's tongue grows, the frenulum becomes located farther back. In most instances, therefore, an infant suspected of being tongue-tied has a normal tongue at birth; it just seems short to parents who are unaware of a newborn's appearance. This condition rarely causes speech difficulty or destructive pressure on gingival tissue. If it does, then surgical release can be performed, but this is rare.

Showing parents other newborns or photographs of normal tongues is helpful in convincing them a short frenulum is normal. Explore with them why they are concerned. Is there a child in the family with a speech disorder or a cleft lip and palate? Do the parents need assurance in any other way that their child is all right?

Thyroglossal Cyst

A thyroglossal cyst arises from an embryogenic fault that leaves a cyst formed at the base of the tongue, which then drains through a **fistula** (opening) to the anterior surface of the neck (Lin & Deschler, 2008). This condition may occur as a dominantly inherited trait. The cyst may involve the hyoid bone (the bone at the anterior surface of the neck at the root of the tongue) or may contain aberrant thyroid gland tissue. As the cyst fills with fluid, swelling and obstruction can lead to respiratory difficulty from pressure on the trachea. If infected, the cyst appears swollen and reddened, with drainage of mucus or pus from the anterior neck.

The cyst is surgically removed to avoid future infection of the space or, if thyroid tissue is present, the possibility of developing thyroid carcinoma later in life. Observe infants closely in the immediate postoperative period for respiratory distress, because the operative area will develop some edema from surgical trauma. Position infants on their sides so secretions drain freely from their mouths. Intravenous fluid therapy is given after surgery until the edema at the incision recedes somewhat and swallowing is safe once more (approximately 24 hours). If the mother is breastfeeding but the infant is NPO, encourage her to express her milk manually to preserve her milk supply. Observe infants closely the first time they take fluid orally to be certain they do not aspirate. Be certain parents feed their infant before the infant is discharged from the surgical unit so they can see that the infant is swallowing safely. This is important to help them develop confidence in themselves as parents and their ability to feed the infant at home in a relaxed and comfortable way.

Cleft Lip and Palate

The maxillary and median nasal processes normally fuse between weeks 5 and 8 of intrauterine life. In infants with **cleft lip,** the fusion fails to occur in varying degrees, causing this disorder to range from a small notch in the upper lip to total separation of the lip and facial structure up into the floor of the nose, with even the upper teeth and gingiva absent. The deviation may be unilateral or bilateral. The nose is generally flattened because the incomplete fusion of the upper lip has allowed it to expand in a horizontal dimension (see Fig. 7.12). Cleft lip is more prevalent among boys than girls. It occurs at a rate of approximately 1 in every 750 live births. This incidence is significantly higher in the Asian population, 1 in 300, and significantly lower in the black population, 1 in 2000. About 46% of children have combined cleft lip and palate, 21% only a cleft lip, and 33% only a cleft palate. Almost 30% of children with cleft lip and palate deformity have associated birth defects or the cleft palate occurs as only a portion of a larger syndrome (Hoffman, 2008).

Cleft lip occurs as a familial tendency or most likely occurs from the transmission of multiple genes. Formation may be aided by teratogenic factors present during weeks 5 to 8 of intrauterine life, such as a viral infection or possibly a

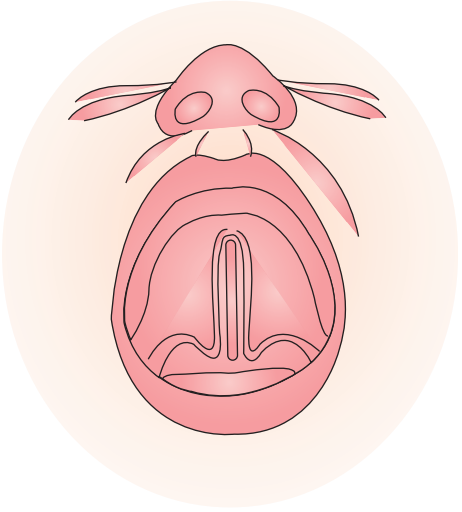

FIGURE 27.1 Appearance of a cleft palate. Both the hard and soft palate are involved.

deficiency of folic acid (Novak, 2007). Parents of a child with a cleft lip should be referred for genetic counseling to ensure they understand that they have about a 4% chance of having another child with a cleft lip or palate or future children are at a greater risk than usual for this problem.

The palatal process closes at approximately weeks 9 to 12 of intrauterine life. A **cleft palate,** an opening of the palate, is usually on the midline and may involve the anterior hard palate, the posterior soft palate, or both (Fig. 27.1). It may be a separate anomaly, but as a rule it occurs in conjunction with a cleft lip. As a single entity, it tends to occur more frequently in girls than boys. Like cleft lip, it appears to be the result of polygenic inheritance or environmental influences. In connection with cleft lip, the incidence is approximately 1 in every 1000 births. As a single entity, it occurs in approximately 1 in every 2000 births (Hoffman, 2008).

Assessment

Cleft lip may be detected by a sonogram while an infant is in utero. If not detected then, it is readily apparent on inspection at birth. Cleft palate can be determined by depressing the newborn's tongue with a tongue blade. This reveals the total palate and the extent of any cleft present. Be sure to have good lighting to visualize the palate clearly. Because cleft palate is a component of many syndromes, a child with a cleft palate must be assessed for other congenital anomalies.

Therapeutic Management

If a cleft lip is discovered while the infant is still in utero, fetal surgery can repair the condition, although this procedure is not usually attempted. If the disorder is not discovered until birth, a cleft lip is repaired surgically shortly thereafter, often at the time of the initial hospital stay or between 2 and 10 weeks of age. Some infants may have a nasal mold apparatus applied before surgery to shape a better nostril (Ezzat et al., 2007). Because the deviation of the lip interferes with nutrition, infants may be a better surgical risk at birth than they are after a month or more of poor nourishment. Early repair also helps infants experience the pleasure of sucking as soon as possible. It is equally important from a psychological standpoint that these disorders be repaired early. Parents can find it extremely difficult to bond with an infant whose face is deformed in this way. This is not a sign of a "bad" parent, but it is reality and a problem that requires intervention. Because facial contours change as a child grows, a revision of the original repair or a nasal rhinoplasty to straighten a deviated nasal septum may be necessary when the child reaches 4 to 6 years of age.

The optimal time for repair of cleft palate is controversial as early repair increases speech development but may result in a necessary second-stage repair as the child's palate arch grows. A two-stage palate repair, with soft palate repair at 3 to 6 months of age and hard palate repair at 15 to 18 months of age, may be recommended (van Aalst, Kolappa, & Sadove, 2008).

Currently, the results of surgical repair of cleft lip and cleft palate are excellent (Fig. 27.2). It is helpful to show parents photographs of babies with good repairs to assure them that their child's outcome can also be this successful. Do not use the older term for this condition, *harelip,* when talking with parents about the problem. Before modern surgical techniques were available, children were left with large lip scars, gross speech impediments, and a poor appearance after surgery. The word "harelip" tends to be associated with these negative outcomes rather than with the current positive outlook.

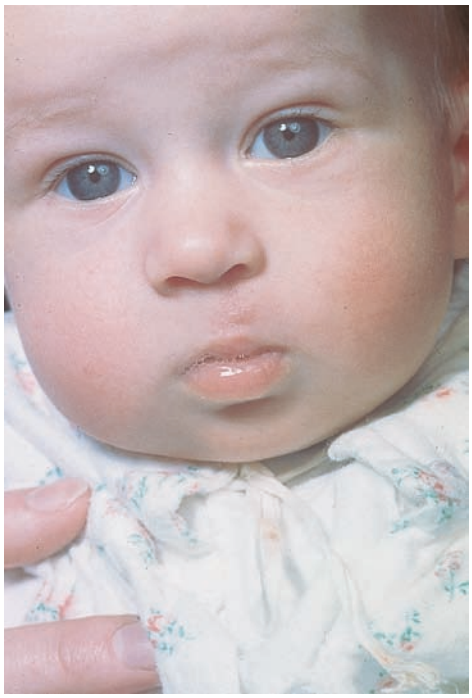

FIGURE 27.2 Infant showing surgical repair of cleft lip. Parents can be encouraged that the results of cleft lip repair are generally excellent. (Photo Researchers, Inc.)

Because palate repair narrows the upper dental arch, there may be less space in the upper jaw for the eruption of teeth, causing poor teeth alignment. All children born with a cleft palate need follow-up treatment by a pedodontist, or a dentist skilled in children's dental problems, so that as the child grows, extractions or realignment of teeth can be done as indicated (Cheng, Moor, & Ho, 2007). They also need follow-up to detect if speech or hearing difficulty occurs.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for imbalanced nutrition, less than body requirements, related to feeding problem caused by cleft lip or palate

Outcome Evaluation: Newborn ingests an adequate diet of 50 kcal/lb (110 kcal/kg) in 24 hours; weight is maintained within 10% of birth weight.

Preoperative Period. Before a cleft lip or palate is repaired, feeding the infant is a problem because the infant has difficulty maintaining suction (Glenny et al., 2009). In addition, it is important that the child does not aspirate.

It may be possible for an infant with a cleft lip to breastfeed because the bulk of the mother's breast tends to form a seal against the incomplete upper lip. Although the baby needs the enjoyment of sucking, some surgeons do not want a baby to breastfeed or suck on a nipple before surgical correction of the

disorder to avoid any local bruising of tissue. Therefore, the best feeding method for the child with cleft lip may be to support the baby in an upright position and feed the infant gently using a commercial cleft lip nipple. A Breck feeder, an apparatus similar to a bulb syringe, or a Haberman feeder may also be used (Fig. 27.3). If the surgical repair will be done immediately, the mother will be able to breastfeed as early as 7 to 10 days after surgery. Teach her how to pump or manually express breast milk to maintain a milk supply for this time. If surgery will be delayed for 1 month, she will need to decide whether she wants to continue to express milk for this long a period; continuing support from the nursing staff could be important to encourage her to do this.

Be certain an infant with a cleft lip is bubbled well after feeding because of a tendency to swallow air caused by the inability to grasp a nipple or syringe edge securely with the mouth. If a cleft extends to the nares, an infant will breathe through the mouth, causing the oral mucous membranes and lips to become dry. Offering small sips of fluid between feedings can help keep the mucous membranes moist and prevent cracks and fissures that could lead to infection.

Infants with cleft palate cannot suck effectively either, because pressing their tongue or a nipple against the roof of their mouth would force milk up into their pharynx, leading to aspiration. The most successful method for feeding this infant, like the child with cleft lip, therefore, is to use a commercial cleft palate nipple that has an extra flange of rubber to close the roof of the mouth. The nipple can be used with a plastic bottle that can be squeezed gently to increase the flow of the feeding to compensate for poor sucking. A Breck feeder may also be used.

FIGURE 27.3 (**A**) Specialty feeding devices used for infants with cleft lip and cleft palate. (**B**) An infant uses a Haberman Feeder™.

If surgery is delayed beyond 6 months of age or the time solid food would be introduced, teach parents to be certain any food offered is soft. Particles of coarse food could invade the nasopharynx and cause aspiration. Infants whose surgery is delayed to this point can be fitted with a plastic palate guard to form a synthetic palate and help prevent this.

Postoperative Period. After surgery for cleft lip or palate, an infant is kept NPO for approximately 4 hours. The infant is then introduced to liquids (plain water). Begin the process with only a small amount to prevent vomiting.

It is important that no tension is placed on a lip suture line; avoiding tension helps keep the sutures from pulling apart and leaving a large scar. During this immediate postoperative period, the infant is usually fed using a specialized feeder because this causes less suture line tension than bottle feeding or breastfeeding.

After palate surgery, liquids are generally continued for the first 3 or 4 days, and then a soft diet is followed until healing is complete. Ask parents what fluids the child prefers so they can be available after surgery.

After a cleft palate repair, when children begin eating soft food, they should not use a spoon, because they will invariably push it against the roof of the mouth and possibly disrupt sutures. If being fed rather than being allowed to use a spoon himself evokes an intense reaction, it is better to leave a child on a liquid diet until the sutures are removed. Be certain milk is not included in the first fluids offered because milk curds tend to adhere to the suture line. After a feeding, offer the child clear water to rinse the suture line and keep it as clean as possible.

Nursing Diagnosis: Risk for ineffective airway clearance related to oral surgery

Outcome Evaluation: Child's respiratory rate remains between 20 to 30 respirations per minute without retractions or obvious distress.

Because of the local edema that occurs after cleft lip or palate surgery, observe children closely in the immediate postoperative period for respiratory distress. Before surgery, the infant with a cleft lip breathed through the mouth. After surgery, the infant now has to learn to breathe through the nose, possibly adding to respiratory difficulty. Generally, however, this is not a problem because newborns normally are strict nose-breathers.

Infants may need suction to remove mucus, blood, and unswallowed saliva. When performing suctioning, be gentle and do not touch the suture line with the catheter. After cleft lip surgery, place infants on their side to allow mouth secretions to drain. Support them well so they do not turn onto their abdomen, as this could put pressure on the suture line, possibly tearing

it. Placing them in an infant bouncy chair is another possibility.

Nursing Diagnosis: Impaired tissue integrity at incision line related to cleft lip or cleft palate surgery

Outcome Evaluation: Incision line appears clean and intact and free of erythema or drainage during postoperative period.

After cleft lip surgery, the suture line is held in close approximation by a Logan bar (a wire bow taped to both cheeks; Fig. 27.4) or an adhesive bandage such as a Band-Aid simulating a bar that brings together the incision line but does not cover the incision. Assess the Logan bar or Band-Aid–simulated bar after each feeding or cleaning of the suture line to be certain it is secure and continues to protect the suture line from tension. Furnish adequate pain relief so, if possible, the infant does not cry, because crying increases tension on the sutures. To help avoid crying, try to anticipate the infant's needs. Have formula ready to feed on demand—do not wait until after the infant is awake and crying. Help the parents use whatever measures, such as rocking, carrying, or holding, that are necessary to make the infant feel secure and comfortable. The baby also will need to be bubbled well after a feeding because there is a tendency to swallow more air than the average infant.

Nothing hard or sharp must come in contact with a recent cleft suture line. Observe infants after palate repair carefully to be certain they do not put toys with sharp edges into their mouths. They should not use a straw to drink, nor should they brush their own teeth—they will certainly brush the suture line accidentally. Keep elbow restraints in place as necessary when no one is with them so they do not put their fingers in their mouth and poke or pull at the sutures. Most children run their tongue over their sutures because of the odd feeling in the roof of their mouth, and most children this age do not respond to a caution not to do this. Because this often occurs when children have nothing to think about, help the parents provide diversional activities such as reading or singing to them.

If parents will be continuing to give an analgesic such as acetaminophen (Tylenol) after they return home, be certain they are aware of the correct dosage and time schedule for administration. Be sure they can demonstrate measures to protect the suture line at home until healing is complete.

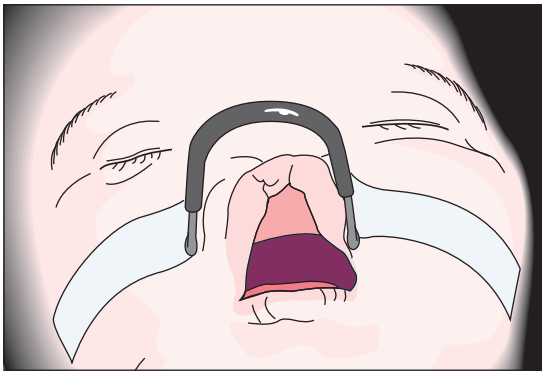

FIGURE 27.4 A Logan bar is an apparatus that may be used to protect the surgical incision for a cleft lip repair.

Nursing Diagnosis: Risk for infection related to surgical incision

Outcome Evaluation: Infant's temperature is below 98.6° F (37° C) axillary; incision site is clean, dry, and intact without erythema or foul drainage.

Infection, and subsequent scarring, may result if crusts from serous drainage are allowed to form on a cleft lip suture line. Most surgeons prescribe cleaning the suture line with sterile water, sterile saline, or 50% hydrogen peroxide in sterile water used with sterile cotton-tipped applicators after every feeding or whenever the normal serum that forms on suture lines accumulates. Use a smooth, gentle, rolling motion to apply the solution. Do not rub, because this can loosen sutures. If hydrogen peroxide is used, it will foam as it reacts with the protein particles at the suture line. Rinse the area with sterile water afterward. Gently dry the suture line with a dry sterile cotton-tipped applicator. Remember that an infant has sutures on the inside of the lip that need the same meticulous care as those visible on the outside.

Nursing Diagnosis: Risk for impaired parenting related to the birth of an infant who is physically challenged

Outcome Evaluation: Parents state a belief in a positive outcome for child; demonstrate positive coping behaviors, evidenced by holding and helping with infant care.

To promote bonding, parents need to hold and interact with their infant during both the preoperative and postoperative periods. Caution them the incision line will appear swollen in the immediate postoperative period. Reassure them this appearance will improve over time. As soon as the child's sutures have been removed, the infant may be bottle fed (with an ordinary bottle) or breastfed. Caution both the breastfeeding mother (who has been maintaining her milk supply through expression) and the formula-feeding mother that because the infant has never sucked before, time will be needed to learn, just as does a newborn.

Notice whether the parents look at their baby's face while feeding the baby. Help them to understand that any negative feelings directed toward the child or themselves, such as sadness or anger their baby was born this way, are normal. This does not instantly make them feel better about what has happened, but the knowledge that what they are experiencing is normal can help them begin to deal with such emotions. Many communities have support groups for parents of children born with a cleft lip or palate. Referral to these groups can be helpful (Box 27.2).

Nursing Diagnosis: Risk for situational low self-esteem related to facial surgery

Outcome Evaluation: Child participates in normal childhood activities that involve contact with other people; states activities he or she enjoys at health care visits; demonstrates age-appropriate developmental milestones.

BOX 27.2 ✻ Focus on Evidence-Based Practice

Does the timing of a cleft lip repair make a difference in mother–child interaction?
To answer this question, researchers compared mother–infant attachment in 94 infants who were born with a cleft lip and 96 nonaffected infants at 2, 6, and 12 months. They then compared cognitive development and infant behavior at 18 months. The infants who were born with cleft lips received either early (immediate) repair or late repair (3–4 months). Results of the study revealed that both the infants with cleft lip and control infants scored equally well on measures of behavior problems or attachment regardless of the timing of the surgical repair. Those infants who had a late surgical repair, however, scored lower on cognitive functioning (measured by the Bayley Scale of Mental Development) at 18 months than those infants with an early surgical repair. As parent–child interaction is important in gaining early cognitive development, this difference could reflect difficulties with parent–child interaction.

Based on the above, what type of role modeling would you demonstrate when caring for a newborn with a cleft lip?

Source: Murray, L., et al. (2008). The effect of cleft lip and palate, and the timing of lip repair on mother–infant interactions and infant development. *Journal of Child Psychology and Psychiatry and Allied Disciplines, 49*(2), 115–123.

If a scar remains after cleft lip surgery, children may need some help adjusting to it until a cosmetic repair can be completed later in life. Reinforce children's positive attributes, stressing that the scar is only one small aspect of who they are. As children reach adolescence, you may need to review a familial inheritance pattern of cleft lip so they are informed of the possible risk of transmission to their own children.

Nursing Diagnosis: Risk for infection (ear) related to altered slope of eustachian tube with cleft palate surgery

Outcome Evaluation: Parents state possible signs and symptoms of ear infection and state importance of early treatment; parents list signs of diminished hearing and appropriate agencies for support and guidance.

Changing the contour of the palate when it is repaired also changes the slope of the eustachian tube to the middle ear. This can lead to a high incidence of middle ear infection (otitis media) because organisms are more readily able to reach this area from the oral cavity. Review the signs of infection such as fever, pain, pulling on the ear, or discharge from the ear with parents. Also remind them of the importance of reporting pharyngeal infection to their primary care provider promptly so it can be treated before the infection spreads to the middle ear. Because the eustachian tube may remain partially closed because of its changed position, serous otitis media (accumulation of fluid in the middle ear) also tends to occur more frequently in these children than in others. If this happens, myringotomy tubes may be inserted to drain middle ear fluid and help protect hearing (see Chapter 50). Be certain that parents understand the need for routine screening for hearing loss during childhood, because this is a common early sign of serous otitis media.

Nursing Diagnosis: Risk for impaired verbal communication related to cleft palate

Outcome Evaluation: Family members voice satisfaction with child's speech; developmental milestone of clearly articulated two-word sentences by age 2 years is met.

Infants with a cleft palate will begin to make speech sounds at the normal time (age 2 months), although their speech may be guttural and harsh. By 9 months, when other infants begin to say meaningful words ("bye-bye," "mama," "dada"), assuming the cleft palate is still unrepaired, speech sounds will be unclear. Some parents try to discourage their baby from talking, thinking if the child does not talk until after the cleft palate repair is made, a speech impediment will not develop. Speech occurs at a specified developmental time, however, and despite the unfused palate it should be encouraged at these age-appropriate times. A child with a cleft palate can enunciate vowel sounds with the most clarity, so these are the sounds a parent should encourage the child to voice. Words such as "me," "they," "no," "mama," "home," "moon," "rain," "yell," and "row" are words consisting largely of vowel sounds and can be enunciated most clearly by the child before a cleft palate repair.

Almost all children who have had cleft palates continue to have accompanying speech problems after the repair (Brunnegard & Lohmander, 2007). The soft palate must function for the child to pronounce "p" and "b" sounds. If cleft palate surgery is going to be delayed much past age 2 years (as might happen if the child has other congenital anomalies, such as heart disease), a plastic prosthesis to cover the incomplete palate may be prescribed. This allows the child to articulate more normally.

Children do not spontaneously outgrow faulty speech patterns, so training by a speech therapist may be necessary. Commonly used exercises children are asked to perform include blowing games, such as blowing a feather or a table tennis ball (a blowing motion is what is required to pronounce "p" and "b").

Pierre Robin Syndrome

The Pierre Robin syndrome (also called Pierre Robin sequence) is a triad of micrognathia (small mandible), cleft palate, and glossoptosis (a tongue malpositioned downward). It is an example of cleft palate occurring as only one part of a syndrome (Hoffman, 2008). It is rare, occurring only once in every 8500 births (Lidsky, Lander, & Sidman, 2008). Children may have associated disorders of congenital glaucoma, cataracts, or cardiac disorders. They need thorough physical and genetic assessments to be certain that none of these associated disorders are present.

Observe all infants with Pierre Robin syndrome carefully to be certain they are not developing an airway obstruction. They may need frequent nasopharyngeal suctioning to remove unswallowed saliva. Beginning at birth, children with this syndrome are apt to have episodes in which they have difficulty breathing because, as a result of their small jaws, their tongues are too large for their mouths. This discrepancy causes the tongue to drop backward and obstruct the airway. Obstruction is most likely to occur when the child is in a supine position. Unlike well infants, no infant with this syndrome should be placed in a supine position to sleep; they are in grave danger of anoxia if left in this position. Use a side-lying position instead. Occasionally, infants have such extensive airway obstruction that attaching a suture to the anterior aspect of the tongue and pulling it forward is used to provide relief. The suture is attached to the mucous membrane of the lower lip, creating an artificial tongue-tied condition.

Parents need instructions to feed these infants with the same care and concern given all children with cleft palate. A gastrostomy tube or button may be inserted to relieve feeding difficulty (see Chapter 37). As the child grows older, the jaw will grow somewhat, although the mandible will always be small. Growth, coupled with a repair of the cleft palate, will decrease the respiratory problems.

Parents of the child with Pierre Robin syndrome take on a great deal of responsibility when they assume their infant's care. Be certain they have the name and number of a health care provider they can call when they have questions. Many of these parents grow exhausted during the first few weeks of their child's life, afraid they may fall soundly asleep at night and miss their child having respiratory difficulty. Using a respiratory monitor at night can be helpful to give assurance that the infant is breathing. As parents' confidence grows in their ability to provide care, this problem lessens, but it may be months or even years before a high level of confidence is achieved.

Tracheoesophageal Atresia and Fistula

Between weeks 4 and 8 of intrauterine life, the laryngotracheal groove develops into the larynx, trachea, and beginning lung tissue. The esophageal lumen forms parallel to this. A number of anomalies may occur if the trachea and esophagus are affected by some teratogen that does not allow the two organs to separate but remain connected.

Esophageal atresia is obstruction of the esophagus. Often a fistula (opening) occurs between the closed esophagus and the trachea. The five usual types of esophageal atresia that occur are:

1. The esophagus ends in a blind pouch; there is a tracheoesophageal fistula between the distal part of the esophagus and the trachea (see Fig. 27.5A).
2. The esophagus ends in a blind pouch; there is no connection to the trachea (see Fig. 27.5B).
3. A fistula is present between an otherwise normal esophagus and trachea (see Fig. 27.5C).
4. The esophagus ends in a blind pouch. A fistula connects the blind pouch of the proximal esophagus to the trachea (see Fig. 27.5D).
5. There is a blind end portion of the esophagus. Fistulas are present between both widely spaced segments of the esophagus and the trachea (see Fig. 27.5E).

These are all serious disorders because during a feeding, milk can fill the blind esophagus and overflow into the trachea, or a fistula can allow milk to enter the trachea, resulting in aspiration. The incidence of tracheoesophageal fistula is approximately 1 in 3000 live births (Fowler & Lee, 2008).

Assessment

Tracheoesophageal atresia must be ruled out in any infant born to a woman with hydramnios (excessive amniotic fluid). Hydramnios occurs because normally a fetus swallows amniotic fluid during intrauterine life. A fetus with a tracheoesophageal atresia cannot swallow, so the amount of amniotic fluid can grow abnormally large. Many infants with tracheoesophageal fistula are born preterm because of the accompanying hydramnios, compounding their original problem with immaturity. The infant needs to be examined carefully for other congenital anomalies that could have occurred from the

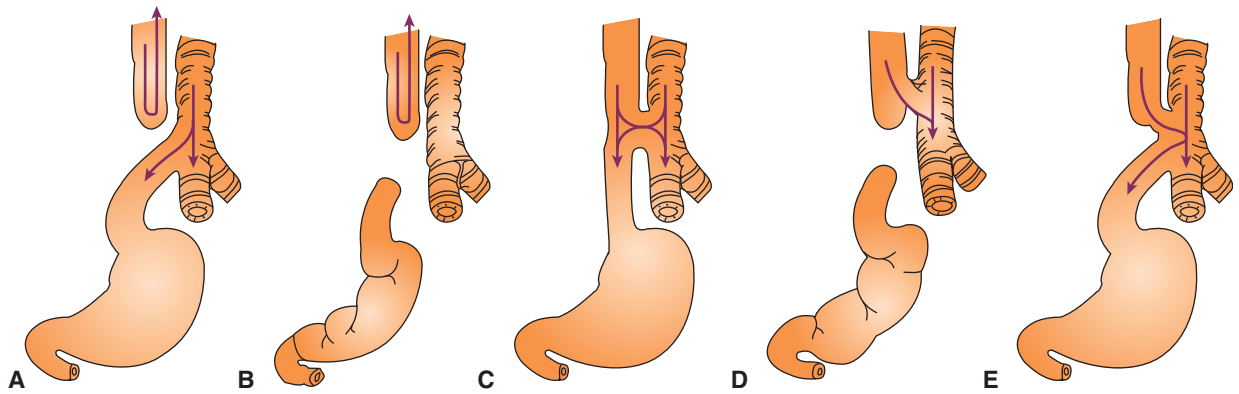

FIGURE 27.5 Esophageal atresia and tracheoesophageal fistula. (**A**) In the most common type of esophageal atresia, the esophagus ends in a blind pouch. The trachea communicates by a fistula with the lower esophagus and stomach (approximately 90% of infants with the defect have this type). (**B**) Both upper and lower segments end in blind pouches (5%–8% of infants with the defect have this type). (**C**) Both upper and lower segments communicate with the trachea (2%–3% of infants with the defect have this type). (**D**) Very rarely, the upper segment ends in a blind pouch and communicates by a fistula to the trachea, or (**E**) a fistula connects to both upper and lower segments of the esophagus.

teratogenic effect at the same week in gestation, such as *v*ertebral, *a*nal, *c*ardiac, *t*racheo*e*sophageal, *r*enal, and *l*imb anomalies (a VACTERL syndrome) (Pelluard-Nehme et al., 2007).

If not diagnosed in utero, diagnosing a child who has a tracheoesophageal fistula before the infant is first fed is important. Otherwise, the infant will cough, become cyanotic, and have obvious difficulty breathing as fluid is aspirated. Newborns who have so much mucus in their mouths that they appear to be blowing bubbles should be suspected of having tracheoesophageal fistula. The condition can be diagnosed with certainty if a catheter cannot be passed through the infant's esophagus to the stomach or the stomach contents cannot be aspirated. If doing this, use a firm catheter because a soft one will curl in a blind-end esophagus and appear to have passed. If a radiopaque catheter is used, it can be demonstrated coiled in the blind end of the esophagus on radiography. A flat-plate radiograph of the abdomen or ultrasound also may reveal a stomach distended with the air that is passing from the trachea into the esophagus and stomach. Either a barium swallow or a bronchial endoscopy examination can also reveal the blind-end esophagus and fistula.

Therapeutic Management

Emergency surgery for the infant with tracheoesophageal fistula is essential to prevent the development of pneumonia from leakage of stomach secretions into the lungs or dehydration or an electrolyte imbalance from lack of oral intake. Antibiotics may be prescribed to help prevent infection. A gastrostomy may be performed (under local anesthesia) and the tube allowed to drain by gravity to keep the stomach empty of secretions and prevent reflux into the lungs. Upper right lobe pneumonia from aspiration is one of the major complications of this disorder.

Surgery consists of closing the fistula and anastomosing the esophageal segments. It may be necessary to complete the surgery in different stages and to use a portion of the colon to complete the anastomosis if the esophageal segments are far apart from each other. Observe infants closely at postoperative days 7 to 10, when sutures dissolve, because leaks occurring at anastomosis sites can occur at this time. If this occurs, fluid and air leak out into the chest cavity, and pneumothorax (collapse of the lung) can occur.

In some infants, some stenosis or stricture at the anastomosis site remains. If this occurs, esophageal dilatation at periodic intervals to keep the repaired esophagus fully patent may be necessary. Gastroesophageal reflux may also occur after a repair if the esophagus is left shorter than usual (Fowler & Lee, 2008). This can lead to recurrent fistula formation from the presence of stomach acid in the esophagus.

The ultimate prognosis for children with this disorder will depend on the extent of the repair necessary, the condition of the child at the time of surgery, and the presence or absence of other congenital anomalies. If the defect is a simple fistula, it can be repaired by endoscopic technique and application of fibrin glue to seal the fistula (Richter et al., 2008). Even with larger disorders, if surgery can be performed before pneumonia develops, the prognosis is good. However, the mortality rate for the condition remains high because of the presence of other congenital disorders and low birth weight that often accompanies the tracheal abnormality.

Nursing Diagnoses and Related Interventions

Outcomes established for the child with tracheoesophageal fistula must be realistic in terms of the extent of the disorder, the timing of anticipated surgery, and the stage of grief or readiness for decision making and planning the parents have reached.

Nursing Diagnosis: Risk for imbalanced nutrition, less than body requirements, related to inability to take in oral feedings

Outcome Evaluation: Child maintains weight within 10% of birth weight; maintains weight in same percentile on growth curve.

Before surgery, because oral fluid cannot be given until the esophagus is repaired, intravenous therapy or total parenteral nutrition can supply fluid and calories. This is continued for a time after surgery until the possibility of vomiting from the anesthetic is decreased. Then the infant may be fed orally, may be continued on total parenteral nutrition, or may be started on gastrostomy feedings, depending on whether the surgery could be completed in one stage or not. Early introduction of oral fluid may help to ensure patency of the esophagus because it helps to decrease adhesion formation at the anastomosis site and also allows the infant the enjoyment and practice of sucking. If formula is given by gastrostomy feedings, introduce it into the tube slowly and allow it to run by gravity pressure only to prevent fluid from entering the esophagus and putting pressure on the suture line. After the feeding, the end of the tube should be elevated, covered by sterile gauze, and kept in the elevated position. Do not clamp it closed. In this way, any air introduced during the feeding will bubble from the tube and not enter the esophagus and pass the fresh suture line. This also helps to ensure that if the infant should vomit the feeding, the vomitus will be projected into the gastrostomy tube and will not contaminate the fresh sutures. Most newborns enjoy sucking a pacifier during gastrostomy feedings for sucking pleasure. If a mother wishes to breastfeed, she can manually express breast milk for the gastrostomy feedings.

If the child is to return home to await a second-stage operation, the gastrostomy tube will be left in place for a month or two. Therefore, parents must learn how to do gastrostomy feedings. Be certain they know to continue usual infant care, such as holding or talking to the infant in the face of this different feeding method.

Nursing Diagnosis: Risk for infection related to aspiration or seepage of stomach secretions into lungs

Outcome Evaluation: Child's temperature remains below 98.6° F (37° C) axillary; absence of rales on auscultation.

Preoperative Care. Before surgery, position the infant upright in an infant chair or on the right side to prevent gastric fluid from entering the lungs from the fistula. Because the infant cannot swallow mucus, frequent oropharyngeal suctioning is necessary. A catheter may

be passed into the blind-end esophagus and attached to low continuous or intermittent suction to keep this segment of the esophagus from filling with swallowed saliva and causing aspiration from overflow. Irrigation of the catheter may be necessary to keep it patent, because mucus tends to dry and plug it.

If surgery will be delayed, the infant may have a cervical esophagostomy (the distal end of the blind esophagus is brought to the surface just over the sternum so that mucus can drain). Apply a protective ointment liberally to protect skin. Use absorbent gauze around the opening to absorb moisture and prevent excoriation of the skin. A consult by a wound, ostomy, and continence therapy nurse may be needed to prevent further skin irritation.

Keeping the infant under a radiant heat warmer with a high-humidity oxygen source helps to maintain body heat and liquefy bronchial secretions while awaiting surgery. Try to keep the infant from crying; with crying, air enters the stomach from the trachea, distending the stomach and possibly causing vomiting with aspiration into the lungs. A pacifier may help relax a baby and also satisfy a sucking need.

Postoperative Care. After surgery, the infant will have one or two chest tubes in place because the chest cavity was entered for the repair. The posterior tube drains collecting fluid; the anterior tube allows air to leave the chest space, re-expanding the lungs. Care of the child with chest tubes is discussed in Chapter 41.

In the first few days after surgery, observe the infant closely for respiratory distress. Continue to suction saliva from the mouth as ordered because mucus tends to accumulate in the pharynx from surgical trauma. Suctioning must be done only shallowly, however, to prevent the suction catheter from touching the suture line in the esophagus. Turn the child frequently to discourage fluid from accumulating in the lungs. Humidified oxygen helps to keep respiratory secretions moist. Keep an infant laryngoscope and endotracheal tube readily available at the bedside in case extreme edema develops, increasing the infant's risk for airway obstruction.

Nursing Diagnosis: Risk for impaired skin integrity related to gastrostomy tube insertion site

Outcome Evaluation: Skin surrounding gastrostomy tube remains clean and dry, without erythema.

Gastric secretions, which are highly acidic, may leak onto the skin from the gastrostomy site, leading to skin irritation. Protect the skin by using a cream or commercial skin protection system. Consulting with a wound, ostomy, and continence therapy nurse can be helpful to reduce the possibility of skin irritation.

Omphalocele

An **omphalocele** is a protrusion of abdominal contents through the abdominal wall at the point of the junction of the umbilical cord and abdomen (Fig. 27.6). The herniated organs are usually the intestines, but they may include stomach and liver. They are usually covered and contained by a thin transparent layer of amnion and chorion with the umbilical cord protruding from the exposed sac. When the defect is less than 4 cm, it is termed a hernia of the umbilical cord; when greater than 10 cm, it is a true omphalocele. This condition occurs because at approximately weeks 6 to 8 of intrauterine life, the fetal abdominal contents, growing faster than the fetal abdomen, are extruded from the abdomen into the base of the umbilical cord. At 7 to 10 weeks, when the abdomen has enlarged sufficiently, the intestine returns to the abdomen. Omphalocele occurs when the abdominal contents fail to return in the usual way. The occurrence is associated with chromosomal aberrations. A previous association between serotonin-reuptake ingestion during pregnancy has proven to be false (Louik et al., 2007).

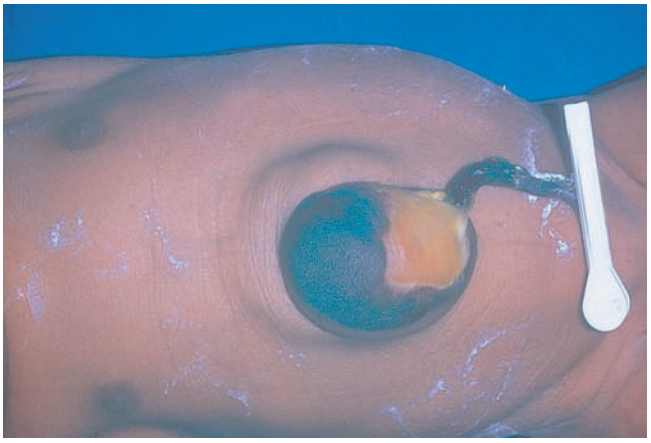

FIGURE 27.6 Omphalocele. This large example seen at birth contains intestine and liver. (Ansary/Custom Medical Stock Photograph.)

Assessment

The incidence of omphalocele is about 1 in 5000 live births. Many omphaloceles are diagnosed by prenatal sonogram. It may also be revealed by an elevated maternal serum α-fetoprotein (MSAFP) examination (see Chapter 11) during pregnancy (Smith & Henderson, 2007). If not, the presence of omphalocele is obvious on inspection at birth. When an omphalocele is identified in utero, cesarean birth may be performed to protect the exposed intestine. If this is the only disorder identified, however, vaginal birth can be allowed to proceed. Be sure to document the omphalocele's general appearance and its size in centimeters at birth.

Therapeutic Management

Most infants will have surgery within 24 hours to replace the bowel before the thin membrane surrounding it ruptures or becomes infected. It is often difficult to replace the entire bowel with immediate surgery because the infant's abdomen, which did not need to grow to accommodate the abdominal contents, is smaller than usual. If the total bowel were replaced into this small abdomen, respiratory distress could result from the pressure of the visceral bulk on the diaphragm and lungs. Also, the bowel might not have room for effective peristalsis. If the omphalocele is small, a one-stage repair may be possible (van Eijck et al., 2008). If large, one surgical approach is the use of a prosthetic patch repair that bridges the

unformed gap on the abdomen with a synthetic material with the skin drawn tight and closed over the patch. A second approach is to replace only a portion of the bowel. The remainder is contained by a Silastic pouch termed a "silo" suspended over the infant's bed. Over the next 5 to 7 days, bowel is gradually returned to the abdomen. During this time, the infant can be fed by total parenteral nutrition to supply nutrients and keep the bowel from filling with air or stool.

Nursing Diagnoses and Related Interventions

Outcomes established for the infant with omphalocele must be realistic in terms of the extent of the disorder, the timing of anticipated surgery, and the stage of grief or readiness for decision making and planning that the parents have reached. Omphalocele is a shock to parents; it is a condition that is obviously severe yet one that is generally unknown.

Nursing Diagnosis: Risk for infection related to exposed abdominal contents

Outcome Evaluation: Child's temperature remains below 98.6° F (37° C) axillary; skin surrounding omphalocele remains clean, dry, and intact, without erythema or foul drainage.

Before surgery, it is important that the lining of peritoneum covering the omphalocele not be ruptured or allowed to dry out and crack; if this happens, infection and malrotation of the uncontained intestine can occur, complicating the surgical repair. Exposure of intestine to air also causes a rapid loss of body heat. Therefore, immediately place the baby in a warmed incubator. Do not leave the infant under a radiant heat source because this will quickly dry the exposed bowel. To keep the sac moist, cover it with either sterile saline-soaked gauze or a sterile plastic bowel bag until surgery. Because of the large amount of exposed intestinal surface, the saline used must be at body temperature to prevent lowering body temperature. If the omphalocele is large, infants may be prescribed a topical application of a solution such as silver sulfadiazine to prevent infection of the sac.

The prognosis for a final successful surgical repair is good. Except for a large abdominal scar, the child who had an omphalocele will be the child originally envisioned by parents. If the size of the scar is a problem for the child in later life, cosmetic surgery can reduce its appearance.

Nursing Diagnosis: Risk for imbalanced nutrition, less than body requirements, related to exposed abdominal contents

Outcome Evaluation: Child's weight remains within 10% of birth weight; skin turgor is good; specific gravity of urine is 1.003 to 1.030.

A nasogastric tube is inserted at birth to prevent intestinal distention, which would enlarge the bowel lumen, making it even more difficult to replace. Do not feed the infant orally or allow the infant to suck on a pacifier until the bowel repair is complete, as doing so would distend the exposed bowel with food or air and also make its return to the abdomen more difficult. Some infants have an accompanying **volvulus** (a twisting of the bowel causing obstruction), which is another reason to omit oral feedings. After surgery, the infant is maintained on total parenteral nutrition. Once the final stage of bowel repair is completed, a normal infant diet can be introduced gradually. Observe infants carefully for signs of obstruction such as abdominal distention, constipation, diarrhea, or vomiting when they begin oral feedings.

Infants with omphalocele can be hospitalized or receive home care for a long time (a minimum of 1 or 2 months) waiting for a second-stage or even a third-stage operation, depending on the extent of bowel involved. If the infant is hospitalized, encourage parents to visit frequently. Be sure the infant has age-appropriate toys available for stimulation.

Parents can become distressed that their child's operation is being done in such small stages. Offer support to help them accept that this treatment method is the best way to manage this type of intestinal disorder.

Gastroschisis

Gastroschisis is a condition similar to omphalocele, except that the abdominal wall disorder is a distance from the umbilicus, usually to the right, and abdominal organs are not contained by a membrane but rather spill freely from the abdomen (Thilo & Rosenberg, 2008). Also, a greater amount of intestinal content tends to herniate, increasing the potential for volvulus and obstruction. The condition occurs because of ischemia to blood vessels that supply the abdominal wall during the first trimester of pregnancy. For unknown reasons, it is increasing in incidence from about 2 in 10,000 births to 4.5 per 10,000 births, particularly in young mothers (Lund, Bauer, & Berrios, 2007). The care and surgical procedure are the same as those for omphalocele. Children with gastroschisis often have decreased bowel motility, and even after surgical correction may have difficulty with absorption of nutrients and passage of stool. Long-term follow-up may be necessary to ensure that nutrition and elimination are adequate (Raab, 2007).

✔ Checkpoint Question 27.1

What is the most important consideration in the care of the child with an omphalocele at birth?

a. Position the infant on his stomach to contain the intestine.
b. Wrap the omphalocele in cold icy gauze to prevent fever.
c. Keep the infant seated upright under a radiant warmer.
d. Contain the intestine in a sterile saline–lined bowel bag.

Intestinal Obstruction

If canalization of the intestine does not occur in utero at some point in the bowel, an **atresia** (complete closure) or **stenosis** (narrowing) of the fetal bowel can develop. The most common site of this occurrence is in the duodenum.

Obstruction may occur because the mesentery of the bowel twisted as the bowel re-entered the abdomen (after being contained in the base of the umbilical cord early in intrauterine life) or from looseness of the intestine in the abdomen after it has returned (Ingoe & Lange, 2007). This twisting pattern is termed a volvulus and continues to be a problem for the first 6 months of life until the infant develops firmer intestinal supports. Obstruction also can occur because of thicker-than-usual meconium formation, blocking the lumen (meconium plug or meconium ileus).

Assessment

Intestinal obstruction may be anticipated if the mother had hydramnios during pregnancy (swallowed amniotic fluid could not be absorbed effectively by the fetus) or if more than 30 mL of stomach contents can be aspirated from the newborn stomach by catheter and syringe at birth (fluid is not passing freely through the tract). If the obstruction is not revealed by either of these findings, then symptoms of intestinal obstruction in the neonate are the same as at any other time in life: the infant passes no meconium or may pass one stool (meconium that formed below the obstruction) and then not pass any more; the abdomen becomes distended and tender. As the effect of the obstruction progresses, the infant will vomit. Remember that many neonates spit up feedings when burped. This rapid ejection of milk smells barely sour. True vomiting is usually sour-smelling (stomach acid has acted on it) and occurs spontaneously without coughing or back-patting.

Obstructions are rare above the ampulla of Vater, the junction of the bile duct with the duodenum, so vomitus will be bile stained (greenish). Because meconium is black, vomitus may also be dark. Bowel sounds increase with obstruction because of the increase in peristaltic action that occurs as the intestine attempts to push stool pass the point of obstruction. Waves of peristalsis may be apparent across the abdomen. The infant may evidence pain by crying—hard, forceful, indignant crying—and by pulling the legs up against the abdomen. The child's respiratory rate will increase as the intestine fills and the diaphragm is pushed up against the lungs and lung capacity decreases. An abdominal flat-plate radiograph or sonogram will reveal no air below the level of obstruction in the intestines. A barium swallow or barium enema x-ray film may be used to reveal the position of the obstruction.

Therapeutic Management

When bowel obstruction is confirmed, an orogastric or a nasogastric tube is inserted and then attached to low suction or left open to the air to prevent further gastrointestinal distention from swallowed air (see Chapter 37). Always use low intermittent suction with decompression tubes in neonates. Pressure greater than this can irritate and ulcerate their stomach lining.

Intravenous therapy is necessary to restore fluid, and immediate surgery is scheduled because bowel obstruction is an emergency that must be treated before dehydration, electrolyte imbalance, or aspiration of vomitus occurs (Ingoe & Lange, 2007).

Repair of the obstruction (with the exception of meconium plug syndrome) is accomplished by laparoscopy or through an abdominal incision. The area of stenosis or atresia is removed, and the bowel is anastomosed. If the repair is anatomically difficult or the infant has other anomalies that interfere with overall health, a temporary colostomy may be constructed and the infant discharged to home care, with surgery rescheduled at about 3 to 6 months of age. Care of the child with a colostomy is discussed in Chapter 37. A final surgical procedure will restore the child to full health unless a large portion of the bowel had to be removed, which would have an impact on nutrient absorption (short bowel syndrome).

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for deficient fluid volume related to vomiting

Outcome Evaluation: Child's skin turgor is good; pulse rate is 100 to 120 beats per minute; no further vomiting occurs; urine output is at least 30 mL/hr.

Once an obstruction is suspected, keep an infant NPO to prevent the bowel from filling, and compounding the problem, and to prevent vomiting and aspiration. Vomiting in neonates is always serious, not only because aspiration may occur but also because infants lose fluid rapidly, which results in dehydration. They also lose chloride (a component of the hydrochloric acid found in stomach contents), and this leads to metabolic alkalosis. The body attempts to compensate for the loss of chloride by excreting potassium, which can cause infants to become hypokalemic quickly. Keeping an infant NPO, restoring fluid by intravenous therapy, and monitoring laboratory values for electrolyte balance until surgery can be scheduled are crucial.

Meconium Plug Syndrome

A **meconium plug** is an extremely hard portion of meconium that has completely blocked the intestinal lumen, causing bowel obstruction. The cause is unknown but probably reflects normal variations of meconium consistency. Meconium plugs usually form in the lower end of the bowel because this meconium formed early in intrauterine life and has the best chance to become dry and obstruct the bowel lumen. It may be associated with Hirschsprung's disease and is strongly associated with cystic fibrosis (Balfour-Lynn, 2008).

Assessment

Because the obstruction is low in the intestinal tract, signs of obstruction such as abdominal distention and vomiting may not occur for at least 24 hours. Typically, the infant will be identified first as an infant who has had no meconium passage and is past 24 hours of age. A gentle rectal examination may reveal the presence of hardened stool, although the plug may be too high up in the bowel to be palpated. A radiograph or sonogram may reveal distended air-filled loops of bowel up to the point of obstruction. A slightly hypertonic water-soluble contrast agent enema not only may reveal the level of obstruction but also may be therapeutic in loosening the plug.

Therapeutic Management

The administration of saline enemas (never use tap water in newborns because it can lead to water intoxication) may

cause enough peristalsis to expel the plug. Instillation of acetylcysteine (Mucomyst) with diatrizoate (Hypaque) rectally may also be prescribed to dissolve the plug. Gastrografin, a highly osmotic radiographic substance, can be administered as an enema. The substance pulls fluid into the bowel because of its low osmotic pressure, allowing the stool to soften and the plug to pass. Infants need to be well hydrated before and after the procedure or they can become hypovolemic from the effect of the contrast medium.

Once the thickened portion of meconium has been passed, the infant should have no further difficulty and, over the next several hours, may pass a great amount of stool. Observe the infant for further passage of meconium (should occur at least once daily) over the next 3 days, however, to be certain that additional plugs do not exist farther up in the bowel. If an infant is going to be discharged before this time, instruct parents on the importance of observing for meconium and also about phoning their primary care provider should the infant have no further bowel movements while at home.

Occasionally, a neonate passes a small plug of hardened meconium—hard enough it would have caused an obstruction except that it is so small—in the first 1 or 2 days of life. Be certain to record and report such a finding, because the infant will need close observation for continued defecation, the same as for the infant who actually had an obstruction, to be certain that there is not a larger and truly obstructing plug higher in the bowel.

Assess the family history of a newborn who has a meconium plug for cystic fibrosis, a recessively inherited disorder (see Chapter 40), or aganglionic megacolon (Hirschsprung's disease), a polygenic inherited disorder (see Chapter 45), as these disorders may be the cause of the hardened meconium. Hypothyroidism is yet another disorder that may present with constipation or hardened stool in newborns. Additional signs of hypothyroidism include a large protruding tongue, lethargy, and subnormal body temperature. Both hypothyroid and cystic fibrosis screening is done along with phenylketonuria screening. Be certain this blood test is obtained in any newborn with a meconium plug.

Meconium Ileus

Meconium ileus (obstruction of the intestinal lumen by hardened meconium) is a specific phenomenon that occurs almost exclusively in infants with cystic fibrosis (Kerby et al., 2008). It reflects extreme meconium plugging. A genetically recessive disease, with cystic fibrosis, the enzyme that moistens and makes all body fluids free-flowing is absent. All body fluids are therefore thick and tenacious. Cystic fibrosis (see Chapter 40) is most often thought of as a lung disorder, because the most severe manifestation of tenacious secretions is in the lung; tenacious lung fluid leads to stasis and infection and alveolar obstruction that reduces air exchange. Intestinal and pancreatic secretions are affected also, however, and this may be signaled at birth by hardened obstructive meconium at the ileus level from lack of pancreatic trypsin secretion (meconium ileus). This will lead to the usual symptoms of bowel obstruction: no meconium passage, abdominal distention, and vomiting of bile-stained fluid. If the obstruction is too high for enemas to reduce it, the bowel must be incised and the hardened meconium removed by laparotomy. The infant must be further assessed for cystic fibrosis in the following months.

What if... On the second day of life you notice Baby Sparrow, who was born with meconium staining, is spitting up green mucus? Would it be safe to assume this is meconium-stained mucus? Is there a possibility the baby is vomiting bile-stained vomitus?

Diaphragmatic Hernia

A diaphragmatic hernia is a protrusion of an abdominal organ (usually the stomach or intestine) through a defect in the diaphragm into the chest cavity. This usually occurs on the left side, causing cardiac displacement to the right side of the chest and collapse of the left lung. It occurs in approximately 1 in 2000 to 4000 live births. There is no difference between male and female incidence (Warner, 2007).

It occurs because early in intrauterine life, the chest and abdominal cavity are one; at approximately week 8 of growth, the diaphragm forms to divide them. If the diaphragm does not form completely, the intestines can herniate through the diaphragm opening into the chest cavity (Fig. 27.7).

Assessment

Diaphragmatic hernia is occasionally detected in utero by a sonogram. If extreme, surgery to remove the bowel from the chest can be attempted by fetoscopy while the fetus is still in utero. More often, however, the condition is diagnosed at birth. Newborns with a diaphragmatic hernia will have respiratory difficulty from the moment of birth, because at least one of the lobes of their lungs cannot expand completely (and may not have fully formed). Their abdomen generally appears sunken because it is not as filled with intestine as in the normal newborn. Breath sounds will be absent on the affected side of the chest cavity. There may be cyanosis and intercostal or subcostal retractions. These infants have a potential for developing persistent pulmonary hypertension because blood cannot perfuse readily through the unexpanded lung. This leads to right-to-left shunting through the foramen ovale in the heart and also causes the ductus arteriosus to remain patent. One condition, then, has led to another,

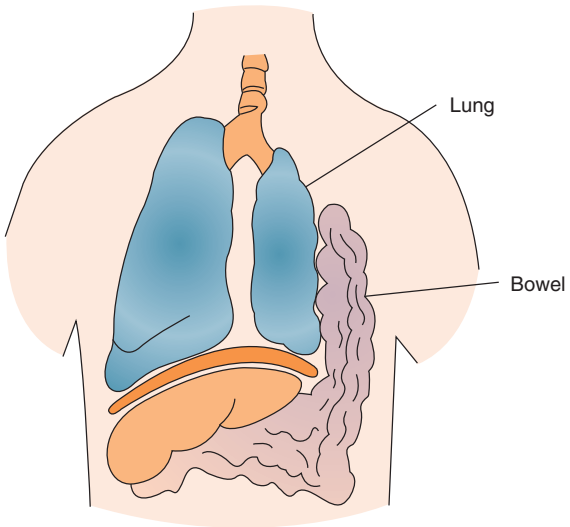

FIGURE 27.7 Diaphragmatic hernia. The bowel loop in the chest compresses the heart and lung on that side.

and heart involvement complicates an already complicated lung picture. The mechanics of right-to-left heart shunts are further discussed in Chapter 41.

Therapeutic Management

Although surgical repair may be delayed until an infant is better stabilized, treatment is usually an emergency surgical repair of the diaphragm and replacement of the herniated intestine back into the abdomen (Moyer et al., 2009). A surgical repair can be accomplished by laparoscopy, a helpful technique for newborns as it requires less anesthesia and cold exposure (Harres, 2007). Difficult repairs may require a thoracic incision and the placement of chest tubes. If the disorder of the diaphragm is large, an insoluble polymer (Teflon) patch may be used in reconstruction. The repair is complicated if there is not enough room in the abdomen for the intestine to be returned. In these infants, the abdominal incision may not be closed but left open to allow the intestine to protrude abdominally. It is covered by silicone elastomer (Silastic) and left to be closed at a later date after the abdomen has grown.

Over the next week, the compressed lung (if it is normal) will gradually expand and begin to function. If it is hypoplastic from the pressure of the intestine in utero, it will not expand; it will be removed at the time of surgery. Because of poor lung compliance, the infant's postoperative course is often complicated by severe pulmonary hypertension, perhaps requiring therapy with high-frequency oscillatory ventilation, inhaled nitric oxide, or extracorporeal membrane oxygenation (ECMO). The mortality rate of children with diaphragmatic hernia ranges from 25% to 40%, with death often because of associated anomalies of the heart, lung, and intestine (Thilo & Rosenberg, 2008).

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for ineffective airway clearance related to displaced bowel

Outcome Evaluation: Child's respiration rate is 30 to 50 breaths per minute; P_{O_2} is 60 to 100 mm Hg; P_{CO_2} is 30 to 35 mm Hg; lungs are clear to auscultation.

The infant with a diaphragmatic hernia breathes better with the head elevated, as this allows the herniated intestine to fall back as far as possible into the abdomen, providing a maximum amount of respiratory space in the chest. Positioning the infant so the compressed lung is down also allows the unaffected lung to expand most completely. A nasogastric tube or a gastrostomy tube is inserted immediately to prevent distention of the herniated intestine, which would cause further respiratory difficulty. Be certain only low intermittent suction is used to avoid injuring the lining of the stomach. Keep the infant NPO, again, to prevent the bowel from filling and becoming distended.

After surgery, continue to maintain the infant in a semi-Fowler's position in an infant chair to keep the pressure of the replaced intestine off the repaired diaphragm. Keep the infant in a warmed humidified environment to encourage lung fluid drainage from the now uncompromised lungs. Suction the airway as necessary. Chest physiotherapy may be ordered to ensure that lung secretions do not pool and to prevent pneumonia. Positive-pressure ventilation may be ordered to increase lung expansion, although this pressure is kept to a minimum to prevent tearing the undeveloped or previously unopened lung tissue. Maintaining arterial oxygen (P_{O_2}) at a high level of 100 mm Hg and the P_{CO_2} at a low level of 30 to 35 mm Hg may help to prevent arterial vasoconstriction of the hypoplastic lung, thereby improving lung function.

Nursing Diagnosis: Risk for imbalanced nutrition, less than body requirements, related to NPO status

Outcome Evaluation: Child's skin turgor remains good; weight is maintained within 10% of birth weight or between a percentile curve on growth chart.

After surgery, to prevent pressure on the suture line in the diaphragm by a full stomach and bowel, nutrition will be supplied intravenously, such as with total parenteral nutrition. When starting oral feedings, be certain to bubble the infant well after feeding to reduce the amount of swallowed air and limit bowel pressure against the diaphragm.

Umbilical Hernia

An umbilical hernia is a protrusion of a portion of the intestine through the umbilical ring, muscle, and fascia surrounding the umbilical cord (Skandalakis et al., 2007). This creates a bulging protrusion under the skin at the umbilicus. It is rarely noticeable at birth while the cord is still present but becomes increasingly noticeable at health care visits during the first year.

Umbilical hernias occur most frequently in African American children and more often in girls than in boys. The structure is generally 1 to 2 cm (0.5 to 1 in) in diameter but may be as large as an orange when children cry or strain. The size of the protruding mass is not as important as the size of the fascial ring through which the intestine protrudes. If this fascial ring is less than 2 cm, closure will usually occur spontaneously and no repair of the disorder will be necessary. If the disorder is more than 2 cm, surgery for repair will generally be indicated to prevent herniation and intestinal obstruction or bowel strangulation. This usually is done when the child is 1 to 2 years of age.

Some parents believe that holding an umbilical hernia in place by using "belly bands" or taping a silver dollar over the area will help to reduce the hernia. These actions can actually lead to bowel strangulation and should be avoided.

Surgery is generally accomplished on an ambulatory outpatient basis. The child returns from surgery with a pressure dressing, which remains in place until the sutures are well healed. Remind parents to sponge-bathe the child until they return for a postoperative visit and the dressing is removed. If the child is not yet toilet-trained, they need to keep diapers folded down below the dressing to prevent contaminating the suture line with stool.

Imperforate Anus

Imperforate anus (Fig. 27.8) is stricture of the anus (Vick et al., 2007). In week 7 of intrauterine life, the upper bowel elongates

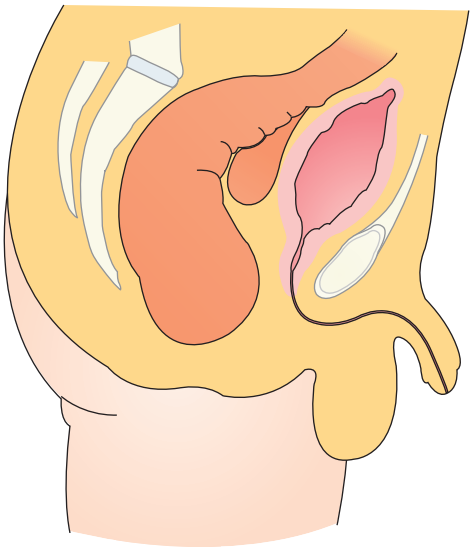

FIGURE 27.8 Imperforate anus. The lower bowel ends in a blind pouch.

to pouch and combine with a pouch invaginating from the perineum. These two sections of bowel meet, the membranes between them are absorbed, and the bowel is then patent to the outside. If this motion toward each other does not occur or if the membrane between the two surfaces does not dissolve, imperforate anus occurs. The disorder can be relatively minor, requiring just surgical incision of the persistent membrane, or much more severe, involving sections of the bowel that are many inches apart with no anus. There may be an accompanying fistula to the bladder in boys and to the vagina in girls, further complicating a surgical repair. The problem occurs in approximately 1 in 5000 live births, more commonly in boys than in girls. Imperforate anus may occur as an additional complication of spinal cord disorders, because both the external anal canal and the spinal cord arise from the same germ tissue layer.

Assessment

The condition may be detected by a prenatal sonogram. It is definitely discovered at birth when inspection of a newborn's anal region reveals that no anus is present, although this observation may not be helpful, because the anus can appear normal and the condition can still exist far inside, so that it is missed on simple inspection. Occasionally, the condition may be revealed because a membrane filled with black meconium can be seen protruding from the anus. A "wink" reflex (touching the skin near the rectum should make it contract) will not be present if sensory nerve endings in the rectum are not intact. If these methods fail to detect the condition, it can be discovered in a newborn by the inability to insert a rubber catheter into the rectum. No stool will be passed, and abdominal distention will become evident. A radiograph or sonogram will reveal the disorder if the infant is held in a head-down position to allow swallowed air to rise to the end of the blind pouch of the bowel. This method is also helpful to estimate the distance the intestine is separated from the perineum or the extent of the correction that will be necessary.

Formerly, when all newborns stayed in the hospital 3 to 4 days after birth, imperforate anus was always discovered. When infants failed to pass stools after the first 24 hours, the reason was investigated. Currently, because newborns are discharged at 2 or 3 days or even a few hours after birth, possibly no one will notice that an infant has not passed a stool in that time. For an infant born in a birthing center or at home, follow-up, therefore, must include assessment of whether the infant is defecating. Collect a urine specimen on infants with imperforate anus so it can be examined for the presence of meconium to help determine whether the child has a rectal–bladder fistula. Placing a urine collector bag over the vagina in girls may reveal a meconium-stained discharge or a rectovaginal fistula.

Therapeutic Management

The degree of difficulty in repairing an imperforate anus depends on the extent of the problem. If the rectum ends close to the perineum (below or at the level of the levator ani muscle) and the anal sphincter is formed, repair involves simple anastomosis of the separated bowel segments. The repair becomes complicated if the end of the rectum is at a distance from the perineum (above the levator ani muscle) or the anal sphincter exists only in an underdeveloped form. All repairs are complicated if a fistula to the bladder or vagina is present. If the repair will be extensive, the surgeon may create a temporary colostomy, anticipating final repair when the infant is somewhat older (6 to 12 months). For a successful repair, it is unnecessary for an internal rectal sphincter to be present as long as the subrectal muscle is judged to be intact.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Imbalanced nutrition, less than body requirements, related to bowel obstruction and inability for oral intake

Outcome Evaluation: Child's weight remains within 10% of birth weight or is maintained on a percentile curve on a growth chart; skin turgor is good.

Preoperative Care. Before surgery, keep the infant NPO to avoid further bowel distention. A nasogastric tube attached to low intermittent suction for decompression will be inserted to relieve vomiting and prevent pressure on other abdominal organs or the diaphragm from the distended intestine. Intravenous therapy or total parenteral nutrition will be started to maintain fluid and electrolyte balance.

Postoperative Care. The newborn will return from surgery with a nasogastric tube still in place. When bowel sounds are present and the nasogastric tube is removed, small oral feedings of glucose water, formula, or breast milk can be begun.

Some infants, who are scheduled for repair in a second-stage operation and who have a temporary colostomy, are not permitted high-residue foods to lessen the bulk of stools. Although this is rarely a problem with infants because their diet naturally is a low-residue one, do not assume that parents know what low residue means. Examples include rice cereal and strained fruits and vegetables. They should avoid unrefined rice and grains, vegetables with fibers, or fruits with peels.

Nursing Diagnosis: Impaired tissue integrity at rectum related to surgical incision

Outcome Evaluation: Incision line remains free of erythema or drainage until it heals by about day 7 after surgery.

If a rectal repair was completed, remember there is a fresh suture line at the rectum. Take axillary or tympanic temperatures rather than rectal temperatures to avoid loosening a suture. Infants should also have no enemas, suppositories, or any other intrusive rectal procedures. It might be helpful to hang a sign above the infant's crib cautioning against any intrusive rectal procedure. Infants may be given a stool softener daily to keep the stool from becoming hard and tearing the healing suture line. Clean the suture line well after bowel movements by irrigating it with normal saline. Placing a diaper under, not on, the infant may be helpful so bowel movements can be cleansed away as soon as they occur. Do not place the infant on the abdomen because, in this position, newborns tend to pull their knees under them, causing tension in the perineal area. A side-lying position is best.

An infant may need rectal dilatation done once or twice a day for a few months after surgery to ensure proper patency of the rectal sphincter. Review this technique (gently inserting a lubricated cot-covered finger into the rectum) with the parents and document that they are able to perform this procedure before the child is discharged. Be certain they also understand the importance of the procedure. The best surgical repair could end in failure if constriction occurs because the parents do not follow up with this procedure. If infants are to be discharged with a prescription for a daily stool softener, be certain parents understand why this is also important and have a plan for remembering the correct times and dosage.

Nursing Diagnosis: Risk for impaired parenting related to difficulty in bonding with infant ill from birth

Outcome Evaluation: Parents hold and comfort infant; describe positive characteristics of infant.

An imperforate anus may be a difficult anomaly for a parent to accept because it deals with a body area that they may not feel comfortable discussing. If it involves a temporary (or permanent) colostomy, learning to care for their infant may be difficult. For these reasons, parents need a great deal of support following the diagnosis. If a final surgical repair can be completed, they can be assured their child will have normal bowel function thereafter. If a final repair could not be surgically achieved, they have the even harder task of caring for a child with a permanent ostomy. They can be assured that children who always have ostomies accept these well as they grow older because they have never known any other method of defecation (see Chapter 37 for a discussion of care priorities for the child with an ostomy).

✔ Checkpoint Question 27.2

What is an important nursing measure for a newborn with a diaphragmatic hernia?

a. Feed the infant immediately to decrease air in the intestine.
b. Keep the infant positioned head down so the intestine can expand.
c. Wrap the infant's abdomen tightly to better contain intestine.
d. Position the infant in an infant chair to contain intestine in abdomen.

PHYSICAL AND DEVELOPMENTAL DISORDERS OF THE NERVOUS SYSTEM

The most common developmental disorders of the nervous system at birth include abnormal accumulation of cerebrospinal fluid (CSF) (hydrocephalus), which has several causes, and abnormalities associated with neural tube closure (meningocele or spinal dysraphism). All these are the result of multifactoral inheritance as well as nutritional deficits (Donahue, 2008).

Hydrocephalus

CSF is formed in the first and second ventricles of the brain and then passes through the aqueduct of Sylvius and the fourth ventricle to empty into the subarachnoid space of the spinal cord, where it is absorbed. **Hydrocephalus** is an excess of CSF in the ventricles or the subarachnoid space (Moe, Benke, & Bernard, 2008). In the infant whose cranial sutures are not firmly knitted, this excess fluid causes enlargement of the skull. If fluid can reach the spinal cord, the disorder is called communicating hydrocephalus or extraventricular hydrocephalus. If there is a block to such passage of fluid, the disorder is an obstructive hydrocephalus or intraventricular hydrocephalus. Hydrocephalus is also classified regarding whether it occurs at birth (congenital) or from an incident later in life (acquired). The cause of congenital hydrocephalus is unknown, although maternal infection such as toxoplasmosis or infant meningitis may be factors (Smith & Henderson, 2007).

An excess of CSF in the newborn occurs for one of three main reasons:

- Overproduction of fluid by a choroid plexus in the first or second ventricle, as could occur from a growing tumor (rare).
- Obstruction of the passage of fluid in the narrow aqueduct of Sylvius (the most common cause). Other common sites of obstruction include the foramina of Magendie and Luschka, the openings that allow fluid to leave the fourth ventricle. Obstruction occurs because infections such as meningitis or encephalitis may leave adhesions behind that block fluid flow. Hemorrhage from trauma or a growing tumor also may obstruct the passage of CSF. An Arnold-Chiari disorder (elongation of the lower brain stem and displacement of the fourth ventricle into the upper cervical canal) is yet another cause.
- An interference with the absorption of CSF from the subarachnoid space if a portion of the subarachnoid membrane is removed, as occurs with surgery for meningocele, or after extensive subarachnoid hemorrhage, when portions of the membrane absorption surface become obscured.

Assessment

Hydrocephalus occurs in approximately 3 to 4 per 1000 live births (Moe, Benke, & Bernard, 2008). With an obstruction

present, excessive fluid accumulates and dilates the system above the point of obstruction. If the atresia is in the aqueduct of Sylvius, the first, second, and third ventricles will dilate. If it is at the exit from the fourth ventricle, all ventricles will dilate. Symptoms may develop rapidly or slowly, depending on the extent of the atresia.

If hydrocephalus is present prenatally, it can sometimes be detected on a prenatal sonogram and can even be shunted in utero. The condition is generally not evident during pregnancy or even at birth, however, because of the effect of intrauterine pressure. It becomes evident in the first few weeks or months of life. The infant's fontanelles widen and appear tense, the suture lines on the skull separate, and the head diameter enlarges. As the fluid accumulation continues, the scalp becomes shiny and scalp veins become prominent. The brow bulges forward (bossing), and the eyes become "sunset eyes" (the sclera shows above the iris because of upper lid retraction). Infants show symptoms of increased intracranial pressure, such as decreased pulse and respirations, increased temperature and blood pressure, hyperactive reflexes, strabismus, and optic atrophy. They may become either irritable or lethargic, and they fail to thrive. They may have a typical shrill, high-pitched cry (Box 27.3).

Treatment is most effective when the disorder is recognized early, because once intracranial pressure becomes so acute that brain tissue is damaged and motor or mental deterioration results, even the best shunting procedure cannot replace and repair this damage to the brain cells. Assisting with detection of hydrocephalus is an important role for nurses in ambulatory child health settings. All children under age 2 years should have their head circumference recorded and plotted on an appropriate growth chart at health care visits, so a child whose head is growing abnormally can be detected (Zahl & Wester, 2008).

Measure the head circumference of all infants within an hour of birth and again before discharge from the health care facility to establish a baseline. Older children who have suffered head trauma severe enough to be seen in a medical facility should have their head circumference noted at the time of the accident; then, if other symptoms of increased intracranial pressure appear, this head circumference measurement may be a meaningful part of the store of information available concerning the child's condition.

In addition to the general enlargement of the head, note any asymmetry that is occurring, because this may suggest the point of obstruction. A skull that is enlarging anteriorly with a shallow posterior fossa, for example, suggests the obstruction is in the aqueduct or third ventricle.

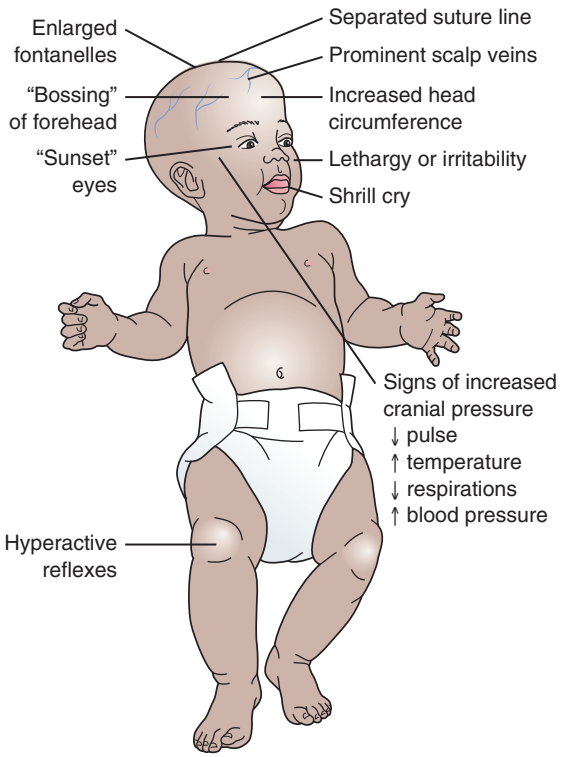
The infant's motor function becomes impaired as the head enlarges, because of both neurologic impairment and atrophy caused by the inability to move such a heavy head. However, as long as a child has more than 1 cm of cerebral tissue present, motor function often is not impaired. Even with an extremely enlarged head, children's intelligence may remain normal, although fine motor development may be affected.

That hydrocephalus is present can be demonstrated by ultrasound, computed tomography (CT), or magnetic resonance imaging (MRI). A skull x-ray film will reveal the separating sutures and thinning of the skull. **Transillumination** (holding a bright light such as a flashlight or a specialized light [a Chun gun] against the skull with the child in a darkened room) will reveal the skull is filled with fluid rather than solid brain (Fig. 27.9). If the hydrocephalus is a noncommunicating type, dye inserted into a ventricle through the anterior fontanelle will not appear in CSF obtained from a lumbar puncture.

Therapeutic Management

The treatment of hydrocephalus depends on its cause and extent. If it is caused by overproduction of fluid, acetazolamide (Diamox), a diuretic, may be prescribed to promote the excretion of this excess fluid. Destruction of a portion of the choroid plexus may be attempted by ventricular endoscopy, or if a tumor in that area is responsible for the overproduc-

Box 27.3 Assessment
Assessing an Infant With Hydrocephalus



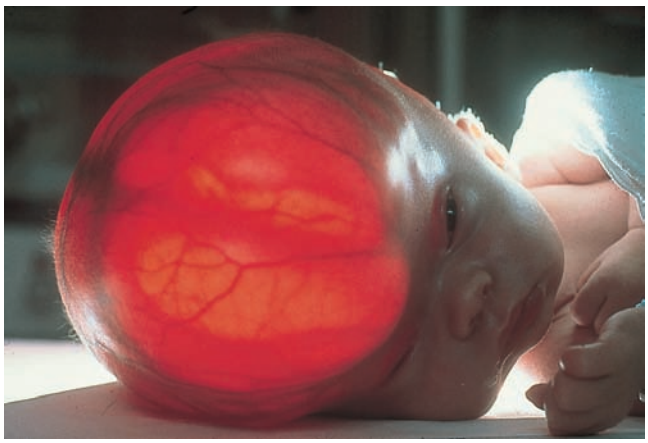


FIGURE 27.9 An infant with hydrocephalus. Transillumination reveals a fluid-filled skull. (Southern Illinois University/Photo Researchers, Inc.)

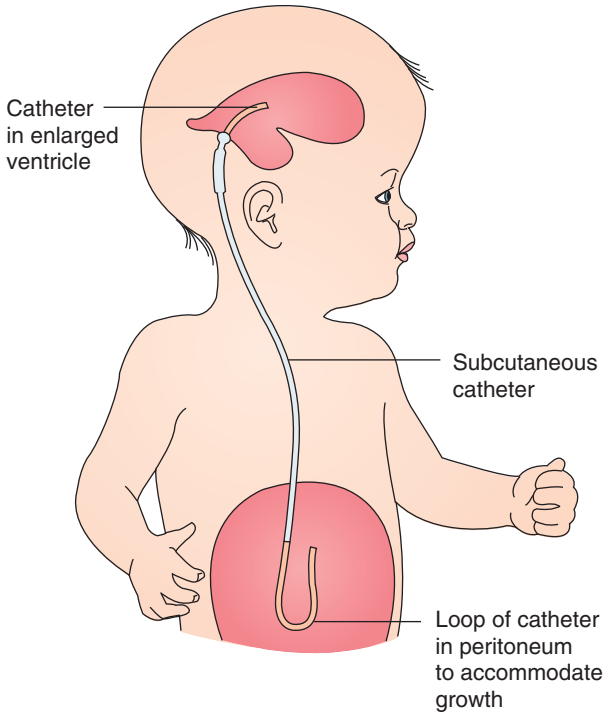

FIGURE 27.10 A ventriculoperitoneal shunt removes excessive cerebrospinal fluid from the ventricles and shunts it to the peritoneum. A one-way valve is present in the tubing behind the ear.

tion of fluid, removal of the tumor should provide a solution. Hydrocephalus is usually caused by obstruction, however, so the treatment usually involves laser surgery to reopen the route of flow or bypassing the point of obstruction by shunting the fluid to another point of absorption.

As ventricular endoscopy is perfected and obstructions in the third or fourth ventricle can be relieved, the next generation of children with hydrocephalus may not need artificial shunting. Children today may still undergo a shunting procedure, however, and you may care for many older children or adults who have shunts in place (Komolafe, Adeolu, & Komolafe, 2008). A shunting procedure involves threading a thin polyethylene catheter under the skin from the ventricles to the peritoneum (Fig. 27.10). Fluid drains via this route into the peritoneum and is absorbed across the peritoneal membrane into the body circulation. This type of shunt usually has to be replaced as the child grows or it will become too short. As another complication, it could become enclosed in a fold of peritoneum and become obstructed or it could become infected (Box 27.4).

The ultimate prognosis for a child with hydrocephalus depends on whether brain damage occurred before shunting and, if a shunt is in place, whether the parents can recognize when it needs to be replaced to prevent increased intracranial pressure.

Nursing Diagnoses and Related Interventions

Nutrition and parent–child bonding are two major concerns for the infant with hydrocephalus. Box 27.5 on nursing care planning illustrates these and other concerns.

Nursing Diagnosis: Risk for ineffective cerebral tissue perfusion related to increased intracranial pressure

Outcome Evaluation: Child shows no increased temperature or blood pressure, or decreased pulse rate, decreased respiratory rate, or decreased level of consciousness; PERLA (pupils equal and reactive to light

BOX 27.4 ✻ Focus on Communication

Baby Sparrow is scheduled to have a ventriculoperitoneal shunt inserted this afternoon. You talk to his mother before surgery.

Less Effective Communication

Nurse: Is there anything I can explain to you about your son's surgery, Ms. Sparrow?
Ms. Sparrow: No. I just want to see him back here with a smaller head.
Nurse: The shunt won't actually make his head smaller. Its purpose is to keep his head from growing any larger.
Ms. Sparrow: What is the chance that he'll die in surgery?
Nurse: All surgery has a risk, certainly, but he should do well.
Ms. Sparrow: But there is a chance he'll die in surgery?
Nurse: You're worrying over nothing. Why don't you relax and go get something to drink until he gets back?

More Effective Communication

Nurse: Is there anything I can explain to you about your son's surgery, Ms. Sparrow?
Ms. Sparrow: No. I just want to see him back here with a smaller head.
Nurse: The shunt won't actually make his head smaller. Its purpose is to keep his head from growing any larger.
Ms. Sparrow: What is the chance that he'll die in surgery?
Nurse: All surgery has a risk, certainly, but he should do well.
Ms. Sparrow: But there is a chance he'll die in surgery?
Nurse: You sound more worried than I'd expect. Is there something specific you're worried about?
Ms. Sparrow: I'd like him to die in surgery. How am I going to take care of a child with such a deformed head?
Nurse: Let's sit down and talk about this some more.

Because surgical procedures are so safe today and the results of surgery for newborns are so successful, it is easy to begin to think of these disorders as more inconvenient than serious: the infant, after all, will grow up with only a few minor problems. To a parent, however, the difference between a child born with one of these conditions and the "perfect" child the parent envisioned can be great. Careful listening is necessary to appreciate the extent of a parent's understanding of the problem. Handling a problem by giving quick reassurance, as in the first scenario here, can lead to missing a parent's concern. Better listening, as in the second scenario, revealed the true problem.

BOX 27.5 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Child With Hydrocephalus

At 3 months of age, Baby Sparrow develops hydrocephalus after repair of his neural tube disorder. He has a ventriculoperitoneal shunt inserted.

Family Assessment ✻ Child lives with 16-year-old mother and her parents and four of mother's siblings. Child's father works as motorcycle mechanic; visits infant frequently. Mother no longer attending school because of child care. Has not named child as yet. Mother asking many questions about the surgery. "This'll fix everything, right? I want a healthy baby."

Client Assessment ✻ A 3-month-old infant whose head circumference has continued to increase since myelomeningocele surgery at birth. Head circumference at birth was 40th percentile, at 60th percentile at 6 weeks of age and now at 80th percentile. Mother noted infant had increasing irritability and lethargy over the last few weeks.

Anterior fontanelle 4 cm × 4 cm; posterior fontanelle 3 cm × 1 cm. Sagittal suture line separated ¼ inch. Scalp veins prominent. Eyes appear sunset. Parents report two episodes of forceful vomiting yesterday. "His cry is so high-pitched and shrill, and he doesn't want anything to drink." Mother is breastfeeding. Cerebral perfusion pressure 55 mm Hg. Blood pressure 100/40; pulse 100 bpm; respirations 16. Afebrile.

Nursing Diagnosis ✻ Risk for ineffective cerebral tissue perfusion related to increased intracranial pressure from hydrocephalus

Outcome Criteria ✻ Infant's vital signs are within age-appropriate parameters; head circumference is maintained at current level; infant responds to auditory stimuli. Cerebral perfusion pressure remains above 50 mm Hg.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Assess if infant is able to turn because of increased head size.	Provide an environment for child that is stimulating yet not tiring (mobile, soft toys in crib). Urge parent to interact with child.	Lack of mobility can lead to pressure ulcers on head as well as insufficient 3-month development.	Child's parent plays with infant. Infant appears interested in age-appropriate toys. No irritated areas on head.
		Consultations		
Nurse/ physician	Assess if neurosurgeon is available for consultation.	Arrange for consultation for mother with neurosurgeon to discuss surgery and child's prognosis.	Viewing a child as totally disabled can cause a parent to not appreciate the child's capabilities.	Neurosurgeon meets with mother to discuss that child's IQ appears normal; shunting will halt head growth.
		Procedures/Medications		
Nurse	Assess infant's neurologic status postoperatively, including response to sound, pupillary response, increasing irritability or lethargy.	Position the infant with the head of the bed elevated 15 degrees and prevent hyperextension, flexion, or rotation of the head. Record cerebral perfusion pressure.	Elevating head of bed aids shunt functioning, helping reduce intracranial pressure. Cerebral perfusion pressure reveals extent of intracranial pressure.	Child's cerebral perfusion pressure remains greater than established parameter. Responds to sound; no increasing irritability or lethargy.
Nurse	Measure and record head circumference every 4 hours. Assess anterior fontanelle for tenseness and bulging.	Document head circumference and appearance of anterior fontanelle.	Head circumference, if increasing, or a tense, bulging fontanelle indicates accumulating CSF.	Child's head circumference does not increase in size; fontanelles no longer feel tense.

		Nutrition		
Nurse/ nutritionist	Observe mother breastfeeding infant.	Encourage mother to breastfeed infant; assist mother with positioning the infant properly, supporting the head without flexion or hyperextension during feeding.	Breast milk is the optimal nutrition for an infant. Proper positioning is important to avoid neck vein compression, which could increase intracranial pressure.	Mother breastfeeds successfully following surgery.
Nurse	Monitor intake and output closely.	Administer osmotic diuretic and corticosteroids as ordered.	Adequate hydration is necessary to ensure renal function. Osmotic diuretics decrease intracranial pressure. Corticosteroids reduce inflammation.	Child's output remains over set parameter. Diuretic and corticosteroids administered as necessary.
		Patient/Family Education		
Nurse/nurse practitioner	Assess the parents' understanding of hydrocephalus and treatment measures.	Review the structure and function of the brain and explain how hydrocephalus develops. Clarify any misconceptions.	Reviewing and clarifying aid in learning and strengthen understanding.	Mother states she understands purpose of shunt to relieve excess CSF.
		Psychosocial/Spiritual/Emotional Needs		
Nurse/nurse practitioner	Assess mother's acceptance of child in light of many congenital disorders and no name for baby as yet.	Observe mother's interaction with infant; remind her that congenital disorders occur in a proportion of all births.	Young mother may have had little experience with life crises. Needs support from health care providers for this crisis.	Mother states she understands child's condition is neither her nor the child's fault; states she can handle the present crisis.
		Discharge Planning		
Nurse	Assess if child's parents have questions about care he will need for future shunt care; if they understand postsurgery appointment is important.	Assist parents with caring for the child as much as possible; offer positive reinforcement frequently.	Caring for the child promotes active participation and parent–infant bonding. Positive reinforcement enhances self-esteem and aids in coping.	Mother and grandmother state they understand future care necessary for shunt; will contact neurosurgeon if any questions regarding child's progress. Mother keeps postsurgery appointment.
Nurse	Assess if home care follow-up will be necessary.	Make referral for home care if needed. Refer parents to support group of other parents of children with hydrocephalus.	Support groups can decrease feelings of isolation, provide opportunities for further learning. Follow-up home care provides continuing support, guidance, and education.	Mother and grandmother state they will attend a support group at least once to evaluate benefit for them. Agree to at least one home visit for follow-up care.

and accommodation); muscle strength equal and strong bilaterally; head circumference is maintained at age-appropriate level.

After a shunt is inserted, the infant's bed is usually left flat or raised only about 30 degrees so the child's head remains level with the body. This is because if the child's head is raised excessively, CSF may flow too rapidly and decompression can then occur too rapidly, leading to possible tearing of cerebral arteries.

A one-way valve is inserted in the shunt that opens when CSF has accumulated to the extent that pressure has increased. It closes when enough fluid has drained to reduce the pressure. The surgeon who performs the shunting procedure writes specific orders about how often the infant is to be turned and to what side after surgery. Often infants are not turned to lie on the side with the shunt to prevent putting pressure on the valve, which might cause it to open and rapidly decompress CSF.

Assess for signs of increased intracranial pressure after surgery such as tense fontanelles, increasing head circumference, irritability or lethargy, decreased level of consciousness, poor sucking ability, vomiting, an increase in blood pressure (difficult to measure accurately in infants unless arterial or umbilical lines are used with Doppler instrumentation), increasing temperature, and a decrease in pulse and respiratory rates (see Chapter 49 for tips on a complete neurologic assessment). Also assess for symptoms of infection such as increased temperature, increased pulse rate, general malaise, and signs of meningitis such as a stiff neck and marked irritability (Box 27.6). Be certain a child receives adequate pain management, because crying elevates CSF pressure.

Nursing Diagnosis: Risk for imbalanced nutrition, less than body requirements, related to increased intracranial pressure

Outcome Evaluation: Child's weight remains within 5th to 95th percentile on height and weight chart; no vomiting occurs.

Because an abdominal incision is involved to thread the catheter into the peritoneum, most children have a nasogastric tube placed during surgery. Keep them NPO until bowel sounds return and the tube can be removed. Introduce fluid gradually in small quantities after removal of the tube as vomiting that results from the introduction of fluid too soon after any surgery causes increased intracranial pressure.

Like other infants, infants with hydrocephalus should be held when being fed if possible. Be certain to support their heads well when moving them to avoid strain on their neck from their heavier than usual head. Hold their head with the whole palm, not just the fingertips, because the skull can thin to such a degree that it can actually be punctured with a stiff, forceful touch. Urge parents to use a rocking chair with an armrest to provide support for their arm while feeding the infant. Otherwise, the infant's head can be so heavy that they cannot spend as much time holding the infant after a feeding as they might otherwise. No contraindications for breastfeeding exist.

BOX 27.6 * Focus on Family Teaching

Caring for a Child With a Ventriculoperitoneal Shunt

Q. Following ventriculoperitoneal shunt surgery, Baby Sparrow's mother asks you, "What do I need to do to care for him?"

A. Here are some helpful things to remember:

- Observe for signs of increased intracranial pressure, such as drowsiness, vomiting, headache, irritability, and anorexia.
- Observe the pump site daily for any sign of swelling or redness.
- Have your child sleep with his head slightly elevated at night to help ensure fluid flow through the tube. Do not allow your child to fall asleep with his head hanging over the side of a couch or bed.
- Do not allow your child to become constipated, because hard stool might press against the shunt in the abdomen and obstruct the flow of fluid. Encourage fruit, vegetables, cereal, and a generous amount of fluid in his diet.
- Do not call attention to the pump behind your child's ear; teach him not to touch the pump when he's nervous or as an attention-getting action.
- Be certain your child wears a helmet for tricycle and bicycle riding (as should all children) to avoid injury to the shunt. Otherwise, there are no special precautions that need to be taken for normal play.
- If your child develops signs of infection such as an increased temperature, phone your primary care provider. Also remind the person that your child has a shunt in place. This is probably a simple infection of childhood but could indicate an infected shunt.
- Be certain to keep your regularly scheduled health assessment visits. As your child grows taller, the shunt will eventually need to be replaced for proper functioning.

Help breastfeeding mothers to find a comfortable position for feeding so that they can be successful with this.

Note how the child sucks. Increased intracranial pressure may be noted first because of poor or ineffective sucking. Vomiting after feeding, without nausea (difficult to detect in a small infant), is also a common first sign of increased intracranial pressure.

Observe for constipation, because straining while passing stool causes increased intracranial pressure. This is not usually a problem with infants who are totally breastfed or formula fed. However, it can be a problem when children return for shunt replacement at an older age. Urge parents to offer adequate fluid and roughage in their child's diet as a preventive measure.

Nursing Diagnosis: Risk for impaired skin integrity related to extra weight and immobility of head

Outcome Evaluation: Child's skin remains clean, dry, and intact, without signs of erythema or ulceration.

The head of an infant with hydrocephalus can become so heavy the infant cannot move it freely. As the skin of the head stretches thin, skin breakdown can occur at the pressure points. Wash the child's head daily and change the position of the head approximately every 2 hours so that no portion of the head rests against the mattress for a long period. A synthetic sheepskin or silicon pad or an air, water, or alternating air mattress may help to relieve pressure points. If a Kling or stockinette bandage is used to hold a surgical head dressing in place, place a piece of gauze or cotton behind the child's ear before the bandage is applied to prevent skin surfaces from touching and becoming excoriated. Make sure the bandage does not become wet from backward-draining oral secretions or shunt leakage.

Nursing Diagnosis: Deficient knowledge related to home care needs of child with hydrocephalus

Outcome Evaluation: Parents state fears regarding ability to provide care but are able to manage this; state signs of increased intracranial pressure for which they should watch; demonstrate competence in shunt care.

Caring for a child with a shunt in place is an ongoing responsibility for parents. If parents do not seem to be asking many questions about the child's care after surgery, do not assume this is because they are taking the child's care in stride. They may be too frightened or not understand neuroanatomy enough to know what questions to ask. An opening such as, "Most parents are a little nervous when they think about taking a child home with a shunt in place; do you feel that way?" gives them an opportunity to admit how they feel. Talking about how nervous they feel about the responsibility will not immediately make them more comfortable with the child's care. However, it can provide them with a starting point to bring their anxiety down to a manageable size. Assure them the health care providers caring for their child are interested in helping and supporting them.

If a valve has been inserted in the shunt, it can be palpated underneath the skin just behind the ear. Remind parents to stress to their child that this strange object is not to be felt continually. A child nervously fidgeting with a pressure pump can inadvertently evacuate CSF from the ventricles at a dangerously rapid rate.

Before an infant is discharged after surgery, be certain the parents have ample opportunity to feed and provide care so they can be comfortable and feel they "know" their infant. Because irritability, lethargy, vomiting, and a change in the baby's cry are signs of increased intracranial pressure, be certain parents know to report these immediately to their primary care provider. Before parents can report a change in the infant's disposition in this way, they must know the infant well, why it is important that they give care while their infant is hospitalized. A referral for home care follow-up may be appropriate to offer further support.

Nursing Diagnosis: Risk for delayed growth and development related to potential neurologic challenge

Outcome Evaluation: Child demonstrates regular observable growth and achieves age-appropriate developmental milestones.

Like all children, children with hydrocephalus need intellectual and emotional stimulation: they need to be talked to, smiled at, and played with. If the child's head is enlarged, turning it to look at things can be difficult. It may be necessary to reposition mobiles or pictures so the child receives adequate visual stimulation. Role-model talking and singing to the child to help parents include these actions in their care.

At the time of hospital discharge, be certain parents have the telephone number of the person they should call if they have a question or concern about their child's condition or care, and a referral for home care follow-up, if appropriate. They also need an appointment for the child's first checkup. Be sure they understand that infection of the shunt is a possibility and a severe complication because it can lead to meningitis. If this should occur, the infant will show signs of increased intracranial pressure as well as an increased temperature. In addition to being hospitalized, receiving the usual treatment for meningitis (see Chapter 49), and receiving intravenous antibiotics, the child may have an extraventricular shunt placed to promote drainage during this time. This allows antibiotics to be administered directly to the CSF and ensures that infected CSF is not draining to the peritoneal cavity, where it could cause peritonitis.

As the child reaches preschool and school age, parents need to confer with the school nurse to make the nurse aware that the child has a shunt in place and that the child may need special head protection for sports activities.

✔ Checkpoint Question 27.3

Baby Sparrow may be developing increased intracranial pressure. What vital sign changes occur with this?

a. Decreased temperature; increased blood pressure.
b. Increased respirations; decreased pulse rate.
c. Increased temperature; decreased pulse rate.
d. Decreased blood pressure; increased temperature.

Neural Tube Disorders

Because the neural tube forms in utero first as a flat plate and then molds to form the brain and spinal cord, it is susceptible to malformation. The term **spina bifida** (Latin for "divided spine") is most often used as a collective term for all spinal cord disorders, but there are well-defined degrees of spina bifida involvement, and not all neural tube disorders involve the spinal cord. All of these disorders, however, occur because of lack of fusion of the posterior surface of the embryo in early intrauterine life. They can be compared with cleft palate or cleft lip—these are also midline closure disorders.

The incidence of neural tube disorders has fallen dramatically in recent years, from 3 to 0.6 per 1000. Such disorders may occur as a polygenic inheritance pattern, but poor nutrition, especially a diet deficient in folic acid, appears to be a major contributing factor (Lumley et al., 2009). As a result,

pregnant women are advised to ingest 600 micrograms of folic acid daily to help prevent these disorders. The risk of bearing a second child with a neural tube disorder once one child is born with such a disorder increases to as much as 1 in 20. For this reason, women who have had one child with a spinal cord disorder are advised to have a maternal serum assay or amniocentesis for AFP levels to determine if such a disorder is present in a second pregnancy (levels will be abnormally increased if there is an open spinal lesion). Serum assessment of MSAFP is done at week 15 of pregnancy, when AFP reaches its peak concentration. If the result is elevated, an amniocentesis is then done to assess the level of AFP in amniotic fluid. A prenatal sonogram is also helpful to determine the presence of the disorder (see Chapter 11 for further discussion of these prenatal assessments).

Types of Disorders

Anencephaly. Anencephaly is absence of the cerebral hemispheres. It occurs when the upper end of the neural tube fails to close in early intrauterine life. It is revealed by an elevated level of AFP in the maternal serum or on amniocentesis and confirmed by a prenatal sonogram.

Infants with anencephaly may have difficulty in labor because the underdeveloped head does not engage the cervix well. Many such infants present in a breech position. On visual inspection at birth, the disorder is obvious (Fig. 27.11). Children cannot survive with this disorder because they have no cerebral function. Because the respiratory and cardiac centers are located in the intact medulla, however, they may survive for several days after birth.

When the condition is discovered prenatally, parents are offered the option of abortion. An ethical problem has arisen in several instances when parents, aware that the child cannot survive, elect to carry the infant to term so the organs can be used for transplant. Nurses need to think through their feelings about caring for such infants, because it can be difficult to give care to a child who will most likely die or who has been born only to help others live.

FIGURE 27.11 An infant with anencephaly. (Joseph R. Siebert, PhD/Custom Medical Stock Photograph.)

Microcephaly. Microcephaly is a disorder in which brain growth is so slow that it falls more than three standard deviations below normal on growth charts. The cause might be a disorder in brain development associated with an intrauterine infection such as rubella, cytomegalovirus, or toxoplasmosis. Microcephaly may also result from severe malnutrition or anoxia in early infancy.

The prognosis for a normal life is guarded in children with microcephaly and depends on the extent of restriction of brain growth and on the cause. Generally the infant is cognitively challenged because of the lack of functioning brain tissue. True microcephaly must be differentiated from *craniosynostosis* (normal brain growth but premature fusion of the cranial sutures), which also causes decreased head circumference. Infants with craniosynostosis have abnormally closed fontanelles and often show bossing of the forehead and signs of increased intracranial pressure similar to infants with hydrocephalus. With surgery, craniosynostosis can be relieved and brain growth will be normal.

Spina Bifida Occulta. Spina bifida occulta occurs when the posterior laminae of the vertebrae fail to fuse. This occurs most commonly at the fifth lumbar or first sacral level but may occur at any point along the spinal canal. The normal spinal cord is shown in Figure 27.12A. Spina bifida occulta may be noticeable as a dimpling at the point of poor fusion; abnormal tufts of hair or discolored skin may be present (Sponseller, 2007). Simple spina bifida occulta is a benign disorder; it occurs as frequently as in one of every four children (see Fig. 27.12B).

The term "spina bifida" is often used to denote all spinal cord anomalies. Because of this usage, parents, when told that their child has a spina bifida occulta, may interpret this as meaning their child has an extremely serious disorder. Help clarify the degree of defect for them.

Meningocele. If the meninges covering the spinal cord herniate through unformed vertebrae, a meningocele occurs. The anomaly appears as a protruding mass, usually approximately the size of an orange, at the center of the back (see Fig. 27.12C). It generally occurs in the lumbar region, although it might be present anywhere along the spinal canal. The protrusion may be covered by a layer of skin or only the clear dura mater.

Myelomeningocele. In a myelomeningocele, the spinal cord and the meninges protrude through the vertebrae the same as with a meningocele. The difference is that the spinal cord ends at the point, so motor and sensory function is absent beyond this point (see Fig. 27.12D). Because this results in lower motor neuron damage, the child will have flaccidity and lack of sensation of the lower extremities and loss of bowel and bladder control. Infants' legs are lax, and they do not move them; urine and stools continually dribble because of lack of sphincter control. Children often have accompanying talipes (clubfoot) disorders and developmental hip dysplasia. Hydrocephalus accompanies myelomeningocele in as many as 80% of infants because of the lack of an adequate subarach-

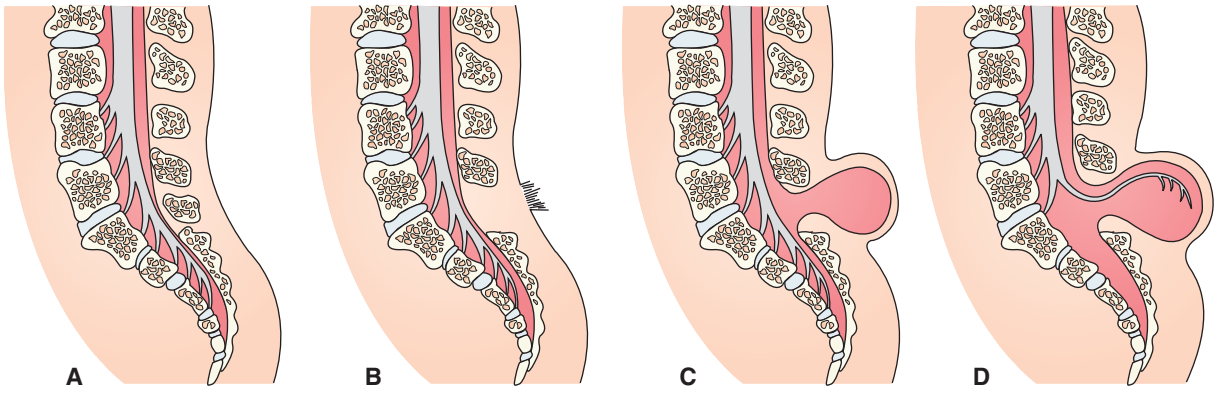

FIGURE 27.12 Degrees of spinal cord anomalies. (**A**) Normal spinal cord. (**B**) Spina bifida occulta. (**C**) Meningocele. (**D**) Myelomeningocele.

noid membrane for CSF absorption; the higher the myelomeningocele occurs on the cord, the more likely it is that hydrocephalus will accompany it. It is generally difficult to tell from visual appearance whether the disorder is myelomeningocele or the simpler meningocele (Fig. 27.13). A CT or ultrasound scan or MRI will reveal this.

Encephalocele. An encephalocele is a cranial meningocele or myelomeningocele. The disorder occurs most often in the occipital area of the skull but may occur as a nasal or nasopharyngeal disorder. Encephaloceles generally are covered fully by skin, but they may be open or covered only by the dura. It is difficult to tell from the size of the encephalocele if only CSF is trapped in the protruding meninges or whether brain tissue could also be involved. Transillumination of the sac will reveal solid substance or fluid in the sac. CT, MRI, or ultrasound will reveal the size of the skull disorder.

Assessment

Neural tube disorders may be discovered during intrauterine life by prenatal ultrasound, fetoscopy, amniocentesis (discovery of increased AFP in amniotic fluid), or analysis of AFP in the maternal serum. If the condition is discovered in utero, it may be possible to close the lesion by fetoscopic surgery. Infants may be born by cesarean birth to avoid pressure and injury to the spinal cord. Observe and record whether an infant born with a neural tube disorder has spontaneous movement of the lower extremities to assess if the child has lower motor function. Also assess the nature and pattern of voiding and defecation. A normal infant appears to be "always wet" from voiding but actually voids in amounts of approximately 30 mL and then is dry for 2 or 3 hours before voiding again. An infant without motor or sphincter control voids continually. This pattern is the same for defecation. Observing these features aids in differentiating between meningocele and myelomeningocele. Differentiation will be further established by ultrasound or MRI.

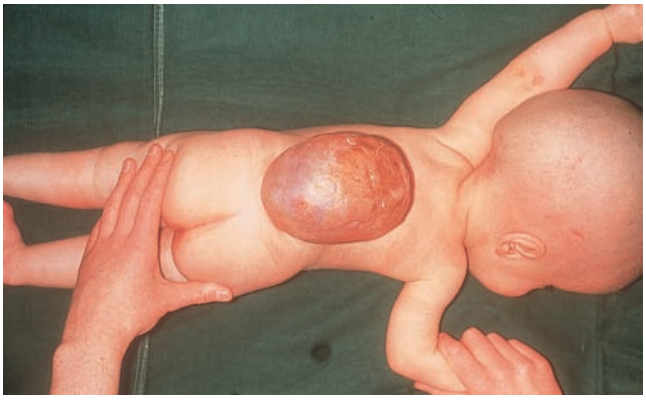

FIGURE 27.13 A myelomeningocele. The infant also has hydrocephaly and a subluxated hip. (NMSB/Custom Medical Stock Photograph.)

Therapeutic Management

Children with spina bifida occulta need no immediate surgical correction. The parents should be made aware of the defect, however, so they are not surprised if it is revealed on a spinal x-ray taken for some reason later in life. Some children may eventually need surgery to prevent vertebral deterioration because of the unbalanced spinal column.

Treatment for a meningocele, myelomeningocele, or encephalocele involves immediate surgery to replace the contents that are replaceable and to close the skin disorder to prevent infection. In the past, surgery for neural tube disorders was done only after the infant had survived the newborn period. Currently, it is done as soon after birth as possible (usually within 24 to 48 hours) so infection through the exposed meninges does not occur.

Surgery for repair of a meningocele or myelomeningocele is not without risk, and brain disorders accompanying an encephalocele may limit the child's cognitive potential. The loss of meninges removed by surgery may limit the rate of absorption of CSF. This may lead to a buildup of CSF, resulting in hydrocephalus. Parents need a great deal of support to care for a child with a myelomeningocele because their child has multiple challenges. The child with myelomeningocele will continue to have paralysis of the lower extremities and loss of bowel and bladder function after surgery because the absent lower cord cannot be replaced. Table 27.1 provides a classification of motor function ability according to the location of spinal cord disruptions.

TABLE 27.1 ✻ Motor Function Ability in Children With Myelomeningocele

Spinal Cord Lesion	Resultant Effects
T6–12	Complete flaccid paralysis of the lower extremities; weakened abdominal and trunk musculature in higher lesions; kyphosis and scoliosis common; ambulation with maximal support
L1–2	Hip flexion present; paraplegia, ambulation with maximal support
L3–4	Hip flexion, adduction, and knee extension present; hip dislocation common; some control of hip and knee movement possible; ambulation with moderate support
L5	Hip flexion, adduction, and varying degrees of abduction; knee extension and weak knee flexion; paralysis of the lower legs and feet; ambulation with moderate support
S1–2	As above, with preservation of some foot and ankle movement; ambulation with minimal support
S3	Mild loss of intrinsic foot muscular function possible; ambulation without support

Nursing Diagnoses and Related Interventions: Immediate Concerns ✻

Although parents of an infant with a myelomeningocele were told before surgery that their child's spinal disorder is a type that means motor and sensory function are absent in the child's lower extremities, the parents do not necessarily "hear" this information. Only after surgery do they begin to comprehend the extent of the condition. When the child is discharged from the hospital, be certain the parents understand what is the next step they need to follow for further care. This prevents them from feeling deserted when they most need support—the time when they first begin to appreciate what this problem will mean to them in the coming years, and what it will mean to their child throughout life.

Nursing Diagnosis: Risk for infection related to rupture or bacterial invasion of the neural tube sac

Outcome Evaluation: Neural tube sac remains intact; axillary temperature remains below 98.6° F (37° C).

If the exposed meningeal sac is allowed to dry, it can crack, allowing CSF to drain and microorganisms to enter. Pressure on the protruding mass is a prime reason why the sac ruptures, leading to quick decompression of the CSF (which can lead to herniation of the brainstem into the spinal cord and interference with respiratory and cardiac centers) and possibly to infection (meningitis). Such pressure may also force CSF from the sac into the spinal column, increasing intracranial pressure. Therefore, it is crucial to prevent drying of and pressure on the exposed membrane.

Preoperative Positioning. Before surgery, use sterile gloves and sterile linens when caring for the infant. Position infants carefully to prevent pressure on the exposed meninges, either in a prone position or supported on their side. When they are on their side, use a rolled blanket or diaper placed behind their upper back (above the disorder) and a separate one behind their lower back (below the disorder). This way, no pressure will be exerted on the lesion, and the infant will be protected from rolling backward onto it. Placing infants on their abdomen has the added advantage of keeping the flow of feces and urine away from the spinal defect as well as keeping it free from pressure. A folded towel under the abdomen helps to flex the infant's hips, reduce pressure on the sac, and ensure good leg position. If an infant is lying on a side, putting a folded diaper between the legs prevents skin surfaces from touching and rubbing (and also helps to keep the hips from internally rotating). Always notice the position of the infant's legs. If they are paralyzed because of lack of motor control, the infant cannot move and straighten them to a more comfortable position.

Placing a piece of plastic or sturdy plastic wrap below the meningocele on the child's back like an apron and taping it in place is another method of preventing feces from touching the open lesion. A sterile wet compress of saline, antiseptic, or antibiotic gauze over the lesion may be used to keep the sac moist. Rather than remove this to wet it again and risk rupturing the sac, merely add additional fluid.

Although no pressure should be exerted on the open lesion by a top sheet, make certain that the child is adequately warm. The presence of the sac adds to the amount of body surface area exposed, thereby increasing heat loss. The infant may need to be kept in an incubator to maintain body heat if a large area of the back cannot be covered. Use caution when placing the infant under a radiant heat source for warmth because radiant heat can dry the lesion and cause cracking. Any seepage of clear fluid from the defect should be reported promptly, because this is probably escaping CSF. Checking any leakage for evidence of glucose will confirm the fluid is CSF (urine or mucus will not test positive for glucose).

Postoperative Care. After surgery, a child is again placed on the abdomen until the skin incision has healed (about 7 days). The same careful precautions against allowing urine or feces to touch the incision area are necessary.

Nursing Diagnosis: Risk for imbalanced nutrition, less than body requirements, related to difficulty assuming normal feeding position.

Outcome Evaluation: Child's skin turgor is good; weight is maintained within 10% of birth weight; specific gravity of urine remains between 1.003 and 1.030.

To maintain nutrition, help parents hold the infant in as normal a feeding position as possible. Make certain that a supporting arm does not press against the lesion. Remind the parents that when bubbling the infant, they should not pat the back over the defect. If the defect is large and the risk in picking up the infant is too great, the infant may be fed while lying on the side in bed or prone on a specialized bed frame. Raise the infant's head slightly by slipping a folded diaper under it. Stroke the head, arms, or upper back while the infant sucks to give the child the same comfort and assurance at feeding time as a baby receives while being held. Infants may enjoy a pacifier after feeding, because they do not experience the same enjoyment of sucking while feeding that would be experienced if they could be held and cuddled. All new parents have some difficulty getting comfortable with feeding an infant. Parents who must feed their child in an unusual position or with an infant on a support frame will have even more difficulty. Role-model a warm, comforting parental role so parents can begin to form a positive parent–child interaction.

Children with increased intracranial pressure tend to suck poorly. If this complication develops after surgery, breastfeeding may be difficult. Parents need a realistic explanation of the treatment planned for the child so they can decide whether to continue breastfeeding. If it is necessary to forgo breastfeeding for this child, you can assure parents that the child will thrive on commercial formula.

Nursing Diagnosis: Risk for ineffective cerebral tissue perfusion related to increased intracranial pressure.

Outcome Evaluation: Child's head circumference remains within present percentile on growth chart; signs and symptoms of increased intracranial pressure are absent.

Preoperative Care. Increasing head size from poor absorption of CSF (hydrocephalus) is a common complication of neural tube disorders. To detect increased head size (development of hydrocephalus), measure head circumference once daily (or more frequently if ordered) in the preoperative period. Head circumference measurements are accurate only if the tape measure is placed on the same points of the child's head each time. Placing an indelible or ballpoint pen mark on the forehead just above the eyebrows and at the most prominent point of the occiput allows different people to measure the head during the day and yet be sure that they all measure at the same point.

Postoperative Care. Children may develop hydrocephalus after surgery as well, probably because of interference with subarachnoid absorption of CSF. The shortening of the meninges can create an Arnold-Chiari disorder (see later) or can cause traction of the hindbrain into the spinal cord. Observe the child frequently for signs of increased intracranial pressure such as changes in vital signs, neurologic signs such as pupillary changes, or an increase in head circumference or bulging fontanelles, as well as behavioral changes such as irritability or lethargy to help detect if this is happening.

Nursing Diagnosis: Risk for impaired skin integrity related to required prone positioning.

Outcome Evaluation: Infant's skin remains intact, without erythema or ulceration.

Preserving skin integrity is a major problem before surgery because the constant prone position puts pressure on the infant's knees and elbows. Laying the infant on a synthetic sheepskin helps reduce friction; after surgery, use paper tape or stockinette for dressing changes or place protective dressings such as Stomahesive on the skin under the area where the tape will touch. Change diapers frequently to prevent excessive contact of acid urine with skin. If hydrocephalus has developed, the head will be heavy and pressure areas at the temples can occur if the head is not repositioned about every 2 hours.

Nursing Diagnoses and Related Interventions: Long-term Concerns

Nursing Diagnosis: Impaired physical mobility related to neural tube disorder

Outcome Evaluation: Child ambulates with the least amount of accessory equipment possible.

Help parents begin to plan stimulation activities their infant can accomplish with limited mobility. Encourage them to take the infant to the places children normally accompany parents—relatives' homes, shopping, the zoo, and so forth as encouraging children to be independent helps them lead as active a life as possible (Davis et al., 2007). (Fig. 27.14).

FIGURE 27.14 A child born with a neural tube disorder demonstrates her ability to walk using braces and a crutch. (Alexander Tsiara/Photo Researchers, Inc.)

Parents will need to perform passive exercises to prevent muscle atrophy and formation of contractures if a child has impaired lower extremity motor control. The child may need leg braces to help maintain good alignment and enable walking with crutches. Parents are generally anxious to do something for their child and follow routines of passive exercises well if they are given sufficient support for their accomplishments at health care visits. As the child grows older, tendon transplants or osteotomy may be necessary to prevent contractures and poor bone alignment. Because children with myelomeningocele have no sensation in their lower extremities, parents should make a routine of inspecting the child's lower extremities and buttocks daily for any area of irritation or possible infection. Teach children as they grow older to do this themselves. When children are using a wheelchair, be certain they press with their arms on the armrests to raise their buttocks off the wheelchair seat at least once every hour to help provide adequate circulation to lower extremities.

Nursing Diagnosis: Risk for impaired elimination related to neural tube disorder

Outcome Evaluation: Child demonstrates ability to independently manage bowel and bladder elimination by school age.

To ensure bladder emptying, an intermittent clean urinary catheterization technique may be taught to parents (inserting a clean catheter through the urethra into the bladder every 4 hours to drain urine from the bladder; Box 27.7). As children reach early school age, they can learn this technique for themselves. Prescription of a drug such as oxybutynin chloride (Ditropan) may improve bladder capacity and allow a child to need less frequent catheterization (Box 27.8) (Karch, 2009). It is possible to place artificial bladder sphincters in some children to help establish continence. In some children, a continent urinary reservoir or ureterosigmoidostomy (see Chapter 46) is constructed to bypass the nonfunctioning bladder. Children who are begun on intermittent clean catheterization from birth require fewer bladder augmentation procedures as they grow older.

Arnold-Chiari Disorder (Chiari II Malformation)

An Arnold-Chiari disorder is caused by overgrowth of the neural tube in weeks 16 to 20 of fetal life. The specific anomaly is a projection of the cerebellum, medulla oblongata, and fourth ventricle into the cervical canal. This causes the upper cervical spinal cord to jackknife backward, obstructing CSF flow and causing hydrocephalus. A lumbosacral myelomeningocele is also present in approximately 50% of children with this anomaly (Donahue, 2008).

The prognosis for the child with an Arnold-Chiari malformation depends on the extent of the disorder and the surgical procedure possible. Because of the upper motor neuron involvement, gagging and swallowing reflexes may be absent, increasing the risk for tracheal aspiration. Serious levels of sleep apnea may occur that also require surgical intervention (Tubbs et al., 2007).

BOX 27.7 ✻ Focus on Family Teaching

Instructions for Clean Intermittent Catheterization

Q. Baby Sparrow's mother needs to learn clean intermittent catheterization for her son. She asks you, "How do I do this?"

A. Here are some helpful guidelines to follow:

1. Remember that the purpose of intermittent catheterization is to keep the bladder empty by using clean technique and frequent emptying so microorganisms do not have time to grow in urine in the bladder. Always use clean equipment and catheterize at least every 4 hours.
2. Always carry catheterization equipment with you when away from home (a plastic bag containing a clean catheter and water-soluble lubricant). This enables you to stay longer away from home if you wish. If you will be using a public lavatory, you might want to include a presoaped washcloth rather than have to use rough paper towels.
3. To begin catheterization, wash your hands in warm, soapy water. This reduces the chance you will introduce germs from your hands into your child's bladder.
4. Next wash around your child's urinary meatus with a clean washcloth or paper towel and warm, soapy water. Rinse the washcloth and wash again with clear water. This reduces the chance that germs on the child's skin will be pushed into the bladder.
5. Coat the tip of a clean catheter with water-soluble lubricant. This reduces friction and makes the catheter slide into the bladder easily.
6. Quickly but gently insert the catheter into the urinary meatus approximately 3 inches. Urine should begin to flow immediately through the catheter. Let this drain into a collecting basin.
7. When urine stops flowing, gently remove the catheter. To reuse the catheter, clean it with soap and water, rinse with clear water, and replace in the plastic bag with the lubricant or replace with a new cathether.
8. Be certain that on special days such as family celebrations or vacation you do not forget the importance of catheterization.
9. As your child reaches school age, you can teach him how to do this himself. He will need to insert the catheter about 6 inches. Be certain he will be able to have access to a school bathroom every 4 hours during the day.
10. Phone your health care provider if urine is blood-tinged, smells foul, or is cloudy rather than clear or if your child appears to have pain in his abdomen or lower back or has an elevated temperature. These may be symptoms of a urinary tract infection.

PHYSICAL AND DEVELOPMENTAL DISORDERS OF THE SKELETAL SYSTEM

Either genetic or environmental factors can compromise fetal physical growth to such an extent they result in skeletal disorders in the newborn.

BOX 27.8 ✻ Focus on Pharmacology

Oxybutynin Chloride (Ditropan)

Classification: Oxybutynin is an anticholinergic, urinary antispasmodic.

Action: Relaxes smooth muscle to relieve symptoms of bladder instability associated with neurogenic bladder (Karch, 2009).

Pregnancy Risk Category: C

Dosage: 5 mg orally twice daily

Possible Adverse Effects: Drowsiness, dizziness, blurred vision, decreased sweating

Nursing Implications

- Advise the parents to give or have the child take the medication exactly as prescribed.
- Alert the parents about the need for frequent bladder examinations during treatment to document the drug's effect.
- Ask the child to report drowsiness or blurred vision. Caution the child not to attempt activities that require balance while taking the drug.
- Caution the child and parents that with decreased sweating, body temperature can rise. Encourage the parents to keep the child's environment cool and avoid high temperatures.

Absent or Malformed Extremities

Congenital skeletal disorders may result from reasons such as maternal drug ingestion, virus invasion during pregnancy, or amniotic band formation in utero. In most instances, however, the cause of the anomaly cannot be established. Children born without an extremity or with a malformed extremity can be fitted with a prosthesis early in life. In most instances, children will have better function if the malformed portion of an extremity is amputated before a prosthesis is fitted. This is a difficult decision for parents to make, however, because it is one that they cannot undo later. They need assurance that hands with malformed fingers, for example, will not later grow to become normal. A well-fitted prosthesis that a child learns to use at an early age will provide more function and allow a more normal childhood and adult life than if the original disorder is left unchanged (Fig. 27.15). Lower extremity prostheses are fitted as early as age 6 months (so an infant will learn to stand at the normal time). Upper extremity prostheses are fitted this early also, so an infant can handle and explore objects readily.

Introducing a prosthesis early also prevents a child from adjusting to a missing extremity, such as writing with the feet or sliding across a floor rather than walking. Children can become so proficient at these adjustments that later in life they do not see the advantage of a prosthesis and refuse to use one. Although these self-adjustments may be cute in infants, in the long run they greatly limit a child's potential.

Learning to use a hand prosthesis takes weeks to months. Help parents think of interesting activities when introducing the prosthesis so the child can see immediately how useful it will be to use. Gait training for use of lower extremity prostheses begins with the use of parallel bars and proceeds to independent walking and mastery of steps.

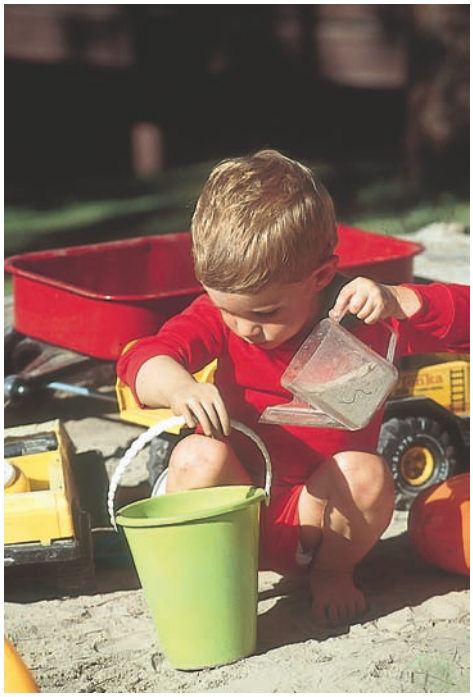

FIGURE 27.15 A young child learns to use a hand prosthesis during play. (M. Grecco/Stock Boston.)

Children who are born with an absent extremity may need help in mastering not only the use of a prosthesis but also a positive body image of themselves as whole. If possible, in the newborn period, introduce parents to the rehabilitation team who will be following their child. Further steps then will be outlined for them to help them move past the helplessness they may feel to more positive action. Visiting with a child who uses a prosthesis well can be a great help in convincing parents that their child can lead a normal life. Children with a congenital extremity loss do not grieve over the lost extremity as do adults or older children, which means they are often better prepared to move on quickly to rehabilitation.

Finger and Toe Conditions

Finger or hand deformities occur in about 3% of all births. **Polydactyly** is the presence of one or more additional fingers or toes. When an entire extra finger or toe forms, the supernumerary digit is usually amputated in infancy or early childhood. These extra fingers are often just cartilage or skin tags, and removal is simple and cosmetically sound. In **syndactyly** (two fingers or toes are fused), the fusion is usually caused by a simple webbing (Fig. 27.16); separation of the digits into two sound and cosmetically appealing ones is usually successful. In other instances, the bones of the fingers or toes are also fused, and cosmetic appearance and function cannot be fully reconstructed.

These hand anomalies are always upsetting to parents (one of the first things that new parents do is count the fingers and toes of newborns). They may need time to air their feelings and concerns. They may need reassurance at health maintenance visits throughout their child's development that the child is normal in other ways so they can accept and help

FIGURE 27.16 Syndactyly. (JPD/Custom Medical Stock Photograph.)

the child develop self-esteem. Children need this same type of assurance so they can think of themselves as well people.

Chest Deviations

Pectus excavatum is an indentation of the lower portion of the sternum (Mavanur & Hight, 2008). Children usually are born with this condition, but they may also develop it after chronic obstructive lung disease or rickets. As a result, lung volume decreases and the heart is displaced to the left. This condition can be repaired, either for cosmetic reasons or to expand lung volume. With pectus carinatum, the sternum is displaced anteriorly, increasing the anterior-posterior diameter of the chest. This condition also can be repaired for physiologic or cosmetic reasons.

Torticollis (Wry Neck)

Torticollis is a term derived from *tortus* (twisted) and *collum* (neck). Torticollis (wry neck) occurs as a congenital anomaly when the sternocleidomastoid muscle is injured and bleeds during birth (Waldman & Manista, 2007). This tends to occur in newborns with wide shoulders when pressure is exerted on the head to deliver the shoulder. The infant holds the head tilted to the side of the muscle involved; the chin rotates to the opposite side. The injury may not be noticeable in the newborn and may become evident only as the original hemorrhage recedes and fibrous contraction occurs at 1 to 2 months of age. A thick mass over the muscle can usually be palpated at this time.

To relieve torticollis, parents need to begin a program of passive stretching exercises, lying the infant on a flat surface and rotating the head through a full range of motion. In addition, parents should always encourage the infant to look in the direction of the affected muscle. They can encourage this by holding the child to feed in such a position that the child must look in the desired direction. Placing a mobile on the child's crib to encourage the child to look toward the affected side also is helpful. Speaking to and handing the child objects from the affected side to make the child look that way are also helpful exercises.

If manual stretching is begun early and consistently by the parents, further treatment usually is not necessary. Help parents understand that these actions are important therapy and not just games. Otherwise, the exercises seem so simple parents may not take them seriously. In the few instances in which simple exercises are not effective and the condition still exists at 1 year of age, surgical correction followed by a neck immobilizer will be necessary. If extreme injury to the muscle occurred, torticollis can lead to the continued elevation of one shoulder. Although a rare complication, this has the potential to lead to scoliosis later in life.

Parents may ask about the use of botulism (Botox) injections, because adults who develop spastic torticollis may receive this type of treatment (Benecke & Dressler, 2007). It is not recommended or necessary for most infants.

✔ Checkpoint Question 27.4

What is an important care measure to teach parents of a child with torticollis?

a. Encourage the infant to turn his head to stretch the neck.
b. Wrap the infant's neck in a warm towel twice daily.
c. Massage the infant's shoulders and torso at bedtime.
d. Administer 1 grain of aspirin with each bottle feeding.

Craniosynostosis

Craniosynostosis is premature closure of the sutures of the skull. This may occur in utero or early in infancy because of rickets or irregularities of calcium or phosphate metabolism; it also occurs as a dominantly inherited trait (Elias, Tsai, & Manchester, 2008). It occurs more often in boys than in girls.

This condition needs to be detected early because premature closure of the suture line will seal the skull closed and compromise brain growth. When the sagittal suture line closes prematurely, the child's head tends to grow anteriorly and posteriorly. If the coronal suture line fuses early, the orbits of the eyes become misshapen, and the increased intracranial pressure may lead to exophthalmos, nystagmus, papilledema, strabismus, and atrophy of the optic nerve with consequent loss of vision. Premature closure of the coronal suture line is associated with syndactyly. Therefore, closely observe all infants with syndactyly for head circumference. Conversely, assess all infants with craniosynostosis for syndactyly. Cardiac anomalies, choanal atresias, or disorders of elbows and knee joints are also associated with craniosynostosis.

Measure head circumference on all children age 2 years or younger at health maintenance visits and compare these measurements with normal head circumference charts. The posterior fontanelle normally closes at 2 months of age, the anterior fontanelle at 12 to 18 months. Children whose fontanelles close before these typical times need continued assessment to ensure that craniosynostosis is not developing.

Craniosynostosis is diagnosed by radiography or ultrasound, which reveals the fused suture line. If the suture line is the sagittal one, treatment may involve only careful observation; if the coronal suture line is involved, it will need to be surgically opened to prevent brain compression and an abnormally shaped head (Elias, Tsai, & Manchester, 2008).

Achondroplasia

Achondroplasia (chondrodystrophia) is a failure of bone growth inherited as a dominant trait. It causes a disorder in cartilage production in utero. The epiphyseal plate of long

bones cannot produce adequate cartilage for longitudinal bone growth, which results in both arms and legs becoming stunted.

Because the bones of the cranium are of membranous origin, they continue to grow normally. Children's heads will therefore appear unusually large in contrast to their extremities. The forehead is prominent and the bridge of the nose is flattened. Because this is a cartilage, not a brain, problem, intelligence proceeds normally. Children's trunks are of near-normal size, but a thoracic kyphosis (outward curve) and lumbar lordosis (inward curve) of the spine may develop.

Achondroplasia can be diagnosed in utero or at birth by comparing the length of extremities to the normal length (in the average child, the arms can be extended to the distance of the midthigh) or by radiography, which will reveal characteristic abnormally flaring epiphyseal lines. People with achondroplasia rarely reach a height of more than 4 feet 6 inches (140 cm). Women with this condition will have difficulty with childbearing because of a small pelvis, generally necessitating a cesarean birth.

Children with achondroplasia become aware of their appearance as early as the preschool years. They are apt to become acutely aware of their appearance during school age, when they realize they look different from other children. Children may be prescribed growth hormone to increase their ultimate height or, although controversial, leg lengthening may be possible (Horton, Hall, & Hecht, 2007). Ideally, such children have parents who have adjusted well to their own short stature and therefore have developed good self-esteem and can implant these qualities in their child.

Children should be informed that, as with all dominantly inherited disorders, there is a high probability that their children will inherit the disorder. Adolescence may be a particularly difficult time for these children as they realize that occupational and reproductive options may be limited for them. Continued guidance or counseling can help them to emerge from this period with feelings of high self-esteem in themselves as adults.

What if... Baby Sparrow's mother tells you she wants to let her newborn die rather than undergo palliative surgery to close the neural tube disorder? Whose rights should be honored, the parent's or the child's, and how should these rights be determined? What would be your role?

Talipes Disorders

Talipes is a word formed from the Latin words *talus* ("ankle") and *pes* ("foot"). The talipes deformities are ankle–foot disorders, popularly called clubfoot (Forster & Fraser, 2007). The term "clubfoot" implies permanent crippling to many people, so avoid using this term when discussing talipes disorders with parents. With the orthopedic correction techniques currently available, correction should leave the child with normal foot position. However, shoe size may vary as much as two shoe sizes, and the child may have asymmetry of leg length.

Approximately 1 in every 1000 children is born with a talipes disorder, occurring more often in boys than in girls. It probably is inherited as a polygenic pattern. It usually occurs as a unilateral problem (Eilert, 2008).

Some newborns have a pseudo-talipes disorder that has developed because of their intrauterine position. In these infants, the foot looks to be turned in but can be brought into a straight position by manipulation. In a true disorder, the foot cannot be properly aligned without further intervention. Be certain to demonstrate to parents that if a pseudo-disorder is present, the foot can easily be brought into line or is not deformed. Otherwise, the first time parents fit booties or shoes on the infant, they will notice this and worry that the foot is misshapen.

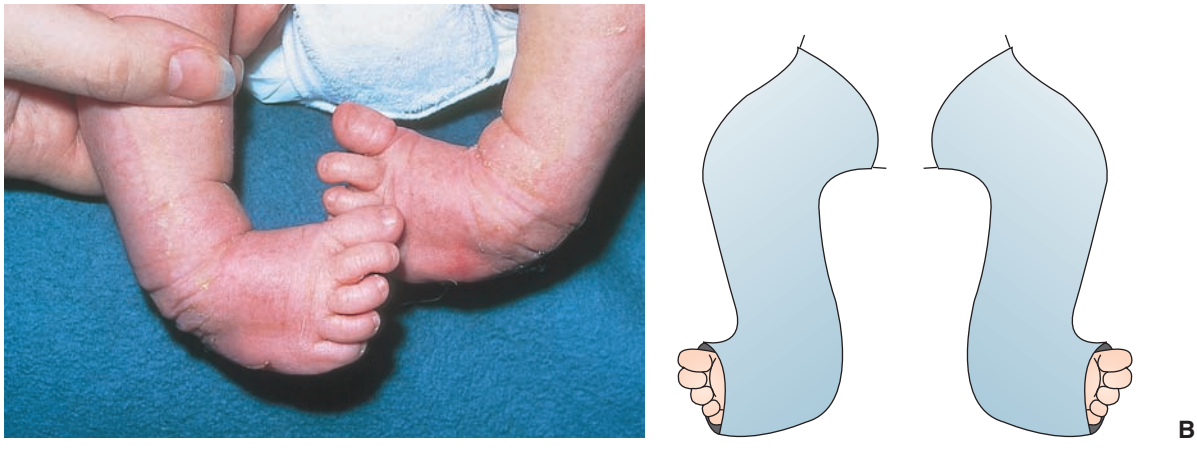
A true talipes disorder can be one of four separate types: plantarflexion (an equinus or "horsefoot" position, with the forefoot lower than the heel); dorsiflexion (the heel is held lower than the forefoot or the anterior foot is flexed toward the anterior leg); varus deviation (the foot turns in); or valgus deviation (the foot turns out). Most children with talipes deformities have a combination of these conditions or have an equinovarus (Fig. 27.17A) or a calcaneovalgus disorder (a child walks on the heel with the foot everted).

Assessment

The earlier a true disorder is recognized, the better will be the correction. Make a habit of straightening all newborn feet to the midline as part of initial assessment to detect this disorder.

Therapeutic Management

Correction is achieved best if it is begun in the newborn period. A cast is applied while the foot is placed in an



A B

FIGURE 27.17 (**A**) Talipes equinovarus. (SPL/Photo Researchers, Inc.) (**B**) Casts for bilateral equinovarus.

overcorrected position. Although the disorder involves the ankle, the cast extends above the knee to ensure firm correction (see Fig. 27.17B). (Care of the child in a cast is discussed in Chapter 51.) Because talipes casts are high on the leg, change diapers frequently to prevent a wet diaper from touching the cast and causing it to become soaked with urine or meconium. Review with parents how to check the infant's toes for coldness or blueness and how to blanch a toenail bed and watch it turn pink to assess for good circulation. Because a newborn cannot report pain except by generalized crying, crying episodes in the infant must be evaluated carefully. Such crying may be because of colic, hunger, or wet diapers; it might also be because of the tingling feeling of circulatory compression (as when a foot is "asleep") from too tight a cast.

Infants grow so rapidly in the neonatal period that casts for talipes deformities must be changed almost every 1 or 2 weeks. If a mother has a complication of childbirth or is exhausted from childbirth (depression because of the child having been born congenitally challenged may manifest itself as exhaustion), be certain she knows to make arrangements for another family member to bring the infant to the hospital for cast changes.

After approximately 6 weeks (the time varies depending on the extent of the problem), the final cast is removed. After this, parents may need to perform passive foot exercises such as putting the infant's foot and ankle through a full range of motion several times a day for several months. These seem like simple maneuvers, so be sure to stress their importance to the parents; otherwise, they are easy exercises to omit when people's lives are busy. The infant may have to sleep in Denis Browne splints (shoes attached to a metal bar to maintain position; see Chapter 51) or high-top shoes at night for a few more months.

Although a successful correction cannot be guaranteed, the prognosis for a full correction is good. For children who do not achieve correction by casting, surgery is yet another option to achieve a final correction.

Developmental Hip Dysplasia

Developmental hip dysplasia (often referred to as congenital hip dysplasia) is improper formation and function of the hip socket (Eilert, 2008). The disorder occurs in 1 in 1000 births. It may be evident as subluxation or dislocation of the head of the femur (Fig. 27.18).

With this disorder, the acetabulum of the pelvis is flattened or shallow. This prevents the head of the femur from remaining in the acetabulum and rotating adequately. In a subluxated hip, the femur "rides up" because of the flat acetabulum; in a dislocated hip, the femur rides so far up that it actually leaves the acetabulum. Why the disorder occurs is unknown, but it may be from a polygenic inheritance pattern. It may also occur from a uterine position that causes less-than-usual pressure of the femur head on the acetabulum.

Developmental hip dysplasia occurs most often in children of Mediterranean ancestry. It is found six times more frequently in girls than in boys, possibly because the hips are normally more flaring in females and possibly because the maternal hormone relaxin causes the pelvic ligaments to be more relaxed. Therefore, the femur does not press as effectively into the acetabulum during intrauterine life, deepening

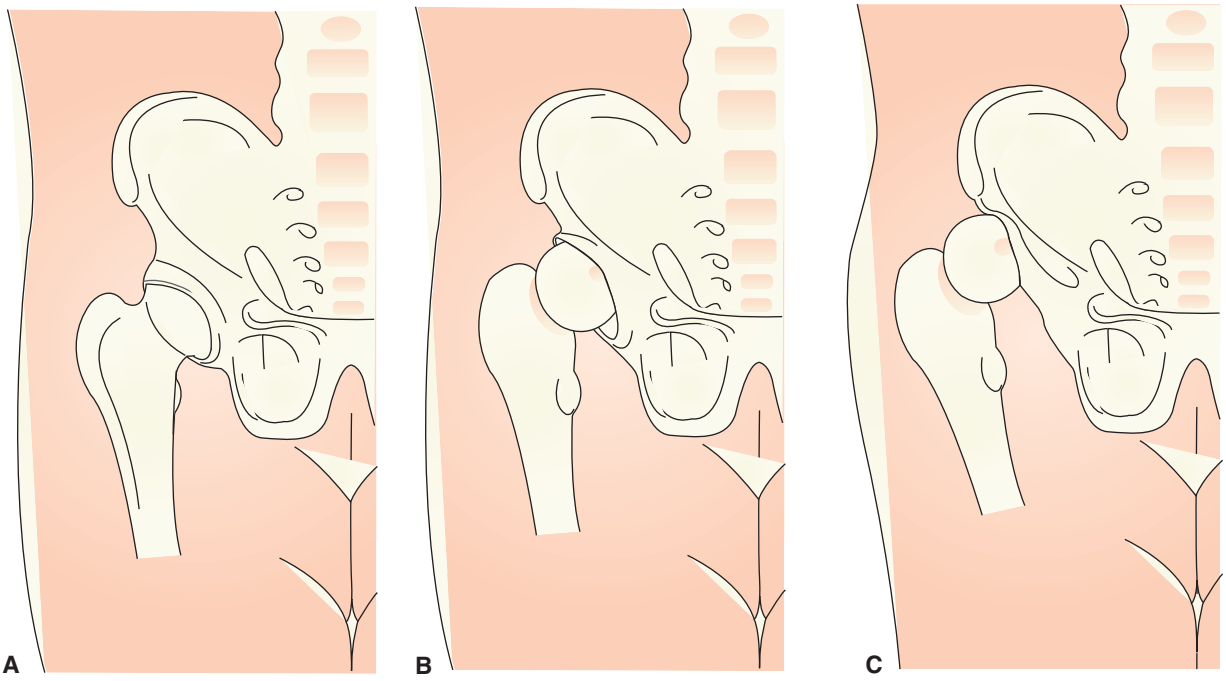


FIGURE 27.18 Hip dysplasia. (**A**) A normal femur head and acetabulum. (**B**) A subluxated hip. The femur head is "riding high" in the shallow acetabulum. (**C**) A dislocated hip. The femur head is not engaged in the shallow acetabulum.

the space. Involvement usually is unilateral. Sociocultural methods of childrearing, such as the way infants are carried, may promote or decrease the extent of the involvement.

Assessment

Detecting developmental hip dysplasia in the newborn is important because the longer the condition goes undetected, the more difficult it is to correct. Sometimes the affected leg may appear slightly shorter than the other one because the femur head rides so high in the socket. This is most noticeable when the child is lying supine and the thighs are flexed to a 90-degree angle toward the abdomen. One knee will appear to be lower than the other (a Galeazzi sign (Fig. 27.19A). An unequal number of skin folds may be present on the posterior thighs (see Fig. 27.19B). This finding is unreliable, however, because some infants with normal hips have an uneven number of posterior thigh skin folds. Subluxated or dislocated hips are best assessed by noting whether the hips abduct (Box 27.9).

In some infants, the hip abducts properly at a newborn assessment, but at the time of a health maintenance visit at 4 to 6 weeks, a secondary shortening of the adductor muscles will have occurred, and the disorder will be evident. Hip dysplasia is difficult to detect at birth in an infant who was born from a footling or frank breech presentation because the knees are stiff and do not flex readily. Always assess hip function in these infants at each health maintenance visit. Tight adductor muscles occur in children with cerebral palsy, so this disorder must be ruled out. Radiography, ultrasound, or MRI will reveal the shallow acetabulum and a more lateral placement of the femur head than is ordinarily seen.

Therapeutic Management

Correction of subluxated and dislocated hips involves positioning the hip into a flexed, abducted (externally rotated) position to press the femur head against the acetabulum and cause it to deepen its contour by the pressure. Splints, halters, or casts may be used. The small number of children who do not achieve correction by these methods will have surgery and a pin inserted to stabilize the hip.

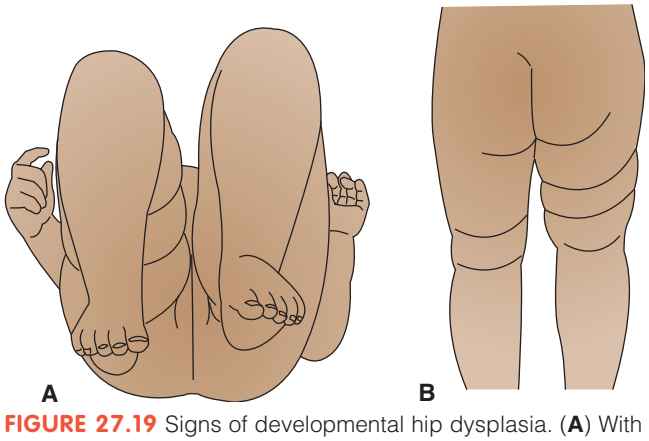

FIGURE 27.19 Signs of developmental hip dysplasia. (**A**) With child in a supine position, the right knee on the side of the subluxation appears lower than the left because of malposition of the femur head. (**B**) Asymmetry of skin folds and prominence of the trochanter on the right side.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Deficient parental knowledge related to splint, halter, or cast correction for hip dysplasia

Outcome Evaluation: Parents verbalize correct technique for and correctly demonstrate application and removal of splint or halter device and care of device or cast.

Multiple Diapers or Splints. Often splint correction (to hold the legs in a frog-leg, or abducted, externally rotated position) is begun during the newborn's initial hospital stay by placing two or three diapers on the infant. The extra bulk of cloth between the child's legs effectively separates and spreads them. Many brands of disposable diapers are cut narrow between the legs so they do not offer this much bulk and will not work as well as cloth diapers.

The way that parents carry infants may contribute to the formation of hip dysplasia. Infants who are carried straddled on their parents' hips, the way Latin American mothers carry their infants, may have less hip dysplasia than those carried with their legs consistently brought together, such as Native American infants carried on swaddling boards. Swaddling babies is comforting. Be certain, however, these parents understand that bringing this child's legs together with a tight swaddling blanket will not be good for this infant.

Pavlik Harness. A Pavlik harness is an adjustable chest halter that abducts the legs. It is the method of choice for long-term therapy because it reduces the time interval for therapy to 3 to 4 weeks and simplifies care (see Fig. 27.20B). Soft plastic stirrups (booties) with quick-fastening closures such as Velcro attach to leg extension straps and hold the hips flexed, abducted, and externally rotated. Instruct parents to lay the infant supine, grasp the infant's thighs and abduct them to place the femoral head into the acetabulum, and then apply the harness. The harness is then worn continually except for bathing. Advise parents to assess the skin under the straps daily for irritation or redness.

A Pavlik harness does not show under a shirt and long trousers and promotes gentle reduction of the hip. However, if a hip is completely dislocated, a Pavlik harness may not be firm enough to hold the hips in the proper position. In addition, the harness will be ineffective if parents remove it too frequently.

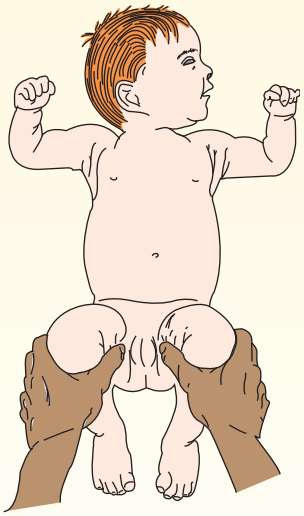
Spica Cast. If a hip is fully dislocated or the subluxation is severe, an infant may be placed immediately in a frog-leg, A-line cast or a spica cast to maintain an externally rotated hip position (see Fig. 27.20C). These casts are heavy and are so wide that dressing infants or sitting them in an infant car seat or bassinet can be

Box 27.9 Nursing Procedure ✻ Assessing Ortolani's and Barlow's Signs

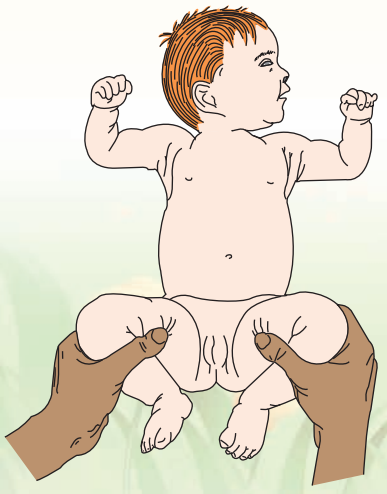
Purpose: To assist in detecting developmental hip dysplasia

Procedure

1. Lay the infant supine and flex the knees to 90° at the hips.
2. Place your middle fingers over the greater trochanter of the femur and your thumb on the internal side of the thigh over the lesser trochanter.



3. Abduct the hips while applying upward pressure over the greater trochanter, and listen for a clicking sound.
4. Next, with your fingers in the same position, and holding the hips and knees at 90° flexion, apply a backward pressure (down and laterally) and adduct the hips. Note any feeling of the femoral head slipping.



Principle

1. Proper positioning ensures accurate results.
2. Placing your fingers in this way allows for abduction of the hips.
3. Normally, no sound is heard. A clicking or clunking sound is a positive Ortolani's sign and occurs when the femoral head re-enters the acetabulum.
4. Normally, the hip joint is stable. A feeling of the femur head slipping out of the socket posterolaterally is a positive Barlow's sign indicative of hip instability associated with developmental hip dysplasia.

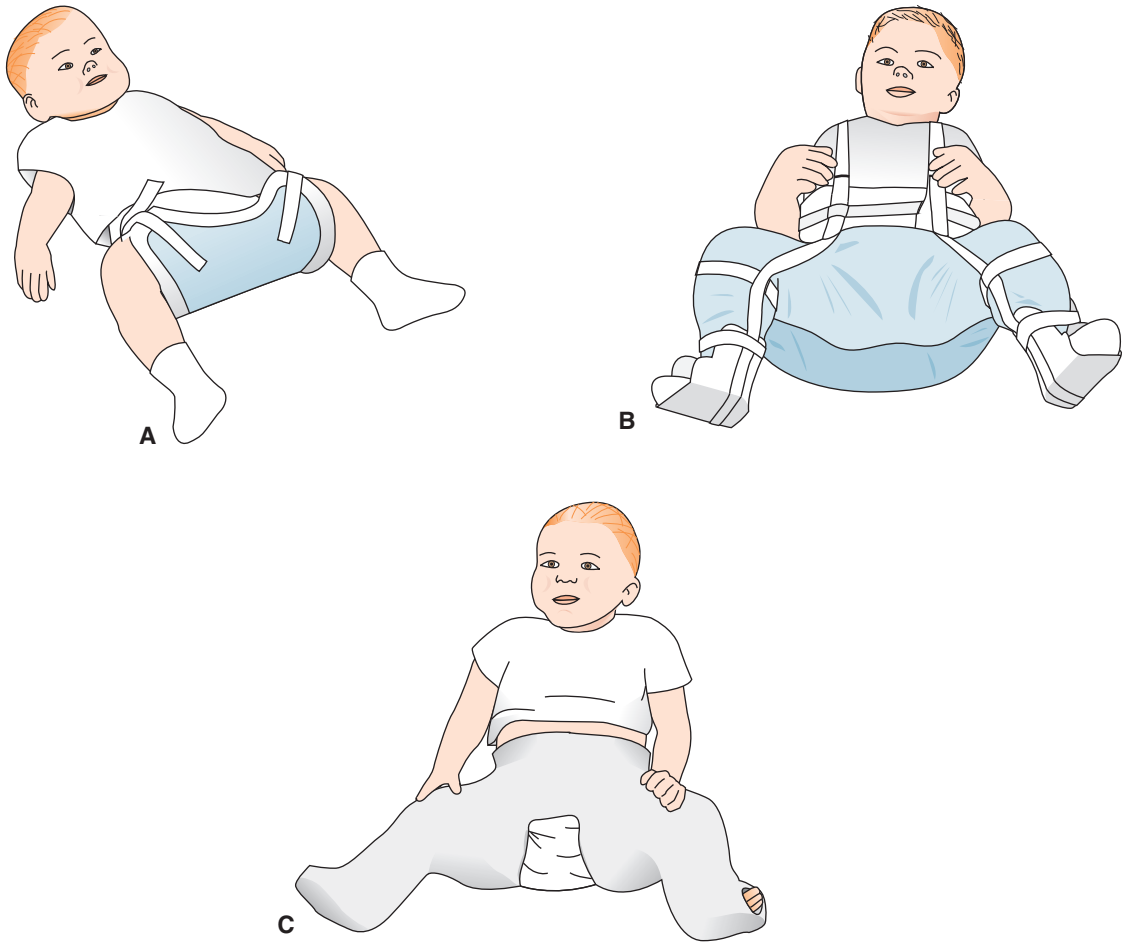


FIGURE 27.20 (**A**) Hip abduction splint (Frejka splint) holds the hips in an abduction position, forcing the femur head into the acetabulum. (**B**) A Pavlik harness. (**C**) A hip abduction cast for correction of subluxation of the hip.

difficult. Be certain parents have a car seat that can be modified to accommodate a large cast. Newborns are unable to report that a cast is causing circulatory constriction, so they need to be assessed hourly for circulation to the extremities for the first 24 hours the cast is in place and daily thereafter. Teach parents how to do this type of neurovascular assessment (check temperature and circulation in toes) before they take an infant home from the hospital so they can prevent circulatory compression from a rapidly growing leg outgrowing a cast. Casts will be changed periodically but maintained for 6 to 9 months. If a reduction maneuver for congenital dislocated hip was forceful, causing tension in the soft tissues around the hip, the resulting compression of the joint may cause transient blockage of the blood supply to the femoral head or avascular necrosis. In its severest form, this can lead to femoral head death and loss of future growth at the proximal growth plate causing unequal leg lengths (Eilert, 2008).

General Care Guidelines. No matter what type of therapy is used—double-diapering, harness, or cast—surgery may still be necessary for a final correction. Making parents aware of this from the start prevents them from thinking their child's condition is so serious that the usual methods of treatment failed. It helps them from becoming discouraged or dissatisfied with health care. It also helps them to accept from the beginning that this condition will be a long-term care concern. Some children will be 2 years old before the final cast or harness is removed.

The child and parents will be visiting their orthopedist frequently during these early years. Assess that parents also schedule general health maintenance visits for routine immunizations and overall growth and development assessment. Spend time during health maintenance visits talking with them about infant stimulation. Because the child is not fully mobile, special adaptations are necessary. Teach parents to hold their child for feeding and to rock and cuddle the infant, even though a large cast or a brace may be bulky and awkward. They need to bring experiences to the infant because the child cannot crawl and walk toward interesting objects in the environment. A child's wagon can supply convenient and fun transportation. The child may also be able to lie prone and move about on a large skateboard. Many parents worry that the child who is still in a large cast at the

normal age for walking (12 months) will never learn to walk. They can be assured that this is not a problem; when the cast is removed, the child will quickly catch up with this developmental step.

✔ Checkpoint Question 27.5

Children with developmental hip dysplasia have Pavlik harnesses prescribed. You would advise the parents of a child with this type of therapy that their child:

a. Will be anesthetized to have the harness applied.
b. Will experience dull pain all the time it is in place.
c. Will need to wear this for only 1 or 2 weeks.
d. Should wear it all day except for clothing changes.

Key Points for Review

- Learning about the way a child will be physically challenged immediately after birth helps parents adjust most easily. Advocate for parents by helping them obtain as much information as they need about their child's condition.
- Parent–infant bonding can be difficult to establish when a child is hospitalized at birth. Assess family relationships at health maintenance visits to see that bonding is occurring.
- Cleft lip and palate result from the failure of the maxillary process to fuse in intrauterine life. Surgical repair is possible early in life, with a good prognosis for both these conditions.
- Tracheoesophageal atresia and fistula occur from failure of the trachea and esophagus to divide appropriately in intrauterine life. Surgical intervention often needs to be performed in several stages.
- Omphalocele is the protrusion of abdominal contents through the abdominal wall at birth, protected only by a peritoneal membrane. When the membrane is not present, this is called gastroschisis. Although several stages of repair are often necessary, surgical correction has a good outcome.
- Intestinal obstruction can result from atresia (complete closure) or stenosis (narrowing) of a part of the bowel. Correction is surgical removal of the narrowed bowel portion.
- A meconium plug occurs when an extremely hard portion of meconium blocks the lumen of the intestine. Infants with meconium plug syndrome need to be observed for continuing bowel function and need to be assessed for cystic fibrosis, because a meconium plug is often a symptom of this.
- Diaphragmatic hernia occurs when the abdominal organs protrude through a defect in the diaphragm into the chest cavity. This prevents the lungs from fully expanding at birth. These infants are critically ill at birth and need extensive surgical correction.
- Imperforate anus is stricture of the anus, resulting in inability to pass stool. The infant may have a temporary colostomy created before a final surgical correction can be completed.
- Physical developmental disorders of the nervous system include hydrocephalus (excess cerebrospinal fluid in the ventricles) and spina bifida (incomplete closure of the spinal cord). Infants with hydrocephalus need surgery to relieve a ventricular obstruction or have a shunt implanted from their ventricles to the peritoneal cavity to remove excess cerebrospinal fluid. Children with myelomeningocele, the most severe form of neural cord disorder, face permanent loss of lower neuron function and require continued rehabilitation.
- Absent or malformed extremities may range from absence of a finger to absence of an entire limb. Children may need physical therapy and teaching on how to use a prosthesis to gain full mobility and function.
- Developmental hip dysplasia is the improper formation and function of the hip socket; talipes deformities are foot and ankle deformities. Children may need extensive bracing and casting to correct these disorders.

CRITICAL THINKING EXERCISES

1. Bobby Jo Sparrow is a 16-year-old teenager whose newborn has been admitted to the neonatal intensive care unit because of a neural tube disorder and congenital hip dysplasia. Ms. Sparrow is obviously upset over the diagnosis. She says, "I'm a good person. The only thing I did wrong during pregnancy was to take some cough medicine, so how could this have happened?" How would you answer her? What type of advice would be most helpful to her?
2. Baby Sparrow has developmental hip dysplasia and will be placed in a Pavlik harness. What suggestions could you make to his mother to help her instill a strong sense of trust in her child? A sense of autonomy?
3. You notice Baby Sparrow's mother is obviously upset at her child's appearance. She does not want to feed the baby and voices the thought of placing him for adoption. In contrast, the child's father, age 22, handles the baby warmly and asks questions about surgery. No grandparents visit. What interventions would you want to begin with this family?
4. Examine the National Health Goals related to children born with physical or developmental disorders. Most government-sponsored funds for nursing research are allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to the Sparrow family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to families with an infant who has a physiologic or developmental challenge. Confirm your answers are correct by reading the rationales.

Unit 5

The Nursing Role in Health Promotion for a Childrearing Family

This page intentionally left blank.

Chapter

28 Principles of Growth and Development

KEY TERMS

- abstract thought
- accommodation
- assimilation
- autonomy versus shame or doubt
- centering
- cognitive development
- conservation
- development
- developmental milestones
- developmental task
- egocentrism
- growth
- identity versus role confusion
- industry versus inferiority
- initiative versus guilt
- integrity versus despair
- maturation
- permanence
- reversibility
- role fantasy
- schemas
- sensorimotor stage
- temperament
- trust versus mistrust

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe principles of growth and development and developmental stages according to major theorists.
2. Identify National Health Goals related to growth and development that nurses can help the nation achieve.
3. Use critical thinking to analyze ways that paths to achieving a new developmental stage remain family centered.
4. Assess a child to determine the stage of development that has been achieved.
5. Formulate nursing diagnoses that address wellness as well as both a potential for and an actual delay in growth and development.
6. Identify expected outcomes for nursing goals for a growing child.
6. Plan nursing interventions to assist a child in achieving and maintaining normal growth and development such as encouraging a parent to read to a child.
7. Implement nursing care such as suggesting age-appropriate play materials to support normal growth and development.
8. Evaluate outcome criteria for achievement and effectiveness of care.
9. Identify areas of nursing care related to growth and development that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of growth and development with nursing process to achieve quality maternal and child health nursing care.

John Olson is a 6-year-old boy you see in an emergency department because he has a broken leg from a bicycle accident. At 4 months of age, John was taken away from his mother because she was not caring for him adequately. He was then moved back and forth among 12 different foster homes until he was finally adopted at age 3½. His adoptive parents have 3-year-old twins of their own. They tell you although John has lived with them for 3 years, they find him cold and unloving. They ask you what they can do to change this. Nurses are directly responsible for assessing the growth and development of children in many health care settings. Previous chapters discussed childbearing and what an important time the first weeks after birth can be in a child's life. This chapter adds information about growth and development that is important for all the continuing years of a child's life.

How has John's background contributed to his behavior? What stage of psychosocial development does he not seem to have achieved? How could his adoptive parents help him at this point?

All children pass through predictable stages of growth and development as they mature. Parents often ask what to expect from their children regarding their developmental progress at health care visits. Such visits provide opportunities for you not only to assess present growth and development but also to supply anticipatory guidance on the topic.

For these reasons, including growth and development is essential in the establishment of complete and effective nursing care plans for children. This chapter addresses the most important factors to assess for each age group. Later chapters supply detailed descriptions of individual age groups. National Health Goals related to growth and development are presented in Box 28.1.

FIGURE 28.1 Growth and development are assessed by both observation and specific testing. Here a 12-month-old demonstrates mastery of well-coordinated and intentional hand movements.

Nursing Process Overview

For Promotion of Normal Growth and Development

Assessment

Measure and plot height and weight on a standard growth chart for children at all health care visits to document growth is occurring and the child's growth remains within a constant percentile. Take a health history from both parents and the child and observe what specific activities the child can accomplish to establish whether **developmental milestones** (major markers of normal development) are being met (Fig. 28.1). Document a 24-hour recall history for nutritional intake, sleep, and a description of school and play behaviors. Periodic screening tests (i.e., the Denver II, vision tests, and audiometry screening) should be scheduled at standard times, as discussed in Chapter 34. For the most accurate assessments, be certain to account for illness, sleepiness, fatigue, or "bad days" (a day on which a child did not test well).

Nursing Diagnosis

When assessment is completed, a child profile can be devised and needs and problems identified. Examples of nursing diagnoses applicable to this area include:

- Risk for delayed growth and development related to lack of age-appropriate toys and activities
- Delayed growth and development related to prolonged illness
- Readiness for enhanced family coping related to parent's seeking information about child's growth and development
- Health-seeking behaviors related to appropriate stimulation for infants
- Imbalanced nutrition, less than body requirements, related to parental knowledge deficit regarding child's protein need
- Deficient knowledge related to potential long-term effects of obesity in school-age child

Outcome Identification and Planning

To provide holistic nursing care, consider all aspects of a child's health (physical, emotional, cultural, cognitive,

BOX 28.1 * Focus on National Health Goals

National Health Goals that address growth or development of children include:

- Reduce the prevalence of growth restriction among low-income children aged 5 and younger to less than 5% from a baseline of 8%. Growth restriction is defined as height-for-age below the fifth percentile on a standard growth chart.
- Reduce the occurrence of developmental disabilities in children such as cognitive challenge from a baseline of 131 per 100,000 to a target of 124 per 100,000
- Reduce the identification of autism from a baseline of 50 months to 48 months of age.
- Reduce the proportion of children and adolescents who are overweight or obese from a baseline of 11% to 5% (http://www.nih.gov).

Recognizing normal growth and development patterns for children helps to determine if children are following normal development and when referrals are needed. Nursing research topics that could add information in this area are: Are there differences between urban and rural children in the way they approach childhood problems? How do characteristics of temperament affect the way children respond to hospitalization? What are specific ways the environment of children influences health? What can nurses do to help reduce the obesity epidemic in children?

spiritual, nutritional, and social), remembering that each child's developmental progress is unique. Children cannot be forced to achieve milestones faster than their own timetable will allow. However, through anticipatory guidance, children can be encouraged to reach maximum developmental potential. Nurses can play important roles in suggesting expected outcomes and guidance to both a child and family on ways to encourage child development and preparing children for new experiences.

Not all nations foster the growth and development of children in the same manner, in part because of cultural variations. Childhood in the United States covers a relatively long period. In other countries, childhood is short because girls are asked to assume domestic responsibilities early in life and outside or farm work is required early for boys. In some countries, the predominant theory of child-rearing is protective nurturing. Children are not rushed into new experiences like toilet training or beginning school. In others, it is customary to treat children in a harsh, strict manner, using shame or corporal punishment for discipline. Praising children for learning a new skill may be viewed as unnecessary or actually harmful, because this could result in a child being subject to evil forces. In some Asian cultures, an infant's personality is thought to depend not so much on genetic or environmental influences but on the year and time of birth.

What foods children receive depends very much on culture also. Vegetables such as jicama and chayote, for example, may not even be recognized by children in the northeast United States but are popular with those in the southwest.

Asking a parent questions such as, "What do you do when your baby cries?" "What kind of things do you think a 2-year-old should be able to do?" "What do you do when your 4-year-old misbehaves?" can help you to isolate and better understand cultural differences. Recognizing cultural variations this way helps to plan care that is specific to a particular child and family.

Planning should include a child's family as growth and development proceed within a family context. To develop psychosocially, children continue to need emotional support from loved ones, just as they need nutritional support to grow physically. Parents of a child with a developmental delay may use denial as a protective mechanism for a long time. This means that planning may have to be centered first on helping parents accept what is happening; plans for a child may have to be delayed until the parents are convinced a problem exists. Helpful Web sites to use for parent referral are the Sutter Health Network (http://www.Kids.Sutterhealth.org) and the Learning Place (http://www.Learningplaceonline.com).

Implementation

Interventions to foster growth and development include encouraging age-appropriate self-care in a child and suggesting age-appropriate toys or activities to parents. It may be necessary to help parents accept a child's delayed growth or motivate a child to reach anticipated upper limits. Role modeling is an important ongoing intervention with both children and families. Modeling, for example, can demonstrate that problem solving is a more effective approach to life's challenges than "acting out" behaviors.

Outcome Evaluation

Evaluation for specific growth and developmental milestones (see Chapters 29 through 33) must be ongoing to be accurate and useful, because many children do not test well on any given day. Ongoing evaluation is necessary also because it provides an opportunity for early detection of various problems. If a child has difficulty achieving one developmental task, for example, the next one may be difficult to achieve as well. Evaluation must also be comprehensive. If a developmental task involves only gross motor function, it may not be apparent that something is wrong with a child's fine motor function until the child is asked to perform fine motor tasks in school. Examples of expected outcomes are:

- Child, 5 years of age, expresses less negativism at next clinic visit.
- At 9-month checkup, parents describe how they have made a safe space in their home for their infant to crawl so that he is not confined to a playpen.
- Parents list household tasks they believe are appropriate for a 6-year-old child by next office visit.
- Parents state the pattern they are using to phase out high-carbohydrate, nonnutritive snacks for their preschooler.

GROWTH AND DEVELOPMENT AND THE ROLE OF THE NURSE

Information about growth and development is important in all phases of childcare.

Health Promotion and Illness Prevention

Determining a child's developmental stage is often the primary focus of a health interview. For instance, during her child's 24-month checkup, a mother might ask if it is normal that her child cannot yet pedal a tricycle. This question, or any other questions about a child's developmental progress, cannot be answered without a full understanding of the average ranges of motor coordination.

Parenting style and competence are major influences on the behavioral and mental health of children (Coren & Barlow, 2009). In addition to reassurance that their child is doing well, parents also need periodic anticipatory guidance regarding their child's development. For example, it would be important to discuss additional home safety with a parent when a child is approaching the age for creeping. Parents should be cautioned to think about fencing open stairways and clearing cleaning compounds out of bottom cupboards. Parents of a child who is almost 1 year old will appreciate being cautioned that their child's appetite may decrease during the coming year; armed with this knowledge, they will not interpret a child's rejection of food as the beginning of a feeding problem but will see it as a usual step in development. The parent of a child approaching puberty generally welcomes a discussion on how to prepare a child for this challenging growth phase.

If anticipatory guidance is not offered at appropriate times, it can be useless. Information given too early is forgotten by the time it is needed. Given too late, parents may have already addressed (or ignored) the issue, possibly not

in the most growth-enhancing way for their child. To be able to supply anticipatory guidance this way at the appropriate time or to plan nursing care to meet the needs of children and families, you must be able to recognize the predictable stages of growth and development, from newborn to young adult, through which each child passes (Goldson & Reynolds, 2008).

Health Restoration and Maintenance

It is equally essential to consider developmental stages when caring for a sick child or one having surgery. Preparing a 5-year-old child for surgery, for example, would be ineffective unless you know how much a 5-year-old child can be expected to comprehend. You would need to assess if a child will understand things such as an anesthetic is a gas, what a surgeon is, and what stitches are or how to best explain what these are. It is just as important to keep developmental stages in mind when teaching parents; for example, you need to evaluate whether an oral form of medicine is appropriate for a child or if a child is too young to coordinate tongue and throat muscles.

Physical growth is another important factor to consider, because disease affects children differently at various stages of growth. A 12-year-old child who has fractured a long bone, for example, has a potentially more serious fracture than an 8-year-old child who fractures the identical bone. The 8-year-old child must metabolize enough calcium to meet two major needs: healing the fracture site and maintaining healthy bone cells. The 12-year-old child, who is undergoing a period of rapid growth, must meet three needs: calcium for healing and maintaining existing healthy bone cells and an additional amount for rapid bone growth. If a child does not take in adequate calcium during the healing period to supply the extra amount for growth, the affected limb could be left shorter than its mate. Recommending extra calcium could help ensure no permanent disability results.

PRINCIPLES OF GROWTH AND DEVELOPMENT

Growing up is a complex phenomenon because of the many interrelated facets involved. Children do not merely grow taller and heavier as they get older; maturing also involves growth in their ability to perform skills, to think, to relate to people, and to trust or have confidence in themselves.

The terms "growth" and "development" are occasionally used interchangeably, but they are different. **Growth** is generally used to denote an increase in physical size or a quantitative change. Growth in weight is measured in pounds or kilograms; growth in height is measured in inches or centimeters. **Development** is used to indicate an increase in skill or the ability to function (a qualitative change). Development can be measured by observing a child's ability to perform specific tasks such as how well a child picks up small objects such as raisins, by recording the parent's description of a child's progress, or by using standardized tests such as the Denver II. **Maturation** is a synonym for development.

Psychosexual development is a specific type of development that refers to developing instincts or sensual pleasure (Freudian theory). Psychosocial development refers to Erikson's stages of personality development. Moral development is the ability to know right from wrong and to apply these to real-life situations. Kohlberg is a theorist who studied this.

Cognitive development refers to the ability to learn or understand from experience, to acquire and retain knowledge, to respond to a new situation, and to solve problems (see the section below on Piaget's theory of cognitive development). It is measured by intelligence tests and by observing children's ability to function effectively in their environment.

Patterns

Neither physical growth nor aspects of maturation occur haphazardly; several principles govern this process (Box 28.2). As shown in Figure 28.2, general growth, such as growth of respiratory, digestive, renal, musculoskeletal, and circulatory tissue, proceeds fairly smoothly during childhood. Certain body tissues, however, mature more rapidly than others. Neurologic tissue (spinal cord and brain) grows so rapidly the first 2 years that the brain reaches mature proportions by 2 to 5 years. Lymphoid tissue (spleen, thymus, lymph nodes, and tonsillar tissue) also grows rapidly during infancy and childhood so children are protected against infection. Although the spleen is not usually palpable in adults, the spleen is palpable 1 or 2 cm below the left ribs in preschool children because of this rapid growth. In 5-year-olds, tonsillar tissue has already reached its peak size (about twice that of an adult). On assessment, young school-age children appear to have large tonsils (the back of their throat seems to be "all tonsils"). In contrast, reproductive organs (genital tissue) show little growth until puberty.

✔ Checkpoint Question 28.1

John is 6 years old. What body system is reaching its peak point of development at this time?

a. Neurologic system.
b. Lymphatic system.
c. Reproductive system.
d. Musculoskeletal system.

FACTORS INFLUENCING GROWTH AND DEVELOPMENT

Genetic inheritance, or whether a child receives healthy genes or genes that will lead to an illness, and environmental influences, such as whether the family a child is born into has sufficient funds to supply adequate food, are two primary factors that determine a child's pattern of growth and development. Temperament (the typical way a child reacts to situations) is an example of genetic influence. Whether a fetus enjoyed a healthy uterine existence is an example of environmental influence (Barnes-Powell, 2007). Whether a child receives good nutrition, beginning with being breastfed, is another (Hale, 2007). A unique combination of these factors determines how each child grows and matures (Shulruf et al., 2007).

Genetics

From the moment of conception when a sperm and ovum fuse, the basic genetic makeup of an individual is cast.

BOX 28.2 ✻ Principles of Growth and Development

Growth and development are continuous processes from conception until death. Although there are highs and lows in terms of the rate at which growth and development proceed, at all times a child is growing new cells and learning new skills. An example of how the rate of growth changes is a comparison between that of the first year and later in life. An infant triples birth weight and increases height by 50% during the first year of life. If this tremendous growth rate were to continue, the 5-yr-old child, ready to begin school, would weigh 1600 lb and be 12 ft 6 in tall.

Growth and development proceed in an orderly sequence. Growth in height occurs in only one sequence—from smaller to larger. Development also proceeds in a predictable order. For example, the majority of children sit before they creep, creep before they stand, stand before they walk, and walk before they run. Occasionally, a child will skip a stage (or pass through it so quickly that the parents do not observe the stage). Occasionally, a child will progress in a different order, but most children follow a predictable sequence of growth and development.

Different children pass through the predictable stages at different rates. All stages of development have a range of time rather than a certain point at which they are usually accomplished. Two children may pass through the motor sequence at such different rates, for example, that one begins walking at 9 mo, another only at 14 mo. Both are developing normally. They are both following the predictable sequence; they are merely developing at different rates.

All body systems do not develop at the same rate. Certain body tissues mature more rapidly than others. For example, neurologic tissue experiences its peak growth during the first year of life, whereas genital tissue grows little until puberty.

Development is cephalocaudal. *Cephalo* is a Greek word meaning "head"; *caudal* means "tail." Development proceeds from head to tail. Newborns can lift only their head off the bed when they lie in a prone position. By age 2 mo, infants can lift both the head and chest off the bed; by 4 mo, the head, chest, and part of the abdomen; by 5 mo, infants have enough control to turn over; by 9 mo, they can control legs enough to crawl; and by 1 yr, children can stand upright and perhaps walk. Motor development has proceeded in a cephalocaudal order—from the head to the lower extremities.

Development proceeds from proximal to distal body parts. This principle is closely related to cephalocaudal development. It can best be illustrated by tracing the progress of upper extremity development. A newborn makes little use of the arms or hands. Any movement, except to put a thumb in the mouth, is a flailing motion. By age 3 or 4 mo, the infant has enough arm control to support the upper body weight on the forearms, and the infant can coordinate the hand to scoop up objects. By 10 mo, the infant can coordinate the arm and thumb and index fingers sufficiently well to use a pincerlike grasp or be able to pick up an object as fine as a piece of breakfast cereal on a highchair tray.

Development proceeds from gross to refined skills. This principle parallels the preceding one. Once children are able to control distal body parts such as fingers, they are able to perform fine motor skills (a 3-yr-old colors best with a large crayon; a 12-yr-old can write with a fine pen).

There is an optimum time for initiation of experiences or learning. Children cannot learn tasks until their nervous system is mature enough to allow that particular learning. A child cannot learn to sit, for example, no matter how much the child's parents have him or her practice, until the nervous system has matured enough to allow back control. Children who are not given the opportunity to learn developmental tasks at the appropriate or "target" times for that task may have more difficulty than the usual child learning the task later on. A child who is confined to a body cast at 12 mo, the time the child would normally learn to walk, may take a long time to learn this skill once free of the cast at, say, age 2 yr. The child has passed the time of optimal learning for that particular skill.

Neonatal reflexes must be lost before development can proceed. An infant cannot grasp with skill until the grasp reflex has faded nor stand steadily until the walking reflex has faded. Neonatal reflexes are replaced by purposeful movements.

A great deal of skill and behavior is learned by practice. Infants practice over and over taking a first step before they accomplish this securely. If children fall behind in growth and development because of illness, they are capable of "catch-up" growth to bring them equal again with their age group

Although each child is unique, certain gender-related characteristics will influence growth and development. In addition to physical characteristics such as eye color and height potential, inheritance determines other characteristics such as learning style and temperament. An individual may also inherit a genetic abnormality, which could result in disability or illness at birth or later in life.

Gender

On average, girls are born lighter (by an ounce or two) and shorter (by an inch or two) than boys. Boys tend to keep this height and weight advantage until prepuberty, at which time girls surge ahead because they begin their puberty growth spurt 6 months to 1 year earlier than boys. By the end of pu-

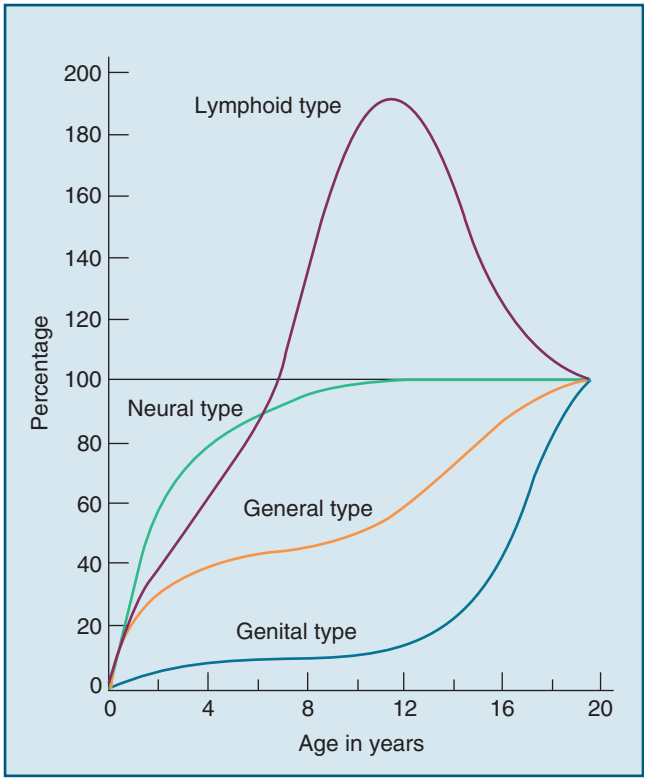

FIGURE 28.2 Main types of postnatal growth of various body tissue types. (Redrawn from Scammon, R. E. [1930]. The measurement of the body in childhood. In Harris, J. A., et al. [Eds.]. *The measurement of man* [pp. 214–226]. Minneapolis: University of Minnesota Press, with permission.)

berty (14 to 16 years), boys again tend to be taller and heavier than girls. This difference in growth patterns is reflected in the different growth charts used for boys and girls (see Appendix E).

Health

A child who inherits a genetically transmitted disease may not grow as rapidly or develop as fully as a healthy child, depending on the type of illness and the therapy or care available for the disease. Before insulin was discovered in 1922, for example, many children with type 1 diabetes mellitus died in early childhood; those who lived were left physically challenged. Currently, with good health supervision and insulin therapy, the effects of type 1 disease can be so minimized that children with diabetes both thrive and grow. Diabetes is still a major factor in the health of children, however. As more and more children in developed countries become obese, type 2 diabetes now has begun to occur in children as young as school-age (Hussain et al., 2007).

Intelligence

Children with high intelligence do not generally grow faster physically than other children, but they do tend to advance faster in skills. Occasionally, children of high intelligence fall behind in physical skills because they spend their time with books or mental games rather than with games that develop motor skills and so do not receive practice in these areas.

Temperament

Temperament is the usual reaction pattern of an individual, or an individual's characteristic manner of thinking, behaving, or reacting to stimuli in the environment (Chess & Thomas, 1995). Unlike cognitive or moral development, temperament is not developed by stages but is an inborn characteristic set at birth. Understanding that children are not all alike—some adapt quickly to new situations and others adapt slowly, and some react intensely and some passively—can help parents better understand why their children are different from each other and help them care for each child more constructively.

Reaction Patterns

Chess and Thomas (1995) identified nine separate characteristics that define temperament or how children react to situations. Each child's pattern is made up of a combination of these individual elements.

Activity Level. The level of activity among children differs widely. Some babies are constantly on the go and rarely quiet. They wiggle and squirm in their crib as early as 2 weeks of age. Parents put such children to sleep in one end of a crib and find them in the other end an hour later; such children will not stay seated in bathtubs and refuse to be confined in playpens. Other babies, by contrast, move little, stay where they are placed, and appear to take in their environment in a quieter, more docile way. Both patterns are normal; they merely reflect two extremes of *motor activity,* one characteristic of temperament.

Rhythmicity. A child who has *rhythmicity* manifests a regular rhythm in physiologic functions. Even as infants, such children tend to wake up at the same time each morning, are hungry at regular 4-hour periods, nap the same time every day, and have a bowel movement at the same time every day. They are predictable and easy to care for because their parents learn early on what to expect from them. On the other end of the scale are infants with an irregular rhythmicity. They rarely awaken at the same time 2 days in a row. They may go a long time without eating one day and the next day appear hungry almost immediately after a feeding. Such children may be more difficult to care for because it is difficult to plan a schedule for them. Parents must constantly adapt their own routine to the child's routine.

Approach. *Approach* refers to a child's response on initial contact with a new stimulus. Some children approach new situations in an unruffled manner. They smile and "talk" to strangers and accept a first feeding or a new food without spitting up or fussing. They explore new toys without apprehension. Other children demonstrate withdrawal rather than approach to new situations. They cry at the sight of strangers, new toys, and new foods; they fuss the first time they are placed in a bathtub. They are difficult to take on vacation or to meet a new childcare provider because they react so fearfully to new situations.

Adaptability. *Adaptability* is the ability to change one's reaction to stimuli over time. Infants who are adaptable can change their first reaction to a situation without exhibiting extreme distress. The first time such children are placed in a bathtub they might protest loudly, for example, but by the third time they sit splashing happily. This is in contrast to infants who cry for months whenever they are put into a bathtub or who cannot seem to accustom themselves to a new bed, new car seat, or new caregiver.

Intensity of Reaction. Some children react to situations with their whole being. They cry loudly, thrash their arms, and begin temper tantrums when their diapers are wet, when they are hungry, and when their parents leave them. Others rarely demonstrate such overt symptoms of anger or have a mild or low-intensity *reaction to stress.*

Distractibility. Children who are easily distracted or who can easily shift their attention to a new situation (*distractibility*) are easy to care for. If they are crying over the loss of a toy, they can be appeased by the offer of a different one. Other children cannot be distracted in this way; their parents may describe them as stubborn, willful, or unwilling to compromise because they persistently return to an activity or refuse to adapt or change.

Attention Span and Persistence. *Attention span* is the ability to remain interested in a project or activity. Like other aspects of temperament, this varies among children. Some play by themselves with one toy for an hour; others spend no more than 1 or 2 minutes with each toy. The degree of *persistence* also varies. Some infants keep trying to perform an activity even when they fail time after time; others stop trying after one unsuccessful attempt.

Threshold of Response. The *threshold of response* is the intensity level of stimulation that is necessary to evoke a reaction. Children with a low threshold need little stimulation; those with a high threshold need intense stimulation before they become upset over a situation.

Mood Quality. A child who is always happy and laughing has a positive *mood quality*. Obviously, this can make a major difference in the parents' enjoyment of a child. Parents are bound to spend more time with a child who is always happy than with a child who has a negative mood quality.

Nursing Implications Regarding Temperament

Three categories of temperament are shown in Box 28.3. Children who have a normal activity level and regular rhythmicity, who approach and adapt to new situations easily, and who have a long attention span, a high level of persistence, and a positive mood quality are "ideal" or "easy" children to care for, from a parent's point of view. Highly active infants are much more difficult for parents to care for, especially if they demonstrate irregular physiologic rhythms, withdrawal rather than approach, and little ability to adapt. Such children require more planning and creative distraction measures.

It is useful to talk to parents about their child's reactivity patterns at health maintenance visits because these patterns tend to persist: the way a child will react in the future depends a great deal on the way a child reacts today. A child who withdraws from rather than approaches a first toy, for example, may react the same way to toilet training or starting day care. The parents of such a child will need to focus on extra preparation for new activities more than will the parents of a child who approaches new situations easily. Parents who are aware their baby shies away from new experiences such as baths and new foods will be able to take it in stride when their child is slow to adapt to a Head Start program at age 4; they will know it is simply their child's method of coping.

Bringing these characteristics to parents' attention helps them better understand their child and lays the foundation for beginning to accept and respect the child as an individual. It is essential for successful childrearing (Foley, 2007).

Noticing children's temperamental characteristics as they are admitted to a hospital can help you anticipate children's probable reactions to procedures or pain. For example, a child with a mild reactivity pattern may not show a great deal of response to even acute pain, but a child with an intense pattern may react as strongly to minor discomfort as to major pain, making it difficult to evaluate the true level of pain the child is experiencing.

One instrument that is helpful in evaluating temperament is the Carey-McDevitt Infant Temperament Questionnaire (Carey & McDevitt, 1978). This consists of 95 responses and can be answered by a parent in approximately 25 minutes. General categories center on the child's responses to feeding, sleeping, soiling and wetting, dressing, bathing, and diapering, as well as to people and new situations.

Parents fill out the questionnaire when their infant is between 4 and 8 months of age (before this, temperament is not developed enough to be evident). The parent reads each

BOX 28.3 ✻ Categories of Temperament

The Easy Child
Children are rated as "easy to care for" if they have a predictable rhythmicity, approach and adapt to new situations readily, have a mild to moderate intensity of reaction, and have an overall positive mood quality. Most children are rated by their parents as being in this category.

The Difficult Child
Children are "difficult" if they are irregular in habits, have a negative mood quality, and withdraw rather than approach new situations. Only about 10% of children fall into this category.

Slow-to-Warm-Up Child
Children fall into this category if they are overall fairly inactive; respond only mildly and adapt slowly to new situations, and have a general negative mood. About 15% of children display this pattern. When discussing this temperament with parents, try to use positive terms such as "ways to find a healthy fit for your child" rather than stressing ways the child is hard to manage.

behavioral description and then selects the option that most accurately describes the child. If an item does not apply at all, the parent crosses it out. Finally, parents are asked to describe general impressions of the child's temperament, activity level, positive and negative moods, and distractibility.

Although individual children show characteristics from all groups, most children can be categorized into one of four groups:

1. Difficult: arrhythmic, withdrawing, low in adaptability, intense, and negative in mood
2. Slow to warm up: inactive, low in approach and adaptability, and negative in mood
3. Intermediate: some characteristics of both groups
4. Easy: rhythmic, approaching, adaptable, mild, and positive in mood

Environment

Although children cannot grow taller than their genetically programmed height potential allows, their adult height may be considerably less than genetic potential if their environment hinders their growth in some way. For example, a child could receive inadequate nutrition because of a family's low socioeconomic status; a parent could lack childcare skills or not give a child enough attention; or a child could have a chronic illness (O'Shea et al., 2007). Many illnesses lower children's appetite; others, such as certain endocrine disorders, directly alter their growth rate. Having a parent who abuses alcohol or other substances can cause such inconsistency in care it affects mental health (Fitzgerald & Das Edien, 2007; Motz, Leslie, & DeMarchi, 2007).

Environmental influences, however, are not always detrimental (Dooley & Stewart, 2007). For example, children with phenylketonuria, an inherited metabolic disease, can achieve normal growth and development in spite of their genetic makeup if their diet (a part of the environment) is properly regulated. The following environmental influences are those most likely to affect growth and development.

Socioeconomic Level

Because health care and good nutrition both cost money, children born into families of low socioeconomic means may not receive adequate health supervision or good nutrition. Poor health supervision can leave them without immunization against measles or other childhood illnesses and therefore vulnerable to diseases that could cause permanent neurologic damage if complications occur (Demicheli et al., 2009). Poor nutrition can also leave them vulnerable to disease as antibody formation depends on a good protein intake (Rolfes, Pinna, & Whitney, 2009).

Parent–Child Relationship

Cultural norms within a family play a role in determining when a child is expected to achieve particular developmental milestones. Children who are loved thrive better than those who are not. Either parent or a nonparent caregiver may serve as the primary caregiver or form a primary parent–child love relationship. It is the quality of time spent with children, not the amount of time, that is important. Loss of love from a primary caregiver, as might occur with the death of a parent, or interruption of parental contact through hospitalization, imprisonment, divorce, or inadequate parental love, can interfere with a child's desire to eat, improve, and advance. Helping parents feel involved in their child's care is important in both health care and childcare settings (Knitzer, 2008).

Ordinal Position in the Family

The position of a child in the family (first-born child, middle child, youngest child, only child) and the size of the family have some bearing on a child's growth and development. An only child or the oldest child in a family, for example, generally excels in language development because conversations are mainly with adults. Youngest children may develop language more slowly, especially if older children talk "baby talk" with them. Children learn by watching other children, however, so a youngest child who has many examples to watch may excel in other skills, such as toilet training at an early age.

Health

Diseases that come from environmental sources can have as strong an influence on growth and development as genetically inherited diseases. Infants cared for in neonatal intensive care units, for example, may develop some decrease in hearing because of the overstimulation of sound, an example of health being directly influenced by the environment (Thomas & Uran, 2007). Children who have residual heart impairment as a result of contracting rheumatic fever might be limited in their ability to play an active sport. The eventual degree of disability will depend not only on the damage caused by the actual disease but also on the attitudes of the people around the child—how disabled they believe the child to be (Ulrich, 2007).

Treating children as if they were sick or vulnerable to sickness is referred to as "vulnerable child syndrome" (Green & Solnit, 1964). Fortunately, if an illness does not last long, most children achieve "catch-up" growth afterward.

Nutrition

In the past 20 years, nutrition has become a major focus of health promotion and disease prevention in the United States because the quality of a child's nutrition during the growing years (including prenatally) has a major influence on health and stature (Rolfes, Pinna, & Whitney, 2009). Poor maternal nutrition may limit the growth and intelligence potential of a child from the moment of birth. Children whose diets lack essential nutrients show inadequate physical growth. A lack of energy and stamina prevents children from learning at their best intellectual level. In some communities, as many as 50% of American children are obese today (Kline, 2008). Children who eat too many carbohydrates and become obese may develop motor skills more slowly than other children because physical movement is more tiring for them. Obese children are sometimes taunted by their playmates and may become loners or have difficulty relating to their peers because of behavior problems or depression about their weight.

Nutrition also plays a vital role in the body's susceptibility to disease because poor nutrition limits the body's ability to resist infection. Lack of calcium could leave a child prone

to rickets, a disease that affects growth by causing shortening or bowing of long bones. Lack of vitamins can lead to visual impairments, poor healing, and poor bone growth (Ondrak & Morgan, 2007).

Poor nutrition also plays a major role in the development of chronic illness. Of the eight leading causes of death in adults, six have been linked to dietary excesses: heart disease, cancer, cerebrovascular disease, diabetes mellitus, cirrhosis, and arteriosclerosis. It is clear, too, that dietary habits have a cumulative effect; for instance, although heart disease is not one of the top causes of death in children, the arterial changes that cause cardiovascular disease begin in childhood. Increased consumption of food and alcohol, decreased levels of exercise, and smoking all lead to a greater incidence of these diet-related diseases in adult life. Establishing healthy eating patterns early in life, therefore, can contribute to better health in adult years.

Food Guide Pyramid Guidelines for a Healthy Diet

Basic guidelines for a healthy diet have been outlined by a variety of governmental groups, including the U.S. Department of Agriculture (USDA) and the U.S. Department of Health and Human Services. In 1992, a food guide pyramid was developed by the USDA to illustrate these guidelines. It was updated in 2005 to emphasize variety, moderation, and balance and suggest a range of daily servings from each major food group (USDA, 2005). Table 28.1 lists recommended servings for children from the five pyramid food groups. In addition, good nutrition in children should follow a number of "healthy eating" guidelines:

Eat a Variety of Foods. Choices from all food pyramid groups—dairy, meat and poultry, fruits, vegetables, cereals and grains—should be included in meals every day (vegetarians omit meat and poultry but supplement this with vegetable protein). It is also important to vary choices within each food group, as not all foods within a group are nutritionally equivalent.

Balance the Food You Eat With Physical Activity—Maintain or Improve Your Weight. Although the tendency for obesity may be inherited, being overweight in early life also appears to play a role. Urge parents to be certain their infants receive all the nutrients they need for the substantial growth they are undergoing (including a percentage of fat, because this is important for myelination of nerves); at the same time, it is important that infants not be overfed so they do not become obese. Balancing a lifestyle of physical activity with sound nutrition, such as omitting sugar-heavy soft drinks, helps to do this (Vartanian, Schwartz, & Brownell, 2007). Physical activity, balanced with calcium intake, is the secret to strong bones and reduction of osteoporosis later in life (Ondrak & Morgan, 2007).

Choose a Diet With Plenty of Grain Products, Vegetables, and Fruits. Foods with starch and fiber are more beneficial for gastrointestinal function than more processed foods. Fiber, in particular, has been linked to the lowered incidence of a variety of illnesses such as constipation and perhaps colon cancer in later life. Fiber can be included as early as during preschool years in the form of whole-grain cereals and raw fruits such as apples.

Choose a Diet Low in Fat, Saturated Fat, and Cholesterol. The American diet has changed substantially over the past 10 years to reflect this important goal. Many adults now consume low-fat diets, substituting nonfat milk for whole milk,

TABLE 28.1 ✻ Servings of the Five Pyramid Food Groups for Children

		Recommended Daily Amounts		
Group	**Foods**	***Children 2–6 yr***	***Older Children***	**Major Nutrients Provided**
Bread, cereals, rice, pasta	Whole-grain and enriched	6 servings	6–11 servings	Thiamine, niacin, riboflavin (if enriched); iron (if enriched); incomplete protein, carbohydrates
Vegetables	Vegetables (yellow and green)	3 servings	3–5 servings	Vitamin A, iron, calcium, carbohydrates (include vitamin A source at least every other day)
Fruit	Fruit	2 servings	2–4 servings	Vitamin C (include vitamin C daily); carbohydrates
Milk, yogurt, cheese	Whole milk and other milk products except butter	2 servings	2–3 servings	Calcium, phosphorus, complete protein, riboflavin, niacin, vitamin D (if vitamin D–fortified milk used), fats
Meat, poultry, fish	Muscle meats (veal, beef, pork) dry beans, eggs; fish; poultry	2 servings	2–3 servings	Complete protein, iron, thiamine, riboflavin, niacin, vitamin B_{12}, fats
Fats, oils, sweets	Candy, cake, fried foods	Use sparingly	Use sparingly	Essential fatty acids, carbohydrates

Data from U.S. Department of Agriculture (USDA). (2005). *Dietary guidelines for Americans.* Washington, DC: USDA.

decreasing their consumption of eggs and other high-cholesterol sources, and reducing their consumption of red meat. For children, fat intake does not need to be restricted for the first 2 years of life. Thereafter, fat intake can be tailored to meet the guidelines of 30% total intake for both children and adults. Some foods now contain Olestra, a synthetic fat. Do not recommend this for children (or urge parents to offer this sparingly) until further study is completed because of the danger of fat-soluble vitamins being excreted and lost with the product.

Choose a Diet Moderate in Sugars. Too much sugar in a diet can contribute to both dental caries and obesity. In addition, refined sugar such as that used in soft drinks, prepared foods, candy, and chocolate represents "empty" calories: it is high in calories yet provides no essential nutrients. Although children need adequate carbohydrates for energy, parents can give their children a good start by preventing excessive sugar intake.

Choose a Diet Moderate in Salt and Sodium. The taste for salt is acquired. If unsalted or only lightly salted solid food is offered to infants, they do not develop a desire for heavily salted foods. It is helpful to assess the diet of school-age children and check whether they are eating a diet heavier in salt than necessary because of many salty after-school snacks.

If Drinking Alcoholic Beverages, do so in Moderation. Adolescents are at increased risk for establishing unhealthy patterns of alcohol use, particularly binge drinking. Educating them about the long-term consequences of alcohol use is as important as educating them on the importance of healthy nutrition for growth (see Chapter 33).

Components of a Healthy Diet

Eating a variety of foods from all five pyramid food groups in moderation is a way of guaranteeing the intake of a balanced diet of proteins, carbohydrates, fats, vitamins, and minerals (Fig. 28.3).

Protein. Protein is the major component of bones, skin, hair, and muscle and is responsible for a wide variety of essential functions in the body. Because it is essential for growth, protein intake is crucial for children. Complete proteins contain all amino acids; incomplete proteins do not. Mixing these two types of incomplete protein (pasta and beans, for example) common dietary staples, furnishes complete protein.

Carbohydrate. Carbohydrates are the main and preferred fuel of the body to supply energy, so they are essential to the functioning of most body systems, the neurologic system in particular. This is why carbohydrates are so important to infants and toddlers, whose brain cells are actively growing. Sugar supplies an immediate but short-term source of energy; starches, as a rule, supply sustained energy.

Fat. Dietary fat is also a source of energy to the body. It can be an immediate energy source or can be stored if not used, then released when energy is required. Some fat deposits also serve as insulating material for subcutaneous tissues; in infants, fats are necessary to ensure myelination of nerve fibers.

FIGURE 28.3 Good nutritional habits developed early in life provide a child with a health advantage.

Vitamins. Vitamins are organic compounds that are essential for specific metabolic actions in cells. They do not produce energy but are needed by cells to produce energy. For children, fat-soluble vitamins (A, D, K, and E) are mainly supplied by fortified dairy products, fortified cereals, and plant oils or fish oils. Such vitamins can leave the gastrointestinal tract and be used by the body only by being absorbed along with fat molecules. Once absorbed, they are used by the cells for growth and function or are stored in the liver and fat cells for later use. Because fat-soluble vitamins can be stored by the body, an infant or child can ingest too many of them, although overdosing usually occurs from supplements rather than dietary sources. Water-soluble vitamins (B complex and C) do not need fat for absorption but are not stored well in the body, so they must be taken daily to maintain effective levels in the body. Sources and functions of essential vitamins and results of their deficiencies are summarized in Table 28.2.

Minerals. Minerals are necessary to build new cells and regulate body processes such as fluid and electrolyte balance, nerve transmission, and muscle contraction, so they are vital to the health of a growing infant or child. Deficiency in a mineral such as potassium can lead to poor heart function and childhood growth. Minerals are classified according to the amounts needed daily or their importance for body functioning. If more than 100 mg is needed daily, a mineral is a *macronutrient*, or major mineral. If the amount needed is less than 100 mg, it is a *micronutrient*, or minor mineral. Trace minerals refer to those needed in only extremely small amounts. Sources and functions of various minerals and results of their deficiencies are listed in Table 28.3.

TABLE 28.2 ✻ Vitamins Essential for Health

Vitamin	Selected Dietary Sources	Function in Body	Results of Deficiency
Fat-Soluble*			
A (retinol)	Liver, carrots, spinach	Important for night vision and corneal integrity and growth	Keratinization of the eye (xerophthalmia) and blindness
D	Egg yolk, margarine, salmon, fortified milk, fortified cereals	Regulates absorption of calcium and phosphorus for bone growth	Rickets (bone deformity) in growing children
E	Margarine, corn oil, peanuts	An antioxidant that protects red blood cells from destruction by oxygen	In immature infants, severe anemia from destruction of red blood cells
K	Cabbage, spinach, pork. Best source: Green leafy vegetables	Aids blood clotting (synthesis of prothrombin)	Bleeding from lack of sufficient clotting action
Water-Soluble			
B complex:			
Thiamine	Wheat germ, yeast, pork	Important for use of glucose in cells	Beriberi, a disease that causes nerve paralysis
Riboflavin	Beef, chicken, liver, avocados, milk	Breaks down fatty acids and amino acids for energy	Red swollen tongue, inflamed eyes, fissures of lips
Niacin	Peanuts, rice bran, liver	Converts glucose to energy, involved in carbohydrate, protein, and fat metabolism	Pellagra (diarrhea, mental confusion, dermatitis, death)
B_6 (pyridoxine)	Liver, herring, salmon, chicken, fish, pork, eggs	Metabolizes amino acids and glucose	Neuritis, depression, nausea, vomiting
B_{12} (cobalamin)	Lamb, beef kidney, egg yolk, animal products	Blood formation; DNA and RNA synthesis; myelin formation; carbohydrate, protein, and fat metabolism	Macrocytic, megaloblastic anemia (large, nonfunctioning red blood cells)
Folic acid (folacin)	Liver, asparagus, bran	Red and white blood cell structure	Poor red cell formation
C (ascorbic acid)	Broccoli, collards, citrus fruit	Collagen structure, antioxidant	Scurvy (weakness, easy bleeding, joint pain)

*All fat-soluble vitamins can be absorbed only in the presence of lipids and can be transported only in the presence of protein.

Promoting Adequate Nutritional Intake in Vegetarian Diets

Families may select vegetarian diets for many reasons:

- Economic: Vegetables and grains are less expensive than animal-based food.
- Ecologic: If everyone ate lower on the food chain, world hunger could be reduced.
- Medical or health-related: Avoiding animal foods stops the ingestion of hormones and chemicals used in meat and poultry production and lowers serum cholesterol, thereby reducing the frequency of atherosclerosis and obesity; avoiding red meat may reduce the likelihood of developing colon cancer as well. Because of the association between saturated fat and bowel cancer and atherosclerosis, the number of families avoiding red meat will probably increase in the future.
- Philosophical: A belief that killing animals for food is unnecessary.
- Religious: Religions such as Hindu and Seventh-Day Adventist promote a vegetarian lifestyle.

Increasing numbers of adults of childrearing age are vegetarians; therefore, many women during pregnancy and children during their years of most rapid growth eat such diets (Cox, 2008). Although a balanced vegetarian diet can be sufficient during childhood, careful assessment and family education are necessary to ensure that it is adequate for growth. Urge parents to become knowledgeable about good nutrition so they are aware of ways to include essential nutrients for growing children in vegetarian diets, particularly if their children participate in active sports.

Four main types of vegetarian diets are usually seen:

- A lacto-ovo-vegetarian diet includes dairy products ("lacto"), eggs ("ovo"), and plants (vegetables, fruits, and grains).
- An ovovegetarian diet includes eggs but excludes dairy products.

TABLE 28.3 ✻ Minerals Essential for Health

Mineral	Selected Dietary Sources	Function in Body	Results of Deficiency or Excess
Macronutrients			
Calcium	Milk, hard cheese	Formation of bone and teeth; muscle contractility	Improper bone growth and maintenance shown by diseases such as rickets in children
Phosphorus	Milk, meats	Formation of bone and teeth; used in cell structure; aids use of glucose	Deficiency unlikely as long as calcium and protein needs are met
Sodium	Table salt	Regulates fluid volume and pH	Deficiency rare but excess leads to hypertension in genetically determined individuals
Chloride	Table salt	Formation of hydrochloric acid; regulates body fluid with sodium	Deficiency rare except with vomiting, which causes loss of hydrochloric acid
Potassium	Meats, dried fruits	Major cation of cells; essential for electrical conduction in muscle and therefore in heart action	Deficiency leading to muscle weakness and heart irritability; occurs in people taking diuretics, because potassium is excreted with urine
Sulfur	Milk, meat, eggs	Essential for protein formation and cell growth	Deficiency rare as long as protein intake is adequate
Magnesium	Cocoa, nuts, green leafy vegetables	Relaxation of muscles after contraction	Deficiency leads to muscle contraction
Micronutrients			
Iodine	Seafood, dairy, iodized salt	Formation of thyroxine and regulation of metabolic rate	Reduced basal metabolic rate and goiter (enlarged thyroid gland)
Iron	Meats, fish, dried fruits, nuts, fortified cereals	Formation of hemoglobin; transport of oxygen to body cells	Deficiency leads to microcytic (small) and hypochromic (pale) red blood cells (iron-deficiency anemia); excess leads to infiltration of tissue (hemosiderosis)
Copper	Nuts, raisins, legumes	Formation of collagen and nerve fiber	Anemia, neutropenia, and severe bone demineralization
Fluoride	Fluoridated water	Reduces dental caries and demineralization from bone	Dental caries
Zinc	Meat, eggs, seafood	Formation of eyes, male reproductive organs, insulin, and taste sensation	Diabetes-like symptoms because of decreased insulin production; poor taste sensation leading to poor food intake
Manganese	Nuts, grains, legumes	Formation of enzymes	Deficiency unlikely
Molybdenum	Organ meats, grains	Mobilizes iron in body	Deficiency apparently unknown
Cobalt	Many sources	Formation of red blood cells in bone marrow	Deficiency rare as long as animal food sources are ingested
Selenium	Seafood, kidney, liver	Immunoglobulin formation and prevention of oxidation of cells	Deficiency unknown
Chromium	Meat, cheese, grains	Glucose metabolism	Deficiency seen only in severe malnutrition
Silicon	Many sources	Aids growth of connective tissue and bone	Retarded growth and bone deformity
Nickel	Many sources	Duplication of growth of cells	Has not been determined to be essential for health in humans
Vanadium	Many sources	Lipid metabolism	Has not been determined to be essential for health in humans
Tin	Many sources	Blood formation	Has not been determined to be essential for health in humans

- A lactovegetarian diet includes dairy products but excludes eggs.
- A vegan diet excludes all animal products and consists of only vegetables, fruits, and grains.

The vegan diet is most restrictive, so it is usually recommended that parents consult with a dietitian or nutritionist to ensure their children receive adequate nutrients on this diet. A fifth type of vegetarian diet is a macrobiotic diet, which falls between vegetarian and vegan diets. Its main sources of protein are grains, seeds, and nuts, but small quantities of egg, fish, and wild game can be added. All families who eat vegetarian diets need to ensure that their children receive adequate amounts of several specific nutrients.

Protein. Lacto-ovo-vegetarian, ovovegetarian, and lactovegetarian diets provide all of the essential amino acids for growth (both eggs and dairy products provide complete proteins). Vegan diets can also supply essential amino acids by cereal and legume combinations such as peanut butter and wheat bread, corn and lima beans, pasta and beans, corn tortillas and beans, or chickpeas and sesame seeds. Complementary proteins do not have to be eaten at the same meal to be effective, as long as varied plant proteins are consumed over the course of a day.

Calcium. Dairy products such as milk and cheese supply calcium as well as protein. When these are not eaten, calcium must be obtained from other sources, by eating green leafy vegetables such as broccoli or spinach or grain products such as calcium-fortified tofu or soy flour.

Iron. As there may be an association between iron-deficiency anemia and learning deficits, children need to consume good sources of iron (McCann & Ames, 2007). Meat is the best source of iron. With meat omitted from a diet, parents should include this from foods such as legumes, whole grains, fortified cereals, dark-green leafy vegetables, or dried fruits. Vitamin C enhances the duodenal absorption of iron found in plants, so eating fruits and vegetables rich in vitamin C such as oranges or broccoli aids iron absorption.

Vitamins. Vitamin B_{12} is unique among vitamins because it is present only in animal products (Rolfes, Pinna, & Whitney, 2009). This includes eggs and milk. Children who totally omit animal sources, therefore, need to have this vitamin supplemented daily. Reliable supplements of B_{12} include vitamin B_{12} tablets or fortified foods such as commercial breakfast cereals, soy beverages, and some brands of nutritional yeast.

Riboflavin is normally supplied by fortified milk. However, it may be supplied by soy milk, vegetables, or brewer's yeast, all of which contain all the B vitamins except B_{12}, so riboflavin is usually adequate in a vegetarian diet daily without additional supplementation. Good sources of riboflavin in vegan diets are whole and enriched grains and cereals, nuts, and dark-green leafy vegetables.

Vitamin D is necessary for calcium and phosphorus metabolism and is normally supplied in fortified milk. It is not present in plant foods and therefore must be supplemented in a vegan or ovovegetarian diet by vitamin D drops or tablets. Exposure to sunshine is generally an inadequate source (Rolfes, Pinna, & Whitney, 2009).

Minerals. Zinc is present primarily in animal foods but is also present in brewer's yeast, nuts, and wheat germ. Iodine is supplied normally by seafood. In a vegan or vegetarian diet, it can be supplied by seaweed and iodized table salt. Many families add a small amount of powdered kelp (a seaweed) to food two or three times a week to ensure an adequate iodine intake.

Total Calories. Plant foods have fewer total calories than meats. Therefore, one serving of nuts and one serving of legumes are recommended in place of two meat servings. All other recommended serving sizes for various caloric level patterns are the same as those presented in the usual food guide pyramid (see Appendix K).

What if... John's mother tells you she cannot afford to buy meat, explaining she can get more food for the family if she purchases mostly pasta and cereals? How would you help her plan meals that are low in cost but high in nutritional value?

THEORIES OF DEVELOPMENT

A *theory* is a systematic statement of principles that provides a framework for explaining some phenomenon. Developmental theories provide road maps for explaining human development.

A **developmental task** is a skill or a growth responsibility arising at a particular time in an individual's life, the achievement of which will provide a foundation for the accomplishment of future tasks. It is not so much chronologic age as the completion of developmental tasks that defines whether a child has passed from one developmental stage of childhood to another. For example, children are not toddlers just because they are 1 year plus 1 day old; they become toddlers when they have passed through the developmental stage of infancy. For reference, however, childhood is generally divided into the age periods shown in Table 28.4.

A number of theories have been proposed to describe how children grow emotionally, psychologically, and intellectually as they pass through these different periods. Sociocultural theories stress the importance of environment on growth and development. Learning theory proposes children are like blank pages that can be shaped by learning (Horowitz, 1994). Epigenetic theories stress that genes are the true basis for growth and development. Previously discounted as too simplistic, epigenetic theories are being revised and given new credence based on new knowledge about genes now available through the National Genome Project or the mapping of all the body's genes (Fisler & Warden, 2007). Still other theories deal mainly with negative aspects of childrearing that can cause mental illness in children, either immediately or later, when a child reaches adulthood (see discussion on Freud that follows). Erikson discusses positive aspects necessary for normal growth and for development of a mentally healthy and productive adult (Coles, 2001).

TABLE 28.4 ✻ Basic Divisions of Childhood

Stage	Age Period
Neonate	First 28 days of life
Infant	1 mo–1 yr
Toddler	1–3 yr
Preschooler	3–5 yr
School-age child	6–12 yr
Adolescent	13–21 yr

Freud's Psychoanalytic Theory

Sigmund Freud (1856–1939), an Austrian neurologist and the founder of psychoanalysis, offered the first real theory of personality development (Edmundson, 2007). Freud based his theory on his observations of mentally disturbed adults. He described adult behavior as being the result of instinctual drives that have a primarily sexual nature (*libido*) that arise from within the person and the conflicts that develop between these instincts (represented in the individual as the *id*), reality (the *ego*), and society (the *superego*). He described child development as being a series of psychosexual stages in which a child's sexual gratification becomes focused on a particular body part. Freud's stages of childhood are summarized in Table 28.5.

Infant

Freud termed the infant period the "oral phase" because infants are so interested in oral stimulation or pleasure during this time. According to this theory, infants suck for enjoyment or relief of tension, as well as for nourishment.

Toddler

Freud described the toddler period as an "anal phase" because during this time, children's interests focus on the anal region as they begin toilet training. Elimination takes on new importance for them. Children find pleasure in both the retention of feces and defecation. This anal interest is part of toddlers' self-discovery, a way of exerting independence, and probably accounts for some of the difficulties parents may experience in toilet-training children of this age.

Preschooler

During the preschool period, children's pleasure zone appears to shift from the anal to the genital area. Freud called this period the "phallic phase." Masturbation is common during this phase. Children may also show exhibitionism, suggesting they hope this will lead to increased knowledge of the two sexes.

School-Age Child

Freud saw the school-age period as a "latent phase," a time in which children's libido appears to be diverted into concrete thinking. He saw no developments as obvious as those in earlier periods appearing during this time.

Adolescent

Freud termed the adolescent period the "genital phase." Freudian theory considers the main events of this period to be the establishment of new sexual aims and the finding of new love objects.

Criticisms of Freud's Theory

To construct his theory, Freud relied on his knowledge of people with mental illness or looked at circumstances that led to mental illness. This "looking at illness" rather than "looking at wellness" perspective limits the applicability of the theory as a health promotion measure, although the behaviors he discussed are as observable as ever.

Erikson's Theory of Psychosocial Development

Erik Erikson (1902–1996) was trained in psychoanalytic theory but later developed his own theory of psychosocial development, a theory that stresses the importance of culture and society in development of the personality (Erikson, 1993). One of the main tenets of his theory, that a person's social view of self is more important than instinctual drives in determining behavior, allows for a more optimistic view of the possibilities for human growth. While Freud looked at ways mental illness develops, Erikson looked at actions that lead to mental health. Erikson describes eight developmental stages covering the entire life span. At each stage, there is a conflict between two opposing forces. The resolution of each conflict, or accomplishment of the developmental task of that stage, allows the individual to go on to the next phase of development. Table 28.5 shows Erikson's developmental stages through adolescence compared to Freud's.

The Infant

According to Erikson, the developmental task for infants is learning **trust versus mistrust** (other terms are "learning confidence" or "learning to love"). Infants whose needs are met when those needs arise, whose discomforts are quickly removed, who are cuddled, played with, and talked to, come to view the world as a safe place and people as helpful and dependable. However, when their care is inconsistent, inadequate, or rejecting, this fosters a basic mistrust: infants become fearful and suspicious of the world and of people. Like a burned child who avoids fire, emotionally burned children may shun the potential pain of further emotional involvement and carry this attitude through later stages of development. Such children can be "stuck" emotionally at this stage, although they continue to grow and develop in other ways.

Fortunately, because not all children achieve developmental tasks readily, each task need not be resolved once and for all the first time it arises. The problem of trust versus mistrust, for example, is not resolved forever during the first year of life but arises again at each successive stage of development. Children who enter school with a sense of mistrust may come to trust a teacher with whom they form a close relationship; given this second chance, children may overcome early mistrust. On the other hand, children who come through infancy with a vital sense of trust intact may still have a sense of mistrust activated at a later stage if their parents are divorced or separate under unpleasant circumstances.

TABLE 28.5 ✻ Summary of Freud's and Erikson's Theories of Personality Development

	Freud's Stages of Childhood		Erikson's Stages of Childhood	
	Psychosexual Stage	*Nursing Implications*	*Developmental Task*	*Nursing Implications*
Infant	Oral stage: Child explores the world by using mouth, especially the tongue.	Provide oral stimulation by giving pacifiers; do not discourage thumb-sucking. Breastfeeding may provide more stimulation than formula feeding because it requires the infant to expend more energy.	Developmental task is to form a sense of trust versus mistrust. Child learns to love and be loved.	Provide a primary caregiver. Provide experiences that add to security, such as soft sounds and touch. Provide visual stimulation for active child involvement.
Toddler	Anal stage: Child learns to control urination and defecation.	Help children achieve bowel and bladder control without undue emphasis on its importance. If at all possible, continue bowel and bladder training while child is hospitalized.	Developmental task is to form a sense of autonomy versus shame. Child learns to be independent and make decisions for self.	Provide opportunities for decision making, such as offering choices of clothes to wear or toys to play with. Praise for ability to make decisions rather than judging correctness of any one decision.
Preschooler	Phallic stage: Child learns sexual identity through awareness of genital area.	Accept children's sexual interest, such as fondling their own genitals, as a normal area of exploration. Help parents answer child's questions about birth or sexual differences.	Developmental task is to form a sense of initiative versus guilt. Child learns how to do things (basic problem solving) and that doing things is desirable.	Provide opportunities for exploring new places or activities. Allow play to include activities involving water, clay (for modeling), or finger paint.
School-age child	Latent stage: Child's personality development appears to be nonactive or dormant.	Help children have positive experiences with learning so their self-esteem continues to grow and they can prepare for the conflicts of adolescence.	Developmental task is to form a sense of industry versus inferiority. Child learns how to do things well.	Provide opportunities such as allowing child to assemble and complete a short project so that child feels rewarded for accomplishment.
Adolescent	Genital stage: Adolescent develops sexual maturity and learns to establish satisfactory relationships with the opposite sex.	Provide appropriate opportunities for the child to relate with opposite sex; allow child to verbalize feelings about new relationships.	Developmental task is to form a sense of identity versus role confusion. Adolescents learn who they are and what kind of person they will be by adjusting to a new body image, seeking emancipation from parents, choosing a vocation, and determining a value system.	Provide opportunities for an adolescent to discuss feelings about events important to him or her. Offer support and praise for decision making.

FIGURE 28.4 A toddler enjoys active, independent exploration as part of building a sense of autonomy.

The Toddler

Erikson defines the developmental task of the toddler age as learning **autonomy versus shame or doubt.** Autonomy (self-government or independence) builds on children's new motor and mental abilities. Children take pride in new accomplishments and want to do everything independently, whether it is pulling the wrapper off a piece of candy, selecting a vitamin tablet out of the bottle, flushing the toilet, or replying, "No!" If parents recognize toddlers need to do what they are capable of doing, at their own pace and in their own time, then children develop a sense of being able to control their muscles and impulses during this time. When caregivers are impatient and do everything for them, this enforces a sense of shame and doubt. If children are never allowed to do things they want to do, they will eventually doubt their ability to do them; they will stop trying and cannot do them. If children leave this stage with less autonomy than shame or doubt, they can be disabled in their attempts to achieve independence and may lack confidence in their abilities to achieve well into adolescence and adulthood (Fig. 28.4).

The Preschooler

The developmental task of the preschool period is learning **initiative versus guilt.** Learning initiative is learning how to do things. Children can initiate motor activities of various sorts on their own and no longer merely respond to or imitate the actions of other children or of their parents. The same is true for language and fantasy activities.

Whether children leave this stage with a sense of initiative outweighing a sense of guilt depends largely on how parents respond to self-initiated activities. When children are given much freedom and opportunity to initiate motor play such as running, bike riding, sliding, and wrestling or are exposed to such play materials as finger paints, sand, water, and modeling clay, their sense of initiative is reinforced. Initiative is also encouraged when parents answer a child's questions (intellectual initiative) and do not inhibit fantasy or play activity. If children are made to feel their motor activity is bad (perhaps in a small apartment or a hospital), their questions are a nuisance, or their play is silly and stupid, they may develop a sense of guilt over self-initiated activities that will persist in later life. Those who do not develop initiative may later have limited brainstorming and problem-solving skills; they wait for clues or guidance from others before acting.

What if... John's father does not allow his preschool twins to play freely because he demands an orderly household? They begin to show signs of poor initiative. How would you counsel this parent?

The School-Age Child

Erikson viewed the developmental task of the school-age period as developing **industry versus inferiority,** or accomplishment rather than inferiority. During the preschool period, children learned initiative—how to do something. During school age, children learn how to do things *well.* A school-age child, while doing a project will ask, "Am I doing a good job? Am I doing this right?" When they are encouraged in their efforts to do practical tasks or make practical things and are praised and rewarded for the finished results, their sense of industry grows (Fig. 28.5). Parents who see their children's efforts at making and doing things as merely "busy work" or who do not show appreciation for their children's efforts may cause them to develop a sense of inferiority rather than pride and accomplishment.

During the elementary school years, a child's world grows to include the school and community environment, and success or failure in those settings can have a lasting impact. Children with an intelligence quotient of 80 or 90 (slightly below normal), for example, may have a particularly traumatic school experience, even when their sense of industry is rewarded and encouraged at home. Their learning style may be so different from the average child's they have difficulty competing with children of average ability; this causes repeated failures in their efforts to learn, reinforcing their sense of inferiority. On the other hand, children whose sense of industry has not been supported at home may have it revital-

FIGURE 28.5 School-age children develop a sense of industry by working on projects that result in a feeling of accomplishment.

ized at school through the efforts of a committed teacher. A nurse during a hospitalization could also fulfill this role.

The Adolescent

Erikson believed the new interpersonal dimension that emerges during adolescence is a sense of **identity versus role confusion.** To achieve this, adolescents must bring together everything they have learned about themselves as a son or daughter, an athlete, a friend, a fast-food cook, a student, a garage band musician, and so on, and integrate these different images into a whole that makes sense. If adolescents cannot do so, they are left with role confusion; that is, they are left unsure of what kind of person they are and are uncertain what they can do or what kind of person they can become. Some adolescents seek a negative identity: being identified as a drug abuser or runaway may be preferable to having no identity at all. Body piercing and tattooing can help establish identity as they are outward expressions of who adolescents think they are (Box 28.4).

The Young Adult

The developmental crisis of the young adult is achieving a sense of **intimacy versus isolation.** Intimacy is the ability to relate well with other people, not only with members of the opposite sex but also with one's own sex to form long-lasting friendships.

A sense of intimacy grows out of earlier developmental tasks, because people need a strong sense of identity before they can reach out fully and offer deep friendship or love. Because there is always the risk of being rejected or hurt when offering love or friendship, individuals cannot offer it if they do not have confidence they can cope with rejection or if they did not develop a sense of trust as an infant. Parents without a sense of intimacy may have more difficulty than others accepting a pregnancy and beginning to love a newborn child.

The Middle-Aged Adult

The developmental task of middle age is to establish a sense of **generativity versus stagnation.** People extend their concern from just themselves and their families to the community and the world. They may become politically active, work to solve environmental problems, or participate in far-reaching community or world-based decisions.

People with a sense of generativity are self-confident and better able to juggle their various lives (mother, soccer coach, church member, teacher, political party chairperson, gourmet cook). People without this sense become stagnated or self-absorbed. Those who have devoted themselves to only one role are more likely to find themselves at the end of middle age with a narrow perspective and lack of ability to cope with change. Women without a sense of generativity may have more difficulty than others accepting a late-in-life pregnancy and a new role of childbearing and childrearing.

The Older Adult

Older adults play a role in childrearing today because many of them give childcare to young children while parents work. The developmental task of older adults is **integrity versus despair.** Older adults with integrity feel good about the life choices they have made; those with a feeling of despair wish life could begin over again so that things could turn out differently. A sense of integrity is helpful in a grandparent who provides childcare, as it helps children develop a sense of trust and learn initiative (Bernal & Anuncibay, 2008).

BOX 28.4 ✻ Focus on Evidence-Based Practice

Is body piercing or tattooing increasing in incidence in adolescents?

Body piercing or tattooing can be a means of establishing identify in adolescents. To establish whether the incidence of students with either a body piercing or tattoo is increasing, researchers asked 454 undergraduate college students in 2001 and 661 students in 2006 at an eastern U.S. university if they presently had a piercing or tattoo. In the year 2001 group, 60% of females and 42% of males had a body piercing; 26% of females and 22% of males had a tattoo. In the 2006 group, 62% of females and 36% of males had a body piercing; 21% of females and 23% of males had a tattoo. Researchers did not count pierced earlobes in females in the results but they did count ear cartilage as piercing (accounting for the substantially higher incidence in females). Overall, both body piercing (51% and 49%) and tattooing (24% and 22%) stayed roughly the same during these time periods. The medical complications reported for piercing (17% and 19%) also remained the same but was a cause for concern as almost one-fifth of students reported having a complication, most frequently an infection, at the piercing site.

Based on the above study, what symptoms would you want adolescents to inspect for following a body piercing to be certain they aren't developing a complication?

Source: Mayers, L. B., & Chiffriller, S. H. (2008). Body art (body piercing and tattooing) among undergraduate university students: "then and now". *Journal of Adolescent Health, 42*(2), 201–203.

Criticism of Erikson's Theory

Erikson's main contribution to human development was the creation of stages so that development can be broken down into separate phases for study. A criticism of his theory is that life does not occur in easily divided stages, and trying to divide it that way can create superficial divisions.

✔ Checkpoint Question 28.2

John, 6 years old, is a school-age child. What must he learn, according to Erikson, to complete the developmental task of this period?

a. How to be creative.
b. How to think abstractly.
c. How to trust others.
d. How to do things well.

Piaget's Theory of Cognitive Development

Jean Piaget (1896–1980), a Swiss psychologist, introduced concepts of **cognitive development** or the way children learn and think that have roots similar to those of both Freud and Erikson and yet separate from each (Wadsworth, 2003). Piaget defined four stages of cognitive development; within each stage are finer units or **schemas.** Each period is an advance over the previous one. To progress from one period to the next, children reorganize their thinking processes to bring them closer to adult thinking. These stages of cognitive development are summarized in Table 28.6.

The Infant

Piaget referred to the infant stage as the **sensorimotor stage.** Sensorimotor intelligence is practical intelligence, because words and symbols for thinking and problem solving are not yet available at this early age. At the beginning of infancy, babies relate to the world through their senses, using only reflex behavior. As infants progress through this stage (which includes the schemas of primary and secondary circular reactions and coordination of secondary reactions, as defined in Table 28.6), they learn the basic concept that people are entities separate from objects. Piaget used the term "primary" to refer to activities related to a child's own body and the term "circulatory reaction" to show that repetition of behavior occurs (infants accidentally bring their thumb to their mouth, enjoy the sensation of sucking, and so repeat it).

The term "secondary" refers to activities that are separate from a child's body. An example of secondary schema learning is when a baby hits a mobile, notices that this makes it move, and so hits it again. During this secondary schema, infants also learn that objects in the environment—bottle, blocks, bed, or even a parent—are permanent and continue to exist even though they are out of sight or changed in some way. For example:

- Infants will search for a block hidden by a blanket, knowing the block still exists.
- Infants can recognize that a parent remains the same person whether dressed in a robe and slippers or pants and a T-shirt.
- Infants play peek-a-boo because they realize the person playing with them exists behind his or her hands.
- Infants learn they are a separate entity from objects. They learn where their body stops and their bed, playthings, or parent begins.

A great deal of the mouthing and handling of objects by infants and the delight of watching a caregiver appear is part of primary and secondary schemas and discovering **permanence.** The world begins to make sense and the developmental task of achieving trust falls into place when the concept of permanence has been learned (infants know their parents exist and will return to them). Gaining a concept of permanence also contributes to "eighth-month anxiety," a stage in which infants continue to cry for their parents because they know their parents still exist even when out of sight.

During the final phase of the infant year (coordination of secondary reactions), infants begin to demonstrate goal-directed behavior. After noticing that hitting a mobile makes it move, infants then reach for and hit a music box nearby, in this way actively seeking new experiences. It is important for infants to have stimulating objects around for exploring in this way so that experimenting and learning can proceed.

The Toddler

The toddler period is one of transition as children complete the final stages of the sensorimotor period (defined in Table 28.6 as tertiary circular reaction and invention of new means) and begin to develop some cognitive skills of the preoperative period, such as symbolic thought and egocentric thinking. In the tertiary circular reaction schema, children use trial and error to discover new characteristics of objects and events. A toddler sitting in a high chair who keeps dropping objects over the edge of the tray is exploring both permanence and the different actions of toys. During the schema of "invention of new means," children become able to think through actions or mentally project the solution to a problem. If given a box, a toddler will investigate how the top of the box can be removed; if given a second box, even one that varies in shape, the child can foresee how the top can be removed. Toddlers following a ball that has rolled under a coffee table no longer have to follow the ball's path to retrieve it but can project where it will have rolled and walk around the coffee table to find it again.

During the period of *preoperational thought*, children relearn on a conceptual level some of the lessons they mastered as infants at the sensorimotor level, before having language. Now, children are able to use symbols to represent objects. They may have difficulty viewing one object as being different from another, however. On a walk through a department store decorated with teddy bears, for example, children are not sure whether they are seeing a succession of bears or if the same bear keeps reappearing as if it is following them, asking to be taken home.

Toddlers draw conclusions only from obvious facts they see: Daddy is shaving; therefore he must be going to work, because he went to work after he shaved yesterday. This type of faulty reasoning (prelogical reasoning) can lead children to wrong conclusions and faulty judgment.

How children think has many implications for nursing. If you made John's bed yesterday and then he went to surgery, he may cry at the sight of you approaching with clean sheets today, thinking he will have to go to surgery again.

The Preschooler

Piaget saw preschool children as moving on to a substage of preoperational thought termed *intuitive thought*. During this time, children tend to look at an object and see only one of its characteristics (referred to as **centering).** For example, they see that a banana is yellow but do not notice it is also long. Centering is noticeable when children are learning about medicine (they observe it tastes bitter but cannot understand it is also good for them).

Centering contributes to the preschooler's lack of **conservation** (the ability to discern truth, even though physical properties change) or **reversibility** (ability to retrace steps). For example, if preschoolers see water being poured from

TABLE 28.6 ✻ Piaget's Stages of Cognitive Development

Stage of Development	Age Span	Nursing Implications
Sensorimotor		
Neonatal reflex	1 mo	Stimuli are assimilated into beginning mental images. Behavior entirely reflexive.
Primary circular reaction	1–4 mo	Hand–mouth and ear–eye coordination develop. Infant spends much time looking at objects and separating self from them. Beginning intention of behavior is present (the infant brings thumb to mouth for a purpose: to suck it). Enjoyable activity for this period: a rattle or tape of parent's voice.
Secondary circular reaction	4–8 mo	Infant learns to initiate, recognize, and repeat pleasurable experiences from environment. Memory traces are present; infant anticipates familiar events (a parent coming near him will pick him up). Good toy for this period: mirror; good game: peek-a-boo.
Coordination of secondary reactions	8–12 mo	Infant can plan activities to attain specific goals. Perceives that others can cause activity and that activities of own body are separate from activity of objects. Can search for and retrieve toy that disappears from view. Recognizes shapes and sizes of familiar objects. Because of increased sense of separateness, infant experiences separation anxiety when primary caregiver leaves. Good toy for this period: nesting toys (i.e., colored boxes).
Tertiary circular reaction	12–18 mo	Child is able to experiment to discover new properties of objects and events. Capable of space perception and time perception as well as permanence. Objects outside self are understood as causes of actions. Good game for this period: throw and retrieve.
Invention of new means through mental combinations	18–24 mo	Transitional phase to the preoperational thought period. Uses memory and imitation to act. Can solve basic problems, foresee maneuvers that will succeed or fail. Good toys for this period: those with several uses, such as blocks, colored plastic rings.
Preoperational thought	2–7 yr	Thought becomes more symbolic; can arrive at answers mentally instead of through physical attempt. Comprehends simple abstractions but thinking is basically concrete and literal. Child is egocentric (unable to see the viewpoint of another). Displays static thinking (inability to remember what they started to talk about so that at the end of a sentence children are talking about another topic). Concept of time is now, and concept of distance is only as far as they can see. Centering or focusing on a single aspect of an object causes distorted reasoning. No awareness of reversibility (for every action there is an opposite action) is present. Unable to state cause–effect relationships, categories, or abstractions. Good toy for this period: items that require imagination, such as modeling clay.
Concrete operational thought	7–12 yr	Concrete operations includes systematic reasoning. Uses memory to learn broad concepts (fruit) and subgroups of concepts (apples, oranges). Classifications involve sorting objects according to attributes such as color; seriation, in which objects are ordered according to increasing or decreasing measures such as weight; multiplication, in which objects are simultaneously classified and seriated using weight. Child is aware of reversibility, an opposite operation or continuation of reasoning back to a starting point (follows a route through a maze and then reverses steps). Understands conservation, sees constancy despite transformation (mass or quantity remains the same even if it changes shape or position). Good activity for this period: collecting and classifying natural objects such as native plants, sea shells, etc. Expose child to other viewpoints by asking questions such as, "How do you think you'd feel if you were a nurse and had to tell a boy to stay in bed?"
Formal operational thought	12 yr	Can solve hypothetical problems with scientific reasoning; understands causality and can deal with the past, present, and future. Adult or mature thought. Good activity for this period: "talk time" to sort through attitudes and opinions.

From Piaget, J. (1961). *The growth of logical thinking from childhood to adolescence*. New York: Basic Books, with permission.

one glass into another glass that is taller and thinner than the first one, they will notice only one changing characteristic. They might say that there is now more water in the second glass (because the level has risen), or there is less water (because the second glass is narrower), even when told that no water has been added or removed. When the water is poured back into the first glass, they still will not understand that the amount of water is unchanged. This immature perception leads children, as it did during the toddler period, to make faulty conclusions. It takes more years of development for children to learn that when thought processes such as knowing that the amount of water did not change and perceptions conflict, thought processes are more trustworthy.

Preschool thinking is also influenced by **role fantasy,** or how children would like something to turn out. Children use **assimilation** (taking in information and changing it to fit their existing ideas) as a part of this. For example, because a child wants to go outside and play, he says the outside is calling him to come and play. Children believe their wishes are as real as facts and dreams are as real as daytime happenings during this stage. They perceive animals and even inanimate objects as being capable of thought and feeling (they say a dog took their doll because the dog was feeling sad; they say a footstool meant to trip them). This is often called "magical thinking." Later, children learn **accommodation** (they change their ideas to fit reality rather than the reverse).

Egocentrism, or perceiving that one's thoughts and needs are better or more important than those of others, is also strong during this period. Preschoolers cannot believe that not everyone knows facts they know; if asked, "What is your name?" they may reply, "Don't you know my name?" As a part of this, children define objects mainly in relation to themselves, so that a spoon is "what I eat with," not just a curved metal object.

The School-Age Child

Piaget viewed school age as a period during which *concrete operational thought* begins as school-age children can discover concrete solutions to everyday problems and recognize cause-and-effect relationships. A child who understands water does not change in amount just because it is poured from one glass to another has grasped the concept of conservation. Conservation of numbers is learned as early as age 7 years, conservation of quantity at age 7 or 8 years, conservation of weight at age 9 years, and conservation of volume at age 11 years. Reasoning during school age tends to be inductive, proceeding from specific to general: school-age children tend to reason that a toy they are holding is broken, the toy is made of plastic, so all plastic toys break easily.

The Adolescent

Piaget saw adolescence as the time when cognition achieves its final form, that of formal operational thought. When this stage is reached, adolescents are capable of thinking in terms of possibility—what could be **(abstract thought)**—rather than being limited to thinking about what already is (concrete thought). This makes it possible for adolescents to use scientific reasoning or also understand deductive reasoning, or reasoning that proceeds from the general to the specific (plastic toys break easily, the toy they are holding is plastic; it will break easily).

Criticism of Piaget's Theory

Piaget has been criticized because he used only a small sample of subjects (his own children) to develop his theory. Because children today begin activities to learn reading much earlier than they did at the time the theory was devised, the age groups and "norms" may no longer be accurate. Learning computer skills at an early age may be changing both the rate and type of children's cognitive development.

Kohlberg's Theory of Moral Development

Lawrence Kohlberg (1927–1987), a psychologist, studied the reasoning ability of boys and, based on Piaget's development stages, developed a theory on the way children gain knowledge of right and wrong or moral reasoning. These stages, as described by Kohlberg (1984), are summarized in Table 28.7.

Recognizing where a child is at according to these stages can help identify how children may feel about an illness such as whether children think it is fair that they are ill. Recognizing moral reasoning also helps determine whether children can be depended on to carry out self-care activities such as administering their own medicine or whether children have internalized standards of conduct so they do not "cheat" when away from external control. Moral stages closely approximate cognitive stages of development, because children must be able to think abstractly (be able to conceptualize an idea without a concrete picture) before being able to understand how rules apply even when no one is there to enforce them.

The Infant

The infant period is a *prereligious stage*. Infants have little concept of any motivating force beyond that of their parents. Infants learn that when they do certain actions, parents give affection and approval; for other actions, parents scold and label the behavior "bad." To support this stage of development, it is important for caregivers to praise infants for doing what they have been asked to do. Caregivers should also know the average infant is trying hard to please; if an infant falls short of doing this, it is probably because of immature development rather than any effort to displease.

The development of trust is important in moral development because infants who develop a sound sense of trust can better develop a spiritual orientation in future years or be bound by a moral conscience (they can trust in a spiritual being as well as humans around them).

The Toddler

Toddlers begin to formulate a sense of right and wrong, but their reason for doing right is centered most strongly in "mother or father says so" rather than in any spiritual or societal motivation. Kohlberg referred to this as a "punishment obedience orientation" (a child is good because a parent says a child must be good, not because it is "right" to be good).

TABLE 28.7 ✻ Kohlberg's Stages of Moral Development

Age (Year)	Stage	Description	Nursing Implications
Preconventional (Level I)			
2–3	1	Punishment/obedience orientation ("heteronymous morality"). Child does right because a parent tells him or her to and to avoid punishment.	Child needs help to determine what are right actions. Give clear instructions to avoid confusion.
4–7	2	Individualism. Instrumental purpose and exchange. Carries out actions to satisfy own needs rather than society's. Will do something for another if that person does something for the child.	Child is unable to recognize that like situations require like actions. Unable to take responsibility for self-care, because meeting own needs interferes with this.
Conventional (Level II)			
7–10	3	Orientation to interpersonal relations of mutuality. Child follows rules because of a need to be a "good" person in own eyes and eyes of others.	Child enjoys helping others because this is "nice" behavior. Allow child to help with bed making and other like activities. Praise for desired behavior such as sharing.
10–12	4	Maintenance of social order, fixed rules, and authority. Child finds following rules satisfying. Follows rules of authority figures as well as parents in an effort to keep the "system" working.	Child often asks what are the rules and is something "right." May have difficulty modifying a procedure because one method may not be "right." Follows self-care measures only if someone is there to enforce them.
Postconventional (Level III)			
Older than 12	5	Social contract, utilitarian law-making perspectives. Follows standards of society for the good of all people.	Adolescents can be responsible for self-care because they view this as a standard of adult behavior.
	6	Universal ethical principle orientation. Follows internalized standards of conduct.	Many adults do not reach this level of moral development.

From Kohlberg, L. (1984). *The psychology of moral development.* New York: Harper & Row, with permission.

Toddlers may not obey requests from people other than their parents because they do not view their authority as being at the same level as their parents' authority. This means that while providing nursing care, it might be necessary to ask a parent to reinforce instructions to be certain a toddler will follow them.

The Preschooler

Preschoolers tend to do good out of self-interest rather than out of true intent to do good or because of a strong spiritual motivation. When asked why it is wrong to steal from a neighbor, for example, a preschooler will answer, "Because my mother won't like me any more." Because of egocentrism, a preschooler may do things for others only in return for things done for him or her. This means it may be necessary to remind children of actions taken on their behalf or trade off actions such as, "Lie still now for me while I change your dressing and I'll read you a story when I'm through."

Children at this age also imitate what they see, so if they see less-than-perfect role models, they may copy those wrong actions, assuming those actions are correct. Preschoolers have great difficulty knowing what rules apply to new situations because they cannot judge whether a previously learned principle of right or wrong can be applied to this new situation (does not recognize that stealing money in a hospital setting is the same as stealing it at home).

The School-Age Child

School-age children enter a stage of moral development termed *conventional development*, a level at which many adults continue to function. Young school-age children adhere to a phase of development termed the "nice girl, nice boy" stage. Children engage in actions that are "nice" or "fair" rather than necessarily right. Sharing, for example, is "nice." Taking turns is "fair." Stealing is not. Young school-age children may lie about their actions to disguise that they have been involved in an action that is not "nice." When asked why it is wrong to steal from a neighbor, the school-age child most often answers, "Because it's not nice or fair."

Later in the school-age period, as children learn about community resources, they become aware that community laws are enforced by crossing guards or police. They may have difficulty following self-care measures reliably when out of a nurse's or parent's sight during this time because they feel it is necessary to obey rules only when the rules can be clearly enforced. At this point, they might answer the question about stealing from a neighbor with, "You shouldn't steal because the police will put you in jail."

The Adolescent

As adolescents become capable of abstract thought, they become capable of internalizing standards of conduct (they do what they think is right regardless of whether anyone is watching). This is termed *postconventional development* and is the mature form of moral reasoning. In this stage, if asked why it is wrong to steal from a neighbor, adolescents answer, "Because it deprives my neighbors of possessions they have earned." Adolescents can carry out self-care measures even when someone else is not present when they enter this stage because they can understand not only the importance of the measures to themselves but also the principle that certain things should be done simply because they are right to do. Many adolescents do not enter this phase of development, however, and as adults they continue at a school-age level, doing right things only when obvious authority or set rules are present.

Criticism of Kohlberg's Theory

Kohlberg's theory is frequently challenged as being male-oriented because his original research was conducted entirely with boys. Carol Gilligan (1993), a sociologist, has suggested that girls may not score well on Kohlberg's scale because, being more concerned with relationships than boys, they make moral decisions based on individual circumstances, a different criterion for decision making.

USING GROWTH AND DEVELOPMENT IN PRACTICE

An assessment of children's growth and development should be included in all children's nursing care plans as whether they are growing and developing within usual parameters is a significant mark of wellness (see Focus on Nursing Care Planning Box 28.5).

✔ Checkpoint Question 28.3

Suppose John, 6 years old, tells you his broken leg wants to get better. What type of thinking is he using?

a. Magical thinking.
b. Deductive reasoning.
c. Concrete operational thinking.
d. Sensorial thought.

BOX 28.5 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Child With a Developmental Concern

John Olson is a 6-year-old boy you see in an emergency department because he has a broken leg from a bicycle accident. His parents tell you although John has lived with them for 3 years, they find him cold and unloving. They ask you what they can do to change this.

Family Assessment ✻ Family lives in a three-bedroom house in suburbs. Father works as a plumber; mother has a part-time job as a substitute grade-school teacher.

Client Assessment ✻ At 4 months of age, John was taken away from his mother because she was not caring for him adequately. He was then moved back and forth among 12 different foster homes until he was finally adopted at age 3½. His adoptive parents have 3-year-old twins of their own.

Nursing Diagnosis ✻ Interrupted family processes related to inability of child to meet parents' developmental expectations

Outcome Criteria ✻ Child demonstrates greater participation in family activities and improved response to parents' attempts to bond with him by 3 months' time.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Assess if family has thought through impact of bicycle accident on daily activities.	Suggest some obvious accommodations needed for cast care: no tub bathing, difficulty with stairs, no bike riding.	If a family is already under stress, an accident can compound the problem.	Family members state that accidents are not anyone's "fault"; are prepared to make adjustments needed.

		Consultations		
Nurse/ physician	Assess if parents feel that psychological counseling would be appropriate for child.	Assist parents with gaining a consultation if they feel they would welcome this.	Consultation with a skilled professional can offer parents information on specific actions to take.	Parents state whether they feel situation merits more skilled help at this time.
		Procedures/Medications		
Physician/ nurse	Assess what emergency actions are necessary for fractured tibia.	Apply cast; give instructions for cast care. Keep pain or discomfort to a minimum.	Definite measures to prevent pain are important in promoting a sense of trust.	Client states he understands cast care; states that emergency department experience was an adventure, not an ordeal.
		Nutrition		
Nurse	Employ a 24-hour recall dietary history to assess for usual calcium and vitamin D intake.	Suggest additional sources of calcium or vitamin D if needed.	Calcium is important for good bone healing and absorbed best in the presence of vitamin D.	Client states he understands calcium will help healing and is willing to ingest more as needed.
		Patient/Family Education		
Nurse	Assess what parents understand about the development of trust in early life.	Suggest ways to initiate a sense of trust by demonstrating dependability and a warm, loving relationship.	A sense of trust can be reinstated at a later developmental stage if it has been lost.	Parents state they are willing to begin more active steps toward improving relationship with son.
		Psychosocial/Spiritual/Emotional Needs		
Nurse	Assess what type of child parents expected to adopt.	Suggest measures that could bring parents and child closer together such as a "game night," always eating meals together, quiet "talk times" before bed.	Identifying differences between expectations and reality can help people understand dissatisfactions.	Client and parents state they are willing to begin active program of shared activities.
		Discharge Planning		
Nurse	Assess if client or parents have any further needs they would like to discuss.	Discuss with client and parents adjustments client will have to make to attend school with a cast in place.	Small needs not met can grow into major needs before a return appointment and interfere further with a sense of trust.	Client and parents state they understand adjustments that need to be made and will work them out together.

Key Points for Review

- Knowledge of growth and development is important in health promotion and illness prevention because it lays the basis for assessment and anticipatory guidance.
- Genetic factors that influence growth and development are gender, ethnicity, intelligence, and health.
- Environmental influences include quality of nutrition, socioeconomic level, parent–child relationship, ordinal position in the family, and environmental health.
- To meet growth and development milestones, children need to follow basic guidelines for a healthy diet, such as eating a variety of foods; maintaining ideal weight; avoiding extreme levels of saturated fat and cholesterol; eating foods with adequate starch and fiber; and avoiding too much sugar, the same as adults.
- Temperament is a child's characteristic manner of thinking, behaving, or reacting. Helping parents understand the effect of temperament is a nursing role.
- Common theories of development are Freud's psychoanalytic theory and Erikson's theory of psychosocial development. Both of these theories describe specific tasks children must complete at each stage of development to become a well-adapted adult.
- Piaget's theory of cognitive development describes ways that children learn. Kohlberg advanced a theory of moral development, or how children use moral reasoning to solve problems they face.
- Although growth and development occur in known patterns, their rate varies from child to child. Caution parents not to be concerned because two siblings are very different as long as they both fit within usual parameters.

CRITICAL THINKING EXERCISES

1. John is the 6-year-old boy you met at the beginning of the chapter. He had lived in many foster homes before he was adopted. His parents state that they find him cold and unloving. What developmental task was John unable to complete because of these frequent moves at such a young age? What actions could his new parents take to try to strengthen this developmental task at this point?
2. John's mother describes her 3-year-old twins as "totally different" from each other. One is shy and quiet and agreeable; the other is aggressive and persistent. What characteristic is she describing? Which child does she probably view as easier to care for? What anticipatory guidance could you give her to help her better understand these differences in her children?
3. Children who are hospitalized for long periods may fall behind in development. What specific measures could you take to promote developmental growth and encourage a sense of autonomy if John were a hospitalized 2-year-old? To promote a sense of industry if he were hospitalized at age 10 years?
4. Examine the National Health Goals related to growth and development of children. Most government-sponsored funds for nursing research are allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to John's family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to principles of growth and development. Confirm your answers are correct by reading the rationales.

Chapter

29 Nursing Care of a Family With an Infant

KEY TERMS

- baby-bottle syndrome
- binocular vision
- deciduous teeth
- eighth-month anxiety
- extrusion reflex
- hand regard
- natal teeth
- neck-righting reflex
- neonatal teeth
- object permanence
- pincer grasp
- seborrhea
- social smile
- thumb opposition

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe normal infant growth and development and associated parental concerns.
2. Identify National Health Goals related to infant growth and development that nurses can help the nation achieve.
3. Use critical thinking to analyze methods of care for an infant to be certain care is family centered.
4. Assess an infant for normal growth and development milestones.
5. Formulate nursing diagnoses related to infant growth and development and associated parental concerns.
6. Identify expected outcomes to promote optimal infant growth and development needs.
7. Plan nursing care to meet an infant's growth and development needs such as teaching parents to childproof their home.
8. Implement nursing care related to normal growth and development of an infant such as encouraging eye/hand coordination.
9. Evaluate expected outcomes for achievement and effectiveness of care.
10. Identify areas related to nursing care of an infant that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of infant growth and development with nursing process to achieve quality maternal and child health nursing care.

You meet Ms. Simpson, 19, at a pediatric clinic when she brings in her 2-month-old son, Bryan. She looks tired. She tells you she is exhausted because her baby is "awake all night, crying constantly." She stopped breastfeeding and changed him to formula to see if that would help. It didn't. She tells you his bowel movements are normal. When you weigh Bryan, you find he has gained weight well. When you talk to him, he demonstrates a social smile. Previous chapters described the newborn and the capabilities with which children are born. This chapter adds information about the dramatic changes, both physical and psychosocial, that occur during the first year. Such information can build a base for care and health teaching for the age group.

What condition common to early infancy might Ms. Simpson be describing? Is this normal infant behavior? What factors might be playing a role? What suggestions could you make to help her enjoy caring for Bryan more?

Traditionally, infancy is designated as the period of time from 1 month to 1 year of age. In these important months, an infant undergoes such rapid development that parents sometimes believe their baby looks different and demonstrates new abilities every day. During this time, an infant triples birth weight and increases length by 50%. Infant's reflexes develop and senses sharpen and, with the process of attachment to primary caregivers, they form a first social relationship. Because of the growth and learning potential that occurs, this first year is a crucial one. Without proper nutrition, a baby will not grow and physically thrive, and without proper stimulation and nurturing care by consistent caregivers, an infant may not develop a healthy interest in life or a feeling of security essential for future development.

As a result, infant health promotion is the subject of much concern. National Health Goals addressing this important developmental stage are highlighted in Box 29.1.

Although infant health care visits are scheduled less frequently than formerly, a standard schedule is for 2-week, 2-month, 4-month, 6-month, and 12-month visits (American Academy of Pediatrics [AAP], 2009). These visits are as important for the parents as they are for an infant because they provide an opportunity for parents to ask questions about their child's growth pattern and developmental progress. They also provide opportunities for health care providers to assess for potential problems. Anticipatory guidance offered at these visits can help parents prepare for the rapid changes that mark the first year of life. When appropriate, encouraging parents to join clubs or networking groups helps to increase their knowledge base and confidence level as well.

Table 29.1 details the usual procedures for infant health maintenance visits. The vaccines administered during the first year are discussed in Chapter 34 and also listed in Appendix J.

BOX 29.1 ✻ Focus on National Health Goals

A number of National Health Goals focus on promotion of health during the infant year. These are:

- Increase the proportion of mothers who breastfeed until 1 year of age from a baseline of 16% to 25%.
- Reduce the incidence of early childhood caries such as those caused by baby-bottle syndrome from a baseline of 18% to 11%. Special target population: parents and caregivers with less than high school educations.
- Reduce the rate of fetal and infant deaths from a baseline of 7.5 per 1000 to 4.5 per 1000.
- Increase the rate of use of child automobile restraints in children 4 years and under from a baseline of 92% to 100%.
- Increase the percentage of healthy full-term infants who are put down to sleep on their backs from a baseline of 35% to 70%.
- Increase to at least 90% the proportion of infants who receive all recommended immunizations for an infant at appropriate intervals (http://www.nih.gov).

Nurses can help the nation achieve these goals by educating parents about the importance of not putting an infant to bed with a bottle of milk or juice, the use of infant car seats, and continuing breastfeeding for a full year. A number of areas related to these topics that could benefit from additional nursing research include effective ways mothers can comfort an infant in a car seat without removing the infant from the seat; characteristics of programs that are successful in promoting breastfeeding; and effective ways to teach about immunizations so that parents secure those recommended for infants.

Nursing Process Overview

For Healthy Development of an Infant

Assessment

Nursing assessment of an infant begins with an interview with the primary caregiver. Important areas to discuss include nutrition, growth patterns, and development. An infant's height, weight, and head circumference are important indicators of growth, so they should be measured and plotted on standard growth charts (Brayden, Daley, & Brown, 2008). These charts represent average growth and can determine if the baby's growth remains within the same relative percentile at each checkup.

Physical assessment of an infant must be done quickly yet thoroughly because a baby can tire or become hungry, making it difficult to judge overall behavior and temperament. The primary caregiver should be present to make a child feel comfortable. Using a calm approach helps the infant remain calm as well.

Nursing Diagnosis

Much of your assessment of an infant and family will focus on basic needs such as sleep, nutrition, and activity and the parents' adjustment to their new role. Examples of nursing diagnoses are:

- Ineffective breastfeeding related to maternal fatigue
- Disturbed sleep pattern (maternal) related to baby's need to nurse every 2 hours
- Deficient knowledge related to normal infant growth and development
- Imbalanced nutrition, less than body requirements, related to infant's difficulty sucking
- Health-seeking behaviors related to adjusting to parenthood
- Delayed growth and development related to lack of stimulating environment
- Risk for impaired parenting related to long hospitalization of infant
- Readiness for enhanced family coping related to increased financial support
- Social isolation (maternal) related to lack of adequate social support
- Ineffective role performance related to new responsibilities within the family

Outcome Identification and Planning

Outcomes established for infant care need to be realistic based on the family's new circumstances. Parents of infants,

TABLE 29.1 ✻ Health Maintenance Schedule, Infant Period

Area of Focus	Methods	Frequency
Assessment		
Developmental milestones	History, observation	Every visit
	Denver Developmental Screening Test (DDST II)	At 3 months and 1 year
Growth milestones	Height, weight, head circumference plotted on standard growth chart; physical examination	Every visit
Nutritional adequacy	History, observation	Every visit
Parent-child relationship	History, observation	Every visit
Sleep positioning counseling	Discussion of placing infants on back to sleep	Every visit up to 9 months
Injury and violence counseling	Discussion of safety measures to take with infants	Every visit
Vision and hearing screening	Observation and history	Every visit
Dental health	History, physical examination	Every visit after teeth erupt
Anemia	Hematocrit, hemoglobin	9- or 12-month visit
Lead screening	Finger stick	9- or 12-month visit
Tuberculosis screening	PPD test	12-month visit
Immunizations		
Diphtheria, pertussis, tetanus (DPT) vaccine	Review of history and health record; teaching caregiver about any risks and side effects; administering immunization in accordance with health care agency policies	2-, 4-, and 6-month visits
Haemophilus influenzae type B (HiB) vaccine		2-, 4-, 6-, and 12-month visits
Hepatitis A vaccine		12-month visit
Hepatitis B vaccine		Birth, 2-month, and 12-month visits
Inactivated poliomyelitis vaccine		2-, 4-, and 6-month visits
Influenza vaccine		Yearly at 6-month or more visit.
Pneumococcal vaccine		2-, 4-, 6-, and 12-month visits
Rotovirus vaccine		2-, 4-, and 6-month visit
Varicella vaccine		12-month visit

Source: American Academy of Pediatrics (AAP). (2009). *Recommendations for preventive pediatric health care.* Washington, DC: Author.

especially first-time parents, must do a lot of adjusting, and this takes time. Try to suggest activities that can be easily incorporated into the family's lifestyle. If your assessment data indicate that a child needs more exposure to language and you know both parents work during the day, for example, you might suggest the parents ask their child's caretaker to talk to their infant more. Encourage parents to spend additional time each evening reading or reciting nursery rhymes to their baby. The combined interventions should increase the baby's language skills. Helpful Web sites about growth and development to recommend are the BabyCenter (http://www. Babycenter.com) and Dr. Greene (http://www.DrGreene.com). Helpful Web sites to alert parents about safety are the American Association of Poison Control Centers (http://www.aapcc. org) and the AAP (http://www.aap.org). For questions about car seats, parents can consult the U.S. Department of Transportation National Highway Traffic Safety Administration (http://www.nhtsa.dot.gov). The national 800 telephone number for a poison control center is 1-800-222-1222.

Implementation

One of the most important interventions of the infant period is teaching new parents about how to care for their infant and keep the infant safe. Whenever possible, this information should be anticipatory so parents can prepare for ways to care for and protect their infant as the infant grows.

Outcome Evaluation

Evaluate expected outcomes at each visit to detect changes in parents' understanding of caring for their infant. Help parents understand all aspects of infant care, not just a single element.

Examples of expected outcomes include:

- Mother states she feels fatigued but able to cope with sleep disturbance from night waking.
- Parents state five actions they are taking daily to encourage bonding.
- Father states both he and spouse are adjusting to new roles as parents.
- Parents verbalize appropriate techniques they use to stimulate infant.
- Infant demonstrates age-appropriate growth and development.
- Infant exhibits weight, height, and head and chest circumference within acceptable norms.

GROWTH AND DEVELOPMENT OF AN INFANT

Infants grow rapidly both in size and in their ability to perform tasks. Although development follows set patterns, some of it is dependent on cultural factors. One difference is in the way mothers carry their infants. Many mothers tend to carry infants in their arms, while other women carry their infant in a shoulder sling or on their hip or in a forward-facing harness, positions that allow a woman to continue to work or walk while holding an infant close.

The amount of infant bathing that is done is also inconsistent across cultures. In the United States, most infants are bathed daily. In colder climates or countries where clean water is not readily available, infant bathing is more limited. The use of diapers varies also. In hot climate countries, infants are often not diapered. Being aware of these cultural differences leads to better understanding of the reasons for an individual woman's particular method of childrearing. Box 29.2 shows the typical appearance of a well infant.

Physical Growth

The physiologic changes that occur in the infant year reflect both the increasing maturity and growth of body organs. The following sections will discuss the changes that are typically seen in the first year of life.

Weight

As a rule, most infants double their birth weight by 6 months of age and triple it by 1 year. During the first 6 months, infants typically average a weight gain of 2 lb per month. During the second 6 months, weight gain is approximately 1 lb per month. The average 1-year-old boy weighs 10 kg (22 lb); the average girl weighs 9.5 kg (21 lb). An infant's weight, however, is relevant only when plotted on a standard growth chart and compared to that child's own growth curve (see Appendix E).

Height

An infant increases in height during the first year by 50%, or grows from the average birth length of 20 inches to about 30 inches (50.8 to 76.2 cm). Height, like weight, is best assessed if it is plotted on a standard growth chart. Infant growth is most apparent in the trunk during the early months. During the second half of the first year, it becomes more apparent as lengthening of the legs. At the end of the first year, the child's legs may still appear disproportionately short and bowed. For accuracy, measure infants lying supine on a measuring board (see Nursing Procedure 34.8, Chapter 34).

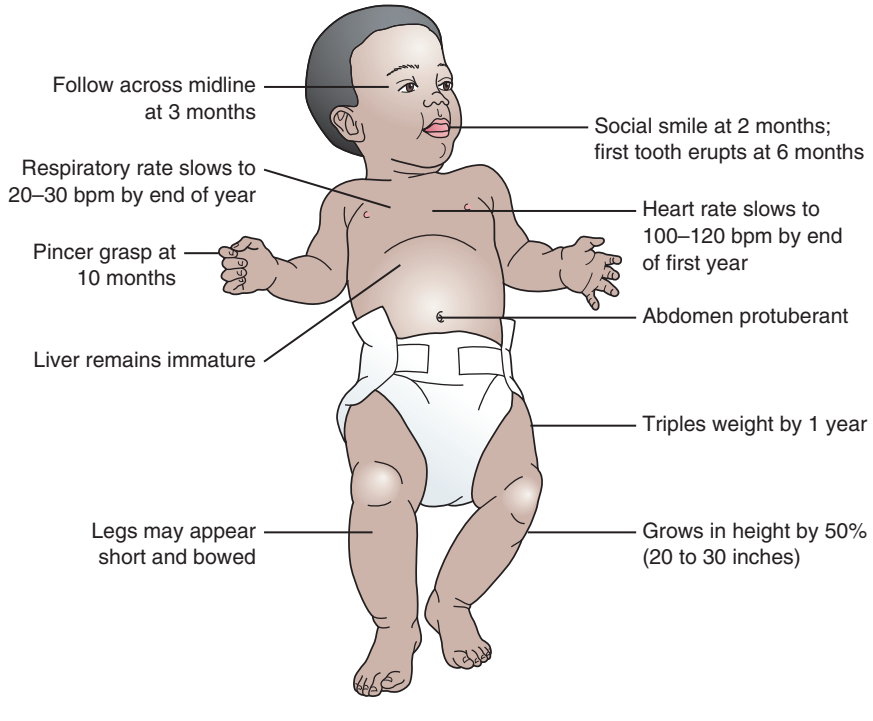
Head Circumference

By the end of the first year, the brain has already reached two thirds of its adult size. Head circumference increases rapidly during the infant period to reflect that rapid brain growth.

Some infants' heads appear asymmetric until the second half of the first year. This may occur from always being placed in one sleeping position, causing the skull bones to flatten on that side. Suggest to parents that they place the infant on the back to sleep and prone when playing to prevent this. This early head distortion gradually corrects itself as the

Box 29.2 Assessment

Assessing the Average Infant



child sleeps less and spends more time with the head in an erect position. Persistence of asymmetry may suggest an infant is not receiving enough stimulation or is spending the majority of time lying in bed.

Body Proportion

Body proportion changes during the first year from that of a newborn to a more typical infant appearance. The mandible becomes more prominent as bone grows. By the end of the infant period, the lower jaw is prominent and remains that way throughout life.

The circumference of the chest is generally less than that of the head at birth by about 2 cm. It is even with the head circumference in some infants as early as 6 months and in most by 12 months. The abdomen remains protuberant until the child has been walking well for some time, generally well into the toddler period. Cervical, thoracic, and lumbar vertebral curves develop as infants hold up their head, sit, and walk.

Lengthening of the lower extremities during the last 6 months of infancy readies the child for walking and often changes the appearance from "baby-like" to "toddler-like."

Body Systems

In the cardiovascular system, heart rate slows from 120 to 160 beats per minute to 100 to 120 beats per minute by the end of the first year. The heart continues to occupy a little over half the width of the chest. Pulse rate may begin to slow with inhalation (sinus arrhythmia), but this does not become marked until preschool age. That the heart is becoming more efficient is shown by a decreasing pulse rate and a slightly elevated blood pressure (from an average of 80/40 to 100/60 mm Hg).

Infants are prone to develop a physiologic anemia at 2 to 3 months of age. This occurs because the life of a red cell is 4 months so the cells the child had at birth are disintegrating, but new cells are not yet being produced in adequate replacement numbers. Hemoglobin in an infant becomes totally converted from fetal to adult hemoglobin at 5 to 6 months of age. Infants experience a second decrease in serum iron levels at 6 to 9 months as the last of iron stores established in utero are used.

The respiratory rate of an infant slows from 30 to 60 breaths per minute to 20 to 30 breaths per minute by the end of the first year. Because the lumen (tubal cavity) of the respiratory tract remains small and mucus production by the tract to clear invading microorganisms is still inefficient, upper respiratory infections occur readily and tend to be more severe than in adults.

At birth, the gastrointestinal tract is immature in its ability to digest food and mechanically move it along. These functions mature gradually during the infant year. Although the ability to digest protein is present and effective at birth, the amount of amylase, necessary for the digestion of complex carbohydrates, is deficient until approximately the third month. Lipase, necessary for the digestion of saturated fat, is decreased in amount during the entire first year.

The liver of an infant remains immature, possibly causing inadequate conjugation of drugs (if a drug should be necessary for treatment of illness) and inefficient formation of carbohydrate, protein, and vitamins for storage. Until age 3 or 4 months, an **extrusion reflex** (food placed on an infant's tongue is thrust forward and out of the mouth) prevents some infants from eating effectively. Infants can drink from a cup almost as newborns as long as a parent controls the fluid flow. An infant can independently drink from a cup by age 8 or 10 months.

The kidneys remain immature and not as efficient at eliminating body wastes as in an adult. The infant is also unable to concentrate urine as much as an adult, which causes them to be more prone to dehydration. The endocrine system remains particularly immature in response to pituitary stimulation, such as adrenocorticotropic hormone, or insulin production from the pancreas. Without these hormones functioning effectively, an infant may not be able to respond to stress effectively.

An infant's immune system becomes functional by at least 2 months of age; an infant can actively produce both IgG and IgM antibodies by 1 year. The levels of other immunoglobulins (IgA, IgE, and IgD) are not plentiful until preschool age, the reason infants continue to need protection from infection.

The ability to adjust to cold is mature by age 6 months. By this age, an infant can shiver in response to cold (which increases muscle activity and provides warmth) and has developed additional adipose tissue to serve as insulation. The amount of brown fat, which protected the newborn from cold, decreases during the first year.

Although the fluid in body compartments shifts to some extent, extracellular fluid accounts for approximately 35% of an infant's body weight, with intracellular fluid accounting for approximately 40% by the end of the first year, in contrast to adult proportions of 20% and 40%, respectively. This proportional difference increases an infant's susceptibility to dehydration from illnesses such as diarrhea, because loss of extracellular fluid could result in loss of over a third of an infant's body fluid.

Teeth

The first baby tooth (typically a central incisor) usually erupts at age 6 months, followed by a new one monthly. However, teething patterns can vary greatly among children. Figure 29.1 illustrates the usual ages of baby tooth eruption by tooth type.

Some newborns (about 1 in 2000) may be born with teeth (called **natal teeth**) or have teeth erupt in the first 4 weeks of life (called **neonatal teeth**). The mandibular central incisors (see Fig. 29.1) are the teeth most frequently involved in this early growth. These very early teeth may be membranous and so be reabsorbed (supernumerary or extra teeth). If they are loosely attached, they should be removed before they loosen spontaneously and are aspirated by an infant. In most infants, however, natal or neonatal teeth are deciduous or are fixed firmly. These should not be removed because no other teeth will grow to replace them until the permanent teeth erupt at age 6 or 7. **Deciduous teeth** (temporary or baby teeth) are essential for protecting the growth of the dental arch (Mueller, 2008).

Motor Development

An average infant progresses through systematic motor growth during the first year that strongly reflects the princi-

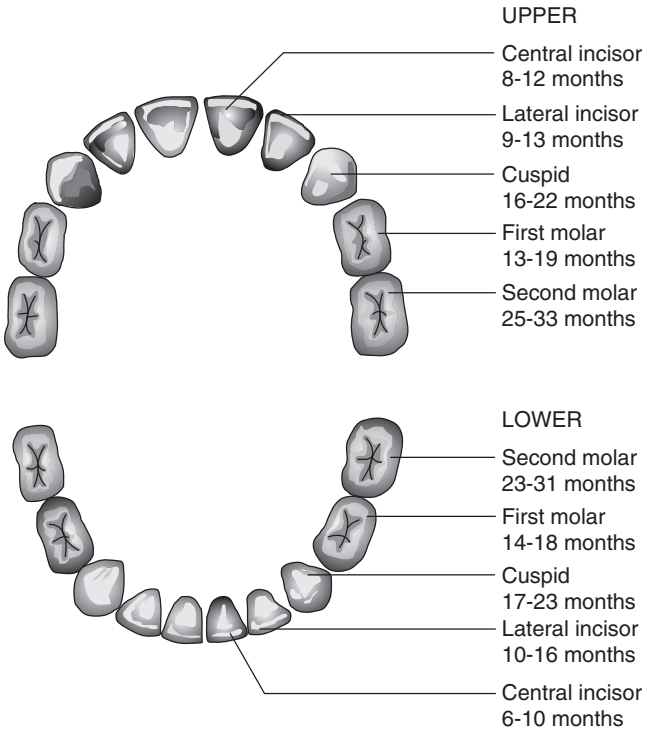


FIGURE 29.1 Eruption pattern of deciduous teeth.

ples of cephalocaudal and gross to fine motor development. Control proceeds from head to trunk to lower extremities in a progressive, predictable sequence. Different infants show individual variations in accomplishing different tasks; the ages given here are averages.

To assess motor development, both *gross motor development* (ability to accomplish large body movements) and *fine motor development*, which is measured by observing or testing *prehensile ability* (ability to coordinate hand movements), should be evaluated.

Gross Motor Development

To assess gross motor development, an infant is observed in four positions: ventral suspension, prone, sitting, and standing.

Ventral Suspension Position. *Ventral suspension* refers to an infant's appearance when held in midair on a horizontal plane, supported by a hand under the abdomen (Fig. 29.2A). In this position, the newborn allows the head to hang down with little effort at control. A 1-month-old child lifts the head momentarily, then drops it again. Two-month-old children hold their heads in the same plane as the rest of their body, a major advance in muscle control. A 3-month-old child lifts and maintains the head well above the plane of the rest of the body in ventral suspension.

A *Landau reflex* develops at 3 months. When held in ventral suspension, an infant's head, legs, and spine extend. When the head is depressed, the hips, knees, and elbows flex. This reflex continues to be present in most infants during the second 6 months of life, but then it becomes increasingly difficult to demonstrate. A child with motor weakness, cerebral palsy, or other neuromuscular defect will not be able to demonstrate the reflex.

At 6 to 9 months, an infant also demonstrates a *parachute reaction* from a ventral suspension position. When infants are suddenly lowered toward an examining table from ventral suspension, the arms extend as if to protect themselves from falling. In children with hemiplegia, the response is noticeable only on the unaffected side. Children with cerebral palsy do not demonstrate this response because they flex their extremities too tightly.

Prone Position. When lying on their stomach, newborns can turn their heads to move them out of a position where breathing is impaired, but they cannot hold them raised (see Fig. 29.2B). By 1 month of age, infants lift their heads and turn them easily to the side. They still tend to keep their knees tucked under the abdomen as they did as a newborn. Two-month-old infants can raise their heads and maintain the position, but they cannot raise their chests high enough to look around yet. Their head is still held facing downward.

A 3-month-old child lifts the head and shoulders well off the table and looks around when prone. The pelvis is flat on the table, no longer elevated. Some children can turn from a prone to a side-lying position at this age.

Four-month-old children lift their chests off the bed and look around actively, turning their heads from side to side. They can turn from front to back. The first time, this tends to occur as an extension of lifting the chest combined with a

A

B

FIGURE 29.2 (**A**) Ventral suspension position. (**B**) Prone position.

neck-righting reflex, which begins at this age. When an infant turns the head to the side, the shoulders, trunk, and pelvis turn in that direction, too. This reflex causes babies to lose their balance and roll sideways when lifting the head up. The baby is frightened by the sudden feeling of rolling free and probably cries. After this happens a few more times, however, a baby begins to delight in this new accomplishment. Most babies turn front to back first and then, 1 month later, back to front. When taking a health history, ask which way a child turned first. Those with spasticity may turn first back to front. This is not necessarily an indication of spasticity, however, because some healthy babies turn back to front first also.

Five-month-old children rest weight on their forearms when prone. They can turn completely over, front to back and back to front. At 6 months, infants rest their weight on their hands with extended arms. They can raise their chests and the upper part of their abdomens off the table.

By 9 months, a child can creep from the prone position. Creeping is a new skill, advanced from hitching (in which infants slide along the floor) that they may have been doing. Creeping means the child has the abdomen off the floor and moves one hand and one leg and then the other hand and leg, using the knees on the floor to locomote (Fig. 29.3).

Sitting Position. When placed on the back and then pulled to a sitting position, a 1-month-old child has gross head lag as in the first days of life (Fig. 29.4). In a sitting position, the back appears rounded and an infant demonstrates only momentary head control. Two-month-olds can hold their head fairly steady when sitting up, although it does tend to bob forward. An infant at this age still has head lag when pulled to a sitting position.

A 3-month-old child has only slight head lag when pulled to a sitting position. A 4-month-old child reaches an important milestone by no longer demonstrating head lag when pulled to a sitting position.

A 5-month-old infant can be seen to straighten the back when held or propped in a sitting position. By 6 months, children sit momentarily without support. They anticipate being picked up and reach up with their hands from this position. Some parents expect a child this age to sit securely and are worried because their sitting posture is still extremely shaky. However, it is more common for a 6-month-old child to have only a limited ability to sit independently (Fig. 29.5). Six-month-old children often sit with their legs spread and their arms stiffened between them, hands on the floor, as a prop. Infants are capable of movement by hitching or sliding backward from this position. Alert parents an infant this young is capable of moving from one spot to another in this way, so they are prepared for this and can prevent accidents.

FIGURE 29.4 An infant is pulled to a sitting position to demonstrate head lag. Notice how evident this is in the very young infant.

FIGURE 29.3 Creeping. The older infant moves forward, carrying his torso above and parallel to the floor.

FIGURE 29.5 A 6-month-old infant sitting. Notice how she is propped with pillows to maintain the position.

FIGURE 29.6 At 8 months an infant sits independently.

FIGURE 29.7 An 11-month-old child cruising along the walls. Further childproofing of the house will be necessary to keep her safe. (From Photo Researchers, Inc.)

A 7-month-old child sits alone, but only when the hands are held forward for balance. An 8-month-old child can sit securely without any additional support (Fig. 29.6). This is a major milestone in development that should always be considered in assessment. Children with delayed cognitive or motor development may not accomplish this step at this time.

At 9 months, infants sit so steadily they can lean forward and regain their balance. They may still lose their balance if they lean sideways, a skill not achieved for another month.

Standing Position. A newborn stepping reflex can still be demonstrated at 1 month of age. In a standing position, an infant's knees and hips flex rather than support more than momentary weight. Two-month-old children, when held in a standing position, hold their head up with the same show of support as in a sitting position. At 3 months, infants begin to try to support part of their weight.

At 4 months, infants begin to be able to support their weight on their legs. They are successful at doing this because the stepping reflex has faded.

A 5-month-old child continues the ability to sustain a portion of weight. The tonic neck reflex should be extinguished, and the Moro reflex is fading. By 6 months, infants support nearly their full weight when in a standing position. A 7-month-old child bounces with enjoyment in a standing position.

Nine-month-old children can stand holding onto a coffee table if they are placed in that position. Some 9-month-old children can pull up to that position. Ten-month-old children can pull themselves to a standing position by holding onto the side of a playpen or a low table, but they cannot let themselves down again as yet.

At around 11 months, a child learns to "cruise" or move about the crib or room by holding onto objects such as the crib rails, chairs, walls, and low tables (Fig. 29.7). At 12 months, children stand alone at least momentarily. Some parents expect children to walk at this time and are disappointed to see they are merely standing. A child has until about 22 months of age to walk and still be within the normal limit, however (Fig. 29.8).

✔ Checkpoint Question 29.1

Bryan is 2 months old. At what age would you expect him to sit securely?

a. 2.5 months.
b. 6 months.
c. 8 months.
d. 12 months.

Fine Motor Development

One-month-old infants still have a strong grasp reflex, and they hold their hands in fists so tightly it is difficult to extend the fingers. As the grasp reflex begins to fade, a 2-month-old child will hold an object for a few minutes before dropping it. The hands are held open, not closed in fists.

At 3 months, infants reach for attractive objects in front of them. Their grasp is unpracticed, however, so they usually miss them. Assure parents this is part of normal development. Otherwise, they may think their child is nearsighted or farsighted or has poor coordination.

By 4 months, infants bring their hands together and pull at their clothes. They will shake a rattle placed in their hand. **Thumb opposition** (ability to bring the thumb and fingers

FIGURE 29.8 There is a wide variation in the age at which children take a first step, typically ranging from 8 to 15 months. Here a child has mastered walking by 1 year.

together) is beginning, but the motion is a scooping or raking one, not a picking-up one, and is not very accurate. An infant is limited to handling large objects (Fig. 29.9). Palmar and plantar grasp reflexes have disappeared.

Five-month-old children can accept objects that are handed to them by grasping with the whole hand. They can reach and pick up objects without the object being offered and often play with their toes as objects. Fisting that persists beyond 5 months suggests a delay in motor development. Unilateral fisting suggests hemiparesis or paralysis on that side.

By 6 months, grasping has advanced to a point where a child can hold objects in both hands. Infants at this age will drop one toy when a second one is offered for the same hand. They can hold a spoon and start to feed themselves (with much spilling). Moro, palmar grasp, and the tonic neck reflex have completely faded. A Moro reflex that persists beyond this point should arouse suspicion of neurologic disease.

FIGURE 29.9 By age 4 months, an infant is able to manipulate large objects.

FIGURE 29.10 An infant almost ready to demonstrate a pincer grasp.

Seven-month-old children can transfer toys from one hand to the other. They hold a first object when a second one is offered. By 8 months, random reaching and ineffective grasping have disappeared as a result of advanced eye–hand coordination.

A major milestone of 10 months is the ability to bring the thumb and first finger together in a **pincer grasp** (Fig. 29.10). This enables children to pick up small objects such as crumbs or pieces of cereal from a highchair tray. They use one finger to point to objects. They offer toys to people but then cannot release them.

At 12 months, infants can draw a semistraight line with a crayon. They enjoy putting objects such as small blocks in containers and taking them out again. They can hold a cup and spoon to feed themselves fairly well (if they have been allowed to practice) and can take off socks and push their hands into sleeves (again, if they have been allowed to practice). They can offer toys and release them.

What if... Bryan learns to pick up very small articles such as marbles by 10 months? How would being able to do this affect an infant's safety?

Developmental Milestones

In addition to the gross and fine motor skills developing at this time, language and play behavior also reach major milestones. Motor and cognitive development and play throughout this year are summarized in Table 29.2.

Language Development

A child begins to make small, cooing (dovelike) sounds by the end of the first month. A 2-month-old child differentiates a cry. For example, caregivers can distinguish a cry that means "hungry" from one that means "wet" or from one that means "lonely." This is an important milestone in development for an infant and also in marking how far a parent has progressed in the task of learning the infant's cues. A first-time parent has more difficulty making the distinction in crying than one who

TABLE 29.2 ✻ Summary of Infant Growth and Development

Month	Motor Development	Fine Motor Development	Socialization and Language	Play
0–1	Largely reflex	Keeps hands fisted; able to follow object to midline		Enjoys watching face of primary caregiver, listening to soothing sounds
2	Holds head up when prone	Has social smile	Makes cooing sounds; differentiates cry	Enjoys bright-colored mobiles
3	Holds head and chest up when prone	Follows object past midline	Laughs out loud	Spends time looking at hands or uses them as toy during the month (hand regard)
4	Grasp, stepping, tonic neck reflexes are fading			Needs space to turn
5	Turns front to back; no longer has head lag when pulled upright; bears partial weight on feet when held upright			Handles rattles well
6	Turns both ways; Moro reflex fading	Uses palmar grasp	May say vowel sounds (*oh-oh*)	Enjoys bathtub toys, rubber ring for teething
7	Reaches out in anticipation of being picked up; first tooth (central incisor) erupts; sits unsteadily (still needs support)	Transfers objects hand to hand	Shows beginning fear of strangers	Likes objects that are good size for transferring
8	Sits securely without support		Has peak fear of strangers (ability to tell known from unknown people)	Enjoys manipulation, rattles and toys of different textures
9	Creeps or crawls (abdomen off floor)		Says first word (*da-da*)	Needs space for creeping
10	Pulls self to standing	Uses pincer grasp (thumb and finger) to pick up small objects		Plays games like patty-cake and peek-a-boo
11	"Cruises" (walks with support)			"Cruises"
12	Stands alone; some infants take first step	Holds cup and spoon well; helps to dress (pushes arm into sleeve)	Says two words plus *ma-ma* and *da-da*	Likes toys that fit inside each other (pots and pans); nursery rhymes; will like pull toys as soon as walking

has experienced this before. An infant's ability to make throaty, gurgling, or cooing sounds also increases at this time.

In response to a nodding, smiling face or a friendly tone of voice, a 3-month-old child will squeal with pleasure. This is an important step in development because it makes a baby even more fun to be with. Parents spend increased time with infants at this age, not just to care for them but because they enjoy their company.

By 4 months, infants are very "talkative," cooing, babbling, and gurgling when spoken to. They definitely laugh out loud. By 5 months, an infant says some simple vowel sounds (for example, "goo-goo" and "gah-gah"). At 6 months, infants learn the art of imitating. They may imitate a parent's cough, for example, or say "Oh!" as a way of attracting attention.

The amount of talking infants do increases at 7 months. They can imitate vowel sounds well (for example, "oh-oh," "ah-ah," and "oo-oo"). By 9 months, an infant usually speaks a first word: "da-da" or "ba-ba." Occasionally a mother may need reassurance that "da-da" for daddy is an easier syllable to pronounce than "ma-ma" for mommy. German mothers report the first word their babies say is "here," as that is "da" in German. By 10 months, an infant masters another word such as "bye-bye" or "no." By 12 months, infants can generally say two words besides "ma-ma" and "da-da"; they use those two words with meaning.

Play

Parents often ask what toys their infant would enjoy. Because 1-month-olds can fix their eyes on an object, they are interested in watching a mobile over their crib or playpen. Mobiles are best if they are black and white or brightly colored and light enough in weight so they move when someone walks by. They should face down toward the infant, not toward an adult standing beside the crib. Musical mobiles provide extra stimulation. One-month-old children also spend a great deal of time watching their parent's face, appearing to enjoy this activity so much a face may become their favorite "toy." Help parents understand they are not spoiling infants by sitting and holding them for long periods of time in their early months. Parents will enjoy recalling such calm moments later, when they are stacking blocks, winding up toys, or playing table games with their growing child.

Hearing is a second sense that is a source of pleasure for children in early infancy. Even newborns "listen" to the sound of a music box or a musical rattle. They stir and seem apprehensive at the sound of a raucous rattle.

Two-month-old infants will hold light, small rattles for a short period of time but then drop them. They are very attuned to mobiles or cradle gyms strung across their crib. They continue to spend a great deal of time just watching the people around them.

Three-month-old children can handle small blocks or small rattles. Four-month-old children need a playpen or a sheet spread on the floor so they have an opportunity to exercise their new skill of rolling over. Rolling over is so intriguing it may serve as a "toy" for the entire month.

Five-month-old infants are ready for a variety of objects to handle, such as plastic rings, blocks, squeeze toys, clothespins, rattles, and plastic keys. All these should be small enough an infant can lift them with one hand, yet big enough the baby cannot possibly swallow them.

A 6-month-old child can sit steadily enough to be ready for bathtub toys such as rubber ducks or plastic boats. Because they are starting to teethe, infants enjoy a teething ring to chew on at this time.

Because 7-month-old children can transfer toys, they are interested in items such as blocks, rattles, or plastic keys that are small enough to be used for this. As their mobility increases, they begin to be more interested in brightly colored balls or toys that previously rolled out of reach.

Eight-month-old children are sensitive to differences in texture. They enjoy having toys that have different feels to them, such as velvet, fur, fuzzy, smooth, or rough items.

The 9-month-old infant needs the experience of creeping. This means time out of a crib or playpen so there is room to maneuver. Many 9-month-olds begin to enjoy toys that go inside one another, such as a nest of blocks or rings of assorted sizes that fit on a center post. Some are more interested in pots and pans that stack rather than toys.

By 10 months, infants are ready for peek-a-boo and will spend a long time playing the game with their hands or with a cloth over their head that they can reach and remove. They can clap and are also ready to play patty-cake. These games have a positive value, just as laughing out loud did for the 3-month-old child. They make a baby feel like an active part of the household. A family feeling begins to grow as the baby can participate in active games.

At 11 months, children have learned to cruise or walk along low tables by holding on. They often find this so absorbing they spend little time doing anything else during the month.

Twelve-month-old infants enjoy putting things in and taking things out of containers. They like little boxes that fit inside one another or dropping small blocks into a cardboard box. As soon as they can walk, they will be interested in pull toys. A lot of time may be spent listening to someone saying nursery rhymes or listening to music.

✔ Checkpoint Question 29.2

How many words does a typical 12-month-old infant use?

a. Two, plus "ma-ma" and "da-da."
b. About 12 words.
c. Twenty or more words.
d. About 50 words.

Development of Senses

Like other facets of development, maturation of the senses proceeds step by step during the infant year.

Vision

One-month-old infants regard an object in the midline of their vision (something directly in front of themselves) as soon as it is brought in as close as about 18 inches (46 cm) away. They follow it a short distance, but not across the midline as yet. They study or regard a human face with a fixed stare. Two-month-old infants focus well (from about age 6 weeks) and follow objects with the eyes (although still not past the midline). Ability to follow and focus this way is a major milestone in development, indicating an infant has achieved **binocular vision**, or the ability to fuse two images into one (Fig. 29.11). Teach parents to make a point of initiating eye-to-eye contact with newborns right from the beginning as a method of stimulating vision as well as promoting socialization.

Three-month-old infants can follow an object across their midline. They typically hold their hands in front of their face and study their fingers for long periods of time (**hand**

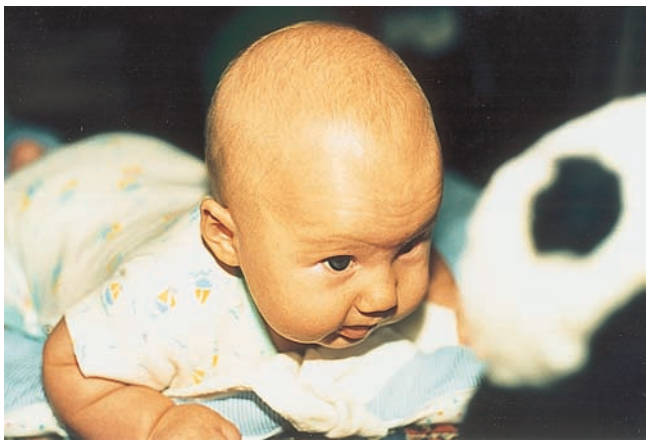

FIGURE 29.11 A 2-month-old infant focuses steadily and lifts her head up while prone. Note her interest in the stuffed bear.

FIGURE 29.12 A 2-month-old infant enjoys watching a simple mobile.

regard). Blind children also demonstrate this phenomenon, however, so it may not be so much a test of vision as of cognitive or exploratory development. Up until 6 months of age, infants may experience difficulty in establishing eye coordination. After 3 months, however, an infant whose eyes still "cross" should be examined by a physician.

Four-month-old infants recognize familiar objects, such as a frequently seen bottle, rattle, or toy animal. They follow their parents' movements with their eyes eagerly. At 6 months, infants are capable of organized depth perception. This increases the accuracy of their reach for objects as they begin to perceive distances accurately.

Seven-month-old children pat their image in a mirror. Their depth perception has matured to the extent they can perform such tasks as transferring toys from hand to hand. By 10 months, an infant looks under a towel or around a corner for a concealed object (beginning of object permanence).

Most parents are aware that infants enjoy mobiles and also a crib mirror (Fig. 29.12). Occasionally they supply so many of these they can overdo the amount of visual stimulation, overwhelming their infant with too many patterns and objects dangling above the crib. Ask parents to consider how all these trappings must appear from an infant's view.

In a hospital environment, assess that an infant is receiving visual stimulation. Add or reduce objects as appropriate. If a child's movement is restricted in any way, move the position of the mobile from time to time. Photographs of family members brought from home or pictures drawn by older brothers or sisters can be posted near an infant's crib. Ask the parents if there are any items from home an infant would normally see during the course of the day while being fed, changed, or bathed. It may be possible to bring those items into the hospital for visual stimulation.

Hearing

Hearing is demonstrated by the 1-month-old child who quiets momentarily at a distinctive sound such as a bell or a squeaky rubber toy. Hearing awareness becomes so acute by 2 months of age that infants will stop an activity at the sound of spoken words. Many 3-month-old infants turn their heads to attempt to locate a sound. At 4 months of age, when infants hear a distinctive sound they turn and look in that direction.

By 5 months of age, infants demonstrate they can localize sounds downward and to the side, by turning their head and looking down. Six-month-olds have progressed to being able to locate sounds made above them. By 10 months, infants can recognize their name and listen acutely when spoken to. By 12 months, infants can easily locate sound in any direction and turn toward it. A vocabulary of two words plus "mama" and "da-da" also demonstrates an infant can hear.

Infants appear to enjoy soft, musical sounds or soft, cooing voices; they are startled by harsh, raucous rattles or loud bangs. Urge parents to choose for an infant's first toys ones that make these types of welcoming sounds. Tape recordings of maternal heart sounds can be soothing to very young infants. For the hospitalized infant, an audiotape of family voices might be a soothing reminder of their presence. Encourage parents to read to their child daily from the beginning of life through the early school-age years, not only because the sound of the parent's voice is comforting but also because this increases language development dramatically (Box 29.3).

Touch

An infant needs to be touched to experience skin-to-skin contact. Clothes should feel comfortable and soft rather than

BOX 29.3 * Focus on Communication

You listen while Bryan's mother dresses her son after a clinic visit.

Less Effective Communication

Ms. Simpson: Don't move. And take your thumb out of your mouth. I have to put on your sweater. All right. Let's go.

Mrs. Ortello is also the mother of a 2-month-old child. You listen to her as she dresses her son as well.

More Effective Communication

Mrs. Ortello: Are you ready to go? It's time to get dressed. Next, we'll pick up Daddy. Then we're going shopping. Remember shopping? That's when you ride in the red car seat while I buy things. I hope you have my shopping gene because we do a lot of shopping. This is your yellow sweater Aunt Mary gave you. Remember her? The funny lady who said you were cute except you have no hair? Okay. We're ready. As soon as I put on my coat, we'll go.

These two women's approaches to talking to their children differ because the second mother seems to understand and appreciate that infants enjoy the sound of a parent's voice. In the first scenario, the mother is only giving instructions. Which infant might you anticipate will develop the largest vocabulary? Which one will be more aware of the names of colors sooner? Nurses can assist parents with more effective communication techniques such as this.

rough; diapers should be dry rather than wet. Teach parents to handle infants with assurance and gentleness. Remind parents that right now their child is a baby; there will be time enough later on to become a strong man or woman.

Because premature infants need to be kept warm while being held, parents are often advised to cuddle an infant next to their bare chest ("skin-to-skin contact"). This is also effective with term infants as a way of promoting close physical contact (Moore, Anderson, & Bergman, 2009).

Taste

Infants demonstrate that they have an acute sense of taste by turning away from or spitting out a taste they do not enjoy. Urge parents to make mealtime a time for fostering trust as well as supplying nutrition by being certain feedings are done at an infant's pace and the amount offered fits the child's needs and not the parent's idea of how much should be eaten.

Smell

Infants can smell accurately within 1 or 2 hours after birth. They respond to an irritating smell by drawing back from it. They appear to enjoy pleasant odors and learn early in life to identify the familiar smell of breast milk. Teach parents to be alert to substances that cause sneezing when sprayed into the air, such as room deodorizers or cleaning compounds, and to keep irritating odors out of the child's environment.

Emotional Development

Socialization, or learning how to interact with others, is an extensive phenomenon. One-month-old infants show they can differentiate between faces and other objects by studying a face or the picture of a face longer than other objects. They quiet best and eat best for the person who has been their primary caregiver.

When an interested person nods and smiles at a 6-week-old infant, the infant smiles in return. This is a **social smile** and is a definite response to the interaction, not the faint, quick "smile" that younger infants, even newborns, demonstrate. It is a major milestone for assessing several areas, most notably vision, motor control, and intelligence. Cognitively challenged children or children with spasticity may not demonstrate a social smile until much later.

By 3 months, infants demonstrate increased social awareness by readily smiling at the sight of a parent's face (Fig. 29.13). Three-month-old infants laugh out loud at the sight of a funny face.

By 4 months, when a person who has been playing with and entertaining an infant leaves, an infant is likely to cry to show how enjoyable is this type of interaction. Infants at this age recognize their primary caregiver and prefer that person's presence to others. By 5 months, infants may show displeasure when an object is taken away from them. This is a step beyond showing displeasure when a person leaves.

By 6 months, infants are increasingly aware of the difference between people who regularly care for them and strangers. They may begin to draw back from unfamiliar people. Seven-month-old infants begin to show obvious fear of strangers. They may cry when taken from their parent, attempt to cling to the parent, and reach out to be taken back. Parents may view this as a bad trait or a regression in socialization. Help them appreciate it is actually a big step forward, because it shows their infant can differentiate between persons and recognizes the difference between persons to trust and others.

FIGURE 29.13 A 3-month-old smiles delightedly at her father's happy face. This indicates increased social awareness.

Fear of strangers reaches its height during the eighth month, so much so this phenomenon is often termed **eighth-month anxiety**, or stranger anxiety (Goldson & Reynolds, 2008). An infant at the height of this phase will not go willingly from a parent's arms to a nurse's. Taking a few minutes to talk to the child and parent first is time well spent.

Nine-month-old infants are very aware of changes in tone of voice. They will cry when scolded, not because they understand what is being said but because they sense their parent's displeasure.

By 12 months, most children have overcome their fear of strangers and are alert and responsive again when approached. They like to play interactive nursery rhymes and rhythm games and "dance" with others. They like being at the table for meals and joining in family activities.

Cognitive Development

In the first month of life, an infant mainly uses simple reflex activity. There is little evidence that infants at this age see themselves as separate from their environment. However, this does not mean they cannot respond actively or interact with people. They tend to enjoy people and faces more than they do objects.

Primary Circular Reaction

By the third month of life, a child enters a cognitive stage identified by Piaget (1966) as *primary circular reaction.* During this time, an infant explores objects by grasping them with the hands or by mouthing them (Fig. 29.14). Infants appear to be unaware of what actions they can cause or what actions occur independently. For example, if an infant's hand should accidentally strike a mobile across the crib, an infant appears to enjoy watching the brightly colored birds move in front of him, but makes no attempt to

FIGURE 29.14 Infants explore the world by mouthing objects or fingering them. This also helps them separate self from environment.

hit the mobile again because he does not realize his hand caused the movement.

Secondary Circular Reaction

At about 6 months of age (cognitive development has wide variation), infants pass into a stage Piaget (1966) called *secondary circular reaction*. During this time, infants can grasp the idea their actions can initiate pleasurable sensations. Now when infants reach for a mobile above the crib, hit it, and watch it move, they realize it was their hand that initiated the motion, and so hit it again.

Infants are still unaware of the permanence of objects by the end of this stage. For example, if an object is hidden from vision (a baby drops it from her hand or it is hidden by a blanket), an infant will not search for it: gone is gone. If any part of the object is exposed, the infant can visualize the whole object and will reach to obtain it.

Coordination of Secondary Schema

Infants of 10 months discover **object permanence**, or become aware an object out of sight still exists. Infants are ready for peek-a-boo once they have gained the concept of permanence. They know their parent still exists even when hiding behind a hand or blanket and wait excitedly for the parent to reappear. If a baby drops a piece of breakfast cereal or a spoon from a highchair tray, although it is out of sight, an infant knows it still exists and will reach for it. Piaget (1966) called this stage of cognitive development *coordination of secondary schema*.

As infants reach 1 year of age, they are capable of reproducing interesting events (they deliberately hit a mobile once; it moves; they hit it again) and producing new events. They drop objects from a highchair or playpen and watch where they fall or roll. This is a frustrating activity for caregivers because it involves a great deal of reaching and picking up. It is an important activity for infants, however, because it confirms their awareness of the permanence of objects and how they are able to control events in their world.

✔ Checkpoint Question 29.3

Which action would show that an infant has developed object permanence?

a. He looks for a Cheerio that falls off his highchair tray.
b. He cries when he is either hungry or lonely.
c. He prefers a large yellow ball to a small red one.
d. He smiles when the mobile on his crib jingles.

HEALTH PROMOTION OF AN INFANT AND FAMILY

The nursing role with infants is wide-ranging because infants are so dependent on their caregivers for safety, learning, and emotional development.

Promoting Achievement of Developmental Task: Trust Versus Mistrust

Erikson (1993) proposed that the developmental task of the infant period is to form a sense of trust. When an infant is hungry, a parent feeds and makes the infant comfortable again. When an infant is wet, a parent changes a diaper and the infant is dry again. When an infant is cold, a parent holds the baby closely. By this process, infants learn to trust that when they have a need or are in distress, a person will come and meet that need.

A synonym for trust in this connotation is love. By the way infants are handled, fed, talked to, and held, they learn to love and recognize they are loved. Infants who have numerous caregivers, who may be fed one day on a rigid schedule and the next only when they are hungry, who sometimes are treated roughly and sometimes gently, can have difficulty learning to trust. If infants cannot trust, they cannot enjoy deeply satisfying interactions with others and can have difficulty trusting themselves or experiencing high self-esteem. They may have difficulty establishing close relationships as adults.

It is important for infants to establish the ability to love, or trust, early in life this way because development is sequential. If a first developmental step is inadequate, this inadequacy can pervade all future steps. In reference to trust, the end result could be an adult unable to instill a sense of trust in a child, perpetuating the inadequacy from generation to generation.

How do parents (or a nurse) encourage a sense of trust in an infant? Trust arises primarily from a sense of confidence that one can predict what is coming next. This does not mean parents should set up a rigid schedule of care for a child. It does imply establishing some schedule—for example, breakfast, bath, playtime, nap, lunch, walk outside, quiet playtime, dinner, story, and bedtime. This gentle rhythm of care gives infants a sense of being able to predict what is going to happen and gives life some consistency. Infants thrive on routine such as the same story read over and over again at bedtime, or the same spoon every day for lunch. Infancy is not too early for children to learn family traditions such as decorating for a holiday that will help them feel secure in the world as they grow. Some parents have difficulty accepting routine as important to a child. They may be so

FIGURE 29.15 An infant's sense of trust develops through warm interpersonal relationships. Here a mother and baby share a "together" moment.

tired of their own work treadmill they want to raise their children as free spirits. Do not discourage this philosophy; however, you might suggest a few modifications to instill some order into infants' lives.

As important to an infant as the rhythm of care is that the care be given largely by one person (Fig. 29.15). This person can be the mother, father, grandparent, a conscientious babysitter, a foster parent, or anyone who can give consistent care. For infants ill at birth who are hospitalized for months, this person is often a primary nurse or case manager. You may have to encourage parents not to feel self-conscious talking to a baby who does not talk back. Pointing out the importance of such interactions and role-modeling them while caring for children help parents use this type of stimulation as they care for their baby's physical needs.

Women who work outside their home during the first year of a baby's life (at least 90% of women today) should try to arrange for one person to care for their child while they are away from home or choose a day care center that will provide a consistent caregiver. Urge them to discuss their methods of child care with alternative caregivers to prevent disrupting an infant's routine. When a child is admitted to a hospital, document and use this information.

Parents should make sure the caretaker they choose will actively interact with their child to provide a sense of trust. Passively caring for infants—not talking to them or touching or stroking them while feeding or changing them—amounts to not being with them. An increasing number of parents are installing video cameras to make sure a caretaker is actively interacting with their baby to instill a sense of trust in their child. Nursing actions designed to help an ill infant develop a sense of trust are detailed in Table 29.3.

Promoting Infant Safety

Accidents are a leading cause of death in children from 1 month through 24 years of age. They are second only to acute infections as a cause of acute morbidity and physician visits (National Vital Statistics System [NVSS], 2009).

Most accidents in infancy occur because parents either underestimate or overestimate a child's ability. Nursing interventions that help parents become sensitive to their infant's developmental progress not only help establish sound parent–child relationships but also guard infant safety (Forsythe et al., 2007) (Box 29.4).

Aspiration Prevention

Aspiration is a potential threat to infants throughout the first year. Round, cylindrical objects are more dangerous than square or flexible objects in this regard. A 1-inch (3.2-cm) cylinder, such as a carrot or hot dog, is particularly dangerous because it can totally obstruct an infant's airway. A deflated balloon can be sucked into the mouth, obstructing the airway in the same way. Educate parents who feed their infant formula not to prop bottles. By doing this, they are overestimating their infant's ability to push the bottle away, sit up, turn the head to the side, cough, and clear the airway if milk should flow too rapidly into the mouth and an infant begins to aspirate.

Other instances of aspiration occur because parents underestimate their infant's ability to grasp and place objects in their mouth. Even a newborn can wiggle to a new position to reach an attractive object such as a teddy bear with small button eyes. Newborns' grasp and sucking reflexes automatically cause them to grasp and pull the object into their mouth. Caution parents to be certain nothing comes within an infant's reach that would not be safe to put into the mouth. Using clothing without decorative buttons, and checking toys and rattles to ensure they have no small parts that could snap off or fall out, are good steps for parents to follow. A test of whether a toy could be dangerous if an infant puts it inside the mouth is whether it fits inside a toilet paper roll. If it does, it is small enough to be aspirated. When solid foods are introduced, encourage parents to offer small pieces of hot dogs or grapes, not large chunks for this reason. Children under about 5 years should not be offered popcorn or peanuts because of this danger of aspiration.

As infants become more adept at handling toys, parents need to reassess toys for loose pieces or parts. If parents are going to offer an infant a pacifier, they should use one that has a one-piece construction with a flange large enough to keep it from completely entering the child's mouth (Fig. 29.16).

Fall Prevention

Falls are a second major cause of infant accidents. As a preventive measure, no infant, beginning with a newborn, should be left unattended on a raised surface. Normal wiggling can bring a baby to the edge of a bed, couch, or table top, resulting in a fall.

Teach parents to be prepared for their infant to roll over by 2 months of age. From that time on, they must be especially vigilant not to leave the baby unattended on a changing table or counter. If the child sleeps in a crib, the mattress should be lowered to its bottom position so the height of the side rails increases; rails should be 2⅜ inches apart, narrow enough so children cannot put their head between them. Two months is about the maximum length of time infants can safely sleep in a bassinet; they need the protection of a crib and high siderails before they turn over.

TABLE 29.3 ✻ Ways for Nurses to Help an Ill Infant Develop a Sense of Trust

Area of Care	Nursing Actions
Nutrition	Encourage mothers to breastfeed if possible; provide privacy and support as necessary.
	Hold the infant no matter what feeding method is used (gavage, total parenteral, oral, enteral). If this is not possible, hold infants for a time after or between feedings so they receive holding equal to what they would ordinarily receive.
	If infant feeding is not oral, provide a pacifier (medical condition considered) five or six times daily for sucking pleasure.
	Hold and comfort after an episode of vomiting, even if not noticeably disturbing to an infant.
Dressing change	Use nonallergenic tape to avoid irritation while applied and pain when removed.
	Use a minimum of tape so the least amount has to be pulled free from sensitive skin (consider using stockinette, rolled gauze, or Kling gauze to hold a bandage in place rather than tape).
	To prevent chilling, be certain irrigation solutions are warm. Minimize exposure of the child during dressing changes to conserve warmth.
	Restrain only those body parts necessary for security.
	Talk to the infant. Hearing an explanation of what you are doing is comforting, not for the meaning of the words but for the nonthreatening tone of your voice.
Medicine administration	Flavor oral medicine to disguise disagreeable taste (being careful not to increase the amount to beyond what the child will take readily). Offer a drink of flavorful fluid afterward to counter medicinal taste.
	Never administer medicine in an infant's formula to prevent changing the formula's taste.
	Comfort the infant after injections or intravenous insertion by holding and rocking, or give immediately to a parent for this. Check intravenous sites frequently (every 30 min) for swelling to prevent infiltration and pain. Hold and play with infants despite tubing and restraints.
Rest	Encourage parents to sit and hold infants; infants sleep in a parent's arms as soundly as they do in bed.
	Rock infants to sleep if this is comforting. If contagion is not a problem, bring cribs to the nursing desk where infants can see you until they fall asleep.
	Always wake infants gently, because it is frightening (for anyone) to be awakened by a stranger.
	If bed rest is necessary, check for irritated elbows, heels, and knees from the infant's skin rubbing against sheets; protect with long sleeves or pants.
Hygiene	Check the temperature of bath water for comfort and to prevent chilling.
	Change diapers frequently to reduce discomfort from irritation.
	To avoid caries and prevent pain, begin tooth-brushing with first tooth.
Pain	Hold and comfort an infant in pain.
	Do not ask parents to hold a child during a painful procedure; it is difficult for them to see their child in pain. Allow them to comfort the child afterward.
	Reduce painful procedures to a minimum; combine blood drawing so only one puncture is necessary for many tests, etc.
Stimulation	Talk to infants while you care for them so they come to know you.
	Remember that infants focus longest on a human face.
	Provide a crib mirror or a mobile, because visual stimulation is satisfying to an infant.
	If no mobile is available, create one from a wire coat hanger, string, or strips of adhesive tape and objects that will suspend easily and are light enough to move from motion of the crib or an air current (colored paper, cotton balls, colored tongue blades). For safety, hang the mobile high enough for the infant to see but not reach.
	During the second half of the first year, remember that infants need to try to crawl. Put a pad or sheet on the floor and encourage infants to come to you or to explore on their own while you stand by to offer reassurance (this is almost impossible to accomplish in a crib).

All of these safety precautions apply to the hospital environment as well as to the home. Be sure crib sides are raised and secure before anyone walks away from the crib, even for just a moment. Also ensure that the space between the mattress and headboard is small enough an infant's head could not become trapped. Make sure cords from nursing call bells or safety pins are out of an infant's reach.

Car Safety

Teaching car safety for infants (as well as for the whole family) is a vital preventive health measure. The use of car seats for newborns is discussed in Chapter 18. Car seats should continue to be used without interruption through the preschool age, or until the child reaches 40 to 60 lb. If parents are firm about keeping infants in car seats even when they get fussy or impatient, children will eventually become more comfortable in seats than outside them. Infants up to 20 lb and 1 year old should be placed in rear-facing seats in the back seat because an inflating front-seat airbag could suffocate an infant (AAP, 2009).

Safety with Siblings

As infants become more fun to play with at about 3 months, older brothers and sisters grow more interested in interacting

BOX 29.4 ✻ Focus on Family Teaching

Accident Prevention Measures for Infants

Q. Bryan's mother is worried about keeping him safe. She asks, "How can I prevent accidents at this age?"

A. Here are some tips to help prevent specific types of accidents:

Potential Accident	Prevention Measures
General	Know the whereabouts of infants at all times. Be aware that the frequency of accidents is increased when parents are under stress. Take special precautions at these times. Choose babysitters carefully and explain and enforce all precautions when sitters are in charge.
Aspiration	Be certain any object that an infant can grasp and bring to the mouth is either safe to eat or too big to fit in the mouth. Do not feed an infant foods such as popcorn or peanuts, because these are easily aspirated. Store baby products such as powder out of infant's reach; powder is high risk for aspiration. Inspect toys and pacifiers for small parts that could be aspirated if broken off; do not make home-made pacifiers.
Falls	Never leave an infant on an unprotected surface, such as a bed or couch, even if the child is in an infant seat. Place a gate at the top and bottom of stairways; do not allow an infant to walk with a sharp object in the hands or mouth (it could pierce the throat in a fall). Raise crib rails and make sure they are locked before walking away from crib. Do not leave a child unattended in a highchair; avoid using an infant walker.
Motor vehicle	Never transport unless an infant is buckled into an infant car seat in the back seat of the car. Be aware of the proper technique for placing an infant in a car seat. Do not be distracted by an infant while driving. Do not leave an infant unattended in a parked car (can become dehydrated from excess heat, move gear shift, or be abducted).
Suffocation	Allow no plastic bags within infant's reach. Do not use pillows in a crib. Store unused appliances such as refrigerators or stoves with the doors removed. Buy a crib that is approved for safety (spacing of rails is not over 2⅜ in [6 cm] apart). Remove constricting clothing such as a bib from neck at bedtime.
Drowning	Do not leave infants alone in a bathtub or unsupervised near water (even buckets of cleaning water).
Animal bites	Do not allow an infant to approach a strange dog; supervise play with family pets.
Poisoning	Never present medication as a candy. Buy medications in containers with safety caps; put away immediately after use. Never take medication in front of infants. Place all medication and poisons in locked cabinets or overhead shelves. Never leave medication in a pocket or handbag. Use no lead-based paint in any area of the home. Hang plants or set on high surfaces. Post telephone number of the poison control center by the telephone.
Burns	Test warmth of formula and food before feeding (use extra precaution with microwave warming). Do not smoke or drink hot liquids while holding or caring for infant. Buy flame-retardant clothing for infants. Use a sunscreen on a child over 6 months when out in direct or indirect sunlight; limit the child's sun exposure to less than 30 min at a time. Turn handles of pans toward back of stove. Use a cool-mist, not a hot-mist, vaporizer; remain in room to monitor so child cannot reach vaporizer. Keep a screen in front of a fireplace or heater. Monitor infants carefully near candles. Do not leave infants unsupervised near hot-water faucets. Do not allow infants to blow out matches (don't teach children that fire is fun). Keep electric wires and cords out of reach; cover electrical outlets with safety plugs.

FIGURE 29.16 Many infants enjoy sucking on a pacifier to help them fall asleep. This may also help prevent sudden infant death syndrome.

with them. You may need to remind parents that children under 5 years of age, as a group, are not responsible enough or knowledgeable enough about infants to be left unattended with them. They might introduce an unsafe toy or engage in play that is too rough for an infant. Some preschoolers may be so jealous of a new baby they will physically harm an infant if left alone.

Bathing and Swimming Safety

As babies begin to develop good back support, many parents begin to bathe them in an adult tub. Caution parents never to leave an infant unattended in a tub, even when propped up out of the water or sitting in a bath ring or bath seat. Normal wiggling can easily cause a baby to slip down under the water. This applies to a hospital setting as well.

Many communities offer infant swim programs for babies as young as 6 months. If their child is enrolled in one of these programs, parents may become overconfident about their infant's ability to operate safely in water. Because children can dog-paddle momentarily in a swimming pool does not mean they can sustain that position for any length of time in a bathtub or pool. Being able to swim momentarily may also cause children to lose their instinctive fear of water and so be in more danger when around water than children who are still naturally more cautious. Such programs may also cause hypothermia and spread microorganisms because infants this age are not yet toilet-trained. Exposure to chlorinated water can damage lung epithelium that may be a precursor to childhood asthma (Bernard et al., 2007).

Childproofing

When infants begin teething at 5 to 6 months, they chew on any object within reach to lessen gum-line pain. Remind parents to check for possible sources of lead paint, such as painted cribs, playpen rails, or windowsills (Keefe, 2007). Paints safe for baby furniture should be marked "Safe for use on surfaces that might be chewed by children." If an infant is going to be allowed to play on the floor, parents should move furniture in front of electrical fixtures or buy protective caps for outlets. Infants are especially fascinated by the holes and will probe them with (often wet) fingers. Parents may need to install safety gates at the top and bottom of stairways as other safety measures.

Urge parents to move all potentially poisonous substances from bottom cupboards and store them well out of their infant's reach. Infants of any age should not be left unattended in carriages, highchairs, grocery shopping carts, or strollers. Baby walkers are extremely dangerous because infants can maneuver them near stairways and fall the length of the stairs.

When infants begin creeping, remind parents to recheck bottom cupboards and stairways for safety. When the child begins to walk, higher areas, such as coffee tables, need to be cleared of dangerous items. In a hospital setting, assess low counter areas for dangerous objects. Do not leave possibly dangerous supplies in an infant's room.

By 10 months, achievement of a pincer grasp makes infants able to pick up very small objects. Remind parents to check play areas or areas such as table tops for pins or other sharp objects that could be swallowed. Some of an infant's toys are now also 10 months old and need to be checked to be certain they are still intact and safe.

Children who can walk may venture into the street or a swimming pool if not carefully supervised (Fig. 29.17). Although they seem very independent and able to take care of themselves, their judgment about what is dangerous is immature. In a hospital setting, a 12-month-old child can

FIGURE 29.17 Once walking begins, the extended range of activities brings an infant in contact with potentially dangerous places or objects unless the house is childproofed. The bathroom is an important place to begin.

wander onto an elevator, out of the hospital, or into a laboratory area, or fall down a flight of stairs if not supervised (Forsythe et al., 2007).

✔ Checkpoint Question 29.4

You review infant safety with Bryan's mother. What are two of the most common types of accidents in infants?

a. Drowning and homicide.
b. Poisoning and burns.
c. Falls and auto accidents.
d. Aspiration and falls.

Promoting Nutritional Health of an Infant

The first choice for feeding an infant during the first 12 months of life is breast milk (see Chapter 19). All the necessary nutrients, vitamins, minerals, and water are provided by human milk for the first 6 months of life, with exception of vitamin K (1 mg intramuscularly is administered at birth); vitamin D (200 IU of oral vitamin D drops is administered daily beginning during the first 2 months of life if there is limited sunlight exposure); vitamin B_{12} if the mother is a strict vegetarian and takes no B_{12} supplement; and fluoride, but only if this is not included in the water supply (Thilo & Rosenberg, 2008). If a woman was iron deficient during pregnancy or has a low iron intake, supplemental iron may be indicated. How long mothers continue to breastfeed is an individual choice, although it is recommended through the entire first year (American College of Obstetricians and Gynecologists [ACOG], 2007). Early weaning from breastfeeding can lead to an increased incidence of obesity (Box 29.5). Prolonged breastfeeding into the preschool period can limit nutrients and might impair a child's growth.

BOX 29.5 ✻ Focus on Evidence-Based Practice

Does the timing of weaning affect infant weight?
Interested in answering this question, researchers assessed the feeding practices of 1-year-old infants through semistructured interviews with their mothers. They also had weights taken at birth, 8 weeks, 7 months, and 14 months. Half of the infants studied were weaned before 4 months (early weaning) and half of them were weaned later than 4 months (late weaning). Results of the study revealed that infants who were weaned early were heavier at 7 and 14 months and gained more weight between 8 and 14 months than those who were weaned later. The researchers concluded that early weaning is related to rapid weight gain in infancy.

Would the above study influence the advice you give parents on when is the ideal time to wean infants from breast or bottle to a cup?

Source: Sloan, S., et al. Early weaning is related to weight and rate of weight gain in infancy. *Child: Care, Health and Development, 34*(1), 59–64.

For infants whose mothers choose not to breastfeed, a commercial iron-fortified formula will supply adequate nutrition (Lawson, 2007) (see Appendix B). Supplementation is unnecessary with iron-fortified commercial formula unless the water supply does not contain fluoride. Infants who are changed to cow's milk before 1 year of age (a practice that is not recommended because the protein in cow's milk is difficult for an infant to digest, possibly leading to such intestinal irritation that slight but continuous gastrointestinal bleeding occurs, resulting in anemia) should receive a supplementary form of vitamin C and iron to make up for the deficiency of these components in cow's milk.

Recommended Dietary Reference Intakes for an Infant

Because children's nutritional needs vary from infancy through adolescence, the recommended allowances of calories, protein, vitamins, and minerals also vary with each period of development.

The entire first year of life is one of extremely rapid growth, so a high-protein, high-calorie intake is necessary. Both commercial formulas and breast milk contain 20 calories/oz. Calorie allowances can be gradually reduced during the first year from a level of 120 per kilogram of body weight at birth to approximately 100 per kilogram of body weight at the end of the first year to prevent babies from becoming overweight.

Although heredity plays a role, a baby who is overweight during the first year of life is more likely to become an obese adult than one whose weight is within normal limits as, once formed, fat cells (adipocytes) remain for life. Breastfed infants gain less weight than those who are formula fed. Delaying the introduction of solid food until 4 to 6 months and avoiding sweet drinks for infants can help avoid obesity in formula fed infants (Thilo & Rosenberg, 2008).

Introduction of Solid Food

From a nutritional standpoint, a normal full-term infant can thrive on breast milk or a commercial iron-fortified formula without the addition of any solid food until 4 to 6 months (Gomella & Haist, 2007). Delaying solid food until this time helps prevent overwhelming an infant's kidneys with a heavy solute load that can occur when protein is ingested. Although difficult to document, it also may delay the development of food allergies in susceptible infants and be another way to help prevent future obesity (Sass, 2007).

Most parents are eager to begin feeding their infant solid food, hoping this will help their child sleep through the night. Some parents do begin solid food before 6 months without apparent ill effects, possibly because much of the food is not processed by the gastrointestinal tract, passing through undigested because of the immaturity of the digestive system and decreased amylase and lipase secretion.

Generally speaking, infants are physiologically ready for solid food when they are nursing vigorously every 3 to 4 hours and do not seem satisfied or taking more than 32 oz (960 mL) of formula a day and do not seem satisfied. Infants are not ready to digest complex starches until amylase is present in saliva at approximately 2 to 3 months. Biting movements begin at approximately 3 months. Chewing movements do not begin until 7 to 9 months. Therefore, foods that require chewing should not be given until this age (Box 29.6).

BOX 29.6 ✻ Focus on Family Teaching

Tips to Help Introduce Solid Foods to Infants

Q. Bryan's mother has already started feeding him solid food. She asks, "When and how should I have begun solid foods?"

A. Infants typically are ready for solid food at 4 to 6 months of age. Use these guidelines to help when you start feeding your infant solid foods:

- Introduce one food at a time, waiting 5 to 7 days between new items.
- Introduce the food before formula or breastfeeding when an infant is hungry.
- Introduce small amounts of a new food (1 or 2 tsp) at a time.
- Respect infant food preferences; a child cannot be expected to like all new tastes equally well.
- Use only minimal to no salt and sugar on solid foods to minimize the number of additives.
- Remember that the extrusion reflex is present for the first 4 to 6 months of life, so any food placed on an infant's tongue will be pushed forward.
- To prevent aspiration, *do not* place food in bottles with formula.
- Introduce foods with a positive, "You'll like this" attitude.

Loss of Extrusion Reflex

When anything is placed on the anterior third of a newborn's tongue, it is automatically extruded or thrust out of the mouth by the tongue (extrusion reflex; Fig. 29.18). This is a life-saving reflex because it prevents infants from swallowing or aspirating foreign objects that touch the mouth. Infants extrude food when a spoonful of it is placed on the tongue in the same way. The reflex fades at 3 to 4 months. Until this time, it may be difficult to get an infant to eat solid food.

FIGURE 29.18 A 3-month-old baby demonstrates an extrusion reflex. Caution parents not to interpret this action as a food dislike but recognize it as the reflex action that it is.

Techniques for Feeding Solid Food

Table 29.4 shows the usual times and patterns for introducing solid food. Teach parents to offer new foods one at a time and allow a child to eat that item for about 1 week before introducing another new food. This system helps parents to detect possible food allergy. For example, if they start egg yolk on Monday and by Tuesday evening the child is breathing noisily or has a rash, they could suspect the child is allergic to eggs. If two new foods had been started on Monday, it would be hard to know which one was suspect. Introducing foods one at a time also helps to establish a sense of trust in infants, because it minimizes the number of new experiences in any one day.

It is best for the first solid food feeding if an infant is held in the parent's arms as if for bottle-feeding or breastfeeding. This reduces the newness of the experience and minimizes the amount of stress associated with it. Some infants accept new experiences of this type readily, whereas other infants

TABLE 29.4 ✻ Suggested Schedule for Introduction of Solid Foods

Age (mo)	Food to Introduce*	Rationale
5–6	Iron-fortified infant cereal mixed with breast milk, orange juice, or formula	Aids in preventing iron-deficiency anemia; the least allergenic type of food; an easily digested food
7	Vegetables	Good source of vitamin A; adds new texture and flavors to diet
8	Fruit	Best source of vitamin C, good source of vitamin A; adds new texture and flavors to diet
9	Meat	Good source of protein, iron, and B vitamins
10	Egg yolk	Good source of iron

*Wheat, tomatoes, oranges, fish, and egg whites should be omitted if there are allergies in the family, because these foods are most likely to cause allergies.
