resist heartily. If an infant does not take readily to solid food, advise parents to wait a few days and then try again. Remind them that this is not a contest to see whose child takes cereal, vegetables, or fruit first.

Babies have distinct taste preferences even at young ages and may spit out a food because they do not like the taste. Even after the extrusion reflex has faded (at approximately 4 months), infants may appear to be spitting out food. This is because infants drink from a bottle or breast by pressing their tongue and the nipple against their hard palate. When an infant tries to eat solid food using the same technique, it appears that the child is spitting it out with the tongue. A parent who knows an infant's cues will be able to distinguish taste preferences from inadequate management of solid food.

Quantities and Types of Food

Infants take different quantities of food according to their preferences and needs. A newborn's stomach can hold approximately 2 tablespoons (30 mL). By 1 year, a stomach can hold no more than about 1 cup (240 mL). For this reason, when they begin eating solid food, infants rarely take more than 2 tablespoons (30 mL) at a time.

Cereal. The first food generally given to infants is infant cereal fortified with B vitamins and iron. These are precooked, fine dry powders to which expressed breast milk or infant formula is added. Initially, cereal should be mixed with enough fluid to make the mixture fairly liquid. As an infant adjusts to eating food from a spoon, parents can gradually thicken it. Adding sugar to cereal is unnecessary. Extra sugar in the diet can lead to diarrhea in young infants and beginning caries in older infants.

Fortified cereal costs no more than unfortified cereal, so remind parents to buy the fortified product. The first cereal introduced is usually rice cereal, because fewer children are allergic to rice products than to wheat and corn products. Usually, it is offered twice a day, morning and evening. Once the child has taken rice cereal for 1 week, parents can try another kind.

Some parents mix cereal with an infant's formula and give it to the child from a bottle. Caution parents to avoid this practice because (a) it is necessary to cut a larger hole in the bottle nipple for the cereal and milk mixture to flow freely, and there is a danger an infant may aspirate if the hole cut is too big; (b) there is a real danger of aspiration if the parent then uses that nipple for formula without cereal added; and (c) it denies the child the opportunity of learning to eat from a spoon and experiencing different food tastes and textures.

Infant cereal is so rich in iron parents should continue feeding it at least through the first year. Ideally, children should eat infant cereal until age 3 or 4 years, as few popularly advertised products can match the nutrients of fortified infant cereal.

Vegetables and Fruit. Because their iron content is generally higher than that of fruits, vegetables are usually the second food added to the diet (at 5–7 months of age). Parents who have a blender, strainer, or grinder can prepare their own. They simply cook a vegetable and then blend or strain it so it does not have to be chewed. Caution parents not to add butter or salt to the preparation, because infants have difficulty digesting fats until almost the end of the first year, and the added salt is unnecessary. Additional sugar is also unnecessary. By filling ice-cube trays with the blended vegetables, parents can make a 1-week supply and defrost a cube at a time. An ice cube is approximately 1 oz, or one-fourth the size of a jar of baby food.

If parents use commercial baby food, they should feed it from a dish rather than directly from the jar. This is because if the spoon carries salivary enzymes from an infant's mouth to the food, the enzymes will quickly liquefy what remains in the jar. Also, there is danger of transferring bacteria (principally streptococci) from an infant's mouth to the jar. Then, if the parent keeps the jar for another feeding in the next 24 hours, bacteria will multiply rapidly because the contents serve as a culture medium. Baby food jars should be refrigerated once they are opened, and manufacturers recommend they be used no longer than 48 hours after they were first opened.

When vegetables are added to the diet, they are usually offered at lunch. Remind parents to offer both green and yellow vegetables. Help them to remember that their own dislike of a particular vegetable does not mean their child will feel the same way about it. If they do convey distaste for a food, their child will pick up on the feeling and will not like the vegetable either.

Fruit is usually offered 1 month after beginning vegetables (at 6–8 months). It can be given in addition to cereal for breakfast and dinner. Raw mashed banana is easy to prepare with just a fork; peaches are easily prepared in a blender. As with vegetables, parents should offer a selection so an infant is exposed to different tastes and textures.

Meat and Eggs. Meat is usually introduced at 9 months. Parents can grind a portion of the meat they have prepared for their own meal so it is tender, or they can use commercially prepared products. If they use commercial baby meat, urge them to use the plain meat products, not vegetable and meat dinners, because these contain mostly vegetables. Chicken has the advantage of being low in cholesterol, but this is not a priority with infants. Beef and pork have more iron than chicken, so encourage parents to offer these more frequently than chicken. When meat is added to an infant's diet, it is usually added as part of the evening meal in place of cereal.

Egg yolks are offered by 10 months of age. Egg yolks contain the bulk of the iron content of eggs; the white contains the bulk of protein. Egg yolk alone should be given at first, because the protein of the egg white can lead to allergy or can be difficult for an infant to digest. Eggs may be prepared by hard-boiling (then adding a little formula or breast milk to the mashed yolk to make it more liquid) or purchased as commercial baby food. Soft-boiling or poaching is not usually recommended, because salmonella, the chief offending microorganism that may be in eggs, may not be killed by these methods. Also, thorough cooking makes protein easier to digest.

Table Food. With the introduction of solid food, encourage parents to establish a three-meal-a-day pattern, if that is the family's lifestyle, and to have the infant join the family at the table. Generally, encourage parents to use homemade foods rather than relying on commercially prepared junior foods,

although commercial foods are now prepared without excessive additives and are convenient for parents who have little preparation time. Mashed potatoes or peas and cut-up meatloaf are examples of table foods that infants older than 6 months of age like to eat and busy parents can prepare quickly. If hot dogs are offered, caution parents to cut them into small bite-size portions; otherwise, they can be aspirated. As infants begin teething, they enjoy dried bread, teething biscuits, or zwieback.

Some infants are too distracted by the activity at a family table to eat well. Parents may find these children eat more if they are fed first and then allowed to have a small amount to "feed themselves" or a cracker to chew on while just sitting at the table and being with the family.

Remind parents that highchairs are one of the most dangerous pieces of baby equipment they own. Urge them always to fasten the restraint and never leave an infant unattended in a highchair, because even a 6-month-old can squirm out of a chair with little effort. Nurses must also keep this in mind when feeding infants in a hospital setting.

Establishment of Healthy Eating Patterns

Some parents may need to be reminded that although rules for infant feeding are designed to promote healthy nutrition, they should individualize their approach according to the cues their child is giving them for readiness.

A child who adapts to change poorly may have difficulty accepting the first solid food, for example, and may have difficulty with each new food. Parents may need support to remember a child is not conducting this struggle out of a desire for conflict but because this is a characteristic of temperament. Giving food to others is interpreted by many as giving love, so refusing food is equated with refusing love. Help parents understand this is not what is happening. Refusing a teaspoonful of carrots is refusing a teaspoonful of carrots, nothing more.

Most infants, however, eat hungrily so feeding problems tend to be reported more frequently as a second-year or toddler problem than as an infant concern. If an infant does refuse to eat, ask the parents what foods they are offering. Have them list exactly the types and amounts of foods the child ate the day before (a 24-hour dietary recall history). It may be apparent from this that enough is being eaten in a day's time and that the parents' expectations are unrealistic for the child's size and age.

If intake is inadequate and the child is, indeed, a fussy eater, ask about the parents' methods of feeding. For example, ask if they are offering a bottle first and then infant food. Infants generally accept the new experience of eating from a spoon better when they are hungry, not when their stomach is full. On the other hand, some babies, particularly those with an intense temperament, may be so hungry at mealtime they cannot tolerate the frustration of spoon-feeding until some of their hunger is relieved. They may need to drink 2 or 3 oz of formula or nurse at the breast for a few minutes before they will eat a spoonful of food.

An infant who is fatigued or overstimulated may not eat well. Providing a quiet environment away from older brothers or sisters before mealtime may solve this problem.

Encourage parents not to force infants to eat if they do not seem hungry. Healthy, happy infants will be hungry at mealtime and will eat. Those who refuse a meal may be tired, distracted, or perhaps ill. Forcing only leads to regurgitation or, if they are ill, vomiting. It also can result in feeding problems or a situation in which infants refuse to eat altogether. Infants who are eating and not thriving or not eating and therefore not thriving should be examined to determine if a cause such as a metabolic disorder or failure to thrive exists (see Chapters 48 and 55).

Weaning

Infants are capable of approximating their lips to a cup so they can drink effectively from one at about 9 months of age. The sucking reflex begins to diminish in intensity between ages 6 and 9 months, which makes this the time to consider weaning.

To wean from formula or breast milk, the mother chooses one feeding a day and then begins offering fluid by the new method at that feeding. She should choose a time of day that is not an infant's fussy period; other than that, the time is immaterial. After 3 days to 1 week, when an infant has become acclimated to the one change, the mother changes a second feeding. Should an illness such as an upper respiratory infection occur or should the child have teething discomfort, there will be setbacks, so no set number of weeks should be prescribed to complete weaning. Infants usually need more fluid during hot weather than cold weather because of increased perspiration. This may make it more difficult to begin weaning during the summer.

Self-Feeding

At approximately 6 months of age, infants become interested in handling a spoon and beginning to feed themselves. Their coordination, unfortunately, has not developed enough for them to use a spoon without a great deal of spilling, so they are much more adept at feeding themselves with their fingers (Fig. 29.19). Parents concerned with neatness can spread newspapers, a plastic tablecloth, or a towel on the floor around a highchair to catch most of the dropped food, and then let the child practice. When an infant becomes fatigued or frustrated at attempts of self-feeding, a parent can then quietly help without

FIGURE 29.19 Self-feeding is not always a neat process for an infant.

making an issue of it. Parents who insist on continuing to spoon-feed past the time infants want to feed themselves can cause infants to balk at eating. Often, a compromise is helpful. If a parent gives the infant a spoon, the child can poke at a cereal dish with it while the parent continues to offer bites from a second spoon. In this way, a child is "in charge" of the feeding yet receptive to taking food from the parent.

When infants no longer attempt to feed themselves at a meal but merely begin to play with their food by squeezing it through their fingers or dabbing it in their hair, it is time to end the meal. This behavior indicates that they have had enough.

Adequate Intake With a Vegetarian Diet

An infant eating a vegetarian diet should continue to be breastfed or ingest an iron-fortified, balanced, commercial formula for the entire first year. If a milk allergy is present, a soy-based formula can be used. When solid foods are added at 6 months, an assortment of foods should be provided, including vegetables such as avocados, potatoes, and broccoli; fruits such as apples, prunes (high in iron), and bananas; infant cereal; tofu; wheat germ; legumes; brewer's yeast; and synthetic vitamin D. Feeding fortified cereal throughout the first year will ensure that iron stores are built. If the diet is to include dairy products, these can be added toward the end of the first year as usual (Conti, 2008).

Because vegetarian diets are high in fiber, infants who eat them may have more frequent and looser-than-normal bowel movements. Teach parents to change diapers frequently to avoid skin irritation. Using less fibrous, more concentrated forms of protein, such as tofu and powdered nuts rather than cereal mixtures, can minimize this problem.

A sound vegetarian diet can be easily designed for the older infant who prefers finger foods, because many vegetables, fruits, and grains such as pieces of oranges, peaches, tomatoes, and crackers and protein or Quom for protein are easily eaten this way (Theobald, 2007).

What if... Bryan's grandmother tells you she believes children should always finish everything on their plate, so as not to waste food? Is always cleaning a plate a good or bad habit for parents to enforce? Why or why not?

Promoting Infant Development in Daily Activities

In the first year, caring for an infant—feeding, bathing, dressing, and so forth—occupies what may seem like nearly all of the parents' waking hours. Worrying about their infant's sleep patterns may take up the rest of their time, often because the parents are not getting enough sleep themselves. All of these basic care-related activities provide important opportunities for caregivers and infants to get to know one another and to become used to each other's personalities and patterns. Nurses can play a key role in teaching parents about these activities and stressing their importance.

Bathing

Except in very hot weather, an infant does not need a bath every day. If a parent is tired and would not enjoy bath time or if some days are just too rushed, a complete bath can be omitted, with only an infant's face, hands, and diaper area washed. Some infants do need their head and scalp washed frequently (every day or every other day) to prevent **seborrhea,** a scaly scalp condition often called cradle cap (Smoker, 2007). If seborrhea lesions do develop, they adhere to the scalp in yellow, crusty patches. The skin beneath them may be slightly erythematous. The patches can be softened by oiling the scalp with mineral oil or petroleum jelly and leaving it on overnight. The crusts can then be removed by shampooing the hair the next morning. A soft toothbrush or fine-toothed comb can be used to help remove crusts.

FIGURE 29.20 An 8-month-old enjoys bath time with his big brother. Parents should always watch carefully while infants and toddlers are in the tub.

Bath time should be fun for an infant and can serve many functions other than just the obvious one of cleanliness (Fig. 29.20). Especially during the second half of the first year, an infant enjoys poking at soap bubbles on the surface of the water or playing with bath toys. Bath time also helps an infant learn different textures and sensations and provides an opportunity to exercise and kick, as well as a good opportunity for a parent to touch and communicate with the child. Teach parents *not* to leave infants alone in tubs as they could easily slip under the water.

Diaper-Area Care

The most effective means of promoting good diaper-area hygiene is to change diapers frequently, about every 2 to 4 hours. However, it is rarely good practice to interrupt the child's sleep to change diapers. If an infant develops a rash from sleeping in wet diapers, air drying or sleeping without a diaper may be a solution.

At each diaper change, the parents should wash the skin with clear water or with a commercial alcohol-free diaper wipe (and perfume-free if an infant has sensitive skin), then pat or allow to air dry. Routinely using an ointment such as Desitin or A&D ointment to keep urine and feces away from an infant's skin is good prophylaxis. Parents do not need to use baby powder. If they choose to, advise them to sprinkle the powder on their hands first, and then apply it to an infant's skin. Caution them not to shake the powder on an infant, to reduce the possibility of aspiration. They should place the container out of the infant's reach after-

ward, or an infant could easily spill it into his mouth and aspirate it.

Care of Teeth

It is well accepted that exposing developing teeth to fluoride is one of the most effective ways to promote healthy tooth formation and prevent tooth decay. The most important time for children to receive fluoride is between 6 months and 12 years of age. A water level of 0.6 ppm fluoride is recommended because this is the level that protects tooth enamel yet does not lead to staining of teeth. In communities where the water supply does not provide enough fluoride, the use of an oral fluoride supplement beginning at 6 months or the use of fluoride toothpaste or rinses after tooth eruption is recommended (Armfield & Spencer, 2007).

Teach parents to ask about the presence of fluoride in the drinking water in their community and help them to determine what, if any, supplementation is necessary. Breastfed infants do not receive a great deal of fluoride from breast milk, so it may be recommended they be given fluoride drops once a day. Teach parents to begin "brushing" even before teeth erupt by rubbing a soft washcloth over the gum pads. This eliminates plaque and reduces the presence of bacteria, creating a clean environment for the arrival of the first teeth. Once teeth erupt, all surfaces should be brushed with a soft brush or washcloth once or twice a day. Children lack the coordination to brush effectively until they are school-age, so parents must be responsible for this activity well past infancy. Toothpaste is not necessary for an infant, because it is the scrubbing that removes the plaque.

The initial dental checkup should be made by 1 year of age; checkups should continue at 6-month intervals until adulthood.

Dressing

Clothing for infants should be easy to launder and simply constructed, so dressing and undressing are not a struggle. Infants enjoy kicking and making gross body movements, so their clothing should not be binding. When they begin to creep, they need long pants to protect their knees. Until they begin to walk, they need only soft-soled shoes or merely socks or booties to keep their feet warm. Even when they begin walking, the soles of their shoes need only be firm enough to protect their feet against rough surfaces. Extremely hard soles and high ankle sides are unnecessary.

Sleep

Sleep needs and habits vary greatly among infants, but most require 10 to 12 hours of sleep at night and one or several naps during the day. Parents are usually advised to let a baby sleep in a separate space rather than in their bed so the parents do not awaken at every toss and squeak. Doing so allows infants to learn to quiet themselves and go back to sleep should they awaken briefly. This may help prevent sleep problems such as night waking in the future. Other parents prefer to have infants sleep with them in a family bed, as they believe this practice promotes a feeling of security (Baddock et al., 2007). Bed sharing also promotes breastfeeding but also has the danger of accidental suffocation. Caution parents not to place pillows in an infant's bed to avoid suffocation. Always place infants on their back to sleep because this position markedly reduces the incidence of sudden infant death syndrome (SIDS). Use of a pacifier while an infant sleeps may further reduce this risk (Damato, 2007). See Chapter 26 for a further discussion of SIDS.

Exercise

Infants benefit from outings in a carriage or stroller because sunlight provides a natural source of vitamin D. In hot weather, caution parents to protect an infant from sunburn by exposing the child to the sun for only very short periods, beginning with 3 to 5 minutes the first day, a little more the next day, and so on up to 15 to 20 minutes at a time. The sun is most intense between 10 AM and 3 PM, so early mornings and late afternoons are the best times for infants to be outside. These short time spans are necessary because the use of sunscreen is not recommended in children until they are at least 6 months old (Lim, 2008).

Toward the end of the first year, infants need space to crawl and then to walk, such as in an enclosed outdoor play space. In addition to providing fresh air, going for leisurely walks while pointing out the sights of the world—trees, birds, dogs, houses, neighbors—helps children develop language.

Parents can judge how much outdoor clothing to put on an infant by how much they need themselves. If an adult needs a winter coat, an infant will need a snowsuit; sweaters may be adequate for both; if an adult needs no outer clothing, an infant probably does not either.

It is not necessary to enroll infants in formal exercise programs for them to secure adequate exercise. Such programs may put unusual strain on muscles and tendons. Infants using infant walkers must be closely supervised, because they can be injured if they maneuver the walker too near a stairway and fall.

Promoting Healthy Family Functioning

A primary task of parents during the infant year is to learn to interpret infants' cues to decipher their needs. It is helpful if they can learn early on to perceive an infant as a separate individual with unique needs. This becomes an easier task by 2 months, when infants can indicate by their particular cry whether they are feeling cold, hungry, wet, or lonely. Parents spend a great deal of time with their infant in these first months, which gives them the opportunity to learn and recognize nonverbal cues and to become aware of their baby's needs.

Parental Concerns and Problems Related to Normal Infant Development

Some of the difficulties parents are apt to have in evaluating the health of infants are shown in Table 29.5. New parents may need reassurance and answers to questions about childcare procedures or health during an infant period because they have not yet learned their child's cues. However, the need for reassurance may be just as great in experienced parents. The unique characteristics of each child require some adjustment from parents.

Teething

Most infants have little difficulty with teething, but some appear very distressed. Generally, the gums are sore and tender

TABLE 29.5 ✻ Common Difficulties Parents Experience in Evaluating the Health of Infants

Difficulty	Suggestions for Improving Assessment
Evaluating pain	Infants manifest pain by fussiness. They can reveal arm and leg pain by immobility of the body part; ear pain by brushing or tugging at the ear; stomach pain by pulling up the legs against the abdomen.
Evaluating degree of reduced activity	Lack of interest in smiling or interaction is an important observation. Increased sleeping or lying supine with legs nonflexed (frog-legged) as if exhausted is important.
Evaluating infant temperature	All parents should learn how to take an axillary or tympanic temperature so they can report a specific degree of fever rather than a subjective finding, such as "feels hot."
Evaluating amount of vomiting or diarrhea	Knowing the number of times vomiting and/or diarrhea has occurred is important. Estimating amount in comparisons with what the child has eaten is helpful as well as estimating an amount (a cupful, etc.). Knowing whether diapers are "soaked" or "stained" with stools is important in estimating amount. Caution parents that vomiting and diarrhea are always serious in infants.

before a new tooth breaks the surface. As soon as the tooth is through, the tenderness passes.

Because of this pain, infants can be resistant to chewing for a day or two and be slightly cranky, possibly because they are a little hungry from not eating as much as usual. High fever, seizures, vomiting or diarrhea, and earache are never normal signs of teething. An infant with any of these symptoms has an underlying infection or disease process requiring further evaluation.

Many over-the-counter medicines are sold for teething pain. As a rule, their use should be discouraged if they contain benzocaine, a topical anesthetic, because if applied too far back in the throat, this could interfere with the gag reflex. Acetaminophen (Tylenol), 10 to 15 mg/kg every 4 hours, up to four times a day, may be used for teething discomfort but parents should check with their infant's health care provider before giving any over-the-counter drug this way. Teething rings that can be placed in the refrigerator provide soothing coolness against the tender gums. An infant who is teething will place almost any object in the mouth, so parents must screen articles within the baby's reach to be certain they are edible or safe to chew.

Thumb-sucking

Sucking is a surprisingly strong need: prenatal ultrasounds even demonstrate fetal thumb-sucking in utero. Many infants begin to suck a thumb or finger at about 3 months of age and continue the habit through the first few years of life. The sucking reflex peaks at 6 to 9 months, whereas thumb-sucking peaks at about 18 months.

Parents can be assured that thumb-sucking is normal and does not deform the jaw line as long as it stops by school age. It does not cause "baby talk" or any of the other symptoms commonly attributed to it. The best approach is to be certain an infant has adequate sucking pleasure and then to ignore thumb-sucking. Making an issue of it rarely causes a child to stop; if anything, it usually intensifies and prolongs it.

Use of Pacifiers

Whether to use pacifiers is a question parents must settle for themselves, depending on how they feel about them and their infant's needs. Infants rarely have such a need for sucking they must have a pacifier in their mouth constantly. Discussing a few pros and cons with the parents clarifies the subject. Use of a pacifier at bedtime may reduce the risk of SIDS as, with a pacifier, a baby rouses periodically from sleep to suck and so does not continue for an extended time in deep phases of sleep.

An infant who completes a feeding and still seems restless and discontent, who actively searches for something to put into the mouth, or who sucks on hands and clothes may need a pacifier. Babies who have colic crave sucking and enjoy pacifiers because their abdomen hurts, and they interpret this as a hunger sensation. If a child is formula fed, parents should check nipples to be certain the holes are small and the rubber is sturdy, so that an infant can suck hard enough to derive pleasure. If the nipples are satisfactory, parents could offer a pacifier after feeding for more sucking. Freudian theory proposes that a child whose sucking needs are met in infancy will not crave as much oral stimulation later in life and is less likely to become a pencil chewer, cigarette smoker, or nail biter or develop pica, the eating of nonfood substances (Nurcombe, 2008).

A major drawback of pacifiers is the problem of cleanliness. If used at times other than bedtime, they tend to fall on the floor or sidewalk and are then put back into an infant's mouth. If not well constructed, they may come apart and be aspirated. Hanging a pacifier on a string around an infant's neck could cause strangulation.

Parents should attempt to wean a child from a pacifier any time after 3 months of age and certainly during the time the sucking reflex is fading at 6 to 9 months unless used at night for sleeping, as the AAP recommends using pacifiers at bedtime as a possible way to reduce the incidence of SIDS (Damato, 2007). Weaning after this age is difficult because a pacifier becomes a comfort mechanism, like a warm blanket or fuzzy toy to which a child may cling.

Head Banging

Some infants rhythmically bang their heads against the bars of a crib for a period of time before falling asleep. This is distressing behavior for parents. Besides fearing that children will hurt themselves, some parents may have heard that blind

children or those with mental illness do this and worry that their child is ill in some way.

Head banging in this limited fashion—beginning during the second half of the first year of life and continuing through to the preschool period, associated with naptime or bedtime, and lasting under 15 minutes—can be considered normal. Children use this measure to relax and fall asleep. Investigating stress factors operating in the house may be helpful. If some of them can be relieved such as parents' overestimation of the child's development, marital discord, illness in another family member, the head banging may decrease, or it may have already become such a strong habit that it will persist for months or even years.

Advise parents to pad the rails of cribs so infants cannot hurt themselves, and reassure them this is a normal mechanism for relief of tension in children of this age. No therapy should be necessary. Excessive head banging done to the exclusion of normal development or activity, or head banging past the preschool period, suggests a pathologic basis, and such children then need a referral for counseling and further evaluation.

Sleep Problems

Sleep problems develop in early infancy because of colic or because an otherwise healthy infant takes longer than usual to adjust to sleeping through the night. Breastfed babies tend to wake more often than those who are formula fed because breast milk is more easily digested, so infants become hungry sooner. In late infancy, the problem of waking at night and remaining awake for an hour or more becomes common. Although an infant may be content and not cry during this time, parents are reluctant to sleep while the child is awake, so they may become extremely fatigued. This is an increasing concern because more and more families today consist of two wage-earning parents; there is no time for parents to nap during the day to make up for sleep lost at night. Suggestions for eliminating or at least coping with night waking are (a) delay bedtime by 1 hour; (b) shorten an afternoon sleep period; (c) do not respond immediately to infants at night so they can have time to fall back to sleep on their own; and (d) provide soft toys or music to allow infants to play quietly alone during this wakeful time. Reassuring parents that infants take varying lengths of time to adjust to night sleeping is helpful in assuring them their child is normal. Suggesting parents use the time they are awake at night to do such things as solve a problem at work, watch the late show, or plan a shopping list may help them view the situation as a constructive time rather than a problem.

Constipation

Breastfed infants are rarely constipated because their stools tend to be loose. Constipation may occur in formula-fed infants if their diet is deficient in fluid. This can be corrected simply with the addition of more fluid.

Some parents misinterpret the normal pushing movements of a newborn to be constipation. When infants defecate, their faces do turn red, and they grimace and grunt. As long as stools are not hard and contain no evidence of fresh blood (as might occur with a rectal fissure), this is normal infant behavior.

If constipation persists beyond 5 or 6 months of age, encourage parents to check with the infant's health care provider about measures to relieve this. Adding foods with bulk, such as fruits or vegetables, and increasing fluid intake generally relieves the problem. Apple juice (3 or 4 oz) or prune juice (0.5 to 1 oz daily) may be given as a temporary measure.

All infants with a history of constipation for more than 1 week should be examined for an anal fissure or tight anal sphincter. Softening stools and thereby relieving the pain of defecation often solves the problem and helps the fissure to heal. If an unusually tight anal sphincter exists, parents will be given instructions to manually dilate the sphincter two or three times daily until it dilates sufficiently. One of the first symptoms of Hirschsprung's disease (aganglionic megacolon, or lack of nerve innervation to a portion of the colon) is constipation. If no stool is present in the rectum of a constipated infant on rectal examination, this disease is suggested (Sondheimer, 2008). A careful history must then be taken to assess for other symptoms of Hirschsprung's disease: ribbon-like stools, bouts of diarrhea, and a distended abdomen (see Chapter 45).

Chronic constipation also may occur in children with congenital hypothyroidism (decreased functioning of the thyroid gland). Therefore, an infant with constipation also should be carefully observed for characteristic signs of hypothyroidism, such as lethargy, protruding tongue, and failure to meet developmental milestones (see Chapter 48). Infants with either Hirschsprung's disease or hypothyroidism need therapy to correct the disorder.

Loose Stools

Many new parents are unfamiliar with the consistency or color of normal newborn stools, so they mistakenly report normal stooling as diarrhea. Stools of breastfed infants are generally softer than those of formula-fed infants. If a mother takes a laxative while breastfeeding, an infant's stools may be very loose. An infant who is formula fed can have loose stools if the formula is not diluted properly.

Occasionally, loose stools may begin with the introduction of solid food, such as fruit. Malabsorption syndrome (celiac disease), or an inability to digest fat, may manifest themselves first by loose stools and a distended abdomen and deficiency of fat-soluble vitamins (see Chapter 45).

When talking to a parent about loose stools, ask about the duration of the loose stools, the number of stools per day, their color and consistency, and whether there is any mucus or blood in them. Is there associated fever, cramping, or vomiting? Does an infant continue to eat well? Appear well? Seem to be thriving? Is an infant wetting at least six diapers daily?

Infants with associated signs and symptoms such as fever, cramping, vomiting, loss of appetite, a decrease in voiding, and weight loss should be examined by their health care provider because this suggests an infectious process. Dehydration occurs rapidly in a small infant who is not eating and is losing body fluid through loose stools.

Colic

Colic is paroxysmal abdominal pain that generally occurs in infants under 3 months of age and is marked by loud, intense crying (Bolte, 2007). An infant cries loudly and pulls the legs up against the abdomen. The infant's face becomes red and flushed, the fists clench, and the abdomen becomes tense. If offered a bottle, the infant will suck vigorously for

a few minutes as if starved, then stop as another wave of intestinal pain occurs.

The cause of colic is unclear. It may occur in susceptible infants from overfeeding or from swallowing too much air while drinking. Formula-fed babies are more likely to have colic than breastfed babies, possibly because they swallow more air while drinking or because formula is harder to digest.

Although infants continue to thrive despite colic, the condition should not be dismissed as unimportant. It is a distressing and frightening problem for parents not only because an infant appears to be in acute pain, but also the distress persists for hours, usually into the middle of the night, so no one in the family gets adequate rest. This is a difficult beginning to a parent–child relationship, which needs to be strong and binding for the parents to enjoy parenting and for an infant to thrive in their care (see Focus on Nursing Care Planning Box 29.7).

Take a thorough history of an infant with signs of colic because intestinal obstruction or infection may mimic an at-

BOX 29.7 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for an Infant With Colic

You meet Ms. Simpson, 19, at a pediatric clinic when she brings in her 2-month-old son, Bryan. She looks tired. She tells you that she is exhausted because her baby is "awake all night, crying constantly." She stopped breastfeeding and changed him to formula to see if that would help. It didn't. She tells you his bowel movements are normal. When you weigh Bryan, you find he has gained weight well. When you talk to him, he demonstrates a social smile.

Family Assessment ✻ Infant lives with single parent and her family (grandfather, grandmother, 26-year-old uncle, and 22-year-old aunt). Grandmother cares for infant while mother works as an exotic dancer from 12 noon to 6 PM.

Client Assessment ✻ Well-proportioned 2-month-old boy. Height and weight at 50th percentile on growth chart. Bottle feeding with intake of approximately 4 oz of commercial formula every 4 hours. Experiencing 2 or 3 soft yellow bowel movements daily. The mother reports, "He's been crying every night lately from about 6 PM till 9 PM. His face gets red, and he pulls his legs up against his belly. I give him a bottle, he sucks for a few minutes like he's starving, and then stops, pulls up his legs, and starts to cry. He's good for my mother in the afternoon; cries from six to nine at night for me. I'm at the end of my rope." Physical examination within normal limits. Diagnosis of colic is made.

Nursing Diagnosis ✻ Compromised family coping related to difficulty managing infant crying episodes

Outcome Criteria ✻ Parent expresses increased confidence in caring for infant and increased feeling of control over situation within 1 week; infant sleeps for at least some of 6 PM to 9 PM period.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Assess what infant's total day is like to try and identify why crying seems confined to evenings.	Make suggestions as needed to see that different caregivers use consistency in care.	Infants with several daily caretakers can have difficulty adjusting to changing feeding techniques.	Parent details a day history for infant.
		Consultations		
Nurse	Determine which nurse practitioner is available for consultation.	Contact nurse practitioner to do physical exam to ensure infant is healthy.	A physical exam will differentiate symptoms of colic from another more serious problem.	Nurse practitioner completes physical exam and makes recommendations.
		Procedures/Medications		
Nurse	Assess what steps parent has taken to try and relieve symptoms.	Suggest the use of a pacifier, sitting infant upright, feeding in quiet environment, riding in car, etc.	Sucking on a pacifier may increase peristalsis and promote passage of gas. An upright position may prevent distention.	Parent states she is willing to try new measures such as a pacifier.

		Nutrition		
Nurse	Assess how parent prepares formula; what technique she uses for bottle feeding and burping infant.	Review methods for formula preparation, bottle holding, and burping as needed; be certain other family members are consistent.	Proper techniques can minimize the amount of air swallowed and possible subsequent development of intestinal gas.	Parent describes formula preparation and infant feeding methods. Confirms other family members are consistent.
		Patient/Family Education		
Nurse	Assess what parent knows about colic, including its incidence, usual timing, symptoms, etc.	Educate parent about common characteristics of colic, including duration, timing, and intensity of crying.	Education promotes better understanding of the problem, alleviating some of the stress and anxiety associated with it.	Parent states she understands symptoms of colic and how common it is in newborns.
		Psychosocial/Spiritual/Emotional Needs		
Nurse/nurse practitioner	Assess what parent thinks is the cause of her infant crying so much in the evening.	Reassure parent she is not the cause of the child's discomfort. It's a coincidence she is giving care at the time colic occurs.	A parent can feel guilty if she is unable to soothe child. Reassurance the problem is not her fault can aid in objective problem solving.	Parent states she understands the problem is not a personal one.
Nurse	Assess parent's level of stress about constant crying.	Caution parent that crying in infants produces frustration in adults. Help parent plan respite time if possible to give relief.	Acknowledging their frustration helps to validate their feelings. A plan of action provides opportunities to regain some control over the situation. Time away can help relieve feelings of frustration and tension.	Parent states she is frustrated but also ready to work on solving problem.
		Discharge Planning		
Nurse	Urge the parent to call for further suggestions if further help is needed. Explain colic generally resolves by 3 months of age.	Advise parent to contact clinic if measures are ineffective by 1 week.	Medication to reduce colic symptoms may be prescribed if nonpharmacologic measures are not effective.	Parent agrees to call in 1 week if crying has not improved.

tack of colic and be misinterpreted by the casual interviewer. Ask parents about the duration of the problem and its frequency (it usually lasts up to 3 hours a day and occurs at least 3 days every week). Ask what happens just before the attack (Colic usually occurs at a time removed from a feeding), and ask the parent to describe the attack itself and associated symptoms. Document the number and type of bowel movements the infant has, because bowel movements are not abnormal with colic. Constipation; narrow, ribbonlike stools; and the presence of blood or mucus in the stool all suggest other problems. A family medical history is important to obtain because allergy to milk may simulate colic.

Determine the baby's feeding pattern (breastfed or bottle fed). If bottle fed, ask about the type of formula and how it is prepared. Ask parents if they are holding the baby upright so air bubbles can rise and whether they burp the infant adequately after feeding. For a breastfed baby, a change in maternal diet such as avoiding "gassy" foods like cabbage might be helpful to reduce or limit colicky periods. It may be helpful to recommend that both breast- and formula-fed infants receive small, frequent feedings to prevent distention and discomfort. Offering a pacifier may be comforting.

Some parents try placing a hot water bottle on their infant's stomach for comfort, but this should be discouraged. A basic rule for any abdominal discomfort is to avoid heat in case appendicitis is developing. This is highly unlikely in so young an infant, but parents will remember they once used heat and may use it again when the child is older. Hot water bottles and heating pads also might burn the delicate skin of infants.

Changing formula bottles to the type with disposable bags that collapse as the baby sucks may help minimize the amount of air swallowed. Taking infants for car rides is often reported as being helpful in soothing colicky babies. Some music boxes simulate the sound of a heartbeat, which also may be helpful. Antiflatulent agents such as simethicone have not been shown to be helpful but may be tried (Srinivasan & Middleton, 2008).

It is important to think of colic as a family problem or else a vicious circle may begin. An infant cries and the parents become tense and unsure. An infant senses the tension and develops more colic. Help parents plan relief time from infant care to relieve their stress level and prevent this cycle.

In most infants, colic disappears almost magically at 3 months of age, probably because it becomes easier to digest food and an infant maintains a more upright position by this time, which allows less gas to form.

Spitting Up

Almost all infants spit up, although formula-fed babies appear to do it more than breastfed babies. Parents who did not handle their infant much in the health care facility where their child was born may discover spitting up only after they take the baby home. They may interpret this as vomiting or think an infant is developing an infection. Ask them to describe carefully what they mean by "spitting up." How long has the baby been doing it? How frequently? What is the appearance of the spit-up milk? Almost all milk that is spit up smells at least faintly sour, but it should not contain blood or bile.

A baby who spits up a mouthful of milk (rolling down the chin) two or three times a day (or sometimes after every meal) is experiencing normal, early-infancy spitting up. Associated signs such as diarrhea, abdominal cramps, fever, cough, cold, or loss of activity suggest illness. If an infant is spitting up so forcefully that milk is projected 3 or 4 feet away, it may be beginning pyloric stenosis (an abnormally tight valve between the stomach and duodenum), which requires surgical intervention. If the spitting up is a large amount with each feeding, parents may be describing gastroesophageal reflux, in which a lax cardiac sphincter from the stomach into the esophagus allows regurgitation of gastric contents into the esophagus. This also requires medical attention (see Chapter 45).

Burping a baby thoroughly after a feeding often limits spitting up. Parents may try sitting an infant in an infant chair for half an hour after feeding. Changing formulas generally is of little value. Reassure parents that spitting up decreases in amount as the baby becomes better at coordinating swallowing and digestive processes (the cardiac sphincter matures). In the meantime, a bib can protect the baby's clothing and the parent. After a few months, the child will naturally stay in an upright position longer, and gravity will help to correct the problem.

Diaper Dermatitis

Some infants have such sensitive skin that diaper dermatitis (diaper rash) is a problem from the first few days of life. It occurs for several reasons.

When parents do not change a child's diaper frequently, feces is left in contact with skin, and irritation may result in the perianal area. Urine that is left in diapers too long breaks down into ammonia, a chemical that is extremely irritating to infant skin. Ammonia dermatitis of this type is generally a problem in the second half of the first year of life, when an infant is producing a larger quantity of urine than before. For some infants, however, it is a problem from the first week.

Frequent diaper changing, applying A&D or Desitin ointment, and exposing the diaper area to air may relieve the problem. Some infants may have to sleep without diapers at night to control the problem.

Whenever the entire diaper area is erythematous and irritated so that the outline of the diaper on the skin can be identified, one must suspect an allergy to the material in the diaper or to laundry products if a commercially washed or home-washed diaper is being used. Changing the brand or type of diaper or washing solution usually alleviates this problem.

If a diaper area is covered with lesions that are bright red, with or without oozing, last longer than 3 days, and appear as red pinpoint lesions, suspect a fungal (monilial or candidiasis) infection. This is discussed in Chapter 43.

Miliaria

Miliaria, or prickly heat rash, occurs most often in warm weather or when babies are overdressed or sleep in overheated rooms. Clusters of pinpoint, reddened papules with occasional vesicles and pustules surrounded by erythema usually appear on the neck first and may spread upward to around the ears and onto the face or down onto the trunk.

Bathing an infant twice a day during hot weather, particularly if a small amount of baking soda is added to the bath water, may improve the rash. Eliminating sweating by reducing the amount of clothing on an infant or lowering the room temperature should bring almost immediate improvement and prevent further eruptions.

Infant Caries (Baby-Bottle Syndrome)

Putting an infant to bed with a bottle of formula, breast milk, orange juice, or glucose water can result in aspiration. It also can lead to decay of all the upper teeth and the lower posterior teeth (Fig. 29.21) (Yost & Li, 2008). Decay occurs

FIGURE 29.21 Baby-bottle syndrome. Notice the extensive decay in the upper teeth. (From K. L. Boyd, DDS/Custom Medical Stock Photograph.)

because while an infant sleeps, liquid from the propped bottle continuously soaks the upper front teeth and lower back teeth (the lower front teeth are protected by the tongue). The problem, called **baby-bottle syndrome**, occurs because the carbohydrate in solutions such as formula or glucose water ferments to organic acids that demineralize the tooth enamel until it decays.

To prevent this problem, advise parents never to put their baby to bed with a bottle. If parents insist a bottle is necessary to allow a baby to fall asleep, encourage them to fill it with water and use a nipple with a smaller hole to prevent the baby from receiving a large amount of fluid. If the baby refuses to drink anything but milk, the parents might dilute the milk with water more and more each night until the bottle is down to water only.

Obesity in Infants

Obesity in infants is defined as a weight greater than the 90th to 95th percentile on a standardized height/weight chart. Obesity occurs when there is an increase in the number of fat cells because of excessive calorie intake. Preventing obesity in infants is important because the extra fat cells formed at this time are likely to remain throughout childhood and even into adulthood. If a child becomes obese because of overingestion of milk, iron-deficiency anemia may also be present because of the low iron content of both breast and commercial milk. Once infant obesity begins, it is difficult to reverse, so prevention is the key (Farrow & Blissett, 2008).

Overfeeding in infancy often occurs because parents were taught to eat everything on their plate, and they continue to instill this concept in their children. This occurs most often with formula-fed infants whose parents urge them to empty their bottle or finish a cereal serving. It can occur any time parents automatically feed an infant when the child cries, rather than investigating what the cry might really mean. As a general rule, an infant should take no more than 32 oz of formula daily. When solid food is introduced, a bottle of water can be substituted for formula at one feeding. Nonfat milk should not be given because it contains so little fat that essential fatty acid requirements may not be sufficient to ensure cell growth.

Another way to help prevent obesity is to add a source of fiber, such as whole-grain cereal and raw fruit, to an infant's diet. These prolong the stomach-emptying time, so they can help reduce food intake. Caution parents about giving obese infants foods with high amounts of refined sugars, such as pudding, cake, cookies, and candy. Encourage parents to learn more about balanced nutrition and to provide this for their entire family.

Concerns of the Family With a Cognitively or Physically Challenged or Chronically Ill Infant

An infant born with a cognitive or physical challenge or an illness is usually hospitalized immediately after birth for diagnosis and treatment. This can result in delayed bonding because the newborn is separated from the parents during this time. Encourage parents to visit an intensive care nursery regularly to help form a strong parent–child attachment. If parents cannot visit, urge them to call the hospital as frequently as they can to inquire about their child. In addition, nurses can supply digital photographs of an infant for parents to take home.

Many of the developmental events of the infant year (social smile, laughing out loud, reaching for an object, uttering the first word, sitting, talking) are activities that encourage parent–child interaction because they make an infant fun to be with and naturally make a parent want to spend more time with the child. Children who are cognitively challenged may not reach these milestones. Children who are physically challenged may be unable to achieve them as well if they cannot reach up and pat their mother's face or hold out arms to be picked up by a father. If children cannot interact with parents in these ways, parents may find themselves equally unable to interact with their children. If infants leave the hospital with a cast or other equipment such as a ventilator for care, parents may be so concerned with these items that they cannot initiate normal singing and playing activities with their children.

To encourage a good parent–child relationship, point out the positive things an infant can do. Perhaps the child's facial expression says, "Pick me up," even though he does not reach up with his hands; perhaps his eyes follow his mother's actions even though he cannot yet call to her.

Helping parents to interact more fully with their infants helps to build a sense of trust in an infant. Without a sense of trust, children have difficulty expressing themselves to others; they may not believe they are lovable or people would want to interact with them. Physically challenged individuals, no matter what their ages, need people around them to give them help at whatever point they cannot meet their own needs. It is unfortunate when physically challenged children cannot reach out for help because they do not have a sense of trust.

Infants who are cognitively or physically challenged or chronically ill experience the same health and growth problems as other infants. Parents may be reluctant to bring up these concerns at health care visits because they believe such problems pale in comparison to the primary illness or condition. When taking the health histories of children with chronic or longstanding medical problems, ask parents about secondary concerns. "What about everyday things? Any problems there?" Treat these concerns seriously, so parents can feel confident about bringing them to your attention at future health care visits. Also mention they are part of normal infant development so parents can begin to view their child apart from the primary illness.

Teething pain, discomfort from diaper rash, and colic are all potential problems in infancy and may occur even more frequently in babies with other illnesses. For instance, parents may not want to "bother" an ill infant with physical care as often as they would a well child. Before homes were well-heated, bathing an ill infant could cause extensive chilling, and many people still believe bathing is not appropriate for ill children. Colic may occur because parents are reluctant to tire ill infants by burping them after a feeding. Parents' attention may be so focused on the primary health problem rather than on everyday concerns, such as diaper care, that diaper dermatitis occurs. The bowel movements of physically disabled or chronically ill children may be looser than normal because of a liquid diet or medicine. Their urine may be more concentrated because of reduced intake. These conditions may also lead to diaper rash. Offering anticipatory guidance to parents can go a long way toward helping them avoid this special concern of infancy.

Nutrition and the Cognitively or Physically Challenged Infant

Nutrition is often a concern for infants who are born physically challenged or are ill at birth. Infants who have fevers because of illness have increased metabolic needs and require more calories than normal. To compound the problem, ill children may become too fatigued to take adequate feedings. If any degree of neurologic involvement exists, sucking and swallowing reflexes may not be coordinated. With gastrointestinal involvement, feeding may be impossible.

To ensure adequate calorie and protein intake, infants may need to be maintained on nasogastric tube or gastrostomy feedings, or total parenteral nutrition. These methods limit the amount of sucking that is possible. Because sucking provides pleasure as well as satisfying thirst, this is a major loss. Provide an infant with nonnutritive sucking experiences if possible to fill this need.

Infants who are ill for a long time may not eat solid foods eagerly once they are introduced because they are not hungry enough to be interested in a new eating method. Help parents to experiment with different foods to find a taste that does appeal to ill children, or teach them to limit foods to only those the child appears to like most from all five food groups to ensure the infant receives adequate nutrition.

✔ Checkpoint Question 29.5

Bryan's mother is concerned about him developing baby-bottle syndrome. What would be her best action to prevent this?

a. Use plastic rather than glass bottles.
b. Boil formula to reduce the curd.
c. Do not put Bryan to bed with a bottle.
d. Check the expiration date on formula.

Key Points for Review

- The infant period is from 1 month to 12 months. Children typically double their birth weight at 4 to 6 months and triple it at 1 year.
- Infants develop their first tooth at about 6 months; by 12 months, they have six to eight teeth.
- Important gross motor milestones during the infant year are lifting the chest off a bed at 2 months, sitting at 6 to 8 months, creeping at 9 months, "cruising" at 10 to 11 months, and walking at 12 months.
- Important fine motor accomplishments are the ability to pass an object from one hand to the other (7 months) and a pincer grasp (10 months).
- Important milestones of language development during the first year are differentiating a cry (2 months), making simple vowel sounds (5 to 6 months), and saying two words besides "ma-ma" and "da-da" (12 months). The more infants are spoken to, the easier it is for them to acquire language.
- Providing infants with proper toys for play helps development. All infant toys need to be checked to be certain they are too large to be aspirated.
- Important milestones of vision development are the ability to follow a moving object past the midline (3 months) and ability to focus securely without eyes crossing (3 months).
- According to Erikson, the developmental task of the infant year is the development of a sense of trust versus mistrust.
- Safety is important. Infants must be protected from falls and aspiration of small objects. A skill an infant cannot accomplish one day, such as crawling, may be accomplished the next.
- Solid food is generally introduced into an infant's diet at 4 to 6 months of age. Before infants can eat solid food, they must lose their extrusion reflex.
- Common concerns related to infant development include teething, thumb-sucking, use of pacifiers, sleep problems, constipation, colic, diaper dermatitis, baby-bottle syndrome (decayed teeth from sucking on a bottle of formula while they sleep), and obesity. Nurses play a key role in teaching parents about these problems and measures to deal with them.
- Remember that parent–infant attachment is critical to mental health. Urge parents to continue to give as much care as possible to sick infants to maintain this important relationship.

CRITICAL THINKING EXERCISES

1. Bryan, the 2-month-old boy you met at the beginning of the chapter, was diagnosed with colic. What are common suggestions you could make to his parents to help reduce his discomfort and crying?
2. Bryan's mother wants to "childproof" her house. What questions would you ask to assess whether the infant's house is safe for him?
3. Bryan's father tells you that he has difficulty feeding Bryan solid food because Bryan "spits out" everything he tries to get him to eat. How could you help this father parent better?
4. Examine the National Health Goals related to growth and development of the infant. Most government-sponsored funds for nursing research are allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to Bryan's family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to nursing care of the family with an infant. Confirm your answers are correct by reading the rationales.

Chapter

30 Nursing Care of a Family With a Toddler

KEY TERMS

- assimilation
- autonomy
- deferred imitation
- discipline
- lordosis
- parallel play
- preoperational thought
- punishment
- tertiary circular reaction stage

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe normal growth and development of a toddler as well as common parental concerns.
2. Identify National Health Goals related to the toddler age group that nurses can help the nation achieve.
3. Use critical thinking to analyze methods of care for toddlers to be certain care is family centered.
4. Assess a toddler for normal growth and development milestones.
5. Formulate nursing diagnoses related to toddler growth and development or parental concerns regarding growth and development.
6. Identify expected outcomes for nursing care of a toddler.
7. Plan nursing care to meet a toddler's growth and development needs, such as anticipatory guidance to prevent problems such as sleep disturbances.
8. Implement nursing care to promote normal growth and development of a toddler, such as discussing toddler developmental milestones with parents.
9. Evaluate expected outcomes for achievement and effectiveness of care.
10. Identify areas related to care of a toddler that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of toddler growth and development with nursing process to achieve quality maternal and child health nursing care.

Jason is a 2½-year-old boy you see at a pediatric clinic. His mother tells you he has changed completely in the past 6 months from an easy-to-care-for baby into a "monster" who refuses to do anything she asks. The only word he says anymore is "no." He has a temper tantrum every night at dinner over some type of food. She tells you this has changed parenting from "fun" to "a real chore."

The previous chapter discussed the growth and development of infants and abilities infants develop in the first year. This chapter adds information about the dramatic changes, both physical and psychosocial, that occur during the toddler years. These changes form the basis for care and health teaching for this age group.

What advice could you give Jason's mother to help her regain a positive view of parenting?

During the toddler period, the age span from 1 to 3 years, enormous changes take place in a child and, consequently, in a family. During this period, children accomplish a wide array of developmental tasks and change from largely immobile and preverbal infants who are dependent on caregivers for the fulfillment of most needs to walking, talking young children with a growing sense of **autonomy** (independence). To match this growth, parents must also change during this period. If a parent enjoyed being the parent to an infant because time could be spent rocking or singing to the child, they may not enjoy being the parent of a toddler as now their task is to support their child's growing independence with patience and sensitivity and to learn methods for handling the child's frustrations that arise from the quest for autonomy. Because healthy children and families are constantly being challenged by the process of normal development, parents often have questions about how to guide their children in different situations and how to cope with special needs and concerns relevant to this age. National Health Goals related to the toddler age group are shown in Box 30.1.

Nursing Process Overview

For Healthy Development of a Toddler

Assessment

Whether a child is seen for a routine checkup or has come to a health care center because of a specific health concern, assessment begins with taking a careful health history. Asking parents about a toddler's ability to carry out activities of daily living offers assessment information not only on the child's developmental progress but also important clues about the child–parent relationship.

Careful observation is another crucial element of nursing assessment of a toddler. This is because parents may become so emotionally involved in a health concern they may not describe it with complete objectivity. On the other hand, parents see their children daily and so are the best source of information and opinion on when a child seems to be acting "out of sorts" or "different" (a typical sign a child may not be feeling well).

Nursing Diagnosis

Nursing diagnoses related to normal growth and development of toddlers usually focus on the parents' eagerness to learn more about the parameters of normal growth and development or issues of safety or care. Examples are:

- Health-seeking behaviors related to normal toddler development
- Deficient knowledge related to best method of toilet training
- Risk for injury related to impulsiveness of toddler
- Interrupted family process related to need for close supervision of 2-year-old
- Readiness for enhanced family coping related to parents' ability to adjust to new needs of child
- Readiness for enhanced parenting related to increased awareness for poison prevention
- Disturbed sleep pattern related to lack of bedtime routine

Outcome Identification and Planning

To help parents resolve a concern during the toddler period, focus largely on family education and anticipatory guidance. Urge them to establish realistic goals and outcomes so they can meet the rapidly changing needs of their toddler and learn to cope with typical toddler behaviors. Otherwise, parents can expect too much of a toddler and grow frustrated instead of enjoying being a parent of a child this age. Helpful Web sites about growth and development to recommend are the BabyCenter (http://www.Babycenter.com) and Dr. Greene (http://www.Dr Greene.com). Helpful Web sites to alert parents about safety are the American Association of Poison Control Centers (http://www.aapcc.org) and the American Academy of Pediatrics (http://www.aap.org). For questions about car seats, parents can consult the U.S. Department of Transportation National Highway Traffic Safety Administration (http://www.nhtsa.dot.gov). The national 800 telephone number for a poison control center is 1-800-222-1222.

Implementation

When teaching about typical toddler behavior, teach parents a good rule is to think of a toddler as a visitor from a foreign land who wants to participate in everything the family is doing but does not know the customs or the language. They need to help their toddler learn these the same as they would that stranger.

Also teach parents not only how to approach a current problem but also how to learn adequate methods for resolving similar situations that are sure to arise in the future. If parents do not learn methods that can be applied throughout their child's growing years, they may win bat-

BOX 30.1 * Focus on National Health Goals

Several National Health Goals relate specifically to safety during the toddler years. These are:

- Increase the rate of use of child automotive restraints in children 4 years and younger to 100% from a baseline of 92%.
- Eliminate elevated blood lead levels in children or improve from a baseline level of 4.4% of children 1 to 16 years of age to 0%.
- Reduce the proportion of children 2 to 4 years of age who have dental caries in their primary or permanent teeth from a baseline of 18% to 11%.
- Reduce the rate of deaths caused by poisonings, from a baseline of 6.8 per 100,000 to 1.5 per 100,000 (http://www.nih.gov).

Nurses can help the nation achieve these goals by continuing to educate parents about the importance of using car seats and childproofing their homes against poisoning. Areas that could benefit from additional nursing research are methods parents can use to keep their toddlers entertained while in automobiles and specific home situations in which poisoning is apt to occur.

tles but lose wars. For instance, parents may find that promising children a treat when they are in the middle of a temper tantrum will stop the tantrum, but it will not prevent other tantrums from occurring in the future (and, in fact, may encourage them). Health visits provide opportunities to help parents learn healthy coping techniques. In addition, demonstrating good communication skills with toddlers can serve as a model for healthy communication behavior with them.

Outcome Evaluation

Expected outcomes must be evaluated frequently during the toddler period because children change so much and learn so many new skills during this time that their abilities and associated parental concerns can change from day to day. Examples of expected outcomes are:

- Parents state child maintains a consistent bedtime routine within the next 2 weeks.
- Parents state they have childproofed their home by putting a lock on kitchen cupboard by next clinic visit.
- Grandmother states she has modified usual activities to conserve strength to care for toddler granddaughter by 1 week's time.

GROWTH AND DEVELOPMENT OF A TODDLER

Assessment of a toddler centers on the child's physical growth and skill development (Panpanich & Gardner, 2009). Box 30.2 describes a typical toddler appearance. Table 30.1 provides some guidelines to help parents evaluate illness at this age.

Physical Growth

While toddlers are making great strides developmentally, their physical growth begins to slow.

Weight, Height, and Head Circumference

Plot weight and height on a standard growth chart at each health care visit (see Appendix E) to determine if progress is normal for that particular child. A child gains only about 5 to 6 lb (2.5 kg) and 5 in (12 cm) a year during the toddler period, much less than the rate of infant growth. As subcutaneous tissue, or baby fat, begins to disappear toward the end of the second year, the child changes from a plump baby into a leaner, more muscular little girl or boy. A toddler's appetite decreases accordingly, yet adequate intake of all nutrients is still essential to meet energy needs (Rolfes, Pinna, & Whitney, 2009).

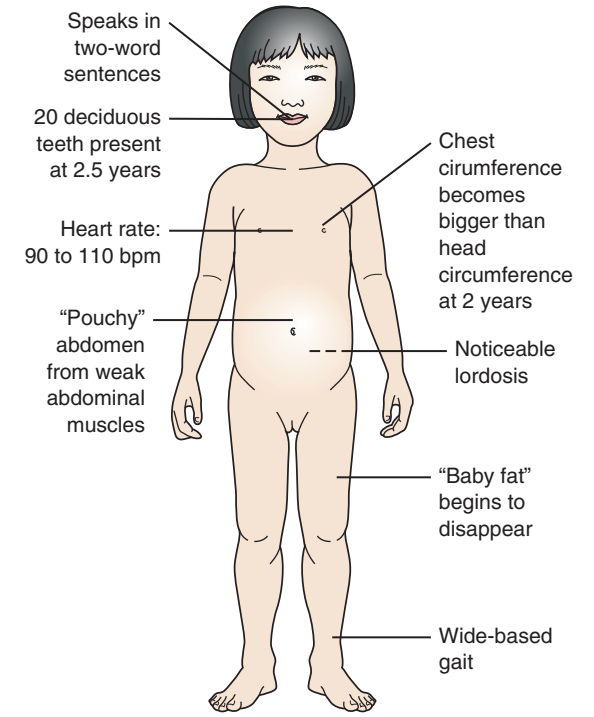
Head circumference increases only about 2 cm during the second year compared to about 12 cm during the first year. Head circumference equals chest circumference at 6 months to 1 year of age. By 2 years, chest circumference has grown greater than that of the head.

Body Contour

Toddlers tend to have a prominent abdomen because although they are walking well, their abdominal muscles are not yet strong enough to support abdominal contents as well as they will later (Fig. 30.1A). They also have a forward curve of the spine at the sacral area **(lordosis).** As they become more experienced at walking, this will correct itself naturally. Many toddlers, in addition, waddle or walk with a wide stance (see Fig. 30.1B). This stance seems to increase the lordotic curve, but it keeps them on their feet.

Box 30.2 Assessment

Assessing the Average Toddler



Body Systems

Body systems continue to mature during this time:

- Respirations slow slightly but continue to be mainly abdominal.
- The heart rate slows from 110 to 90 beats per minute; blood pressure increases to about 99/64 mm Hg.
- The brain develops to about 90% of its adult size.
- In the respiratory system, the lumens of vessels enlarge progressively so the threat of lower respiratory infection becomes less.
- Stomach secretions become more acid; therefore, gastrointestinal infections also become less common.
- Stomach capacity increases to the point a child can eat three meals a day.
- Control of the urinary and anal sphincters becomes possible with complete myelination of the spinal cord so toilet training is possible.
- IgG and IgM antibody production becomes mature at 2 years of age. The passive immunity obtained during intrauterine life is no longer operative.

TABLE 30.1 ✻ Parental Difficulties in Evaluating Illness in a Toddler

Problem	Guidelines for Parents
Evaluating seriousness of illness	Toddlers typically answer "No" to almost all questions. A question such as "Does your arm hurt?" may bring a "No" response even if the arm does hurt. Observing children for indications of illness (holding an arm stiffly, rubbing abdomen, crying when they void) is more helpful. Many toddlers do not know the words to describe a feeling of nausea or a sore throat. They reveal these symptoms by not eating. If the child is normally a light eater, as many are, it is difficult for a parent to appreciate these signs.
Differentiating tiredness from illness	Toddlers tend to whine or sleep when they are either tired or ill. Reviewing the child's day and activity often helps to evaluate what is happening. If the child is not tired (it is not nap or bedtime), or there is not a break in usual routine, crying and whining or temper tantrums suggest illness.
Evaluating nutritional intake	Toddlers are normally fussy eaters compared to infants. Evaluating children regarding whether they are active and growing is better than assessing any one day's food intake. Check weekly intake history.
Age-specific diseases to be aware of	The toddler period is an important age to assess speech development; children should be further evaluated if they cannot use simple sentences composed of a noun and verb ("me go") by 2 years of age. As children begin to walk, they should be observed for abnormal gait. Osteomyelitis (bone infection) occurs with a high frequency in toddlers; symptoms of limping, swollen joints, or arm or leg pain should be regarded as serious until ruled otherwise. Toddlers contract 10–12 mild upper respiratory infections a year. Otitis media (middle ear infection) may occur as a complication of these. The child with an upper respiratory infection who suddenly develops a high fever and pulls or manipulates ears should be seen by a physician. Children who attend day care programs have a high incidence of hepatitis A, *Giardia,* and *Shigella* infections. Teach parents to report jaundice or diarrhea promptly to a health care provider to detect these infections.

A B

FIGURE 30.1 Physical characteristics of toddlers. (**A**) Toddlers typically have a prominent abdomen. (**B**) Toddlers typically walk with an unsteady gait for better stability.

Teeth

Eight new teeth (the canines and the first molars) erupt during the second year. All 20 deciduous teeth are generally present by 2.5 to 3 years of age (Gonsalves, 2008).

Developmental Milestones

The developmental milestones of the toddler years are less numerous but no less dramatic than those of the infant year, because this is a period of slow and steady, not sudden, growth. Toddler development is influenced to some extent by the amount of social contact and the number of opportunities children have to explore and experience new degrees of independence. It is strongly influenced by individual readiness for a new skill. Table 30.2 highlights growth and development milestones of gross and fine motor, language, and play development of the toddler years.

Language Development

Toddlerhood is a critical time for language development, although even this varies among children, because to master language, children need practice time. A child who is 2 years old and does not talk in two-word, noun–verb simple sentences needs a careful assessment to determine the cause. This is beyond a point of normal development. Parents are often worried that lack of language means their child has autism (Johnson, 2008). A delay in language can represent only a temporary setback in development, however.

A word that is used frequently by toddlers and that is a manifestation of their developing autonomy is "no." Toddlers may use the word to mean they are refusing a task, or they do not understand it, or they may only be practicing a sound that they have noticed has potent effects on those around them.

To learn other words, children need exposure to conversation and need to be read to often. Language develops most quickly if parents respect what toddlers have to say so children grasp the use and purpose of language.

Urge parents to encourage language development by naming objects as they play with their child ("ball," "block," "music box," "doll") or when they give their toddler something ("Here is your drink of water," "Let's put on these pajamas," and so on). This helps children grasp the fact that words are not meaningless sounds; they apply to people and objects and have uses. Always answering a child's questions is another good way to do this. Be sure answers for toddlers are simple and brief because they have such a short attention span.

Some toddlers do not develop language readily because they are not called on to use it. When they point at an object, someone hands it to them; when they climb into their highchair, someone places a meal in front of them. In other families, an older child may speak for a younger one. To assess whether parents are encouraging language development, ask them what happens when the child wants something. Do they provide opportunities for the child to ask for things before they supply them? Children should not be made to name an object before they can have it (because their vocabulary is so limited, the objects they could have would be

TABLE 30.2 ✻ Milestones of Toddler Growth and Development

Age (Months)	Fine Motor	Gross Motor	Language	Play
15	Puts small pellets into small bottles. Scribbles voluntarily with a pencil or crayon. Holds a spoon well but may still turn it upside down on the way to mouth	Walks alone well; can seat self in chair; can creep upstairs	4–6 words	Can stack 2 blocks; enjoys being read to; drops toys for adult to recover (exploring sense of permanence)
18	No longer rotates a spoon to bring it to mouth	Can run and jump in place. Can walk up and down stairs holding onto a person's hand or railing. Typically places both feet on one step before advancing.	7–20 words, uses jargoning; names 1 body part	Imitates household chores, dusting, etc.; begins parallel play (playing beside not with another child)
24	Can open doors by turning doorknobs, unscrew lids	Walks up stairs alone still using both feet on same step at same time	50 words, 2-word sentences (noun-pronoun and verb), such as "Daddy go," "me come"	Parallel play evident
30	Makes simple lines or strokes for crosses with a pencil	Can jump down from chairs	Verbal language increasing steadily. Knows full name; can name one color and holds up fingers to show age	Spends time playing house, imitating parents' actions; play is "rough-housing" or active

restricted to 10 or fewer), but parents can reinforce language by rewording a question; for example, "You want the ball?" Reading aloud strengthens vocabulary in the same way. Reading the exact words in a book is not as important to toddlers as pointing to the pictures that accompany them. For example, Jane threw the ball ("See Jane throwing the ball?") or the dog ran away with the ball ("Look, that dog took that ball!").

Children who are very active may use fewer words than children who are less active. Active children are too busy doing things to describe what they are doing or too busy obtaining objects to need to ask for many things. Such children probably have a large unexpressed vocabulary, however, or understand more words (comprehensive vocabulary) than can be expressed (expressive vocabulary).

Because children learn language from imitating what they hear, they will speak like those around them. If they are spoken to in baby talk, their enunciation of words can be poor; if they hear examples of bad grammar, they will not use good grammar. Remind parents that pronouns are difficult for children to use correctly; many children are 3½ or 4 years of age before they can separate the different uses of "I," "me," "him," and "her." Bilingual children interchange words from both languages.

✔ Checkpoint Question 30.1

What type of sentence should Jason, a 2-year-old, have mastered?

a. "Red ripe tomatoes."
b. "Daddy come."
c. "Old MacDonald."
d. "Please, please."

Emotional Development

Children change a great deal in their ability to understand the world and how they relate to people during the toddler years.

Autonomy. The developmental task of the toddler years according to Erikson (1993) is the development of a *sense of autonomy versus shame or doubt*. Children who have learned to trust themselves and others during the infant year are better prepared to do this than those who cannot trust themselves or others.

To develop a sense of autonomy is to develop a sense of independence. A healthy level of autonomy is achieved when parents are able to encourage independence while still maintaining consistently sound rules for safety. Children who are constantly told not to try things because they will hurt themselves may be left with a stronger sense of doubt than confidence at the end of the toddler period. Children who are made to feel it is wrong to be independent may leave the toddler period with a stronger sense of shame than autonomy.

Infants appear to have difficulty differentiating between their bodies and those of others; they think of their bodies as extensions of their parents or their primary caregivers. When infants approach toddlerhood, they begin to make the differentiation. As they recognize they are separate individuals, they also realize they do not always have to do what others want them to do. From this realization comes the reputation toddlers have for being negativistic, obstinate, and difficult to manage.

This reputation is little deserved, however, and exists largely because parents misinterpret children's cues. For example, children's refusal to accept help putting on shoes may be seen by a parent as disobedience, whereas children may view this as insisting on performing a task they can do independently—a positive expression of autonomy.

Socialization. Once toddlers are walking well, they become resistant to sitting in laps and being cuddled. This is not lack of a desire for socialization but a function of being independent. At 15 months, children are still enthusiastic about interacting with people, providing those people are willing to follow them where they want to go. By 18 months, toddlers imitate the things they see a parent doing, such as "study" or "sweep," so they seek out parents to observe and initiate interactions. By 2 or more years, children become aware of gender differences and may point to other children and identify them as "boy" or "girl."

Play Behavior. All during the toddler period, children play beside children next to them, not with them. This side-by-side play (called **parallel play**) is not unfriendly but is a normal developmental sequence that occurs during the toddler period (Fig. 30.2). Caution parents that if two toddlers are going to play together, they must provide duplicate toys or an argument over one toy is likely to occur (Goldson & Reynolds, 2008). Toddlers who have an aggressive personality probably have the most difficulty adapting to play groups (Box 30.3).

The toys toddlers enjoy most are those they can play with by themselves and that require action. Trucks they can make go, squeaky frogs they can squeeze, waddling ducks they can pull, rocking horses they can ride, pegs they can pound, blocks they can stack, and a toy telephone they can talk into are all favorites. These are all toys children can control, giving them a sense of power in manipulation, an expression of autonomy (Fig. 30.3).

Some parents are not prepared for this change in play habits in their child. They wonder why a child who used to

FIGURE 30.2 Parallel play. The toddler usually plays alongside another child rather than cooperatively.

BOX 30.3 ✻ Focus on Evidence-Based Practice

Do aggressive preschool children have lower cognitive ability than nonaggressive children?

To explore the association between cognitive ability and temperament, researchers evaluated 31 children who had previously been rated as aggressive on the Aggressive Behavior Scale of the Achenbach Child Behavior Checklist. Their cognitive ability and temperament were then assessed using the Differential Ability Scale and the Carey Temperament Behavioral Styles Questionnaire respectively. Analysis showed that three different groups of children emerged. The first group (41.9% of the sample) demonstrated low adaptability, low persistence, high activity, negative mood, and low rhythmicity, along with borderline-deficient cognitive scores. The second group (38.7%) demonstrated low adaptability, low persistence, high activity, and negative mood, along with average cognitive scores. The third group (19.4%) demonstrated essentially midrange temperament characteristics and average cognitive scores. All three groups shared the temperamental tendency of a high threshold of response. The researchers concluded that children with varying temperaments and cognitive ability manifest aggressive tendencies. Knowing that they demonstrate a high level of response could help parents to accept this aspect of temperament and possibly avoid situations where it might be most intense.

Based on this study, would it be surprising to find a child with average cognitive scores demonstrating aggressive behavior at preschool?

Source: Sakimura, J. N., et al. (2008). Cognitive and temperament clusters in 3- to 5-year-old children with aggressive behavior. *Journal of School Health, 78*(1), 38–45.

play quietly in her crib is now more interested in banging trucks together. However, they need only watch a toddler tug a pull toy, stop to see if it is following, walk again, and stop and look to see if it is still following to understand the feeling of accomplishment involved in manipulating toys.

At 15 months, children are still in a put-in, take-out stage, so they continue to enjoy stacks of boxes or balls that fit inside each other. They enjoy throwing toys out of a playpen or from a highchair tray as long as someone will pick them up and return them again and again.

The 18-month-old child is walking securely enough to enjoy pull toys. Toys should be strong enough to take a great deal of abuse, because there are many things in the world toddlers do not recognize or know about. This causes them to use toys in ways other than those for which they were designed. An infant sits and softly strokes a stuffed cat, for example; a toddler picks it up by the tail and swings it, pounds it, or pulls at it. There is no need for parents to correct children about the way they are using a toy as long as it appears to give satisfaction. If toddlers find a toy frustrating because they are holding or using it incorrectly, showing them the right way will ease frustration.

FIGURE 30.3 Toddlers enjoy toys that they can manipulate.

By age 2, when toddlers begin to spend time imitating adult actions in their play such as wrapping a doll and putting it to bed, "setting the table," or "driving the car," they begin to use fewer toys than before. The act of imitating has become their play. By the end of the toddler period, both boys and girls begin to like rough-housing and spend at least part of every day in this very active, stimulating type of play (Fig. 30.4). Encouraging parents to schedule this type of play outdoors, where vases or other prized possessions cannot be broken, makes it more acceptable. A child who feels a need for active play is unable to sit down and eat, fall asleep, or play quiet games so may be described as "trouble." It is good to explore with parents the amount of outside or rough-housing time they allow a child each day. A trip in a stroller is not the same kind of activity as walking and running. Stroller walks are good because they provide fresh air and sunshine, but toddlers also need opportunities to engage in strenuous activity. Because of this rough activity, most toddlers have at least one black-and-blue mark on their legs at all times from tripping over their feet while trying to run too fast or jumping or bumping into a chair or doorway.

FIGURE 30.4 Toddlers usually enjoy rough and tumble play.

TABLE 30.3 ✻ Cognitive and Psychosocial Development of a Toddler

Age in Months	Stage	Task
Cognitive		
12–18	Sensorimotor 5	Child experiments by trial and error methods
18–24	Sensorimotor 6	Can pretend and use deferred imitation; object permanence is complete
24	Preoperational thought	Able to use assimilation or change situation to fit thoughts
Psychosocial		
24–36	Autonomy vs. shame or guilt	Learn independence and the beginning of problem solving

From Piaget, J. (1969). *The theory of stages in cognitive development.* New York: McGraw-Hill; and Erikson, E. H. (1993). *Childhood and society.* New York: W. W. Norton; with permission.

Cognitive Development

A toddler enters the fifth and sixth stages of Piaget's sensorimotor thought (Table 30.3). Piaget referred to stage 5 (between 12 and 18 months) as a **tertiary circular reaction stage**, describing a toddler in this stage as "a little scientist" because of the child's interest in trying to discover new ways to handle objects or new results that different actions can achieve (Piaget, 1969). For instance, by trial and error, toddlers discover that cats do not like baths and that cookies on the center of a table can be reached by crawling up onto the table or pulling on the tablecloth. Obviously, this type of scientific investigation can lead to errors or injury. Toddlers have also advanced beyond what they could do as infants in terms of dropping objects and watching where they roll. As infants, to retrieve an article that rolled under a chair, they would crawl under the chair along the same path the object took. Many children at 15 months are able to follow a different path (walk in back of the chair) to obtain the object. This results from increased awareness that the object is permanent and, even if it follows a different direction from the one the child must take, it will be there to retrieve.

By stage 6 (between 18 and 24 months), toddlers are able to try out various actions mentally rather than having to actually perform them—the beginning of problem solving or symbolic thought. Children at this stage are also able to remember an action and imitate it later **(deferred imitation);** they can do such things as pretend to drive a car or put a baby to sleep because they have not seen this just previously but at a past time. Object permanence becomes complete.

At the end of the toddler period, children enter a second major period of cognitive development: **preoperational thought.** During this period, children deal much more constructively with symbols than they did while still in the sensorimotor period of cognition. They begin to use a process termed **assimilation.** Because they are not able to change their thoughts to fit a situation, they learn to change the situation (or how they perceive it) to fit their thoughts. This ability is what causes toddlers to use toys in the "wrong" way. For example, if they are given a toy hammer, instead of pounding with it, they might shake it to see if it rattles, using the toy in a way they had previously played (they have changed the toy's use to fit thoughts, or used assimilation).

HEALTH PROMOTION FOR A TODDLER AND FAMILY

Toddlers tend to develop many upper respiratory and ear infections but otherwise come to health care facilities most often for health maintenance visits (recommended at 15, 18, and 24 months) and the immunizations important at these times. These visits allow you to focus on health promotion and provide an opportunity for early detection of any growth and development delays. Table 30.4 lists specific areas to assess during these visits.

Routine health maintenance visits also provide opportunities to support parents through the normal crises of the toddler period. Ways to encourage parents to promote healthy development of independence in their toddler include listening carefully to their concerns, asking questions to help separate the objective circumstances surrounding a problem from the parents' possible emotional biases, and providing guidelines on how to handle specific problems.

Promoting Toddler Safety

Accidents are the major cause of death in children of all ages. Accidental ingestions (poisoning) are the type of accident that occurs most frequently in toddlers (Dart & Rumack, 2008). Although poisoning can involve medicine such as acetaminophen, it most often occurs from ingestion of cleaning products. Aspiration or ingestion of small objects such as watch or hearing aid batteries, pencil erasers, or crayons is also a major danger for children of this age (Dutta & Barzin, 2008). Urge parents to childproof their home by putting all poisonous products, drugs, and small objects out of reach by the time their infant is crawling, and certainly by the time their infant is walking (Myers, Li, & Shaheen, 2007).

Other accidents that occur frequently in toddlers include motor vehicle accidents, burns, falls, drowning, and

TABLE 30.4 ✻ Health Maintenance Schedule, Toddler Period

Area of Focus	Methods	Frequency
Developmental milestones	History, observation	Every visit
	Formal Denver Developmental Screening Test (DDST II)	18th-month visit
Growth milestones	Height, weight plotted on standard growth chart; physical examination	Every visit
Nutrition	History, observation; height/weight information	Every visit
Parent–child relationship	History, observation	Every visit
Behavior problems	History, observation	Every visit
Vision and hearing defects	History, observation	Every visit
Dental health	History, physical examination; first dental appointment	Every visit; first at 12 months
Anemia	Hematocrit/hemoglobin	24th-month visit
Lead screening	Whole blood lead level	Depending on risk level; 24th-month visit
Tuberculosis	PPD test	Depending on prevalence in community
Urinalysis	Clean-catch urine	24th-month visit
Immunizations		
Diphtheria, tetanus, and pertussis (DPT) vaccine	Check history and past records; inform caregiver about any risks and side effects.	15th- or 18th-month visit (4th)
Haemophilus influenzae type B (HiB) vaccine	Administer immunization in accordance with health care agency policies	12th- or 15th-month visit (4th)
Hepatitis A vaccine		12th- & 18th-month visit (1st & 2nd)
Hepatitis B vaccine		15th- or 18th-month visit (3rd)
Influenza vaccine		Yearly
Measles, mumps, and rubella (MMR) vaccine		12th- or 15th-month visit (1st)
Pneumococcal vaccine		12th- or 15th-month visit (4th)
Varicella vaccine		12th- or 15th-month visit (1st)
Anticipatory Guidance		
Toddler care	Active listening and health teaching	Every visit
Expected growth and developmental milestones before next visit	Health teaching	Every visit
Poison and accident prevention	Educate parents about toddler safety, such as using car seats and bicycle helmets, locking up poisons, and such precautions as removing drawstrings from hooded clothing to prevent strangulation.	Every visit
	Provide telephone number and location of nearest poison control center.	
Problem Solving		
Any problems expressed by caregiver during course of the visit	Active listening and health teaching regarding temper tantrums, toilet training, negativity	Every visit

playground injuries. These occur because toddlers' motor ability jumps ahead of their judgment. To prevent serious injury, a toddler must be supervised at all times. Toddlers can walk surely and swiftly enough so that if they are left outside to play, they can very quickly travel a block away. Because they have no judgment concerning moving cars, they walk across streets with no regard for oncoming cars. Because they cannot swim well, parents need to check whether backyard pools are securely fenced (Thompson & Rivara, 2009). Until children weigh 40 to 60 lb, they need a toddler-size car seat for safety in automobiles (Fig. 30.5). They should be placed in the back seat if the car has a passenger seat airbag (American Academy of Pediatrics [AAP], 2009). They need to wear a helmet as soon as they begin riding a tricycle.

Some 15-month-old children can climb over the side rails of their cribs and enjoy exploring the house early in the morning before anyone else is awake. Parents might have to move their child to a regular bed with a side rail as early as this time to keep the child from falling when climbing out of

FIGURE 30.5 Toddlers should use a car seat for safety while riding in an automobile. (From David J. Sams/Stock Boston.)

a crib. A safety gate on the door of the room is another way to keep a toddler contained and safe.

As the child reaches 2 years of age and begins to imitate housework or repairing a car, parents must be sure the child does not use real cleaning compounds or sharp tools. Box 30.4 summarizes accident prevention measures to encourage parents to take with their toddler.

Lead Screening

The Centers for Disease Control and Prevention (CDC) has set as a goal the elimination of elevated blood lead levels in children (CDC, 2008). All children between the ages of 6 months and 6 years who live in communities with buildings built before 1950 should be tested periodically for the presence of too much lead in their body (lead poisoning). Elevated lead levels are caused by eating, chewing, or sucking on objects (such as windowsills, paint chips, or furniture) that are covered with lead-based paint. Although federal law has prohibited the use of lead in the manufacture of interior and exterior paints since the mid-1970s, many older houses still contain lead paint (Brown, 2008). Additional sources of lead poisoning can include:

- Soil around the exterior of the house and potentially contaminated food grown there
- Dust or fumes created by home renovation
- Pottery made with lead glazes
- Jewelry made from lead or lead alloys
- Colored print in newspapers
- Old water pipes
- Lead-based gasoline—children who live in high-traffic areas are at high risk for contamination by lead fumes
- Lead dust brought home on the clothing of parents who work with lead products such as batteries
- Toys or cribs that were painted with lead-based paint
- Sources in other countries (pertains to immigrant children)

Because lead is toxic to body tissue, ingestion of it leads to serious damage in the brain and nervous system, kidneys, and red blood cells. Levels as low as 10 μg/dL can cause learning and behavioral problems (Keefe, 2007). High levels may result in seizures, cognitive challenges, coma, and even death.

Beginning symptoms of lead poisoning include irritability, headache, fatigue, and abdominal pain (Chen et al., 2007). Often, however, there are no symptoms before damage occurs, which is why blood screening is essential. The AAP Committee on Practice and Ambulatory Medicine (2009) recommends screening for all children between the ages of 9 and 12 months at least once and again at 24 months of age. A small amount of blood taken by a finger prick is analyzed. A positive result (over 10 μg/dL) must be confirmed by further testing. Therapy for lead poisoning is discussed in Chapter 52.

Promoting Nutritional Health of a Toddler

Because growth slows abruptly after the first year of life, a toddler's appetite is smaller than an infant's. Children who ate hungrily 2 months earlier now sit and play with their food. If feeding problems begin at this time, it is often because parents are unaware their toddler's appetite has decreased so food consumption will be less. Because the actual amount of food eaten daily varies from one child to another, teach parents to place a small amount of food on a plate and allow their child to eat it and ask for more rather than serve a large portion the child cannot finish. One tablespoonful of each food served is a good start. Also, cleaning a plate gives a child a feeling of independent functioning, whereas leaving food uneaten may suggest that parents expected something more. It is important to educate parents while the child is still an infant that this decline in food intake will occur so they will not be concerned when it happens.

Allowing self-feeding is a major way to strengthen independence in a toddler. Offering finger foods and allowing a choice between two types of food helps promote independence while exposing children to varied foods (Williamson, 2007). Nutritious finger foods that toddlers enjoy include pieces of chicken, slices of banana, pieces of cheese, and crackers. Most toddlers insist on feeding themselves and generally will resist eating if a parent insists on feeding them. An individual child may react to repeated attempts at being fed by refusing to eat at all. Many toddlers prefer to eat the same type of food over and over because of the sense of security this offers.

Toddlers usually do not like food that is "mixed up" such as casseroles (except maybe spaghetti); they often prefer that different foods do not touch one another on their plate. Frequently they eat all of one item before going on to another. They often prefer brightly colored foods to bland colors.

Toddler Nutrition

Parents may become frustrated when trying to provide adequate nutrition for their toddler because of a toddler's varying and unpredictable appetite and food preferences. Although a toddler's daily food consumption may vary greatly, energy needs are generally met when sufficient food is supplied in a positive environment. Sedentary children ages 1 to 3 years should consume 1000 kcal daily; active children in this age group may need up to 1400 kcal daily (U.S. Department of Agriculture [USDA], 2005). Calories are best supplied by a variety of foods spaced into three meals a day (Krebs & Primak, 2008). Protein and carbohydrate needs are often those most easily met during the toddler period; diets high in sugar should be avoided. Fats should generally not be restricted for children under 2 years old; however, children

BOX 30.4 ✻ Focus on Family Teaching

Common Safety Measures to Prevent Accidents During the Toddler Years

Q. Ms. Matthis tells you, "My toddler is constantly on the go. How can I keep him safe?"

A. Accident prevention must be ongoing while your child is a toddler. Try the following precautions:

Potential Accident	Prevention Measure
Motor vehicles	Maintain child in car seat; do not be distracted from safe driving by a child in a car.
	Do not allow child to play outside unsupervised. Do not allow child to operate electronic garage doors.
	Supervise toddler who is too young to be left alone on a tricycle.
	Teach safety with pedaling toys (look before crossing driveways; do not cross streets) but do not expect that toddler will obey these rules at all times (in other words, stay close by).
Falls	Keep house windows closed or keep secure screens in place.
	Place gates at top and bottom of stairs. Supervise at playgrounds.
	Do not allow child to walk with sharp object in hand or mouth.
	Raise crib rails and check to make sure they are locked before walking away from crib.
Aspiration	Examine toys for small parts that could be aspirated; remove toys that appear dangerous.
	Do not feed toddler popcorn, peanuts, etc.; urge children not to eat while running. Do not leave toddler alone with a balloon.
Drowning	Do not leave toddler alone in a bathtub or near water (including buckets of cleaning water and washing machines).
Animal bites	Do not allow toddler to approach strange dogs.
	Supervise child's play with family pets.
Poisoning	Never present medication as candy. Buy medications with childproof caps; put away immediately after use.
	Never take medication in front of child.
	Place all medication and poisons in locked cabinets or overhead shelves where child cannot reach them.
	Never leave medication in parents' purse or pocket, where child can reach it.
	Always store food or substances in their original containers.
	Know the names of house plants and find out if they are poisonous. (Call regional poison control center for information.)
	Hang plants or set them on high surfaces beyond toddler's grasp.
	Be certain that small batteries or magnets are out of reach.
	Post telephone number of nearest poison control center by the telephone.
	Inspect toys to be certain they are free of lead-based paint.
Burns	Buy flame-retardant clothing.
	Cook on the back burners of stove if possible and turn handles of pots toward back of stove to prevent toddler from reaching up and pulling them down.
	Use cool-mist vaporizer rather than steam vaporizer or remain in room when vaporizer is operating so child is not tempted to play with it.
	Keep screen in front of fireplace or heater.
	Monitor toddlers carefully when they are near lit candles.
	Do not leave toddlers unsupervised near hot-water faucets.
	Check temperature setting for hot-water heater and turn down thermostat if it is over 125° F.
	Do not leave coffee/tea pots on a table where child can reach them.
	Never drink hot beverages when a child is sitting on your lap or playing within reach.
	Do not allow toddlers to blow out matches (teach that fire is not fun); store matches out of reach.
	Keep electric wires and cords out of toddler's reach; cover electrical outlets with safety plugs.
General	Know whereabouts of toddlers at all times. Toddlers can climb onto chairs, stools, etc., they could not manage before; can turn door knobs and go places they could not go before.
	Be aware that the frequency of accidents increases when the family is under stress and therefore less attentive to children. Special precautions must be taken at these times.
	Be aware some children are more active, curious, and impulsive and therefore more vulnerable to accidents than others.

over 2 years old should have a total fat intake between 30% and 35% of calories, with most fat coming from sources of polyunsaturated and monounsaturated fatty acids, such as fish, nuts, and vegetable oils—the same as for adults. *Trans*–fatty acids should be kept to a minimum. Adequate calcium and phosphorus intake is important for bone mineralization. Milk should be whole milk until age 2 years, after which 2% milk can be introduced (Rolfes, Pinna, & Whitney, 2009).

Promoting Adequate Intake With a Vegetarian Diet

Vegetarian diets are adequate for toddlers if parents are well informed about needed vitamins and minerals (Theobald,

2007). A vegetarian diet can be easily designed for a toddler who prefers finger foods, because many vegetables, fruits, and grains such as pieces of oranges, peaches, raisins, chickpeas, tomatoes, and crackers are easily eaten this way. The use of fortified soy milk prevents fluid, protein, B_{12}, and calcium deficiencies. Tofu or Quom should be part of every meal to supply protein.

Promoting Toddler Development in Daily Activities

A toddler's new independence and developing abilities in self-care, such as dressing, eating, and, to a limited extent, hygiene, present special challenges for parents. Learning how to promote autonomy yet maintain a safe, healthful environment should be a major goal for the family.

Dressing

By the end of the toddler period, most children can put on their own socks, underpants, and undershirt (Fig. 30.6). Some may also be able to pull on slacks, pullover shirts (the sleeves of a shirt often confuse a toddler), or simple dresses. Parents may be reluctant to encourage toddlers to dress themselves as it is often easier and quicker to put their clothes on for them because a toddler who is dressed by parents will (usually) be wearing clothes in the correct way. When toddlers dress themselves, they invariably put shoes on the wrong feet and shirt and pants on backward. Encourage parents to give up perfection for the benefit of the child's developing sense of autonomy. If children end up with underpants or shirt on backward, in most instances it does not make that much difference, and toddlers are not likely to feel independent and confident if their attempts at dressing are criticized. If parents feel they must change the child's clothes, they should begin with a positive statement, such as "You did a good job," before making the switch.

During a health assessment, ask parents if their child can put on any clothing. Parents who allow this name those items the child can manage. Parents who do not allow self-dressing will probably describe the daily battle they have about dressing: "She puts up such a fuss, I don't think she will ever do it on her own." These parents may need help to understand the situation: the child may be resisting because she wants to dress herself. Do not judge how much independent exploration parents encourage by what they do in a physician's office or pediatric clinic. In these settings, they may dress a child quickly to show the child the examination is over, or they may simply be in a hurry to get home.

FIGURE 30.6 Getting dressed by himself is a fun morning activity for this older toddler.

As soon as children are up on their feet and walking, they need shoe soles that are firm enough to provide protection from rough surfaces. However, toddlers do not need extremely firm or ankle-high shoes. Because a toddler's arches are still developing, it is better for their arches to provide foot support rather than having it provided by shoes. Sneakers are an ideal toddler shoe because the soles are hard enough for rough surfaces and arch support is limited.

Sleep

The amount of sleep children need gradually decreases as they grow older (Goldson & Reynolds, 2008). They may begin the toddler period napping twice a day and sleeping 12 hours each night, and end it with one nap a day and only 8 hours' sleep at night. Parents who are not aware that the need for sleep declines at this time may view a child's disinterest in sleeping as a problem. A parent's insistence that a child get more sleep may lead to sleeping problems or refusal to sleep at all. If a child cannot fall asleep at night, maybe it is time to omit or shorten an afternoon nap. If a child is so short-tempered at dinnertime that eating is impossible, perhaps the child needs two naps a day. Some toddlers begin having night terrors or wake crying from a bad dream so they receive little sleep as they are reluctant to fall back asleep (Petit et al., 2007).

Usually, toddlers naturally fall asleep when they are tired. They may begin to resist naps, however, as well as nighttime sleep when they become aware for the first time that activities go on while they sleep, so they do not want to miss anything. Caution parents that when they say, "We'll do this after naptime," they wait until then to do it. Otherwise, a child may be reluctant to nap the next day for fear of missing another activity. Also, parents must be sure older siblings do not point out to a toddler all the exciting things a toddler missed while napping.

Other toddlers resist naptime as part of their developing negativism. Parents might minimize this by including a nap as part of lunchtime routine, not as a separate activity: the child always goes from the table directly to bed. The parent can state simply, "It's naptime now," and then give a secondary choice: "Do you want to sleep with your teddy bear or your rag doll?" Toward the end of the toddler period, when children are ready to omit their afternoon naps, they may still be agreeable to a "shoes-off" or quiet-play period until they begin to attend school full time.

As with any other activity of this period, a toddler loves a bedtime routine: bath, pajamas, a story, brushing teeth, being tucked into bed, having a drink of water, choosing a toy to sleep with, and turning out the lights. Parents must be careful, however, not to let a child maneuver them into such a long procedure that sleep is delayed considerably past the time initially set. Although toddlers need to be independent, they also need a feeling of security. Just as adults like to know there are guardrails along steep mountain roads, toddlers, especially when they are tired, like to see parents as firm, consistent people who can be counted on to be reliable over and over (Ward, Rankin, & Lee, 2007).

Many toddlers are ready to be moved out of a crib into a youth bed or regular bed with protective side rails or a chair strategically placed beside it by the end of the toddler period. Moving children to a more grown-up bed is usually preferable to forcing them to sleep in a crib if they no longer feel they should be there. Either children will not fall asleep in the crib or they will scale the side rail and perhaps fall.

Remind parents to stress that sleeping in a regular bed does not give children the right to get in and out of bed as they choose. Some toddlers do well if they are allowed to sleep in a regular bed and a folding gate is placed across the door to their room. This arrangement gives them a feeling of independence but still keeps them safe. When first moved to a bed without side rails, many children are found sleeping on the floor of the room in the morning. There is no harm in this unless it is cold or drafty. Dressing the child in warm pajamas or putting a blanket on the floor might be solutions to help parents accept this.

Bathing

The time for a toddler's bath should depend on the parents' and the child's wishes and schedule. Some parents prefer to bathe a toddler before the evening meal because it has a quieting effect and prepares a child for eating; others prefer to give it at bedtime because it has a relaxing effect and helps a child sleep. The time, however, is not as important as the attempt to establish a sense of routine, a sense that life has order. Learning to be independent is sometimes frightening, and there is security in knowing certain events are predictable.

Toddlers usually enjoy bath time, and parents should make an effort to make it fun by providing a toy, such as a rubber duck, boat, or plastic fish. Bath time is usually so enjoyable for toddlers that parents can use it as a recreational activity or something to do on a rainy day when they can find nothing else to interest their child. Remind parents that although toddlers can sit well in a bathtub, it is still not safe to leave them alone unsupervised. They might slip and get their head under water or reach and turn on the hot-water faucet and scald themselves (Ring, 2007).

Care of Teeth

Toddlers often need between-meal snacks. Encourage parents to offer fruit (bananas, pieces of apple, orange slices) or protein foods (cheese or pieces of chicken) rather than high-carbohydrate items for snacks such as cookies not only for the nutrition involved but also because protein snacks help prevent caries more than sugar snacks by limiting exposure of the child's teeth to carbohydrate. Calcium (found in large amounts in milk, cheese, and yogurt) is especially important to the development of strong teeth and are good for snacks. In addition, children should continue to drink fluoridated water, if it is available, so that all new teeth form with cavity-resistant enamel (Armfield & Spencer, 2007).

For tooth care, toddlers need to have a toothbrush they recognize as their own. Toward the end of the toddler period, they can begin to do the brushing themselves under supervision (almost all children need some supervision until about age 8). Remind parents it is better for a child to brush thoroughly once a day, probably at bedtime, than to do it poorly many times a day. After brushing, parents can use dental floss to clean between the child's teeth and remove plaque.

Urge parents to schedule a first visit to a dentist skilled in pediatric dental care at about 12 months of age for assessment of dentition (Mueller, 2008). Parents can prepare their child for this first and subsequent visits by reading a story about a dentist visit, maintaining a positive attitude about the visit, avoiding the use of frightening words like "drill" or "shot," and answering their child's questions honestly without going into too much detail. Because children rarely have cavities this early, the visit is usually painless and sets a positive stage for future dental supervision visits.

Promoting Healthy Family Functioning

Because learning self-reliance is the primary goal of a child during the toddler period, some parents who enjoyed caring for their child as an infant may find it difficult to have their authority challenged by a toddler. Help parents to understand their responses to these attempts at independence are crucial to the healthy development of their child. Although the child still needs firm limits to feel secure, a child must be given some room to make independent decisions in areas that the parents feel they do not need to control. An outside person, such as a nurse, can provide an important perspective on this issue.

If parents punish children excessively at each move toward independence, children will not fight them indefinitely. Instead, they will begin to feel guilty for wanting to do things independently. Adults without a sense of autonomy feel this way about independent thought. They may follow orders well, but when the job calls for a new program or function, they cannot reach into unknown areas without a great deal of consultation and help.

You may need to caution some parents not to begin to function at the same level as their toddler. An easy reaction to a toddler's refusal to allow a parent to help is, "You won't let me help you with this, so I won't do anything for you." This is a defense mechanism that prevents parents from feeling rejected. Teach parents that refusing to accept help is not refusing to accept love. Refusing to let mother put on a shoe is an instance of refusing to let mother put on a shoe, nothing more.

At bedtime, naptime, or anytime they are tired, toddlers may become much more like their old selves, wanting to sit on a parent's lap and be rocked or picked up and carried. This does not signal babyish behavior or regression in a toddler; it is a natural state between infant and preschool ages.

Parental Concerns Associated With the Toddler Period

Parental concerns of the toddler period usually arise because of a conflict over autonomy.

Toilet Training

Toilet training is one of the biggest tasks a toddler tries to achieve. There are so many theories concerning toilet training that understanding the procedure can become one of the biggest tasks of this period for parents. Most first-time parents ask when to start, when training should be completed, and how to go about it. The answer is that toilet training is an individualized task for each child. It should begin and be completed according to a child's ability to accomplish it, not according to a set schedule. In the United States, toilet training is usually introduced during the toddler period. Like so

many other aspects of childrearing, though, the time when parents begin these activities is culturally determined. In other countries, toilet training may be started as soon as a child can sit, at about 6 months. Although praise is used in the United States as a common means of encouraging toddlers to learn new tasks, other cultures believe praise will bring a child harm by attracting evil spirits; strategies of shame or strict discipline are used instead. Being aware that childrearing practices are not consistent across the world is a help in understanding why parents approach childrearing problems differently and why childrearing advice must be individualized.

Before children can begin toilet training, they must have reached three important developmental levels, one physiologic and the other two cognitive:

- They must have control of rectal and urethral sphincters, usually achieved at the time they walk well.
- They must have a cognitive understanding of what it means to hold urine and stools until they can release them at a certain place and time.
- They must have a desire to delay immediate gratification for a more socially accepted action.

Because physiologic development is cephalocaudal, the rectal and urethral sphincters are not mature enough for control in most children until at least the end of the first year, when tracts of the spinal cord are myelinated to the anal level. A good way for a parent to know that a child's development has reached this point is to wait until the child can walk well independently.

Toilet training need not start this early, however, because cognitively and socially, many children do not understand what is being asked of them until they are 2 or even 3 years old. The markers of readiness are subtle, but as a rule children are ready for toilet training when they begin to be uncomfortable in wet diapers. They demonstrate this by pulling or tugging at soiled diapers; they may bring a parent a clean diaper after they have soiled so they can be changed (Fig. 30.7).

Teach parents not to underestimate the difficulty of the task they are expecting their child to achieve. Infants live by a pleasure principle: they want what they want when they want it. Before they can complete toilet training, they must be able to give up an immediate pleasure—relieving themselves whenever they have the urge—to gain other pleasure later on—improved physical comfort and another step in growing up. For specific tips on how to potty train a toddler, see Box 30.5.

Some toddlers smear or play with feces, often at about the same time that toilet training is started. This occurs because they have become aware of body excretions but have no adult values toward them; stools seem little different from the modeling clay they play with. This activity can be minimized by providing toddlers with play substances of similar texture and by changing diapers immediately after defecation. Teach parents to accept this behavior for what it is: enjoyment of the body and of the self, and the discovery of a new substance. After a child is fully toilet trained, this activity rarely persists.

Ritualistic Behavior

Although toddlers spend a great deal of time every day investigating new ways to do things and doing things they have never done before, they also enjoy ritualistic patterns. They will use only "their" spoon at mealtime, only "their" washcloth at bath time. They will not go outside unless mother or father locates their favorite cap.

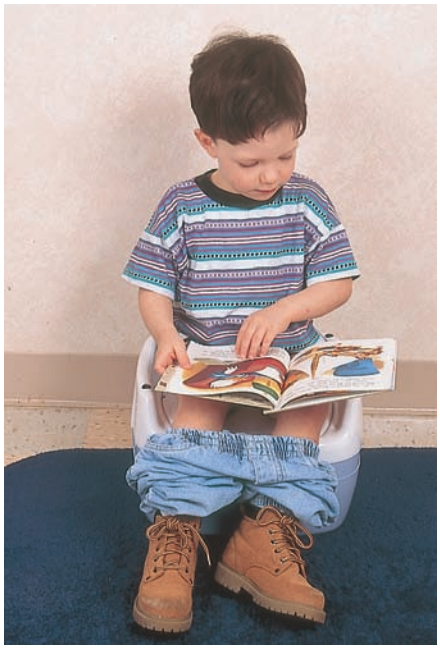

FIGURE 30.7 Toddlers are interested in toilet training as an expression of autonomy.

The child who seems to need an excessive number of objects to cling to or an excessive number of routines, however, may be trying to say, "I need more guidelines, more rules. Don't let me be quite so independent."

What if... Jason's mother tells you he is toilet-trained, but in the hospital he refuses to use a toilet? What would you do?

Negativism

As part of establishing their identities as separate individuals, toddlers typically go through a period of extreme negativism. They do not want to do anything a parent wants them to do. Their reply to every request is a very definite "no."

It is easy for parents to believe their authority is being questioned when this happens and to worry children are becoming so disrespectful they will have difficulty getting along in the world. They can be baffled by the extreme change from happy, cooperative infants who lived to please them to irritating, uncooperative toddlers. They may need some help to realize this is not only a normal phenomenon of toddlerhood but also a positive stage in development. This change indicates that toddlers have learned they are separate individuals with separate needs. It is important that toddlers do this if they are to grow up to be persons who are independent and able to take care of their own needs and desires.

Parents who went away from home for the first time to college or camp might remember they behaved similarly. They may recall they rarely slept or ate sensibly; they tried, in effect, to break every rule their parents used to enforce on them. Most regained their equilibrium in time to find a midpoint between irresponsible independence and common sense.

BOX 30.5 ✻ Focus on Family Teaching

How to Toilet Train a Toddler

Q. Ms. Matthis asks you, "How can I tell if my 2-year-old is ready for potty training? And if he is, how do I start?"

A. Try the following suggestions:

1. Children are physically ready for toilet training when they walk securely. Plan 1 or 2 weeks of psychological "readiness" activities, which will help your child realize the task of toilet training is a step toward growing up. If your child feels toilet training is something only toddlers do, he may react with extreme negativism. Readiness activities may include showing your child that other family members use the toilet; making it clear that bigger people customarily leave urine and feces in the toilet, without suggesting that these materials are dirty or distasteful; and introducing training pants and showing your child that bigger people wear underpants too.
2. Check that training pants pull down readily and that slacks are free of complicated buttons or grippers; otherwise, your child will have accidents because he cannot undress quickly enough.
3. Purchase either a potty chair that sits on the floor or an infant seat that is placed on the regular toilet. The potty chair is low and potentially less frightening to a child, but it must be emptied and cleaned after each use. If you choose an infant seat, place a footstool in front of the toilet so your child has some support for his feet.
4. Put your child on the potty chair or toilet at regular intervals (e.g., when the child wakes up in the morning, after breakfast, during midmorning, before lunch, after lunch).
5. Praise your child if he does urinate or defecate. Remind him to wash his hands.
6. Be careful not to flush the toilet while the child is sitting on it. Two-year-old children are unable to realize they will not be flushed away and may become frightened. Encourage your child to flush the toilet independently after you have helped him get redressed.
7. Do not allow a child to remain on a potty chair for much longer than 10 minutes (less than that if he is resistant). Also, do not allow your child to use the chair to eat or as a play table, so he does not become confused regarding its purpose.
8. If your child is not ready or does not successfully use the potty on a day-to-day basis, have him return to diapers for a short period. Be careful not to make him feel as if this represents failure. Be careful not to equate "good" with being dry and "bad" with being wet. Continue with readiness activities. Reintroduce training pants and attempt toilet training again when your child seems more ready.
9. When boys have mastered defecation, it is time to include urination. Boys enjoy standing to urinate and aiming at objects in a toilet bowl, such as several pieces of breakfast cereal.
10. Some toddlers have difficulty remaining dry at night until they are 3 to 4 years old. Do not pressure your child to accomplish nighttime dryness, but assume that he is doing the best he can do. Put him into training pants for the night by explaining (not punitively) that it is hard to keep dry while he sleeps. After your child has been dry during the night for about 1 month, he has probably mastered nighttime dryness.
11. Do not wake your child during the night and carry him to the bathroom to void. This system may keep him dry during the night, but it does not help him stay dry for long periods. It may even prolong nighttime wetness, because it conditions him to void every 4 hours or so instead of retaining urine for 12 hours while he sleeps.

If parents can recall such circumstances, it helps them to understand this behavior in their toddler is not specific to the age but to the first feeling of independence. They can also remember they meant no vindictiveness by their behavior, so they can realize their child means none. This understanding can help to put the child's "no" into a better light.

Once it runs its course, extreme negativism passes. In the meantime, the more parents try to make children obey them, the more children are likely to resist. Some long-term parent–child interaction problems begin during this period because parents insist on being obeyed totally or are inconsistent in their approach.

A toddler's "no" can best be eliminated by limiting the number of questions asked of the child. A father does not really mean, for example, "Are you ready for dinner?" He means, "Come to the table. It's dinnertime." A mother asks, "Will you come take a bath now?" She means, "It's time for your bath." Making a statement instead of asking a question can avoid a great many negative responses.

A toddler needs experience in making choices, however. To provide the opportunity to do this, a parent could give a secondary choice. "No" is not allowed for the major task, so the parent states, "It's bath time now" but then says, "Do you want to take your duck or your toy boat into the tub with you?" Other examples are, "It's lunchtime. Do you want to use a big or little plate?" or "It's time to go shopping. Do you want to wear your jacket or your sweater?" Although this solution is simple, it is one that parents may not arrive at by themselves because finding a solution is always more difficult for a person in the middle of a problem than for an objective observer. Once they are helped to practice this approach, however, parents usually find it helpful in smoothing out the friction caused by the negativism of the toddler period (Box 30.6).

Discipline

Some parents ask during the last part of the infant year or the early toddler period when they should start to discipline their child or when toddlers are old enough to be punished. Remind parents that "discipline" and "punishment" are not interchangeable terms. **Discipline** means setting rules or

BOX 30.6 ✻ Focus on Communication

Ms. Matthis has brought her 2-year-old son, Jason, to the clinic for a health maintenance visit. Jason is rambunctious and uncooperative. Ms. Matthis is obviously frustrated.

Less Effective Communication

Nurse: Come on, Jason, sit quietly so I can hear your heartbeat.
Jason: No!
Ms. Matthis: Jason, listen to the nurse.
Jason: No!
Nurse: If you promise to sit still, I'll let you play with the stethoscope.
Jason: Okay.
Jason plays with the stethoscope.
Ms. Matthis: Jason, now it's time to give the stethoscope back to the nurse.
Jason: No.
Nurse: There are other children waiting to see me. I really must listen to your heart now.
Ms. Matthis takes the stethoscope from Jason. Jason starts crying.
Ms. Matthis: Jason, if you stop crying and sit still, I'll take you for ice cream on our way home.
Jason: (whimpering a bit) Okay.
Ms. Matthis: Sometimes he can be so difficult.
Nurse: Oh, those terrible twos!

More Effective Communication

Nurse: Jason, I need to listen to your heart so you must be very quiet. Would you rather sit quietly on the chair or the table?
Jason: The table.
Nurse: All right, Jason, jump up.
Jason climbs onto the table and starts to fidget.
Ms. Matthis: Jason, sit still for the nurse.
Jason: No!
Nurse: If you'd like, you can play with the stethoscope for a few seconds. Do you want to listen to your mom's heart or my heart?
Jason: Mom's.
Nurse: Great, now we will both be very quiet so you can hear.
Jason listens to his mother's heart.
Nurse: Good, now it's my turn.
Jason: Okay. (Jason hands back the stethoscope.)
Ms. Matthis: How did you get him to listen so well? At home he never listens. It can be so frustrating.
Nurse: Yes, this can be a frustrating period. By giving Jason choices, you can help him feel more in control without having to directly challenge your authority.

Toddlerhood can be a challenging and frustrating time for parents. You can teach parents effective communication skills to help toddlers assert their independence, while allowing parents to maintain discipline. It is important to show parents that offering choices rather than bribes is a far more effective and long-lasting method of modifying a toddler's behavior. In the first scenario, the nurse and mother both bribe Jason. Jason finally does what they want, but the situation is still frustrating, and his behavior change will not likely be long-lasting. In the second scenario, the nurse demonstrates how to better communicate by offering choices. The situation is much more enjoyable for everyone.

road signs so children know what is expected of them. **Punishment** is a consequence that results from a breakdown in discipline, from the child's disregard of the rules that were learned.

Parents should begin to instill some sense of discipline early in life because part of it involves setting safety limits and protecting others or property: for example, a child must stay away from the fireplace or heater; she must not go into the street; she must not hit other children. Enforcing limits, however, arises out of the day-to-day interaction with the child, out of the rhythm of child care, not out of a set procedure such as, "Today, I'm going to teach discipline." Two general rules to follow are (a) parents need to be consistent and (b) rules are learned best if correct behavior is praised rather than wrong behavior punished.

"Timeout" is a technique to help children learn that actions have consequences. To use "timeout" effectively, parents first need to be certain their child understands the rule they are trying to enforce: for instance, "If you hit your brother, you'll have timeout." Parents should give one warning. If the child repeats the behavior, parents select an area that is nonstimulating, such as a corner of a room or a hallway. The child is directed to go immediately to the "timeout" space. The child then sits there for a specified period of time. If the child cries or shows any other disruptive behavior, the timeout period does not begin until there is quiet. When the specified time period has passed, the child can return to the family. A guide regarding how long children should remain in their "timeout" chair is 1 minute per year of age. Using a timer that rings when time is up lets children know when they can return to the family.

Separation Anxiety

As discussed in Chapter 29, fear of being separated from parents begins at about 6 months of age and persists throughout the preschool period. This universal fear of this age group is known as *separation anxiety*. For this reason, toddlers have difficulty accepting being separated from their primary caregiver to spend the day at a day care center or if they or their primary caregiver is hospitalized. Chapter 36 discusses nursing responsibility for care of toddlers in the hospital as well as the reactions of toddlers to the separation caused by hospitalization and the methods used to minimize these reactions.

Parents may ask what they can do about this problem. They believe they have a right to leave their child in a babysitter's or center's care, but how can they tolerate the crying at the door? Most toddlers react best to separation if a regular babysitter is employed or the day care center is one with consistent caregivers. Many are more comfortable if they are cared for in their own home. It helps if they have fair warning that they will have

a babysitter. For example, they could be told, "Mommy is fixing dinner early because Mommy and Daddy are going to visit some friends tonight. Marsha is going to come and babysit for you. She'll put you to bed. When you wake up in the morning, Mommy and Daddy will be here again."

No matter how well prepared toddlers are, they may cry when the babysitter actually appears or may greet the babysitter warmly only to cry when the parents reach for their coats. It helps if parents say goodbye firmly, repeat the explanation they will be there when the child wakes in the morning, and then leave. Prolonged goodbyes only lead to more crying. Sneaking out prevents crying and may ease the parents' guilt, but it can strengthen fear of abandonment so should be discouraged. This applies to hospital visits as well.

✔ Checkpoint Question 30.2

Jason answers every request of his mother by saying, "No!" How would you suggest she minimize this?

a. Tell Jason she does not want him to say "No" anymore.
b. Answer all Jason's questions by saying, "No!"
c. Reduce the number of questions she asks Jason.
d. Explain he is not using good communication skills.

Temper Tantrums

Almost every toddler has a temper tantrum at one time or another. The child may kick, scream, stamp feet, shout "No, no, no," lie on the floor, flail arms and legs, and bang the head against the floor. Children may even hold their breath until they become cyanotic. If breath holding, the child develops a distended chest (a halt after inspiration), often air-filled cheeks, and increasing distress as the child's body registers oxygen want. This is harmless breath holding; ignoring it will make it ineffective and the child will give it up. True breath holding is a neurologic problem in which children, under stress, appear to "forget" to breathe in or halt breathing after expiration, usually at the peak of anger. They become so short of breath that they slump to the floor. Breath holding can be mistaken for seizures because of the fall to the floor (see Chapter 49). Guidelines that are helpful in differentiating simple breath holding from neurologic disorders are shown in Table 30.5.

Temper tantrums occur as a natural consequence of toddlers' development (Taylor, 2007). They occur because toddlers are independent enough to know what they want, but they do not have the vocabulary or the wisdom to express their feelings in a more socially acceptable way. For example, temper tantrums occur most often when children are tired, just before naptime or bedtime, or during a long shopping trip or visit. Tantrums may be a response to an unrealistic request by a parent: asking children to comb their hair before they are coordinated enough to do so, asking them to pick up toys before they have a feeling of family responsibility, or asking them to share before they can understand what that means. Also, tantrums may occur if parents are saying "no" too frequently in regard to such things as touching the coffee table, getting dirty, using a spoon, or running and jumping so that children feel constantly thwarted. A tantrum may be a response to difficulty making choices or decisions or to pressure from activities such as toilet training. Such children need to express feelings in some way and do so with temper tantrums. These episodes are taxing for the parents; they are also energy-consuming for children.

Box 30.7 offers suggestions for managing temper tantrums. Probably the best approach is for parents to tell a child simply that they disapprove of the tantrum and then ignore it. They might say, "I'll be in the bedroom. When you're done kicking, you come into the bedroom, too." Children who are left alone in a room this way will usually not continue a tantrum but will stop after 1 or 2 minutes and rejoin their parents. Parents should then accept the child warmly and proceed as if the tantrum had not occurred. This same approach works well for nurses caring for hospitalized toddlers.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for compromised family coping related to toddler behavior

Outcome Evaluation: Family states temper tantrums now occur less than two times daily.

Helping parents correct problems early may limit the number of tantrums they must deal with; it will not prevent them, however, because parents cannot anticipate all the circumstances that will cause this reaction. In fact, parents should not feel they must prevent all of them; they are, after all, parents, not mind readers (see Focus on Nursing Care Planning Box 30.8). As the child matures, increases in vocabulary, and is capable of better responses to stress situations, tantrums begin to fade by themselves.

TABLE 30.5 Differentiating Temper Tantrums, Breath Holding, and Seizures

Assessment	Temper Tantrums	Breath Holding	Seizures
Provocation	Usually provoked—parent can state a reason for it (she asked toddler to come to dinner, toddler wanted to finish an activity)	Usually provoked; child very angry; child breathes out and forgets to breathe in	Not provoked
Appearance of cyanosis	Child holds breath, becomes cyanotic, then slumps to floor	Child breathes out, becomes cyanotic, then slumps to floor	Child slumps to floor first, then becomes cyanotic

BOX 30.7 ✻ Focus on Family Teaching

Managing Toddler's Temper Tantrums

Q. Suppose Jason's mother tells you, "I've had it with temper tantrums. I can't stand to watch another one."

A. Here are suggestions to prevent them:

Try to determine the reason for the behavior:

- Do tantrums always occur just before bedtime? If so, you might schedule an earlier bedtime or an afternoon nap.
- Do tantrums occur every time you go shopping? If so, perhaps it would help to schedule two shorter trips each week rather than one long one.
- Do tantrums occur whenever you ask the child to do something? If so, is the child being asked to perform tasks not age-appropriate?
- Do tantrums occur in response to not being able to make a decision? If so, you may have to limit the number of choices you are asking of the child.

Next, be certain it seems like a tantrum, not something more:

- Is there a possibility you are mistaking seizure activity for temper tantrums?
- Could you be confusing neurologic breath holding with a temper tantrum?

Lastly, think through what you do when the child has a tantrum:

- Do you give either material or emotional bribes (e.g., "Come and get a cookie," or "Stop and I'll give you a kiss")? This method is rarely effective because by acceding to the child's wishes, you are encouraging your child to have more tantrums because they are so successful.
- Do you punish the child? Toddlers have a right to express opinions; they just need to be guided to learn a more controlled and mature way of doing that.
- Do you demonstrate adult behavior in managing temper tantrums? For example, if the child shouts or kicks, do you respond, "I can shout as loud as you. I can kick as hard as you"? Instead of showing the child a better way to express feelings, this reinforces the way the child is responding.

BOX 30.8 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Toddler With Temper Tantrums

Jason is a 2½-year-old boy you see at a pediatric clinic. His mother tells you he has changed completely in the past 6 months from an easy-to-care-for baby into a "monster" who refuses to do anything she asks. The only word he says anymore is "no." He has a temper tantrum every night at dinner over some type of food. She tells you this has changed parenting from "fun" to "a real chore."

Family Assessment ✻ Child lives with two parents in three-bedroom home. Father is a ferry boat captain; works 6 days a week. Mother works as a secretary at local university. Finances are "Good. We've worked hard to get where we are."

Client Assessment ✻ Well-nourished 2-year-old boy. Physical findings within normal limits. Mother reports the child is having temper tantrums "at least 20 times a day. He throws himself on the floor and pounds his head and fists." Mother unable to describe any precipitating factors for the tantrums. She states, "He seems to have them just when I start to do something. I could be playing with him one minute, and then I get up to do something, like answer the phone or start dinner, and he starts." Mother reports picking up the child immediately because she fears he will hurt himself. "I just don't know what to do anymore."

Nursing Diagnosis ✻ Health-seeking behaviors related to measures for dealing with and reducing the number of temper tantrums.

Outcome Criteria ✻ Mother describes measures to manage tantrums; reports tantrums have decreased to fewer than 4 a day by end of 1 week.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Ask mother to describe a typical day and to document when tantrums occur and situations that seem to provoke them.	Make suggestions to eliminate periods of stress as revealed by assessment.	Temper tantrums can increase with stress and inability of child to feel independent.	Mother reviews a typical day and identifies times when tantrums are most apt to occur.

(continued)

BOX 30.8 ✻ Focus on Nursing Care Planning (continued)

		Consultations		
Physician	Assess if child has possible neurologic symptoms.	Refer child for full neurologic workup if physical exam suggests the need.	Temper tantrums can be confused with seizures if a careful history is not taken.	Mother agrees to further neurologic testing if suggested.
		Procedures/Medications		
Nurse/nurse practitioner	Assess what measures mother thinks would prevent temper tantrums best.	Work with the mother to develop actions (e.g., ignoring the tantrum, telling child she disapproves of behavior). Encourage mother not to pick up child unless there is actual danger of injury.	Temper tantrums are a way of expressing frustration. Rewarding the behavior prevents the child from learning more mature methods of coping with frustration.	Mother voices agreement to try suggested solutions and to telephone clinic in 5 days if there is no improvement.
		Nutrition		
Nurse practitioner	Assess if child appears well nourished; assess usual dietary pattern.	As eating is a time when tantrums occur, review with mother if her actions are different at this time than others.	Eating is an area in which children can express independence.	Mother lists foods that allow child independent eating, which she will try to serve, to keep meals tantrum-free.
		Patient/Family Education		
Nurse	Assess mother's knowledge of toddler behavior and temper tantrums.	Review normal toddler growth and development, explaining some temper tantrums during this period are natural occurrences.	Information about normal toddler growth and development provides a foundation for further teaching and instruction.	Mother states she understands that tantrums occur because of toddler's limited capabilities to express emotion.
Nurse	Assess why mother is so fearful child will hurt himself during a tantrum.	Inform the mother children rarely hurt themselves during tantrums.	Increased knowledge about the minimal risk of injury during tantrums should help to alleviate the mother's anxiety.	Mother states she has increased understanding about the danger of tantrums.
		Psychosocial/Spiritual/Emotional Needs		
Nurse/nurse practitioner	Assess what mother feels would be most helpful to relieve her degree of stress and frustration.	Suggest she arrange for "time out" breaks for herself by having husband or friend relieve her.	Short periods away from the child can allow her to regroup her thinking.	Mother describes a plan by which she can receive more help with child care from friend, as husband is home only 1 day a week.
		Discharge Planning		
Nurse/nurse practitioner	Review with mother the plan for added support and interventions.	Instruct the mother to keep a diary of the child's behavior and measures used during the next week. Set up an appointment for a telephone conference with the mother next week to review the diary and discuss the child's behavior.	Keeping a diary and reviewing it over the telephone aids in evaluating the child's behavior and the effectiveness of the methods used. Follow-up telephone call also provides an additional opportunity for feedback, teaching, and support.	Mother states she will follow suggestions for managing tantrums; will keep telephone and clinic appointments for follow-up care.

What if... Jason, whom you are caring for in the hospital, has a temper tantrum in the middle of a busy hallway? Would you ignore it or move him to a quieter place?

Concerns of the Family With a Physically Challenged or Chronically Ill Toddler

It may be difficult for children with handicaps or disabilities to achieve a sense of autonomy or independence because they may never be totally independent. It is important for these children to develop as strong a sense of autonomy as possible, though, so they see themselves as independent and can work to become increasingly self-sufficient as they grow older. It takes courage for an adult to do such things as move a wheelchair through a busy airport or a concert crowd. Nursing actions designed to help the challenged or chronically ill child develop a sense of autonomy are outlined in Table 30.6. Most important are actions that allow toddlers to do as much for themselves as possible. If toddlers have physical limitations, for example, they may be unable to explore freely or may not have the physical ability to pound and manipulate toys as the average toddler does. They do have the ability to work at a project while they sit in a chair at a table.

A toddler with a long-term illness or who is physically challenged can be expected to exhibit normal toddler behaviors, such as temper tantrums, and to have normal outlooks, such as negativism. Parents whose child is uncoordinated or has a neurologic disease may mistake temper tantrums for seizure activity. Investigate such activity carefully, and explain to parents the difference between the two. Parents may also mistake particular toddlers' insistence on having their own way as a manifestation of illness. Remind these parents the behavior is more often an indication of age and development rather than of illness so they can respond appropriately.

Toilet training is difficult for a child who is hospitalized at periodic intervals, as success usually requires a consistent caregiver; in addition, hospitalization can result in regressive behaviors. If a chronically ill child has difficulty with ambulation, soiling accidents may occur beyond the usual age because of inability to reach a bathroom easily.

Children who survive a long-term illness are sometimes referred to as medically fragile or vulnerable children (Green & Solnit, 1964). Some parents tend to protect and shelter such a child, and you may have to remind them even though

TABLE 30.6 ✻ Nursing Interventions to Help a Physically Challenged or Chronically Ill Child Develop a Sense of Autonomy

Area	Nursing Action
Nutrition	A special diet may limit typical finger foods. Use imagination to offer other foods not usually eaten this way as finger foods. Allow child to help pour liquid diet for a tube feeding. Toddlers are frightened by vomiting because they have no control over it. Check for possibility of nausea; toddlers have no way to express this other than by not eating.
Dressing changes	A child can hold pieces of tape or put tape in place to maintain sense of control. The child can remove an old bandage if it is not contaminated. Allow children to view their incisions and watch dressing changes; explaining each step of a procedure as you perform it helps a child maintain control.
	Restrain only those body parts necessary during a procedure to allow a child a sense of control.
	Remove all supplies after a procedure, or the child may "redo" the dressing.
Medication	Allow children no choice regarding whether a medicine will be taken. Do allow a child to choose a "chaser," such as milk or juice, after oral medicine. Do not ask a toddler to indicate a choice of site for an injection or intravenous insertion; this is too advanced a decision for a toddler to handle.
Rest	Locate or create a ritual for bedtime (put child into bed, tuck him in, say, "Goodnight, Bobby." Tuck in bear. Say, "Goodnight, Bear"). Allow a choice of toy or cover but not a choice of bedtime or naptime hour.
Hygiene	Allow a child a choice of bathtub toy or clothing. Allow a child to wash face and hands to gain control of the situation.
	Allow the child to put toothpaste on a brush, but you should brush or "touch up" teeth afterward to ensure that all plaque has been removed.
Pain	Encourage a child to express pain ("Say 'ouch' when I pull off the tape").
	Help channel a child's self-expression to what is acceptable (e.g., the child may shout but may not kick).
Stimulation	Provide a toddler with a toy that can be manipulated, such as boxes that fit inside one another and can be taken out again, trucks that can be pushed, and pegs that can be pounded. In a health care setting, items can usually be found that fit together (boxes from central supply or plastic vials from the pharmacy). Another action toy: buy a non-latex balloon and tie it to the crib side to be used as a punching bag; another one tied to the foot of the crib can serve as a leg exerciser.
Elimination	A child who is toilet trained needs to be encouraged to use a potty chair or toilet during an illness. Help children with ureter or bowel stomas to help with changing bags so they are as independent in bowel function as possible.

chronically ill, a toddler will demand independence and has the right to explore. A child who uses a lower-extremity prosthesis, for example, might prefer to crawl somewhere rather than wait for help to put the prosthesis in place. Although this degree of independence is good, parents may have to limit how it is expressed so the child will learn how to use the prosthesis (for example, they could make a rule the child must use the prosthesis to walk but can choose whether to use a spoon when eating).

Nutrition and the Physically Challenged or Chronically Ill Toddler

Toddlers need experience feeding themselves if at all possible. Help parents accept the accidents that occur with self-feeding, particularly if the child has difficulty with coordination; suggest finger foods if possible.

If on a special diet, children may not be allowed to eat finger foods; if they are tube fed, they receive no experience with finger foods at all. For these toddlers, parents should try to provide other, comparable experiences in independence, such as letting them choose what toy to take to bed.

✔ Checkpoint Question 30.3

Jason's mother uses "timeout" for punishment. What is a good rule for this?

a. The child should sit still for as many minutes as his age.
b. The child should sit still for as many minutes as he misbehaved.
c. Timeout activities can include quiet play or reading books.
d. Children are not ready for timeout until school age.

Key Points for Review

- Erikson's developmental task for the toddler period is to form a sense of autonomy or independence versus shame or doubt.
- Toddlers make great strides forward in development, but their physical growth slows.
- A critical milestone of toddler development is being able to form two-word sentences (a noun and a verb) by 2 years of age.
- Toddlers are capable of preoperational thought or are able to deal much more constructively with symbols than they could while infants.
- Important aspects of care are promoting toddler safety, including screening for lead poisoning; promoting toddler development, such as promoting daily activities; and healthy family functioning.
- Toddler appetites decrease from those of the infant, so children eat proportionally less than they did as infants.
- Common concerns of parents during the toddler period are toilet training, ritualistic behavior, negativism, temper tantrums, discipline, and separation anxiety.
- Promoting autonomy in the child who is physically challenged or chronically ill calls for creative planning, because there may be many tasks that must be done for the child to be certain they are done safely.

CRITICAL THINKING EXERCISES

1. Jason is the toddler you met at the beginning of the chapter. His mother tells you he refuses to do anything she tells him to do. What are three questions you would want to ask his mother to help her explore the problem?
2. Jason's father tells you Jason eats "almost nothing." What is the best way to evaluate if a child's intake is adequate? Why does the intake of toddlers decrease from what it was during the infant year?
3. Because his parents both work, Jason is cared for in the morning by his grandmother, a child care teacher in the afternoon, and his parents in the evening. What suggestions could you offer to make toilet training easier with multiple caregivers?
4. Examine the National Health Goals related to growth and development of the toddler. Most government-sponsored funds for nursing research are allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to Jason's family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX types of questions related to toddler growth and development. Confirm your answers are correct by reading the rationales.

Chapter 31

Nursing Care of a Family With a Preschool Child

KEY TERMS

- broken fluency
- bruxism
- conservation
- ectomorphic body type
- Electra complex
- endomorphic body type
- genu valgus
- intuitional thought
- Oedipus complex
- secondary stuttering

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe normal growth and development as well as common parental concerns of the preschool period.
2. Identify National Health Goals related to the preschool period that nurses can help the nation achieve.
3. Use critical thinking to analyze methods of care for preschoolers to be certain care is family centered.
4. Assess a preschooler for normal growth and developmental milestones.
5. Formulate nursing diagnoses related to preschool growth and development and common parental concerns.
6. Identify expected outcomes for nursing care of a preschooler.
7. Plan nursing care to meet a preschooler's growth and development needs, such as planning age-appropriate play activities.
8. Implement nursing care related to normal growth and development of a preschooler, such as preparing a preschooler for an invasive procedure.
9. Evaluate expected outcomes for achievement and effectiveness of care.
10. Identify areas related to care of the preschool-age child that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of preschool growth and development with nursing process to achieve quality maternal and child health nursing care.

Cathy Edwards is a 3-year-old girl. Her father cares for her because her mother is hospitalized as a result of preterm labor for a second pregnancy. Her father tells you he is concerned because Cathy talks constantly with an imaginary friend named Emma. She makes up stories about events that cannot possibly be true. When corrected, Cathy stutters so badly no one can understand her.

The previous chapter described toddler growth and development and the abilities children develop during that period. This chapter adds information about the changes, both physical and psychosocial, that occur during the preschool years. Such information builds a base for care and health teaching for the age group.

Is Cathy's father describing typical preschool behavior, or does Cathy need a referral to a child guidance counselor?

The preschool period traditionally includes ages 3 to 6 years. Although physical growth slows considerably during this period, personality and cognitive growth continue at a rapid rate. This is also an important period of growth for parents. They may be unsure about how much independence and responsibility for self-care they should allow their preschooler. Most children of this age want to do things for themselves—choose their own clothing and dress by themselves, feed themselves completely, wash their own hair, and so forth. As a result, parents of a preschooler may find their child dressed in one red sock and one green sock, going to preschool with unwashed ears, or trying to eat soup with a fork. They need reassurance that this behavior is typical as it is the way that children adjust to new experiences. Parents may also need some guidance in separating those tasks a preschooler can accomplish independently from those that still require some adult supervision so they can set sensible limits. Setting limits this way protects children from harming themselves or others while participating in all the interesting experiences available to them (Thompson & Rivera, 2009). Box 31.1 lists National Health Goals related to the period.

BOX 31.1 ✻ Focus on National Health Goals

A number of National Health Goals are designed to target the preschool population:

- Increase the number of states with laws requiring helmets for bicycle riders under 15 years of age from a baseline of 10 states to 50 states.
- Reduce infectious diarrhea by at least 25% among children in licensed child care centers.
- Reduce acute middle ear infections among children age 4 and younger from a baseline of 344.7 health care visits per 1000 children to 294 visits per 1000 children.
- Increase the rate of use of child auto restraints among children age 4 and younger from a baseline of 92% to 100%.
- Reduce the proportion of children 2 to 4 years of age who have dental caries in their primary or permanent teeth from a baseline of 18% to 11%.
- Reduce the rate of deaths caused by poisoning from a baseline of 6.8 per 100,000 to 1.5 per 100,000 (http://www.nih.gov).

Nurses can help the nation achieve these goals by serving as consultants at day care and preschool settings to be certain that protection from the spread of infectious diseases in these settings is provided and by urging parents to protect against poisoning and to fit their children with helmets before beginning bicycle riding.

A number of questions could benefit from additional nursing research, such as: What practices seem most effective in reducing the spread of infection in day care or preschool settings? What are the barriers to parents buying helmets for this age child? What proportion of parents know the signs and symptoms of common illnesses their child might contract in a child care or preschool setting?

Nursing Process Overview

For Healthy Development of the Preschooler

Assessment

Regular assessment of a preschooler includes obtaining a health history and performing both a physical and developmental evaluation. Preschoolers speak very little during a health assessment; they may even revert to baby talk or babyish actions such as thumb-sucking if they find a health visit stressful. A history that details their usual performance level is therefore very important for accurate evaluation.

Assess a child's weight and height according to standard growth charts (see Appendix E). Keep in mind these charts are based on average weights and heights of white American children, so those for children from other ethnic or cultural backgrounds may not completely agree with these norms. Also assess a child for general appearance. Does the child appear alert? Happy? Active? Healthy? Ask whether a child can play actively without becoming exhausted. Assess the teeth for presence of cavities. Evaluate for a symmetrical gait. As preschoolers develop frequent upper respiratory infections (the average preschooler may have 6 to 12 a year), assess for these as well.

Nursing Diagnosis

Nursing diagnoses for preschoolers typically concern health promotion. Examples are:

- Health-seeking behaviors related to developmental expectations
- Readiness for enhanced parenting related to parent's pride in child

Other nursing diagnoses include:

- Risk for injury related to increased independence outside the home
- Delayed growth and development related to frequent illness
- Risk for poisoning related to maturational age of child
- Parental anxiety related to lack of understanding of childhood development
- Imbalanced nutrition related to child's many food dislikes

Outcome Identification and Planning

For many parents, preschool is a difficult time because a child is at an in-between stage: no longer an infant, although not yet ready for formal school. Planning and establishing expected outcomes for care of the preschooler often begin with establishing a schedule for discussing normal preschool development with the parents (this should be done at all health maintenance visits). Planning for accident prevention such as how to cross streets safely becomes increasingly important as children begin to enjoy experiences away from home. It is important to plan opportunities for adventurous activities or messy play. When asking parents to incorporate adventurous activities or messy material into a preschooler's play, you may be asking them to do something they do not personally enjoy. Most parents do initiate these activities with their child if

they believe they are important, but some are able to do this better than others. Allowing children choices may also be difficult for parents because they want to protect them from making errors. Helpful Web sites about growth and development to recommend are the BabyCenter (http://www.Babycenter.com) and Dr. Greene (http://www.DrGreene.com). Helpful Web sites to alert parents about safety are the American Association of Poison Control Centers (http://www.aapcc.org) and the American Academy of Pediatrics (http://www.aap.org). For questions about car seats, parents can consult the U.S. Department of Transportation National Highway Traffic Safety Administration (http://www.nhtsa.dot.gov). The national 800 telephone number for a poison control center is 1-800-222-1222.

Implementation

Preschool children imitate moods as well as actions. An important nursing intervention, then, is role playing a mood or attitude you would like a child to learn. To project an attitude that health assessment is an enjoyable activity, you might suggest preschoolers participate by listening to their heart or coloring the table paper. Accident prevention is also best taught by role modeling (a parent always crosses streets at the corner and does not start the car until seatbelts are in place).

Outcome Evaluation

Evaluation of expected outcomes needs to be continuous and frequent. Because growth during this period is more cognitive and emotional than physical, parents may report little growth. Evaluating specific areas helps them to see that progress has occurred. Examples of expected outcomes might be:

- Child states importance of holding parent's hand while crossing streets.
- Parent states realistic expectations of 3-year-old's motor ability by next visit.
- Mother reports she has prepared 4-year-old for new baby by next visit.

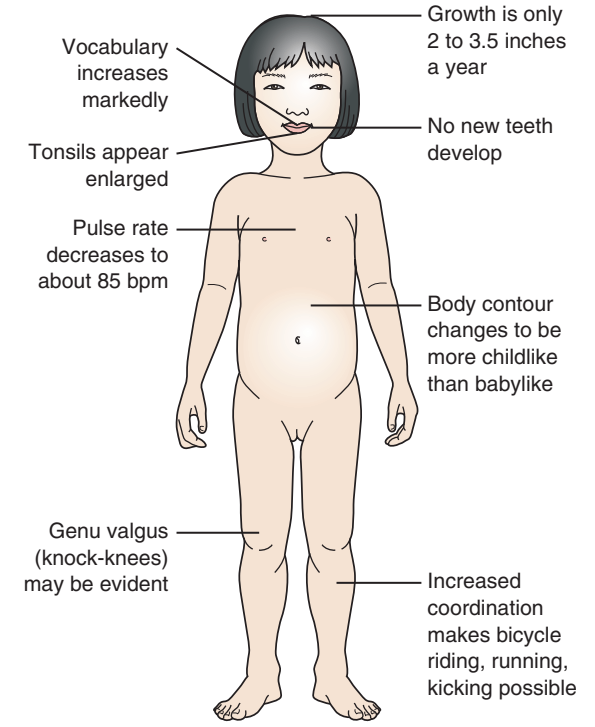
GROWTH AND DEVELOPMENT OF A PRESCHOOLER

Assessment of preschoolers needs to include physical, cognitive, and developmental growth (Box 31.2).

Physical Growth

A definite change in body contour occurs during the preschool years. The wide-legged gait, prominent lordosis, and protuberant abdomen of the toddler change to slimmer, taller, and much more childlike proportions. Contour changes are so definite that future body type—**ectomorphic** (slim) or **endomorphic** (large)—becomes apparent. Handedness begins to be obvious. A major step forward is a child's ability to learn extended language, which is achieved not only by motor but also by cognitive development. Children of this age who are exposed to more than one language or who live in a bilingual family have a unique opportunity to master two languages with relative ease because of this increased cognitive ability.

Box 31.2 Assessment
Assessing the Average Preschooler



Lymphatic tissue begins to increase in size, particularly the tonsils, and levels of IgG and IgA antibodies increase. These changes tend to make preschool illnesses more localized (an upper respiratory infection remains localized to the nose with little systemic fever).

Physiologic splitting of heart sounds may be present for the first time on auscultation; innocent heart murmurs may also be heard for the first time. This type of murmur occurs because of the changing size of the heart in reference to the thorax as the anteroposterior and transverse diameters of the chest reach adult proportions. Pulse rate decreases to about 85 beats per minute; blood pressure holds at about 100/60 mm Hg.

The bladder is easily palpable above the symphysis pubis; voiding is frequent enough (9 or 10 times a day) that play must be interrupted, and accidents may occur if a child becomes absorbed in an activity.

A child who earlier in life had an indeterminate longitudinal arch in the foot generally demonstrates a well-formed arch now. Muscles are noticeably stronger and make activities such as gymnastics possible. Many children at the beginning of the period exhibit **genu valgus** (knock-knees); this disappears with increased skeletal growth at the end of the preschool period.

Weight, Height, and Head Circumference

Weight gain is slight during the preschool years: the average child gains only about 4.5 lb (2 kg) a year. Appetite remains as it was during the toddler years, which is considerably less than some parents would like or expect. Parents may bring a preschooler to a health care facility because they fear their child

is losing weight. When the child's weight is plotted on a growth chart, however, it is evident the child is gaining weight; what parents are noticing is the age-appropriate change in body shape from rounded to slim.

Height gain is also minimal during this period: only 2 to 3.5 in (6 to 8 cm) a year on average (see Appendix E). Head circumference is not routinely measured at physical assessments on children over 2 years of age.

Teeth

Children generally have all 20 of their deciduous teeth by 3 years of age. Preserving these teeth is important as they hold the position for the permanent teeth as the child's jaw grows larger (Mueller, 2008).

Developmental Milestones

Each year during the preschool period marks a major step forward in gross motor, fine motor, and language development. Play activities change focus as the preschooler learns new skills and understands more about the world (Fig. 31.1). Table 31.1 summarizes the major milestones of the period.

Language Development

A 3-year-old child has a vocabulary of about 900 words. These are used to ask questions constantly, up to 400 a day, mostly "how" and "why" questions, such as "Why is snow cold? How do worms hear? What does your tongue do?" A child needs simple answers to such questions so curiosity, vocabulary building, and questioning are encouraged, and also because the depth of a child's understanding is often deceptive. For example, if a parent tells a child shoes should go on with the buckles on the outside, a child may seem to understand but may return in a few minutes to ask, "Why do I have to go outside to put on my shoes?" Words that sound alike but mean different things such as whether and weather can be truly confounding to children of this age.

Four- and 5-year-old children continue to ask many questions. They enjoy participating in mealtime conversation and can describe something from their day in great detail. Preschoolers imitate language exactly, so if they hear less-than-perfect language, this is the language pattern they adopt. They may imitate and use "bathroom language" if not corrected because of the attention from adults this generates.

Preschoolers are egocentric, so they define objects in relation to themselves (a key is not a metal object but "what I use to open a door," and a car is not a means of transportation but "what Mom uses to take me to school").

FIGURE 31.1 Preschoolers like to imitate the roles of adults, as they learn about the world around them.

Whether children are allowed to ask questions is culturally determined and can make a difference in how much vocabulary a child uses. In a society in which children are expected to be seen and not heard, a preschool child may not have the same expressive vocabulary as a child who has been encouraged to ask questions. Recognition that differences among cultures can affect levels of development means that assessment must be individualized and meaningful in terms of the cultural milieu.

Play

Preschoolers do not need many toys. Their imaginations are keener than they will be at any other time in their lives, so they enjoy games that use imitation such as pretending to be teachers, cowboys, firefighters, and store clerks. They imitate exactly what they see parents doing: eating meals, mowing the lawn, cleaning the house, arguing, and so forth, so parents' actions directly influence their behavior (Dooley & Stewart, 2007). Many preschoolers have imaginary friends as a normal part of having an active imagination (Goldson & Reynolds, 2008). These often exist until children formally begin school.

Four- and 5-year-olds divide their time between rough-housing and imitative play. Five-year-olds are interested in group games or songs they have learned in kindergarten or preschool.

TABLE 31.1 ✻ Summary of Preschool Growth and Development

Age (yr)	Fine Motor	Gross Motor	Language	Play
3	Undresses self; stacks tower of blocks; draws a cross	Runs; alternates feet on stairs; rides tricycle; stands on one foot	Vocabulary of 900 words	Able to take turns; very imaginative
4	Can do simple buttons	Constantly in motion; jumps; skips	Vocabulary of 1500 words	Pretending is major activity
5	Draws a 6-part man; can lace shoes	Throws overhand	Vocabulary of 2100 words	Likes games with numbers or letters

✔ Checkpoint Question 31.1

Cathy asks constant questions. How many does a typical 3-year-old ask in a day's time?

a. Less than 50.
b. 100–200.
c. 300–400.
d. 1200 or more.

Emotional Development

Children change a great deal in their ability to understand the world and how they relate to people during the preschool years.

Developmental Task: Initiative Versus Guilt

The developmental task of the preschool years, according to Erikson, is to form a sense of initiative versus guilt (Erikson, 1993).

A child with a well-developed sense of initiative has discovered that learning new things is fun.

If children are criticized or punished for attempts at initiative, they develop a sense of guilt for wanting to try new activities or have new experiences. Those who leave the preschool period with guilt may carry it with them into new situations, such as starting elementary school. They may even have difficulty later in life making decisions about everything from changing jobs to choosing an apartment, because they cannot envision they are capable of solving associated problems.

To gain a sense of initiative, preschoolers need exposure to a wide variety of experiences and play materials so they can learn as much about the world as possible. They are ready to reach outside their homes for new experiences, such as a trip to the zoo or an amusement park (Fig. 31.2). They are interested in seeing new places, and so enjoy going with the family on vacation. These types of experiences lead to increased vocabulary; for instance, at the zoo, preschoolers not only learn words such as *giraffe*, *elephant*, and *bear*, but they also learn to transfer them from abstract concepts to the animals they name.

Urge parents to provide play materials that encourage creative play, such as finger paints, soapy water to splash or blow into bubbles, mud to make into pies, sand to build castles, and modeling clay or homemade dough to mold into figures or make into pretend cookies. These are messy activities, and many parents cannot let a child indulge in them more than once a week, but any experience with free-form play is helpful.

Preschoolers tend to have such active imaginations that they need little guidance in this type of play. They smear both hands into clay or finger paint and create instinctively. Urge parents to support this kind of play but not try to make models. If a parent draws a tree with finger paint, for example, and says, "Now you draw one," a child may decide it is no fun to finger paint because he knows his tree will not look as good as his parent's. As he is not ready for competition, he will drop out of the activity rather than have his drawing shown up as inferior.

Preschoolers may make nothing recognizable out of clay or finger paint, preferring simply to handle the medium. As long as they enjoy the feel of the material, they do not need to make anything. Pressure to make things is not fun and can discourage their interest in learning.

FIGURE 31.2 Preschoolers like exposure to new events and places. Here a 3-year-old is eager to explore the woods during a hike with the family.

Imitation. Preschoolers need free rein to imitate the roles of the people around them. Again, role playing should be fun and does not have to be accurate. If a boy is pretending to be a police officer and is busy putting out fires, or a firefighter and is stopping playmates from speeding, the fact he is freely imitating a role is more important than getting the role absolutely correct. If a parent is concerned a child should separate these two roles accurately, it is usually best not to stop the play to do so. Rather, the next time they are driving past the fire station, the parent could explain this is where firefighters work, and they put out fires, or the police station is where police officers work, and they make sure that people drive safely.

Children generally imitate those activities best that they see their parents performing at home. A young girl will set the table for breakfast, eat with her "husband," help clean off the table, and leave for work. A young boy might cook, pretend to feed a doll, and put the doll to bed as he has seen his father do with a younger sibling. In addition to learning what activities adults carry out at home, preschoolers should also be introduced to their parents' work environments. Such visits not only provide a visual context for the parent's job but also let a child learn such words as photocopier, cash register, assembly line, legal brief, or fax machine.

Today, as many as 90% of mothers of childbearing age work outside the home at least part time. Remind a mother to introduce her preschooler to her "other" self—lawyer, secretary, or telephone repair person—in the same way a child is exposed to the father's outside work side.

Fantasy. Toddlers cannot differentiate between fantasy and reality; they believe cartoon characters or children in books

are real. Preschoolers begin to make this differentiation. They may become so engrossed in a fantasy role, however, they become afraid they have lost their own identity or have become "stuck" in their fantasies. Such intense involvement in play is part of "magical thinking," or believing thoughts and wishes can come true.

Parents sometimes strengthen this feeling without realizing it: they (and you) need to be careful in this regard. A preschooler, for example, may be pretending she is a white rabbit. Her mother walks into the room, is aware of the game, and decides to participate. She says, "That's strange, I don't see Cindy anywhere. All I see is a white rabbit." Then she leaves the room. Cindy can be frightened she has actually become a white rabbit. A better response for the mother would be to support the imitation—this is age-appropriate behavior and a good way of exploring roles—while helping a child maintain the difference between pretend and real. She might say, "What a nice white rabbit you're pretending to be," both supporting the fantasy and yet reassuring a child she is still herself.

In a health care setting, it is particularly important that you let children know they are still recognizable. When examining the ears of a girl who tells you she is a rabbit, comment her ears are all better again, rather than play to the make-believe with remarks about long, furry rabbit ears.

Oedipus and Electra Complexes

Although the development of Oedipus and Electra complexes may have been overstated by Freud because of gender bias, many children do appear to manifest such behavior (Luborsky & Barrett, 2007). An **Oedipus complex** refers to the strong emotional attachment a preschool boy demonstrates toward his mother; an **Electra complex** is the attachment of a preschool girl to her father. Each child competes with the same-sex parent for the love and attention of the other parent. Parents who are not prepared for this behavior may feel hurt or rejected. For example, a daughter prefers to sit beside her father at the table or in the car; she asks her father to tuck her in at night. She is "Daddy's girl." The mother may feel left out of the family interaction when this happens. On the other hand, a boy will ask his mother for the same favors. He wants to sit beside her, to have her read to him, and to tuck him in for the night, and the father may feel left out.

Parents can be reassured that this phenomenon of competition and romance in preschoolers is normal. Parents may need help in handling feelings of jealousy and anger, however, particularly if a child is vocal in expressing feelings toward a parent. It is difficult for a mother to reply calmly to a 3-year-old daughter who is shouting at her, "I hate you! I only love Daddy!" By understanding the motivation behind such a statement, the parent may be able to calmly react by stating, "Well, I don't like to be shouted at, but I still love you."

Gender Roles

Preschoolers need exposure to an adult of the opposite gender so they can become familiar with opposite gender roles. Encourage single parents to plan opportunities for their children to spend some time with adults other than themselves, such as a grandparent, a friend, or a relative of the opposite sex, for this exposure. A preschool teacher may serve as this person. Because most preschool teachers are women, a mother may have to look elsewhere to find an adult male role model. If a child is hospitalized during the preschool period, a male nurse could fill this role.

Children's gender-typical actions are strengthened by parents, strangers, preschool teachers, other family members, and other children. Many parents do not want their child to grow up as they did, with a fixed role as a result of gender stereotyping. Help them understand they reinforce such attitudes by their actions as well as by their words. For example, a father may tell his son it is important for both boys and girls to do housework, but if the father never does dishes, he is teaching his son that managing a household is not a man's job.

Socialization

Because 3-year-olds are capable of sharing, they play with other children their age much more agreeably than do toddlers, which is why the preschool period is a sensitive and critical time for socialization. Children who are exposed to other playmates have an easier time learning to relate to people than those raised in an environment where they never see other children of the same age (Fig. 31.3).

Although 4-year-olds continue to enjoy play groups, they may become involved in arguments more than they did at age 3, especially as they become more certain of their role in the group. This development, like so many others, may make parents worry a child is regressing. However, it is really forward movement, involving some testing and identification of their group role.

Five-year-olds begin to develop "best" friendships, perhaps on the basis of who they walk to school with or who lives closest to them. The elementary rule that an odd number of children will have difficulty playing well together pertains to children at this age: two or four will play, but three or five will quarrel.

FIGURE 31.3 The preschool child begins to develop friendships.

Cognitive Development

At age 3 years, cognitive development according to Piaget is still preoperational (Piaget, 1969). Although children during this period do enter a second phase called **intuitional thought**, they lack the insight to view themselves as others see them or put themselves in another's place (termed *centering*). Because preschoolers cannot make this kind of mental substitution, they feel they are always right. This causes them to argue with the forcefulness that comes from believing they are 100% correct. This is an important point to remember when explaining procedures to preschoolers. They cannot see your side of the situation; they cannot hurry because you must have something done by 10:00 o'clock; they cannot hold still just because you want them to.

Also, preschoolers are not yet aware of the property of **conservation.** This means that if they have two balls of clay of equal size, but one is squashed flatter and wider than the other, preschoolers will insist the flatter one is bigger (because it is wider) or that the intact one is bigger (because it is taller). They cannot see that only the form, not the amount, has changed. This inability to appreciate conservation has implications for nursing care. Preschoolers are not able to comprehend that a procedure done two separate ways is the same procedure. Therefore, if the nurse before you told a child to turn on his right side and then his left side while his bed was made, you may have to allow him to turn those same ways.

Moral and Spiritual Development

Children of preschool age determine right from wrong based on their parents' rules. They have little understanding of the rationale for these rules or even whether the rules are consistent. If asked the question, "Why is it wrong to hit other children?" the average preschooler answers, "Because my mother says it's wrong." When pressed further, the preschooler justifies that conviction with, "It just is, that's all." Because preschoolers depend on their parents to supply rules for them, when faced with a new situation they have difficulty seeing that the rules they know may also apply to a new situation such as a hospital.

Preschoolers begin to have an elemental concept of God if they have been provided some form of religious training. Belief in an outside force aids in the development of conscience; however, preschoolers tend to do good out of self-interest rather than because of strong spiritual motivation (Kohlberg, 1984). Children this age enjoy the security of religious holidays and religious rituals such as prayer and grace before meals because these rituals offer them the same reassurance and security as a familiar nursery rhyme read over and over.

What if... Cathy, 3 years old, understands the rule "Don't steal from stores"? Would she also understand "Don't steal from a hospital"?

HEALTH PROMOTION FOR A PRESCHOOLER AND FAMILY

Preschoolers are old enough to begin to take responsibility for their own actions. The preschooler's safety, nutritional health, daily activities, and family functioning are all affected by this increased responsibility.

Promoting Preschooler Safety

As preschoolers broaden their horizons, safety issues increase. By age 4, children may project an attitude of independence and the ability to take care of their own needs. Part of this is pseudo-independence; they still need supervision to be certain they do not injure themselves or other children while roughhousing and to ensure they do not stray too far from home. Their interest in learning adult roles may lead them into exploring the blades of a lawn mower or an electric saw or a neighbor's pool (Thompson & Rivara, 2009). It is not too early to think about gun safety or being sure that any gun in their home is locked away (DuRant, 2007). They must be reminded repeatedly not to walk in back of or in front of automobiles. Otherwise, a preschooler's thought "I want to play with Mary across the street" can be so quick and so intense a child will run into the middle of the street before remembering the rules "Watch out for cars" and "Don't cross the street."

Because preschoolers imitate adult roles so well, they may imitate taking medicine if they see family members doing so (Box 31.3). A good rule for parents is never to take medicine

BOX 31.3 ✻ Focus on Evidence-Based Practice

Does medicine given for upper respiratory infections pose a major threat for poisoning in preschoolers?
Preschool children usually develop a number of upper respiratory infections a year as this is a time when they are first exposed to other children through preschool or Head Start programs. That makes this the time when children are first introduced to pleasant tasting cough and cold medicines. To investigate whether adverse drug events including poisoning related to common cough and cold medications frequently occur in preschool children, researchers surveyed the emergency departments of 63 U.S. hospitals for a year. During the survey year, 158,520 patients 18 years or younger were treated in emergency departments for unanticipated or adverse drug events. Almost half (49.4%) of these visits occurred in preschool children between 1 and 4 years of age. Unintentional overdose (poisoning) was the most common reason that children were seen (44.9%), followed by allergic reactions (35%) and adverse effects (12.6%). Antimicrobial agents, analgesic medications, and respiratory medications accounted for almost half of adverse drug events (25.2%, 13.7%, and 10.6%, respectively). Fortunately, fewer than 1 in 10 patients (9.5%) required hospitalization or extended observation following these events.

Based on the above, what advice would you want to give parents about using cough or cold medications with preschool children?

BOX 31.4 * Focus on Family Teaching

Common Safety Measures to Prevent Accidents During the Preschool Years

Q. Cathy's father says to you, "My preschooler is so active! How can I keep her safe?"

A. All of the safety measures that apply to toddlers also apply to preschoolers. In addition, try these tips:

Possible Accident	Prevention Measure
Motor vehicles	Teach safety with tricycle (look before crossing driveways; do not cross streets).
	Teach child to always hold hands with a grownup before crossing a street.
	Teach parking lot safety (hold hands with grownup; do not run behind cars that are backing up).
	Children should wear helmets when riding bicycles.
Falls	Supervise preschooler at playgrounds.
	Remove drawstrings from hooded clothing.
	Help child to judge safe distances for jumping or safe heights for climbing.
Drowning	Teach beginning swimming.
Animal bites	Do not allow child to approach strange dogs.
	Supervise child's play with family pets.
Poisoning	Never present medication as a candy.
	Never take medication in front of a child.
	Never store food or substances in containers other than their own.
	Post telephone number of local poison control center by the telephone.
	Teach child that medication is a serious substance and not for play.
Burns	Store matches in closed containers.
	Do not allow preschooler to help light birthday candles, fireplaces, etc. (fire is not fun or a "treat").
Community safety	Teach preschooler that not all people are friends ("Do not talk to strangers or take candy from strangers").
	Define a stranger as someone a child does not know, not someone odd-looking.
	Teach child to say "no" to people whose touching the child does not enjoy, including family members. (When a child is sexually abused, the offender is usually a family member or close family friend.)
General	Know whereabouts of preschooler at all times.
	Be aware that frequency of accidents is increased when parents are under stress. Special precautions must be taken at these times.
	Some children are more active, curious, and impulsive and therefore more vulnerable to accidents than others.

in front of children. Additional safety points for the preschool period are summarized in Box 31.4.

Keeping Children Safe, Strong, and Free

The preschool years are not too early a time to educate children about the potential threat of harm from strangers or even how to address bullying behavior from people (children or adults) they meet at preschool or at play. This includes:

- Warning a child never to talk with or accept a ride from a stranger
- Teaching a child how to call for help in an emergency (yelling or running to a designated neighbor's house if outside, or dialing 911 if near a telephone)
- Describing what police officers look like and explaining that police officers can help in an emergency situation
- Explaining that if children or adults ask them to keep secrets about anything that has made them uncomfortable, they should tell their parents or another trusted adult, even if they have promised to keep the secret
- Explaining that bullying behavior from other children is not to be tolerated and should be reported so they can receive help managing it

It is often difficult for parents to impart this type of information to preschoolers because they cannot imagine their child will ever be in situations in which the information will be needed, nor do they want to terrify their child about the world. However, if the information is presented in a calm yet serious manner, children can begin to use it to build safe habits that will help them later when they are old enough to walk home from school alone or play with their friends, unsupervised, at a public playground.

Motor Vehicle and Bicycle Safety

With more and more cars being equipped with front-seat air bags, make certain parents safely buckle preschoolers into car seats in the back seat (American Academy of Pediatrics [AAP], 2009). Parents should stress the important role of seat belts in preventing injury in accidents and should make it a rule that the car does not move until seatbelts are fastened. Many preschoolers outgrow their first car seats during this period (when they reach 40 lb) and need to graduate to a booster-type seat. Remind parents to check the position of the shoulder harness so it does not go across a child's face or throat.

Preschool is also the right age to promote bicycle safety (Pardi, 2007). Head injuries are a major cause of death and injury to preschoolers, and bicycle accidents are among the major causes of such injuries. Some parents may have already purchased a helmet for their child when the child was

a toddler and riding in a bicycle seat. Once children begin riding independently, however, they definitely need a safety helmet approved for children their age and size. Encourage parents who ride bicycles to demonstrate safe riding habits by wearing helmets as well. Seeing a parent routinely wearing a helmet may well be the most compelling reason for a preschooler to wear one.

What if... Cathy tells you she knows not to leave preschool with anyone who is strange? Is that the same as knowing not to leave with a stranger?

Promoting Nutritional Health of the Preschooler

Like the toddler period, the preschool years are not a time of fast growth, so preschool children are not likely to have ravenous appetites. Offering small servings of food is still a good idea, so a child is not overwhelmed by the amount on a plate and is allowed the successful feeling of cleaning a plate and asking for more. Parents need to check that children are not snacking so frequently that they miss out on planned meals to be certain children receive a complete range of nutrients (Gable, Chang, & Krull, 2007).

Most children are hungry after preschool and enjoy a snack when they arrive home. Because sugary foods can dull a child's appetite for dinner and it is not too soon to begin measures to prevent childhood obesity, urge parents to offer foods such as fruit, cheese, or milk rather than cookies and a soft drink (Rolfes, Pinna, & Whitney, 2009).

Teach parents to make mealtime a happy and enjoyable part of the day for everyone. Some preschool children learn to eat as quickly as possible (and perhaps incompletely) to escape from the table before something unpleasant happens, such as an argument they can sense is brewing. Initiative, or learning how to do things, can be strengthened by allowing a child to prepare simple foods, such as making a sandwich or spreading jelly on toast.

Recommended Dietary Reference Intakes

As with all age groups, foods selected for preschoolers should be based on food pyramid groups, making sure to offer a variety. Preschoolers may not eat a great deal of meat because it can be hard to chew. Many parents ask whether their preschooler needs to take supplementary vitamins because they eat so little. As long as a child is eating foods from all pyramid food groups and meets the criteria for a healthy child such as being alert and active, with height and weight within normal averages, additional vitamins are probably unnecessary.

If parents do give vitamins, remind them a child will undoubtedly view a vitamin as candy rather than medicine because of the attractive shapes and colors of preschool vitamins, so they must be stored out of reach. Caution parents not to give more vitamins than the recommended daily amount, because poisoning from high doses of fat-soluble vitamins or iron can result.

Promoting Nutritional Health With a Vegetarian Diet

A vegetarian diet is usually colorful and therefore appeals to preschoolers. Many vegetables, fruits, and grains are also good snack foods and so are convenient for a child who eats frequently during the day.

If vegetarian diets are deficient in any aspects, they usually lack calcium, vitamin B_{12}, and vitamin D. Check to see a child is ingesting a variety of calcium sources (green leafy vegetables, milk products) as this is so important for bone growth. Vitamin D is found in fortified cereals and milk. Vitamin B_{12} is found almost exclusively in animal products, so a child may need a supplemental source of this (Rolfes, Pinna, & Whitney, 2009).

Promoting Development of the Preschooler in Daily Activities

The preschooler has often mastered the basic skills needed for most self-care activities, including feeding, dressing, washing (with supervision), and brushing teeth (again, with supervision).

Dressing

Many 3-year-olds and most 4-year-olds can dress themselves except for difficult buttons, although there may be a conflict over what a child will wear. Preschoolers prefer bright colors or prints and so may select items that do not match. As with other preschool activities, however, children need the experience of choosing their own clothes. One way for parents to solve the problem of mismatching is to fold together matching shirts and pants so a child sees them as a set rather than individual pieces. If children insist on wearing mismatched clothes, parents should make no apologies for their appearance. A simple statement such as "Mark chose his own clothes today" explains the situation. Anyone who understands preschoolers appreciates that the experience children gain in being able to select their own clothing is worth more than a perfect appearance by adult standards.

Sleep

Many toddlers, going through a typical negative phase, resist taking naps no matter how tired they are. Preschoolers, on the other hand, are more aware of their needs; when they are tired, they often curl up on a couch or soft chair and fall asleep. Many, particularly those who attend afternoon child care or preschool, give up afternoon naps. If they nap at a preschool, they may have some difficulty going to sleep at the usual bedtime established at home.

Children in this age group, however, may refuse to go to sleep because of fear of the dark. Night waking from nightmares or night terrors reaches its peak (Hiscock et al., 2007). This means preschoolers may need a night light, although they did not need one before. A helpful suggestion for parents is to screen out frightening stories or television watching just prior to bedtime and continue familiar bedtime routines.

Exercise

The preschool period is an active phase, so children receive a great deal of exercise. Rough-housing is a good way of getting rid of tension and should be allowed as long as it does not become destructive. In addition, preschoolers love time-honored games such as ring-around-the-rosy, London Bridge, or other more structured games they were not ready for as toddlers. Promoting this type of active game and reducing television

watching can help children develop motor skills as well as be a step toward preventing childhood obesity (Kline, 2008).

Hygiene

Preschoolers can wash and dry their hands adequately if the faucet is regulated for them so they do not scald themselves with hot water. Also, when possible, parents should turn down the temperature of the water heater in their home to under 120° F to help prevent scalds. Preschoolers do not clean their fingernails very well, so these often need "touching up" by a parent or older sibling. The child may also need the assistance of a parent or older sibling to clean the ears during bath time. Hair washing can be a problem, as well. Preschoolers are too heavy for a parent to hold over the sink to rinse their hair, and children may have difficulty keeping the eyes closed well enough or long enough to keep soap out because they insist on opening them to see whether the parent is finished. Hanging a mobile over the tub so they have a reason to look up for rinsing and using a nonirritating shampoo are good suggestions. Although preschoolers may sit well in bathtubs, they should still not be left unsupervised at bath time. Caution parents about not using bubble bath with preschoolers as some girls develop vulvar irritation (and perhaps bladder infections) from exposure to such products.

Care of Teeth

If independent toothbrushing was not started as a daily practice during the infant or toddler years, it should be started during the preschool years. A child should continue to drink fluoridated water or receive a prescribed oral fluoride supplement if fluoride is not provided in the water supply (Armfield & Spencer, 2007).

One good toothbrushing period a day is often more effective than more frequent half-hearted brushings. Although many preschoolers do well brushing their own teeth, parents must check that all tooth surfaces are cleaned. They should floss the teeth, because this is a skill beyond a preschooler's motor ability.

Toothbrushing is generally well accepted by preschoolers because it imitates adults. Electric or battery-operated toothbrushes are favorites because of the adult responsibility involved in handling them. Children must be supervised when using an electric toothbrush, however, and must be taught not to use it or any other electrical appliance near a basin of water.

Encouraging children to eat apples, carrots, celery, chicken, or cheese for snacks rather than candy or sweets is yet another way to attempt to prevent tooth decay. If a child is allowed to chew gum, it should be the sugar-free variety.

Children should have made a first visit to a dentist by 2½ years of age for evaluation of tooth formation. Because this visit usually shows no cavities, this should have been a pain-free experience, so a child should not fear the dentist, and the idea that dentists like to help rather than hurt should have been implanted. If parents did not take a child for this visit previously, it should be done during the preschool period. Deciduous teeth must be preserved to protect the dental arch. If teeth have to be pulled as a result of disease, the permanent teeth can drift out of position or the jaw may not grow enough to accommodate them.

Night Grinding. **Bruxism**, or grinding the teeth at night (usually during sleep), is a habit of many young children (Goddard, 2008). Teeth grinding may be a way of "letting go," similar to body rocking, that children do for a short time each night to release tension and allow themselves to fall asleep. Children who grind their teeth extensively may have greater-than-average anxiety. Children with cerebral palsy may do it because of the spasticity of jaw muscles. If the grinding is extensive, the crowns of the teeth can become abraded. The condition can advance to such an extent that tooth nerves become exposed. If the problem seems to stem from anxiety, identifying and relieving the source of anxiety is essential for treatment. If some damage is evident, refer the family to a pedodontist so the teeth can be evaluated, repaired (capped), and conserved.

Promoting Healthy Family Functioning

Some parents who enjoyed maintaining a rhythm of care for an infant and allowed for ritualistic behavior of a toddler may have difficulty being the parents of a preschooler because more flexibility and creativity are required. Others come into their own as the parents of a preschooler; they delight in encouraging imaginative games and play.

A major parental role during this time is to encourage vocabulary development. One way to do this is to read aloud to a child; another is to answer questions so a child sees language as an organized system of communication. Answering a preschooler's questions can be difficult because the questions are frequently philosophical; for example, "Why is grass green?" A child may listen to an explanation of chlorophyll but then repeat the question, regardless of the clarity of the explanation, because the parent underestimated the extent of the question: a child did not want to know what makes grass green, but why, philosophically, it is not red or blue or yellow. The obvious answer to that is, "I don't know." Parents who are confident can give this answer without feeling threatened. Parents who are less sure of themselves may feel extremely uncomfortable when they realize they do not know the answers to a 4-year-old's questions (Box 31.5).

Discipline

Preschoolers have definite opinions on things such as what they want to eat, where they want to go, and what they want to wear. This may bring them into opposition with parents. A major parental responsibility when this happens is to guide a child through these struggles without discouraging the child's right to have an opinion. "Timeout" is a good technique to correct behavior for parents throughout the preschool years (see Chapter 30). This technique allows parents to discipline without using physical punishment and allows a child to learn a new way of behavior without extreme stress.

Parental Concerns Associated With the Preschool Period

A number of common health problems and fears usually arise during the preschool years.

Common Health Problems of the Preschooler

The mortality of children during the preschool years is low and becoming lower every year as more infectious diseases

BOX 31.5 ✻ Focus on Communication

Cathy's father brings her for a well-child visit. You overhear him talking to his daughter in the waiting room.

Less Effective Communication

Cathy: Why do we have to wait so long?
Mr. Edwards: It's how things work here.
Cathy: Why?
Mr. Edwards: I have no idea.
Cathy: Why is that girl here? Is she sick?
Mr. Edwards: I have no idea.
Cathy: When are we going home?
Mr. Edwards: I have no idea.
Cathy: What's that girl's name?
Mr. Edwards: I have no idea.

More Effective Communication

Cathy: Why do we have to wait so long?
Mr. Edwards: It's how things work here.
Cathy: Why?
Mr. Edwards: People have to take turns. We're waiting for our turn.
Cathy: Why is that girl here? Is she sick?
Mr. Edwards: She might be. Some children are here because they're sick and some are just in for a check-up like you.
Cathy: When are we going home?
Mr. Edwards: As soon as the nurse practitioner checks you over.
Cathy: What's that girl's name?
Mr. Edwards: I don't know. Do you want to ask her?

Preschoolers ask 300 to 400 questions a day as they explore their world. In the first scenario, the father tries to discourage questions by offering almost no answers. In the second scenario, when he tries to answer a child's questions, he is not only supplying information but is also helping a child build vocabulary. Because preschoolers ask so many questions, you may have to encourage parents to continue to answer questions this way. Otherwise, discouraging questions can become the method of interaction.

are preventable. This results in the major cause of death being automobile accidents, followed by poisoning and falls (Centers for Disease Control and Prevention [CDC], 2008).

The number of minor illnesses, such as colds, ear infections, and flu symptoms, is also high. Children who live in homes in which parents smoke have a higher incidence of ear (otitis media) and respiratory infections than others (Kaul & Stevens-Simon, 2008). Children who attend child care or preschool programs also have an increased incidence of gastrointestinal disturbances (such as vomiting and diarrhea) from the exposure to other children (Butterton & Calderwood, 2008).

Many parents find it extremely difficult to cope with the parade of constant minor infections that occur, causing stress between parent and child, an almost monthly battle of "Stay indoors until you feel better," conflict. Children may demonstrate frequent whining or clinging behavior because they do not feel completely well. Such constant illness can cause parents to perceive a child as sickly or not able to cope with everyday life. Whereas parents encouraged independence before, they may now begin to overprotect (to shelter to too great a degree). Give reassurance that frequent minor illnesses are common in preschoolers. As parents become more experienced in handling these conditions, their perception of whether an illness is a problem will change.

Table 31.2 shows the usual health maintenance schedule for preschoolers. Table 31.3 lists common problems parents may have in evaluating a preschooler's illness.

Common Fears of the Preschooler

Because preschoolers' imagination is so active, this can lead to a number of fears. Fears of the dark, mutilation, and separation or abandonment are all very real to a preschooler. These can rise in incidence when combined with the stress of an illness or hospitalization (Anderzen-Carlsson et al., 2007). Although most of these fears can be handled by comforting from parents, in some children, fears are so intensified that they need therapy such as desensitization to the fear (Gordon et al., 2007).

Fear of the Dark. The tendency to fear the dark is an example of a fear heightened by a child's vivid imagination: a stuffed toy by daylight becomes a threatening monster at night. Children awaken screaming because of nightmares. They may be reluctant to go to bed or to go back to sleep by themselves.

If parents are prepared for this fear and understand it is a phase of growth, they are better able to cope with it. It is generally helpful if they monitor the stimuli their children are exposed to, especially around bedtime. This includes television, adult discussions, and frightening stories. Parents are sometimes reluctant to leave a child's light on at night because they do not want to cater to the fear. Burning a dim night light, however, can solve the problem and costs only pennies. Children who awake terrified and screaming need reassurance they are safe, that whatever was chasing them was a dream and is not in their room. They may require an understanding adult to sit on their bed until they can fall back to sleep again (Fig. 31.4). Most preschoolers do not remember in the morning that they had such a dream; they remember for a lifetime they received comfort when they needed it.

If parents take sensible precautions against fear of the dark or nightmares and a child continues to have this kind of disturbance every night, it may be a reaction to undue stress. In these instances, the source of the stress needs to be investigated. Giving sleep medication to counteract the sleep disturbance does not help solve the basic problem, so this is rarely recommended. Fear of the dark can become intensified in a hospital setting and requires careful planning to relieve.

Fear of Mutilation. Fear of mutilation is also significant during the preschool age, as revealed by the intense reaction of a preschooler to even a simple injury such as falling and scraping a knee or having a needle inserted for an immunization. A child cries afterward not only from the pain but also from the intrusiveness of the injury or procedure. Part of this fear

TABLE 31.2 ✻ Health Maintenance Schedule, Preschool Period

Area of Focus	Methods	Frequency
Assessment		
Developmental milestones	History, observation	Every visit
	Formal Denver Developmental Screening Test (DDST II)	Before start of school
Growth milestones	Height, weight plotted on standard growth chart; physical examination	Every visit
Hypertension	Blood pressure	Every visit
Nutrition	History, observation; height/weight information	Every visit
Parent–child relationship	History, observation	Every visit
Behavior problems	History, observation	Every visit
Vision and hearing defects	History, observation	Every visit
	Formal Preschool E and audiometer testing	Before start of school
Dental health	History, physical examination	Every visit
Tuberculosis	PPD test (if there are high-risk factors)	Before start of school
Immunizations		
Diphtheria, pertussis, and tetanus vaccine (DTaP)	Check history and past records; inform caregiver about any risks and side effects; administer immunization in accordance with health care agency policies	Before start of school (4–6 years)
Hepatitis A vaccine		If not previously immunized
Influenza vaccine		Yearly
Measles, mumps, and rubella (MMR) vaccine		Before start of school (4–6 years)
Pneumococcal polysaccharide vaccine (PVV)		If underlying medical conditions
Poliomyelitis (inactivated) vaccine		Before start of school (4–6 years)
Varicella vaccine		4–6 years (2nd)
Anticipatory Guidance		
Preschool care	Active listening and health teaching	Every visit
Expected growth and developmental milestones before next visit	Active listening and health teaching	Every visit
Accident prevention	Counseling about street and personal safety	Every visit
Any problems expressed by caregiver during course of the visit	Active listening and health teaching regarding preschool illnesses and need for imaginative play	Every visit

Source: American Academy of Pediatrics. (2009). *Recommendations for preventive pediatric health care.* Washington, DC: Author.

arises because preschoolers do not know which body parts are essential and which ones—like an inch of scraped skin—can be easily replaced. Boys develop a fear of castration because developmentally they are more in tune with their body parts and are starting to identify with the same-sex parent as they go through the Oedipal phase. Preschoolers can worry that if some blood is taken out of their bodies, all of their blood will leak out. They often lift a bandage to peek at an incision or cut to see if their body is still intact underneath. They dislike procedures such as needlesticks, rectal temperature assessment, otoscopic examination, or having a nasogastric tube passed into their stomach. They need good explanations of the limits of health care procedures such as a tympanic thermometer does not hurt or a finger prick heals quickly or distraction techniques in order to feel safe (Windich-Biermeier et al., 2007).

Fear of Separation or Abandonment. Fear of separation continues to be a major concern for preschoolers. For some children, it intensifies because their keen imagination allows them to believe they have been deserted when they are safe. Their sense of time is still so distorted they cannot be comforted by assurances such as, "Mommy will pick you up from preschool at noon." Their sense of distance is also limited, so making a statement such as "I work only a block away" is not reassuring. Relating time and space to something a child knows, such as meals, television shows, or a friend's house, is most effective. For example, stating, "Mommy will pick you up from preschool after you have had your snack" or showing a child the work site might be more comforting.

Caution parents to be sensitive to such fears when they talk about missing children or if they have their preschooler's fingerprints taken for identification. Children whose chief

TABLE 31.3 ✻ Parental Difficulties Evaluating Illness in a Preschool Child

Difficulty	Helpful Suggestions for Parents
Evaluating seriousness of illness or condition	Preschoolers are eager to please and tend to answer all questions such as, "Does your stomach hurt?" with a yes. Observing the child for signs of illness—refusing to eat, holding an arm stiffly, having to go to the bathroom frequently—is often more productive as an evaluation technique.
Evaluating bowel and bladder problems	Preschoolers are independent in toilet habits for the first time, so parents do not have diaper contents to evaluate. Frequent trips to the bathroom, rubbing the abdomen, and holding genitals are the usual signs of bowel or bladder dysfunction.
Evaluating nutritional intake	Preschoolers begin to eat away from home at friends' houses or at child care, or to stay overnight with grandparents, so parents do not observe daily food intake as accurately as before. Observing whether a child is growing and active is better than monitoring any one day's food intake.
Evaluating bedwetting	Many preschoolers continue to have occasional enuresis at night until school age. If other signs are present—pain, low-grade fever, listlessness—a child should have a urine culture, as persistent bedwetting can indicate a low-grade urinary tract infection.
Evaluating activity vs. hyperactivity	Many lay magazines have articles on hyperactivity in children. Parents often wonder whether their active child is truly hyperactive. As a rule of thumb, if a child can sit through a meal (when he is hungry), watch a half-hour television show (that is his favorite), or sit still while his favorite story is read to him, he is not hyperactive.
Age-specific diseases to be aware of	Preschool age is a time for vision and hearing assessment. For the first time, a child is able to be tested by a standard chart or by audiometry. Urinary tract infections tend to occur with a high frequency in preschool-age girls. Language assessment should be done if a child is not able to make wants known by complete, articulated sentences by age 3 (exceptions are transposing *w* for *r* and broken fluency: "I want-want-want to go").

fear is that they will be abandoned or kidnapped might not hear that fingerprints are being taken to keep them safe, only that someone might take them away from their parents.

A hospital admission or going to a new school often brings a child's fear of separation to the forefront. Help parents thoroughly prepare preschoolers for these experiences so they can survive them in sound mental health (Chapter 36).

FIGURE 31.4 Having mom close by after a bad dream is a comfort to the preschooler.

Behavior Variations

A combination of a keen imagination and immature reasoning results in common behavior variations in preschoolers.

Telling Tall Tales. Stretching stories to make them seem more interesting is a phenomenon frequently encountered in this age group. After a trip to the zoo, for example, if you ask a child of this age, "What happened today?" a child perceives you want something exciting to have happened, so might answer, "A bear jumped out of his cage and ate up the boy next to me." This is not lying, but merely supplying an expected answer. Caution parents not to encourage this kind of storytelling, but instead help the child separate fact from fiction by saying, "That's a good story, but now tell me what really happened." This conveys the idea a child has not told the truth, yet does not squash imagination or initiative.

Imaginary Friends. Many preschoolers have an imaginary friend who plays with them (Goldson & Reynolds, 2008). They tell a parent to "wait for Eric" or "set a place at the table for Lucy." Although imaginary friends are a normal, creative part of the preschool years and can be invented by children who are surrounded by real playmates as well as by those who have few friends, parents may find them disconcerting. If so, ask parents to make certain their child has exposure to real playmates. As long as imaginary playmates do not take center stage in children's lives or prevent them from socializing with other children, they should not pose a problem and

often leave as quickly as they come. In the meantime, they can encourage language development and may provide an outlet for a child to express innermost feelings or serve as a handy scapegoat for behavior about which a child has some conflict.

Parents can help their preschooler separate fact from fantasy about their imaginary friend by saying, "I know Eric isn't real, but if you want to pretend, I'll set a place for him." This response helps a child understand what is real and what is fantasy without restricting a child's imagination or creativity.

Difficulty Sharing. Sharing is a concept that first comes to be understood around the age of 3 years. Before this, children engage in parallel play (two children need two toys and two spaces to play, because they cannot pass one toy back and forth or play together). Around 3 years of age, children begin to understand that some things are theirs, some belong to others, and some can belong to both. For the first time, they can stand in line to wait for a drink, take turns using a shovel at a sandbox, and share a box of crayons. Sharing does not come easily, however; children who are ill or under stress have even greater difficulty with it than usual. Assure parents that sharing is a difficult concept to grasp and that, as with most skills, preschoolers need practice to understand and learn it.

Parents need to accompany experiences with sharing with experiences in learning property rights: "This is my private drawer and no one touches what is in it but me." "That is your dresser top, and no one touches the things on it but you." "A shovel is ours and can be used by everyone playing in the sand pile." Defining limits and exposing children to these three categories (*mine, yours, ours*) helps them determine which objects belong to which category.

Regression. Some preschoolers, generally in relation to stress, revert to behavior they previously outgrew, such as thumb-sucking, negativism, loss of bladder control, and inability to separate from their parents. Although the stress that causes this may take many forms, it is usually the result of such things as a new baby in the family, a new school experience, seeing frightening and graphic television news, stress in the home from financial or other problems, marital difficulties, or separation caused by hospitalization.

Help parents understand that regression in these circumstances is normal, and a child's thumb-sucking is little different from the parents' reaction to stress (smoking many cigarettes, nail biting, overeating), to make it easier for them to accept and understand. Obviously, removing the stress is the best way to help a child discontinue this behavior. The stresses mentioned, however, are not easily removed. New babies cannot be returned, irreparable marriages cannot be patched together, frightening news happens every day, and hospitalizations do occur.

Techniques for minimizing the stress of hospitalization for preschoolers are discussed in Chapter 36. Children's reactions to severe and prolonged stress are discussed in Chapter 54. Children undergoing less severe stress can be assured that although situations are changing, the important aspect of their life—someone still loves them and will continue to take care of them—is not. Thumb-sucking or other manifestations of stress are best ignored; calling them to a child's attention merely causes more stress, because it makes children aware they are not pleasing parents, in addition to experiencing the primary stress.

Sibling Rivalry. Jealousy of a brother or sister may first become evident during the preschool period (Taylor, 2007). This occurs partly because this is the first time that children have enough vocabulary to express how they feel (know a name to call) and partly because preschoolers are more aware of family roles and how responsibilities at home are divided. For many children, this is also the time when a new brother or sister is born.

A firstborn child is rarely allowed the privileges of a second child. The parents were untried, unsure of how far they should let a child venture or what level of responsibility a child could accept when the child was younger, or the firstborn serves as the "trial run" for all children who come after. This phenomenon can lead to sibling rivalry, because children as young as preschool can sense that a younger sibling is being allowed behavior that was not tolerated in them. They are little appeased by the explanation, "Your brother is just a baby."

To help preschoolers feel secure and promote self-esteem, supplying them with a private drawer or box for their things that parents or other children do not touch can be helpful. This can help defend their possessions against younger children who do not appreciate their property rights.

Preparing for a New Sibling

Introduction of a new sibling is such a major happening that parents need to take special steps to be certain their preschooler will be prepared. There is no rule as to when this preparation should begin, but it should be before the time the child begins to feel the difference the new baby will make. This is perhaps when the mother first begins to look pregnant. It is certainly before parents begin to make physical preparations for the new child. It is always less frightening for a child of any age to understand why things are happening, no matter how distasteful they may be, rather than hear people whispering or having parents obviously evading the issue. The unknown is always more fearful than a definite event that can be faced and conquered.

Help parents not to underestimate the significance of a bed to a preschool child. It is security, consistency, and "home." If their preschooler is sleeping in the crib that is to be used for the new baby, it is usually best if the preschooler is moved to a bed about 3 months in advance of the birth. The parents might explain, "It's time to sleep in a new bed now because you're a big boy." The fact that he is growing up is a better reason for such a move than because a new brother or sister wants the old bed. The latter is a direct route to sibling rivalry and jealousy.

If children are to start preschool or child care, they should do so either before the new baby is born or 2 or 3 months afterward, if possible. That way, children can perceive starting school as a result of maturity and not of being pushed out of the house by the new child.

If the mother will be hospitalized for the birth, she should be certain her child is prepared for this separation in advance. As the mother is likely to go to the hospital during the night, it is unrealistic to expect a child in the morning to be happy about the arrival of a new sibling when he realizes the new baby has taken away his mother. Some communities offer preparation for birth classes for preschoolers, the same as for parents, or include children in adult preparation courses to help them master this new experience.

FIGURE 31.5 A preschooler greets a new baby sister. She feels special as dad explains how important it is to be a big sister.

Encourage women to maintain contact with their preschooler during the short time they are hospitalized for the new birth. Some preschoolers may react very coldly to their mothers, turning their head away and refusing to come to them after even a few days' separation when they return home. This is a reaction not to the new baby but to the separation, the same phenomenon that may occur when a child returns home after being hospitalized (see Chapter 36). Allowing the child to visit in the hospital can help relieve this type of separation anxiety.

Ask pregnant women or couples what kind of preparation such as this they are making for older children; ask the mother of a new baby how everything is working out. Most parents find the problem of jealousy is bigger than they anticipated and welcome a few suggestions about how to provide more time for their preschooler during the day and which activities a preschooler would especially enjoy (Fig. 31.5; Box 31.6).

✔ Checkpoint Question 31.2

Cathy will need to change to a new bed because her baby sister will need Cathy's old crib. What measure would you suggest that her parents take to help decrease sibling rivalry between Cathy and her new sister?

a. Ask her to get her crib ready for the new baby.
b. Tell her she will have to share with the baby.
c. Move her to the new bed before the baby arrives.
d. Explain that sisters grow up to become best friends.

Sex Education

Children during the preschool age become acutely aware of the difference between boys and girls, possibly because it is a normal progression in development and possibly because this may be the first time in their lives they are exposed to the genitalia of the opposite sex as they watch while a new brother or sister has diapers changed, they see other children using the bathroom at a preschool, or they see a parent nude.

Preschoolers' questions about genital organs are simple and fact-finding; for example, "Why does James look like that?" or "How does Jasmine pee?" Explanations should be just as simple: "Boys look different from girls. The different part is called a penis." It is important for parents not to convey that these body parts are never to be talked about to leave an open line of communication for sexual questions. Occasionally, girls attempt to void standing up as they have seen boys doing; boys may try sitting down to void as they try to use this new body knowledge.

It is common for preschoolers to engage in masturbation while watching television or being read to or before they fall asleep at night. The frequency of this may increase under stress, as does thumb-sucking. If observing a child doing this bothers parents, suggest they explain that certain things are done in some places but not in others. Children can relate to this kind of direction without feeling inhibited, just as they can accept the fact that they use a bathroom in private or eat only at the table. Calling unnecessary attention to the act can increase anxiety and cause increased, not decreased, activity.

An important part of sex education for preschoolers is teaching them to avoid sexual abuse, such as not allowing anyone to touch their body unless they agree it is all right (see Chapter 32, Box 32.5). Because children have been taught this, remember to ask permission before giving nursing care that involves touching.

Because this may be the time a new brother or sister comes into the family, it is also the most likely time for questions such as, "Where do babies come from?" Because a child

BOX 31.6 ✻ Focus on Family Teaching

Suggestions to Help Minimize Sibling Rivalry

Q. Cathy's father says to you, "Cathy's acting jealous of her new sister and she's not even born yet. How can I reduce sibling jealousy?"

A. This isn't a simple problem, but the following suggestions might help:

- After returning home from the hospital, devote attention to your preschooler and spend some special time together after the baby has gone to bed.
- When friends and family visit, encourage them to spend time with the preschooler as well as the baby. If they bring gifts for the baby, it is often wise for them to bring a small present for the preschooler as well.
- So that your preschooler does not come to expect gifts (promoting sibling rivalry), teach her to help open the baby's gifts. Explain to her that it is the baby's birthday and on her birthday she will receive gifts, too.
- Do not ask your preschooler a question such as, "Do you like your new sister?" It is better to express feelings of empathy such as, "New babies cry a lot. It's hard to get used to that, isn't it?"
- Provide special time for your preschooler during each day, so that when you say, "Mother and Daddy love you just the same," it seems real. This might be a quiet time for talking or reading.
- While feeding the baby, read or tell a story to your preschooler. Some children enjoy feeding a doll while a parent feeds the baby or giving a doll a bath while the baby has one.

FIGURE 31.6 Preschool children are interested in learning where babies grow and have beginning sexual awareness. (From Taeke Henstra/Science Source/Photo Researchers, Inc.)

is asking a simple fact-finding question, parents usually find a simple, factual answer to this type of question is best: "Babies grow in a special place in a mother's body called a uterus." Saying "uterus" rather than "tummy" prevents children from envisioning babies and food all mixed together in their mother's stomach (Fig. 31.6).

It is so natural for preschoolers to ask about where babies come from that those who do not ask are exceptions. Preschoolers who do not ask may be reticent because they sense from a preliminary exploratory question that the subject is closed. A parent could introduce the subject by visiting a new baby in the neighborhood with the child or pointing out a neighbor who is pregnant. The birth of kittens or puppies can also offer the chance to introduce the subject. If a new brother or sister will be born at a birthing center or at home, many parents allow preschoolers to watch the birth. Encourage parents to prepare children well for this experience, or else the sight of their mother in pain and the wonder of birth can become an overwhelming and negative experience rather than a positive one for them.

Preschool children generally do not ask how babies get inside mothers to start growing or how babies get out at the end of the process. Should they ask, a suitable explanation might be, "When a woman and a man love each other and decide they want a baby, the man plants a seed inside the woman. The man's seed and the woman's seed grow together in the special place inside the mother into a new baby." Some parents prefer to say, "God plants a seed." This answer may leave preschool boys feeling cheated that men have such a little role in this wondrous process. Perhaps a compromise statement is, "God helps the man plant a seed." If preschoolers ask how the baby gets out, an answer might be, "The woman goes to the hospital and the doctor or nurse helps the baby get out from the vagina."

Many new books for children explain where babies come from, including descriptions of sexual relations and orgasm. These are helpful for parents to read to a child to increase understanding.

Choosing a Preschool or Child Care Center

A school or child care experience is helpful for preschoolers, as peer exposure appears to have a positive effect on social development (Zoritch, Roberts, & Oakley, 2009). Children who have learned to be comfortable in a preschool group approach school comfortably and ready to learn; children who have played only infrequently in groups during the preschool age are forced into this new situation in kindergarten or first grade. They can be so busy adjusting to this new concept they are left behind in learning new skills. The terms "child care center," and "preschool," are often used interchangeably, so parents cannot depend on the name of a school to define its structure. Traditionally, the main purpose of a child care center is to provide child care while parents work or are otherwise occupied. A preschool is dedicated to stimulating children's sense of creativity and initiative and introducing them to new experiences and social contacts they would not ordinarily receive at home. Head Start programs and many modern child care centers fulfill both functions (Olsen & DeBoise, 2007).

If there are other 3- or 4-year-old children in a neighborhood with whom a child has almost daily contact, and if a parent can supervise organized play dates and projects (providing peer interaction, in which working together is the key), a preschool program may not be necessary. On the other hand, if all the neighborhood children are either older or younger or there is only one other child available to play with during the day, a preschool experience will probably be beneficial. Parents with large families point out that their child gets ample exposure to groups, that every meal is a "group session." This is not a peer group, however. Older siblings give in to the 3- or 4-year-old child, and younger siblings are not capable of peer competition. This situation does not offer the same experience as does preschool.

Be sure parents investigate preschools or child care centers carefully before they enroll their child to be certain their child will be safe there and have an enjoyable experience. Guidelines to aid parents in this assessment are shown in Table 31.4.

To continue to evaluate their child's school experience, urge parents to make a habit of asking children what happened at school, what they learned, and the names of any new friends. For the remainder of the growing years, school will have important effects on their child's development. By taking an active role in education, parents influence what and how their child learns.

Child care centers are often blamed for the spread of infectious disease among the 5-and-under population because bringing together children from so many different homes to one setting each day does increase the risk of spreading contagious disease. Preschoolers in day care settings may develop frequent upper respiratory infections or gastrointestinal illnesses. Outbreaks of cytomegalovirus and human parvovirus (fifth disease) make working in such centers a particular hazard to pregnant women as these are potentially teratogenic. To prevent the spread of infection, children need to wash their hands frequently and cover their mouths when coughing. Child care centers where infants as well as older children are enrolled need to take special precautions against hepatitis A or parasitic infections, as these can be spread by caregivers' not washing their hands or the changing table after changing diapers. Hepatitis may be subclinical in the preschooler,

TABLE 31.4 ✻ Questions to Use in Evaluating Child Care Centers

Question	Finding
Management	
How long has the center been in operation?	Length of operation does not necessarily indicate quality, but it allows you to locate other parents who have used the center to ask about their experience there.
Is the center licensed, registered, approved, or inspected by the appropriate agency?	Ask in your local community what agency has the responsibility for licensing child care centers. If not licensed, its quality is suspect.
What are the qualifications of staff members?	If staff members are teachers, more learning activities will be provided; staff should be qualified to perform cardiopulmonary resuscitation.
Is there a fast turnover rate of staff?	A fast turnover rate means little continuity of care will be provided (and probably suggests dissatisfaction with center administration).
What is the child–staff ratio?	A ratio of 3 or 4 children to 1 staff member provides time for quality interaction.
What is the center's policy on parental visits?	Parents should be able to drop in at any time. Be wary of facilities that restrict parental visiting in any way.
Physical Environment	
Is there adequate space in the center?	There should be opportunities for rough-and-tumble and imaginative play and naptime as well as table activities.
Does the space appear safe?	Stairways should be fenced. No paint should be peeling.
Can children get in and out of the building easily?	A first-floor plan is safest. Fire exits should be well marked. An evacuation plan should be practiced.
Is there a safe play area for children outside?	Find out how often children are taken outside: once or twice a day, or only occasionally for "outings"?
Is there a quiet place for naps?	Ask if a child can nap if tired or has to wait until a set naptime.
Can the bathroom be reached easily?	Both potty chairs and small toilet seats should be available.
If food is provided, does it meet preschool recommendations?	Food should be "preschool friendly."
Is there adequate refrigeration?	Food poisoning is a concern without refrigeration.
Staff Philosophy	
Are the workers warm and affectionate toward the children?	Watch how they greet children. They should ask questions and listen to answers.
Do caretakers spend more of their time performing janitorial tasks (cleaning) and reprimanding children, or can they devote their time to the children?	It is best if cleaning staff is separate from care staff.
Is each child assigned to a particular caregiver on a continuing basis?	Ask staff to describe their care pattern; if this is not planned, little continuity of care results.
Are the children provided stimulating toys and equipment?	Imaginative items, such as a puppet theater, finger paint, and water play, should be included.
How do the staff discipline children? Do they yell or treat the children roughly?	The method should reflect the parents' philosophy. Staff should be able to talk to children calmly without raising their voices in anger.
Is there a planned curriculum?	There should be specific individualized goals the staff hopes to accomplish.
Can the child pursue an individual interest?	Play or learning activities should be individualized.
Health Care Protocols	
How does the center care for an ill child?	There should be access to a nurse. Staff should be able to evaluate for illness. They should know actions to take in an emergency.
What precautions does the staff take to prevent spread of infection?	Counter where diapers are changed should be wiped with a disinfectant; tissues and handwashing facilities should be present.
Does the center follow good sanitary practices?	Be sure the center requires waterproof disposable diapers to minimize contamination of the environment and other children, and separates diaper-changing areas from other activities, especially anything related to food handling. Observe adult caregivers changing diapers. Do they wash hands after each change?

Under what conditions are children not allowed to attend the center?	A center should have a very specific policy on what illness symptoms require a child to be kept home—and they should enforce this policy strictly. For instance, a runny nose may be acceptable, but a fever is not; children with chickenpox should be kept at home until the scabs are healed over. Talk to parents whose children have been at the center long enough to have experienced some illnesses, and find out what the family did and how the center responded.
Children's Behavior	
Do the children appear happy and relaxed? Do they rush to greet any new visitors?	Observe for at least one morning. This could be a sign of boredom with their center's activities and a strong need for adult attention.

but other members of the preschooler's family can develop overt symptoms as the illness spreads through the family (Friedman, 2009).

Preparing a Child for School

At the end of the preschool period, children begin a formal school experience as they enter kindergarten. Parents may wonder whether their child is old enough for this, especially if a child's birthday is in the late summer or early fall. If this is so, urge parents to discuss their concern with school officials to determine whether their child should be registered for kindergarten or delayed for a year. As school involves a great deal of children's time and influences their future greatly, it is important for parents to take time to prepare preschoolers not only physically by being certain their immunizations are up to date but emotionally as well.

Essential to this preparation is the parents' attitude. If school is always discussed as something to look forward to, as an adventure that will be satisfying and rewarding, a child comes to view it as a positive experience. If school is presented as a punishment ("Wait until you get into first grade—your teacher will make you sit up and behave"), there can be little delight in anticipating it.

If a child was not attending preschool, some parents may have to change their child's daily routine a few months in advance of beginning school to accustom a child to waking earlier or going to bed earlier. School has so many new components that it is wise to try to eliminate as many distractions like this as possible.

If a child is to ride a bus to school, a parent might take a child on a municipal bus as an introduction to this form of transportation. If a child is to walk, a trial walk is in order. In either instance, safety should be stressed: "Don't walk behind the bus because the driver can't see you" and "Wait for the crossing guard to help you cross the street."

If a child will be required to take a lunch to school, a parent can introduce this new experience by preparing a bagged lunch at home some noon. If a child is to purchase lunch at school, the parent can play "cafeteria" at home by serving a meal buffet-style and letting a child practice walking from one dish to another to select food.

Some kindergartens suggest children know how to tie their shoes, name basic colors, and print their name before they begin. Parents should familiarize themselves with any such suggestions from the school, but the wisdom of requiring these skills can be questioned. Identifying colors should be established by this age, but some children are not coordinated enough at 4½ years to tie their shoes or print. A better contribution for parents to make toward their children's achievement in school is to instill in their children the concept that learning is fun and a certain child may not always be able to do all the things other children can do, but trying to do individual best is what is important. Trying to make children complete fine motor tasks for which they are not developmentally prepared does not instill that concept.

For children to do well in a formal school setting, they must be able to follow instructions and sit at a table and chair for a short work period. When some parents examine their child's day, they are surprised to realize how few instructions they give their child in a day. They put on the child's coat, pick up the child's toys, and lead the child to the table for dinner. Similarly, they never encourage their child to spend any time in a chair, which is something the child will have to do for at least short periods in school. Coloring at a table rather than on the floor will introduce this situation without any problem.

Finally, going to school is a form of separation and a new experience if a child has not attended child care or preschool, so parents must make preparations for this. It might be good to arrange to have a child stay with another caregiver for part of a day. Staying at school can then be compared with that event.

These are minimum preparations parents can complete to ready their child for school. Caution both parents and children that no matter how hard they try, not everything can be anticipated; school will bring some new happenings that can not be predicted. If a child has been led to believe that learning is fun and new experiences are enjoyable (creating a strong sense of initiative), these unpredictable instances can be accepted as fun. The concept that new experiences are enjoyable will prepare a child not only for a first day at school but for thousands of profitable days and experiences ahead (see Focus on Nursing Care Planning Box 31.7).

BOX 31.7 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Preschooler With Fears

Cathy Edwards is a 3-year-old girl. Her father cares for her because her mother is hospitalized with preterm labor for a second pregnancy. Her father tells you he is concerned because Cathy talks constantly with an imaginary friend named Emma. She makes up stories about events that cannot possibly be true. When corrected, Cathy stutters so badly no one can understand her. At a well-child visit, her father says he is concerned about his daughter's crying at day care.

Family Assessment ✻ Family lives in rented apartment in inner city. Mother is hospitalized with complications of second pregnancy. Father works as city police detective. Mother is stay-at-home mom.
Client Assessment ✻ 3-year-old girl within normal limits for height, weight, and development. Child currently enrolled in all-day preschool program while mother is hospitalized. Father picks child up after his work. Father arrived late to pick child up from preschool last week. She states, "He forgot me." Child refuses to return to preschool. Cries, sticks finger in mouth to make herself vomit, and complains that her stomach hurts when he tries to drop her off now.
Nursing Diagnosis ✻ Fear related to separation and abandonment during preschool period
Outcome Criteria ✻ Child verbalizes fear. Father demonstrates measures to minimize child's fears; reports by 2 weeks that crying episodes at school have decreased.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Ask father to detail a 24-hour day in family to gain clear picture of child's role and capabilities.	Father describes differences in family life since wife has been hospitalized, strain it causes on Cathy.	People are unable to solve a problem until the extent of the problem is clear.	Father details a typical day and may express his wish to continue the preschool experience
		Consultations		
Nurse	Assess if father feels referral to child guidance service is necessary to help reduce fear.	Encourage the father to talk with the preschool staff about the problem and common methods to decrease a child's fear.	Discussion with care providers can help reinforce the measures used by the father, providing consistency and thereby helping to minimize a child's fears.	Father states he will consult with preschool staff to help solve problem.
		Procedures/Medications		
Nurse	Assess what father knows about measures to reduce fear in preschoolers.	Instruct the father in measures to help reduce child's fear, such as reinforcing the time he will return. Will call if he's running late. Post memo to self to pick her up.	Reassurance helps to reduce a child's fear of abandonment.	Father describes steps he will take to be certain he will not be late again at preschool for pick up.
		Nutrition		
Nurse	Assess if child uses threat of vomiting at any other time.	Stress effect of eating disorders is potentially dangerous.	Frequent vomiting in young children can lead to fluid and electrolyte imbalances.	Father states whether he has ever seen pseudovomiting before.

		Patient/Family Education		
Nurse/nurse practitioner	Assess father's knowledge of typical preschool fears such as abandonment, fear of the dark.	Review with the father the typical fears experienced by the preschooler, including those of separation and abandonment.	Knowledge of normal growth and development helps to reduce the father's anxiety about the behavior and possible causes.	Father acknowledges he deals with adults in his business; expresses desire to learn more about preschool period.
		Psychosocial/Spiritual/Emotional Needs		
Nurse	Explore with child why she is so fearful her father will not return for her.	Encourage the father to set up a special time for himself and his daughter in the evening or on weekends, so they have a consistent close time.	Special time for a father and daughter enhances the parent–child relationship. Consistently adhering to this time helps to foster a sense of trust and security and show he is dependable.	Father states he will plan for a special time each week, even if it is difficult to arrange because of wife's hospitalization and his irregular work schedule.
		Discharge Planning		
Nurse	Assess if father would find a follow-up telephone call helpful.	Arrange for a follow-up telephone call (if desired) in one week.	Follow-up provides additional support and means for evaluating the effectiveness of the methods used.	Father states he is receptive to follow-up care.

Broken Fluency

Developing language is such a complicated process that children from 2 to 6 years of age typically have some speech difficulty. A child may begin to repeat words or syllables, saying, "I-I-I want a n-n-new spoon-spoon-spoon." This is called **broken fluency** (repetition and prolongation of sounds, syllables, and words). It is often referred to as **secondary stuttering** because the child began to speak without this problem and then, during the preschool years, developed it. Unlike the adult who stutters, children are unaware that they are not being fluent unless it is called to their attention. It is a part of normal development and, if accepted as such, will pass. It is associated with rapid speech patterns that may also be present in the parents (Savelkoul et al., 2007). A parent who knows a persistent stutterer or who was a persistent stutterer as a child may react to this normal broken fluency of the preschooler in a more emotional way than the problem deserves. If a child becomes conscious of a disrupted speech pattern, it is less likely the problem will correct itself. It is resolved most quickly if parents follow a few simple rules, listed in Box 31.8.

"Bathroom Language"

Many preschoolers imitate the vocabularies of their parents or older children in the family so well during this time that they incorporate swear words into their vocabularies. Parents may have to be reminded that children do not necessarily understand what the words mean; they have simply heard them, just as they have heard hundreds of other words and have decided to use them. Correction should be unemotional; for example, "That's not a word I like to hear you say. When you're angry, why don't you say 'fudge' (or whatever)?" The correcting is no different from that involved when a child uses poor grammar. If parents become emotional, a child realizes the value of such words and may continue using them for the attention they create.

Concerns of the Family With a Physically Challenged or Chronically Ill Preschooler

Learning how to do things when you have physical limitations can be frustrating. Being unable to understand how to do things because of physical or mental limitations can be even more so. To learn problem solving, however, is part of developing a sense of initiative. A preschooler with a disability such as cerebral palsy has a greater need for problem-solving skills than the average child, because even simple procedures such as eating or getting dressed can be difficult if a physical challenge limits the options.

Physically challenged or chronically ill preschoolers should attend a preschool program if at all possible because of the socialization benefits. Many of the learning activities that preschoolers enjoy, such as playing with paint, clay, or soap bubbles, are messy. If a child must remain in bed,

BOX 31.8 ✻ Focus on Family Teaching

Suggestions to Reduce Stuttering in the Preschool Child

Q. Mr. Edwards says to you, "My 3-year-old daughter stutters. What can I do to stop this?"

A. What sounds like stuttering in a preschooler is often broken fluency. Helpful tips to improve fluency are:

- Do not discuss in a child's presence the difficulty she is having with speech. Do not label her a "stutterer." This makes her conscious of her speech patterns and compounds the problem. If you have to think about every word you say, it is difficult not to have trouble speaking.
- Listen with patience to what a child is saying. Do not interrupt or fill in a word for her. Do not tell her to speak more slowly or to start over. These actions make a child conscious of her speech, and her broken fluency increases.
- Talk to her in a calm, simple way. It is difficult for a child to keep up with adult speech. If adults talk slowly to her, she sees no need to rush and so speaks more clearly.
- Protect space for her to talk if there are other children in the family. Rushing to say something before a second child interrupts is the same as rushing to conform to adult speech.
- Do not force a child to speak if she does not want to. Do not ask her to recite or sing for strangers.
- Do not reward her for fluent speech or punish her for nonfluent speech. Broken fluency is a developmental stage in language formation, not an indication of regression or a chronic speech pattern.

parents may be reluctant to offer these types of experiences. A large tray of dry oatmeal or other breakfast cereal with sand shovels or cars and trucks is a good substitute activity for such a child. Although not necessarily neat, these substances (which are available even in a hospital setting) can be swept away easily at the finish of play. Table 31.5 lists nursing actions that can aid a chronically challenged child to solve problems and develop a sense of initiative.

Nutrition and the Physically Challenged or Chronically Ill Preschooler

Experiences with eating help to reinforce a sense of initiative in preschoolers. Chronically ill preschoolers who are limited in the foods they can eat (perhaps they have to maintain a diet of soft foods) or in their ability to help with food preparation may miss this reinforcement. If their appetite is diminished because of illness to the point where they take little or nothing orally, it is still important they continue to join the family at meals. In most households, this is a time for socialization, and preschoolers are ripe for the learning that goes with this type of daily interaction. Encourage parents to include the ill child in family meals and other social occasions whenever possible.

✔ Checkpoint Question 31.3

Cathy's parents want to know how to react to her when she begins to masturbate while watching television. What would you suggest?

a. They give her "timeout" when this begins.
b. They refuse to allow her to watch television.
c. They remind her some activities are private.
d. They schedule a health check-up for vaginal disease.

Key Points for Review

- Although preschoolers grow only slightly and gain just a little weight, they seem much taller than when they were toddlers because their contour changes to more childlike proportions.
- Erikson's developmental task for the preschool period is to gain a sense of initiative or learn how to do things. Play materials ideal for this age group are those that stimulate creativity, such as modeling clay or colored markers.
- Promoting childhood safety is a major role because preschoolers' active imaginations can lead them into dangerous situations.
- Appetite is not large in this age group because this is not a rapid growth time. Preschoolers can be interested in helping with food preparation.
- Common parental concerns during the preschool period are broken fluency, imaginary friends, difficulty sharing, and sibling rivalry.
- Preschool is often the time when a new sibling is born. Good preparation for this is necessary to prevent intense sibling rivalry.
- Preschoolers have a number of universal fears, including fear of the dark, mutilation, and abandonment. All care provided for this age group should include active measures to reduce these fears as much as possible.
- Preschoolers are still operating at a cognitive level that prevents them from understanding conservation (objects have not changed substance although they have changed appearance). This means they need an explanation, for example, of how they will be the same person postoperatively as they were preoperatively.
- Preschoolers are self-centered (egocentric). This makes it difficult for them to share and view someone else's side of a problem. They need good explanations of how a procedure will benefit them before they can agree to it.
- Many preschoolers begin preschool programs or child care. Late in the preschool period, they may be enrolled in kindergarten. Parents often appreciate guidance on how to prepare their children for these new experiences.
- Preschoolers who are physically challenged or who have chronic illnesses may have difficulty achieving a sense of initiative, because they may be limited in their ability to participate in activities that stimulate initiative. They may need special playtimes set aside for stimulation and learning.

TABLE 31.5 ✻ Nursing Actions That Encourage a Sense of Initiative in a Physically Challenged or Chronically Ill Preschooler

Consideration	Nursing Actions
Nutrition	Serving toast or sandwiches cut into animal shapes with cookie cutters, cereal in the form of alphabet characters, or food arranged on a plate to make a face appeals to the imagination and may make a preschooler more interested in food.
	Respect child's food preferences.
Dressing change	Allow preschooler to measure and cut tape or draw a face on it.
	Allow child to see incision site. Explain steps of dressing change as you work to reduce unknowns and areas of fear.
	Provide extra bandages to put on a doll so child can see that bandages themselves are not to be feared.
Medicine	Allow child to choose a chaser such as juice or milk after oral medicine.
	Choosing site for injection or intravenous line is too advanced for the preschooler; do not suggest such choices.
Rest	Provide a light in the room or bring child's bed into hallway so fear of the dark is reduced and child can deal with only reality problems.
	Identify sounds the preschooler might hear in the hospital, such as an air conditioner turning on.
Hygiene	Allow child to choose bathtub toys, clothing.
	Allow child to wash own hands and face.
	Allow child to splash in water as a play activity as well as for cleanliness.
Pain	Encourage preschooler to express pain.
	Allow child to handle syringe or suction catheter, and give "shots" or suction to a doll to alleviate anger or fear.
	Encourage child to ask for analgesic if necessary.
Stimulation	Guessing games encourage a sense of initiative. Draw a dog or a house and ask child to close his or her eyes while you add one more detail to the drawing, such as an ear or a chimney; ask child to identify new item.
	Reverse the game and ask child what you erased from the drawing, or allow child to do own drawing.
	Provide manipulative toys, such as finger paint, soapy water, clay, or dry cereal to use as sand.
	Allow preschooler to accompany you to other departments as a way of teaching more about the hospital.
	Use "Simon Says" games not only for socialization but also to urge treatments, such as deep-breathing exercises.
	Encourage use of playroom for socialization.
	Encourage child to interact with family by drawing pictures for siblings or using the telephone to call home.

CRITICAL THINKING EXERCISES

1. Cathy is the 3-year-old girl you met at the beginning of the chapter. Cathy's father is concerned because Cathy tells exaggerated stories about events at her preschool. How would you recommend her father handle this?
2. Because her family is moving, Cathy will be starting a new preschool next week. What suggestions could you make to her father about choosing a safe setting? How should he prepare Cathy for this experience?
3. Cathy's parents tell you she keeps the entire family awake at night because she is so afraid of the dark. What suggestions could you make to help relieve this problem?
4. Examine the National Health Goals related to growth and development of the preschooler. Most government-sponsored funds for nursing research are allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to Cathy's family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to preschool growth and development. Confirm your answers are correct by reading the rationales.

Chapter

32 Nursing Care of a Family With a School-Age Child

KEY TERMS

- accommodation
- caries
- class inclusion
- conservation
- decentering
- inclusion
- latchkey children
- malocclusion
- nocturnal emissions

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe the normal growth and development pattern and common parental concerns of the school-age period.
2. Identify National Health Goals related to school-age children that nurses can help the nation achieve.
3. Use critical thinking to analyze ways in which the care of school-age children can be more family centered.
4. Assess a school-age child for normal growth and development milestones.
5. Formulate nursing diagnoses that speak to both school-age children and their families.
6. Identify expected outcomes for nursing care of a school-ager.
7. Plan anticipatory guidance to prevent problems of growth and development in a school-age child such as teaching about normal puberty.
8. Implement nursing care to help achieve normal growth and development of a school-age child, such as counseling parents about helping their child adjust to a new school.
9. Evaluate expected outcomes for achievement and effectiveness of care.
10. Identify areas related to care of school-age children that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of school-age growth and development with nursing process to achieve quality maternal and child health nursing care.

Shelly Lewis is a 12-year-old girl who recently started middle school. Her mother tells you that although Shelly, who is overweight, says she likes school, she has developed a lot of nervous habits such as nail biting since school started. Her mother asks if this is normal.

The previous chapter discussed the preschooler and the abilities children develop in those years. This chapter adds information about the dramatic changes, both physical and psychosocial, that occur during the school-age years. Such information builds a base for care and health teaching for this age group.

How would you advise Shelly's mother?

The term "school age" commonly refers to children between the ages of 6 and 12. Although these years represent a time of slow physical growth, cognitive growth and development continue to proceed at rapid rates. Because of this, there are many differences among children from one year to the next. For example, 7- and 10-year-old children have very different needs and outlooks, as do 11- and 12-year-old children. Because of these big differences, always assess children as individuals to understand the particular developmental needs of each child based on what developmental status has been achieved, not on what stage you think the child should have reached (AAP, 2009).

Unlike the infant or toddler periods, whose progress is marked by obvious new abilities and skills such as the ability to sit up or roll over or the ability to speak a full sentence, the development of a school-age child is more subtle and may be marked by mood swings; what the child enjoys on one occasion may not be acceptable on the next. For instance, a child may ask his parents for a guitar and lessons, but then after the family invests in these, he may quickly lose interest in music and prefer soccer. Children of school age may also be more influenced by the attitudes of their friends than previously. They may choose not to do something that was previously enjoyable because no friends are interested in the activity. Parents who make too much of these likes and dislikes may find themselves engaged in unnecessary conflicts with their child. The school-age period is usually the first time children begin to make truly independent judgments. As parents may not be prepared for this, this may also create conflicts with parents. Box 32.1 lists National Health Goals related to the school-age period.

BOX 32.1 * Focus on National Health Goals

A number of National Health Goals address the health of the school-age population:

- Increase the proportion of public and private schools that require daily physical education for all students from a baseline of 17% to a target of 25%.
- Reduce the rate of deaths caused by motor vehicle accidents to no more than 9.2 per 100,000 children from a baseline of 15.6 per 100,000.
- Reduce the proportion of children who have dental caries (in permanent or primary teeth) to no more than 11% from a baseline of 18%.
- Increase children's rate of safety belt use in automobiles from a baseline of 69% to 92%.
- Increase the number of states that require helmet use by bicyclists from 10 to 50 states (http://www.nih.gov).

Nurses can help the nation achieve these goals by urging children to begin and maintain a consistent exercise program, brush teeth and go for dental checkups regularly, and follow safety rules both in and around automobiles. Additional nursing research that would be helpful includes these questions: What is the ideal exercise program that is interesting enough to children that it will hold their attention for a long span of time? What are effective ways to teach street safety to children in the early school years? What strategies are most effective in helping school-age children brush teeth daily?

Nursing Process Overview

For Healthy Development of a School-Age Child

Assessment

Use both history and physical examination to assess growth and development of a school-age child. Include questions about school activities and progress. School-age children are interested and able to contribute to their own health history; to allow for this, it is useful to interview children 10 years or older at least in part without their parents present. During the physical examination, show your respect for children's adult-level modesty by furnishing a cover gown.

Parents of school-age children often mention behavioral issues or conflicts during yearly health visits. Some parents feel they are losing contact with their children during these years. This can cause them to misinterpret a normal change in behavior, especially if they are not prepared for what to expect from their child. Other parents may consider children who behave differently from their siblings as "abnormal" when children are just expressing their own personality.

When problems are discussed in the health care setting, take the history from the parent but also allow the child to express the problem. It may be necessary to obtain the opinion of school personnel (with the parents' permission) regarding the problem or even just determine whether school personnel feel a problem exists. In some instances, a counselor's opinion may be necessary. If the problem is related to a medical condition, its effect on the family should also be assessed, because the illness of a child affects the functioning of the entire family.

Nursing Diagnosis

Common nursing diagnoses pertinent to growth and development during the school-age period are:

- Health-seeking behaviors related to normal school-age growth and development
- Readiness for enhanced parenting related to improved family living conditions
- Anxiety related to slow growth pattern of child
- Risk for injury related to deficient parental knowledge about safety precautions for a school-age child
- Imbalanced nutrition, more than body requirements, related to frequent consumption of snack foods
- Delayed growth and development related to speech, motor, psychosocial, or cognitive concerns

Outcome Identification and Planning

When identifying expected outcomes and planning care, keep in mind that school-age children tend to enjoy small or short-term projects rather than long, involved ones. A child with diabetes, for example, in her early school years may gain a feeling of achievement by learning to assess her own serum glucose level, but she may have difficulty continuing glucose assessment on a regular basis.

Behavior problems need to be well defined before outcomes are identified and interventions planned. Often, it is enough for parents to accept the problem as one consistent

with normal growth and development. A helpful Web site to recommend to parents to learn more about school-age growth and development is the American Academy of Pediatrics (http://www.aap.org). For questions about car seats, parents can consult the U.S. Department of Transportation National Highway Traffic Safety Administration (http://www.nhtsa.dot.gov).

Implementation

School-age children are interested in learning about adult roles, so this means they will watch you to see your attitude as well as your actions in a given situation. When giving care, keep in mind children this age feel more comfortable if they know the "hows" and "whys" of actions. They may not cooperate with a procedure until they are given a satisfactory explanation of why it must be done.

Outcome Evaluation

Yearly health visits covering both physical and psychosocial development are important at this age. It may be useful for parents to look back on problems identified at the last visit and discuss if and how they were resolved. Often, some problems and conflicts fade away without anyone really noticing. As some problems recede, however, others may emerge. At times, the same concerns of parents and the child may appear to be unresolved at each visit. Make sure no underlying problem exists that prevents resolution. Examples of expected outcomes are:

- Parent states he allows child to make own decisions about how to spend allowance.
- Child lists books she and her parents have read together in past 2 weeks.
- Child states he understands his growth is normal, even though he is the shortest boy in his eighth-grade class.
- Child does not sustain injury from sports activities during the summer recess.

GROWTH AND DEVELOPMENT OF A SCHOOL-AGE CHILD

Growth and development for a school-age child occur slowly, and over a relatively long time span so children grow and develop extensively during this period.

Physical Growth

School-age children's annual average weight gain is approximately 3 to 5 lb (1.3 to 2.2 kg); the increase in height is 1 to 2 in (2.5 to 5 cm). Children who did not lose the lordosis and knock-kneed appearance of toddlers during the preschool period lose these now. Posture becomes more erect (Goldson & Reynolds, 2008).

By 10 years of age, brain growth is complete, so fine motor coordination becomes refined. As the eye globe reaches its final shape at about this same time, an adult vision level is achieved. If the eruption of permanent teeth and growth of the jaw do not correlate with final head growth, **malocclusion** (a deviation from the normal) with teeth malalignment may be present.

The immunoglobulins IgG and IgA reach adult levels, and lymphatic tissue continues to grow up until about age 9. Because the lymphatic system grows so rapidly, this results in an abundance of tonsillar and adenoid tissue in the early school years, which is often mistaken for disease during respiratory illness as the tonsils seem so enlarged in the back of the throat. Enlarged tonsils may also result in temporary conduction deafness from eustachian tube obstruction until this tissue recedes normally.

The appendix is also lined with lymphatic tissue, so swelling of this tissue in the narrow tube can lead to trapped fecal material and inflammation (appendicitis) in the early school-age child. Frontal sinuses develop at about 6 years, so sinus headache becomes a possibility (before then, headache in children is rarely caused by a sinus infection).

The left ventricle of the heart enlarges to be strong enough to pump blood to the growing body. Innocent heart murmurs may become apparent because of the extra blood crossing heart valves. The pulse rate decreases to 70 to 80 beats per minute; blood pressure rises to about 112/60 mm Hg. Maturation of the respiratory system leads to increased oxygen–carbon dioxide exchange, which increases exertion ability and stamina. Scoliosis may become apparent for the first time in late childhood. All school-age children over age 8 should be screened for this at all health appraisals (see Chapter 51).

Sexual Maturation

At a set point in brain maturity, the hypothalamus transmits an enzyme to the anterior pituitary gland to begin production of gonadotropic hormones, which activate changes in testes and ovaries and produce puberty. Hormone changes that occur with puberty are discussed in Chapter 5. Table 32.1 describes the usual order for secondary sex characteristics to develop.

Timing of the onset of puberty varies widely, between 10 and 14 years of age. The length of time it takes to pass through puberty until sexual maturity is complete also varies. Sexual maturation in girls usually occurs between 12 and 18 years; in boys, between 14 and 20 years. Puberty is occurring increasingly earlier, however, and, in a class of 10-year-old sixth graders, it is not unusual to discover that more than half of the girls are already menstruating. This means that for sex education to be effective, parents must introduce this material when their children are in grade school, not in middle school or high school.

Sexual and Physical Concerns. The changes in physical appearance that come with puberty can lead to concerns for both children and their parents. School age is a time for parents to discuss with children the physical changes that will occur and the sexual responsibility these changes dictate. This is also a time to reinforce previous teaching with children that their body is their own, to be used only in the way they choose. Specific measures for children to help prevent sexual abuse are discussed later in this chapter. School nurses can play a major role in this type of education as well.

In both sexes, puberty brings changes in the sebaceous glands. Under the influence of androgen, glands become more active, setting the stage for acne (see Chapter 33). Vasomotor instability commonly leads to blushing; perspiration also increases (Kaplan & Love-Osborne, 2008).

Concerns of Girls. Prepubertal girls are usually taller, by about 2 in (5 cm) or more, than preadolescent boys because their typical growth spurt begins earlier. In a culture in which

TABLE 32.1 ✻ Chronologic Development of Secondary Sex Characteristics

Age (yr)	Boys	Girls
9–11	Prepubertal weight gain occurs.	Breasts: elevation of papilla with breast bud formation; areolar diameter enlarges.
11–12	Sparse growth of straight, downy, slightly pigmented hair at base of penis. Scrotum becoming textured; growth of penis and testes begins. Sebaceous gland secretion increases. Perspiration increases.	Straight hair along the labia. Vaginal epithelium becomes cornified. pH of vaginal secretions acid; slight mucous vaginal discharge present. Sebaceous gland secretion increases. Perspiration increases. Dramatic growth spurt.
12–13	Pubic hair present across pubis. Penis lengthens. Dramatic linear growth spurt. Breast enlargement occurs.	Pubic hair grows darker; spreads over entire pubis. Breasts enlarge, still no protrusion of nipples. Axillary hair present. Menarche occurs.

boys are expected to be taller than girls, this can cause concern. Sometimes a girl notices the change in her pelvic contour when she tries on a skirt or dress from the year before and realizes her hips are becoming broader. She may misinterpret this finding as a gain in weight and attempt a crash diet. She can be reassured that broad bone structure of the hips is part of an adult female profile.

Girls are usually conscious of breast development, and whether they are overdeveloped or underdeveloped. Also, breast development is not always symmetrical, so it is not unusual for a girl to have breasts of slightly different sizes. After the condition has been checked during a physical examination, she can be reassured that this development is normal. Supernumerary (additional) nipples may darken or increase in size at puberty. Be sure girls understand that a supernumerary nipple is affected by the hormones in her body in the same way as other breast tissue, so she understands these changes are normal.

Early preparation for menstruation is important for future childbearing and for the girl's concept of herself as a woman (Box 32.2). In addition to an explanation of the reason for menstrual flow, girls need an explanation of good hygiene and reassurance they can bathe, shower, and swim during their periods. They can use either sanitary napkins or tampons; if they choose tampons, they must take precautions to avoid toxic shock syndrome (see Chapter 47).

BOX 32.2 ✻ Focus on Communication

Shelly is a 12-year-old girl who comes to the nurse's office at her school.

Less Effective Communication

Nurse: Hello, Shelly. What can I do for you?
Shelly: I'm having cramps.
Nurse: Are you having your period?
Shelly: No. I haven't started them yet.
Nurse: Describe your cramps to me.
Shelly: Both my sisters started their periods when they were 10.
Nurse: Are you sick to your stomach?
Shelly: I'm the only girl in my gym class who doesn't have her period yet.
Nurse: Let's talk about the cramps. What do you think is causing those?
Shelly: They're not really bad. I'll go back to class.

More Effective Communication

Nurse: Hello, Shelly. What can I do for you?
Shelly: I'm having cramps.
Nurse: Are you having your period?
Shelly: No. I haven't started them yet.
Nurse: Describe your cramps to me.
Shelly: Both my sisters started their periods when they were 10.
Nurse: Are you sick to your stomach?
Shelly: I'm the only girl in my gym class who doesn't have her period yet.
Nurse: You sound as if you're more worried about that than what you came in for.
Shelly: I need to know if I'm all right.
Nurse: Let's talk about that.

In the past, when topics such as menstruation were discussed only in whispers and neither television nor magazines advertised sanitary pads or medicine for menstrual discomfort, most 12-year-old children had little idea about what to expect at puberty. Today, with this information readily available to the public, it is easy to forget that preadolescents, because they may not read magazines or watch adult television shows, still may not know much about what to expect at puberty. Be aware that almost all prepubescent girls are concerned about puberty changes. Through effective communication and listening, you can help them talk about their problems and concerns.

The average age at which menarche (the first menstrual period) occurs is 12.4 years (McDowell, Brody, & Hughes, 2007). Most girls have some menstrual irregularity during the first year or two after menarche. This occurs primarily because a girl's cycles are anovulatory at first. With maturity and the onset of ovulation, cycles become more regular. A preadolescent who is experiencing consistent irregularities in her period should be assessed for malnourishment and obesity as possible influences. Emotions can also cause irregularity. If irregularity continues beyond the first year, a careful history of the girl's school, social, nutrition, level of exercise, and home adjustment should be taken. Dysmenorrhea, or painful menstruation, is discussed in Chapter 47.

Girls also need to know that vaginal secretions will begin to be present. If this is not explained, a girl may fear needlessly that she has contracted an infection. Explain that any secretions that cause vulvar irritation should be evaluated at a health care facility, because this does suggest infection.

Concerns of Boys. Boys who are not prepared for the physical changes of puberty are as equally concerned about them as are girls. Just as girls are keenly aware of breast development, boys are aware of increasing genital size. If they do not know testicular development precedes penis growth, they can worry that their growth will be inadequate. Boys should also be informed that hypertrophy of breast tissue (gynecomastia) can occur in prepuberty (most often in stocky or obese boys), and that this is a transitory phenomenon and, although it may cause self-conscious reactions, it will fade as soon as the male hormones become more mature and active.

Some boys also become concerned because, although they have pubic hair, they cannot yet grow a beard or do not have chest hair—outward, easily recognized signs of maturity. You can assure them that pubic hair normally appears first and that chest and facial hair may not grow until several years later.

As seminal fluid is produced, boys begin to notice ejaculation during sleep, termed **nocturnal emissions.** Preadolescent boys may believe an old myth that loss of seminal fluid is debilitating; also, boys may have heard the term "premature ejaculation" and worry this is a forewarning of a problem in years to come. Both are fallacies.

Teeth

Deciduous teeth are lost and permanent teeth erupt during the school-age period (Fig. 32.1). The average child gains 28 teeth between 6 and 12 years of age: the central and lateral incisors; first, second, and third cuspids; and first and second molars (Fig. 32.2).

Developmental Milestones

As with all ages, you can measure school-age children's progress by whether they meet typical developmental milestones.

Gross Motor Development

School-age development is summarized in Table 32.2. At the beginning of the school-age period (age 6), children endlessly jump, tumble, skip, and hop. They have enough coordination to walk a straight line. Many can ride a bicycle. They can skip rope with practice. A 7-year-old appears quiet compared with a rough-and-tumble 6-year-old. Gender differences usually begin to manifest in play: there are "girl games," such as dressing dolls, and "boy games," such as pretending to be pirates.

FIGURE 32.1 Early-school-age children typically have a missing upper incisor as deciduous teeth are replaced by permanent teeth.

The movements of 8-year-olds are more graceful than those of younger children, although as their arms and legs grow, they may stumble on furniture or spill milk and food. They ride a bicycle well and enjoy sports such as gymnastics, soccer, and hockey.

Nine-year-olds are on the go constantly, as if they always have a deadline to meet. They have enough eye–hand coordination to enjoy baseball, basketball, and volleyball. By 10 years of age, they are more interested in perfecting their athletic skills than they were previously.

At age 11, many children feel awkward because of their growth spurt and drop out of sports activities rather than look ungainly in their attempts. They may channel their energy into constant motion instead: constantly drumming fingers and tapping pencils or feet. This fall in sports participation may bother parents who see sports as the key to popularity or self-esteem.

Twelve-year-olds plunge into activities with intensity and concentration. They often enjoy participating in sports events for charities such as walk-a-thons. They may be refreshingly cooperative around the house, able to handle a great deal of responsibility, and complete given tasks.

Fine Motor Development

Six-year-olds can easily tie their shoelaces. They can cut and paste well and draw a person with good detail. They can print, although they may routinely reverse letters. Seven-year-olds concentrate on fine motor skills even more than they did the year before. This has been called the "eraser year" because children are never quite content with what they have done. They set too high a standard for themselves and then have difficulty performing at that level.

By 8 years of age, children's eyes are developed enough so they can read regular-size type. This can make reading a greater pleasure and school more enjoyable (Fig. 32.3).

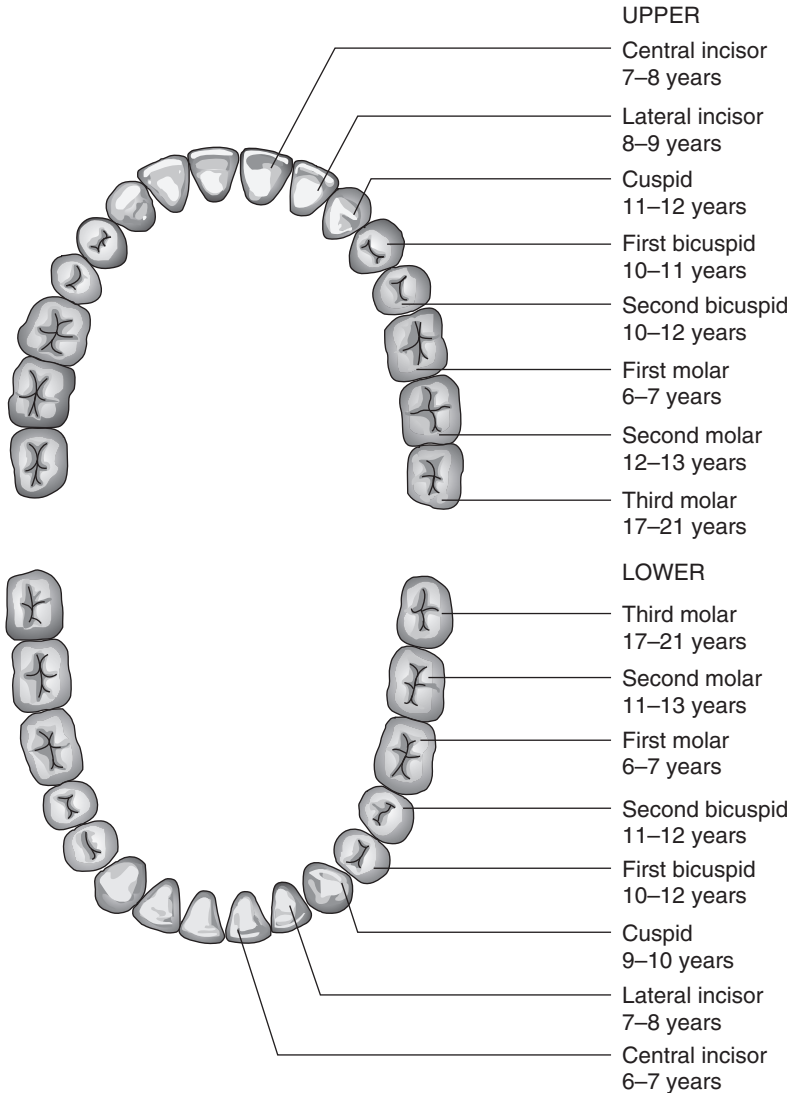

FIGURE 32.2 Eruption pattern of permanent teeth.

Eight-year-olds learn to write script rather than print. They enjoy showing off this new skill in cards, letters, or projects. By age 9, their writing begins to look mature and less awkward.

Older school-age children begin to evaluate their teachers' ability and may perform at varying levels, depending on each teacher's expectations. The middle school curriculum involves more challenging science and mathematics courses than previously and includes good literature. This may be a child's first exposure to reading as a fulfilling and worthwhile experience rather than just as an assignment and may be the time a child is "turned on" to reading.

Play

Play continues to be rough at age 6; however, when children discover reading as an enjoyable activity that opens doors to other worlds, they can begin to spend quiet time with books. Many children spend hours playing increasingly challenging video games, an activity that can either foster a healthy sense of competition or create isolation from others.

By 7 years of age, children require more props for play than when they were younger, which indicates the start of a decline in imaginative play; this may continue unless a child receives adequate encouragement to use imagination. Children also begin to develop an interest in collecting items such as baseball cards, dolls, rocks, or marbles. The type of item may not be as important as the quantity. By age 8, collections may become increasingly structured as children develop skills for sorting and cataloging.

Competitive behaviors can develop and cause children to change the rules in the middle of a game to keep from losing. At about 10 years of age, children become very interested in rules and fairness in competitive play situations (Fig. 32.4). Children also begin discovering the Internet and how other children out there are waiting to talk to them in chat rooms. Not yet wise enough to recognize the dangers talking to strangers can create, this is an activity parents need to supervise. Music and artistic expression also become important during this time. During preteen years, listening to music and learning popular dances take the place of earlier simple games. Both boys and girls seem to feel they are on the verge of something great and anxiously wait to turn 13 and be a teenager.

TABLE 32.2 ✻ Summary of School-Age Development

Age (yr)	Physical Development	Psychosocial and Cognitive Development
6	A year of constant motion; skipping is a new skill; first molars erupt.	First-grade teacher becomes authority figure; adjustment to all-day school may be difficult and lead to nervous manifestations of fingernail biting, etc. Defines words by their use: a key is to unlock a door, not a metal object.
7	Central incisors erupt; difference between sexes becomes apparent in play (video games vs. dolls); spends time in quiet play.	A quiet year; striving for perfection leads to this year being called an eraser year. Conservation (water poured from tall container to a wide, flat one is the same amount of water) is learned; can tell time; can make simple change.
8	Coordination definitely improved; playing with gang becomes important; eyes become fully developed.	"Best friends" develop; whispering and giggling begin; can write as well as print; understands concepts of past, present, and future.
9	All activities done with gang.	Gang age; a 9-year-old club is formed to spite someone, has secret codes, is all boy or all girl; gangs disband and reform quickly.
10	Coordination improves.	Ready for camp away from home; collecting age; likes rules; ready for competitive games.
11	Active, but awkward and ungainly.	Insecure with members of opposite sex; repeats off-color jokes.
12	Coordination improves.	A sense of humor is present; is social and cooperative.

Language Development

Six-year-olds talk in full sentences, using language easily and with meaning. They no longer sound as though talking is an experiment but appear to have incorporated language permanently. They still define objects by their use: a key is to unlock a door; a fork is to eat with.

Most 7-year-olds can tell the time in hours, but they may have trouble with concepts such as "half past" and "quarter to," especially with the prevalence of digital clocks and watches. They know the months of the year and can name the months in which holidays fall. They can add and subtract and make simple change (if they have had experience), so they can go to the store and make simple purchases. Much of children's talk is concerned with these concepts as they practice them and show them off for family or friends.

As children discover "dirty" jokes at about age 9, they like to tell them to friends or try to understand those told by adults. They use swear words to express anger or just to show other children they are growing up. They may have a short period of intense fascination with "bathroom language," as they did during preschool years. As before, if they want to discourage this, parents should make it clear they find such language unacceptable and refrain from using it themselves in their child's presence.

FIGURE 32.3 One of the biggest discoveries of childhood is that reading and writing are fun. Both are activities that can help a child pass the hours of illness.

FIGURE 32.4 By 10 years of age, children are ready for competition. These two children enjoy a game of chess.

By 12 years of age, a sense of humor is apparent. Twelve-year-olds can carry on an adult conversation, although stories are limited because of their lack of experience.

Emotional Development

Ideally, children enter the school-age period with the ability to trust others and with a sense of respect for their own worth. They can accomplish small tasks independently because they have gained a sense of autonomy. They should have practiced or mimicked adult roles and had the opportunity to explore at preschool or other social environments. They should have learned to share, to have discovered that learning is fun and an adventure, and have learned that doing things is more important and more rewarding than watching things being done (a sense of initiative).

Developmental Task: Industry Versus Inferiority

During the early school years, children attempt to master yet another developmental step: learning a sense of industry or accomplishment (Erikson, 1993). If gaining a sense of initiative can be defined as learning how to do things, then gaining a sense of industry is learning how to do things well.

If children are prevented from achieving a sense of industry or do not receive rewards for accomplishment, they can develop a feeling of inferiority or become convinced they cannot do things they actually can do. These children will have difficulty tackling new situations later in life (new job, new school, new responsibility) because they cannot envision how they could be successful in handling them. This can result in frustration in school or work activities.

The questions a preschool child asks reflect curiosity, such as "how," "why," and "what." During the early school years, children concentrate their questions on the "how" of tasks: "Is this the right way to do this?" "Am I making this right?" "Is this good?" Often school-age children will comment, "I can't do anything right" because their craft project does not look perfect or falls short of expectations. School-age children need reassurance they are doing things correctly and this reassurance is best if it comes frequently rather than infrequently after long waits.

The best type of book for school-age children has many short chapters; children feel a sense of accomplishment when they finish each chapter, rather than having to wait until the end of the book. Small chores that can be completed quickly also give this type of reward. Children can survey their finished work and see that they have done a good job. A child may dislike vacuuming, for instance, because the rug may not look very different when the task is complete. Picking up the scattered contents of a toy box, however, is a more obvious task that clearly makes a difference in the appearance of the room.

Hobbies and projects also are enjoyed best if they are small and can be finished within a short time. Most school-age children, for example, prefer putting together two or three fairly simple model-car kits to assembling one extremely complicated kit. The three kits offer three rewards; the involved one delays the reward so long the child may become bored and never complete it. With adolescence will come more respect for quality. Children will realize if they want the better model, they will have to spend the extra energy and attention—quality products involve quality work (Fig. 32.5).

FIGURE 32.5 Assembling this simple model in a short time helps a school-age child gain a sense of industry. (© Stephen Frisch/Stock Boston.)

Home as a Setting to Learn Industry. Parents of a school-age child need to take a step forward in development along with their child. For the first time, they realize their child looks to other role models than themselves. Parents who enjoyed fostering imagination in a preschooler may feel frustrated when a school-age child begins to conform to rules and insists on the "right way" to do things. They may feel they have failed to encourage the child's creativity, but conformity is vital to children at this age. It is how they learn more about their world's rules.

Eight- or 9-year-olds begin to spend more and more time with their peers and less time with their family. They forget to do household chores they once enjoyed, such as setting the table or mowing the lawn, or they may do the work sloppily so they have more time with their friends. Although this may seem like a regression in behavior, it is actually a step of independence away from the parents and into the larger world, a developmental task that will help them become emotionally mature. This is an example of a new role the child is trying out, one of many that will be tried in the process of reaching maturity, when an eventual "right-fit" is found.

School as a Setting to Learn Industry. Adjusting to and achieving in school are two of the major tasks for this age group. Ideally, a child's teacher will think of learning as fun and will encourage a child to plunge into new experiences. Unfortunately, parents must monitor teachers and school activities to make sure their children are being led this way while not being pushed too hard.

Schools are increasingly assuming responsibility for education about sex, safety, avoidance of substances of abuse, and preparation for family living. These discussions are generally

superficial, however, and if the classes are large, they may raise more questions than they answer. Although learning these skills with peers helps children learn other people's opinions in these areas, such classes should not replace parental teaching. If given adequate encouragement and preparation by health care providers, most parents are eager to maintain such responsibility.

Structured Activities. Girl Scouts, Boy Scouts, Campfire Girls, and 4-H clubs are respected school-age activities. If the local chapters are well run by leaders who understand children's needs, they can provide hours of constructive activity and strengthen a sense of industry. Merit badge systems are geared to the needs of school-age children, offering small but frequent rewards. As with school activities, parents should determine the worth of each organization for their individual child.

Urge parents to evaluate competitive sports programs as well. Before children can compete successfully, they must be able to lose a game without feeling devastated—in other words, to be able to say, "I lost because I played badly," not "I lost because I am a bad person." Children do not usually develop sufficient ego strength to do this until they are about 10 years old.

Another problem to consider with organized contact sports is the possibility of athletic injuries. Encourage parents to consider their child's maturity and the risk of injury (see Chapter 51) before they decide whether team competition is right for their child.

Problem Solving. An important part of developing a sense of industry is learning how to solve problems. Parents and teachers can help children develop this skill by encouraging practice. When a child asks, "Is this the right way to do this?" a parent can encourage problem solving by saying, "Let's talk about possible ways of doing it" rather than offering a quick solution.

The world depends on machinery, so mishaps and breakdowns (and therefore sudden changes) do occur. A child who can create an indoor playhouse with a card table and blanket when it is too wet or cold to use an outdoor playhouse will be able, as an adult, to problem solve another solution to a data distribution problem when a computer malfunctions. This attitude of optimism rather than pessimism toward problem solving produces adults who rarely say, "It can't be done." Just as important, it leaves these adults with confidence and a sense of pride, feeling good about themselves because they have control of their environment and abilities.

Learning to Live With Others. School-age children are sometimes so interested in tasks and in accomplishing physical projects that they forget they must work with people to achieve these goals. A good time to urge children to learn compassion and thoughtfulness toward others is during the early school years, when children are first exposed to large groups of other youngsters. Writing thank-you letters and shoveling an older neighbor's sidewalk are examples of activities that can help children develop empathy toward others.

Learning to give a present without receiving one in return or doing a favor without expecting a reward is also a part of this process, and this can be taught by example. Children should see their parents doing such things with an attitude not of "What will I get?" but "What can I contribute?"

Children may show empathy toward others as early as 20 months, but cognitively they cannot relate others' experiences to their own until about 6 years of age. Therefore, it is usually ineffective to lecture a child by saying, "That was cruel to call Mary names." The child may feel she had every right to do so. A better technique is to ask children to put themselves in Mary's place for a minute and imagine how they would feel if they were Mary. A school-age child will generally be able to do this and understand why name-calling hurts and makes children feel rejected. Following this, a simple statement such as, "It doesn't feel good to be called names, does it?" may suffice.

Socialization

Six-year-old children play in groups, but when they are tired or under added stress, they prefer one-to-one contact. In a first-grade classroom, students compete actively for a few minutes of special time with their teacher. At the end of a day, they enjoy time spent individually with parents. You may have to remind parents this is not babyish behavior but that of a typical 6-year-old.

Seven-year-olds are increasingly aware of family roles and responsibility. Promises must be kept, because 7-year-olds view them as definite, firm commitments. These children tattle because they have a strong sense of justice. This tattling may dissolve play groups quickly.

Eight-year-olds actively seek the company of other children. Most 8-year-old girls have a close girlfriend; boys have a close boyfriend. Girls begin to whisper among themselves as they share secrets with close friends, annoying both parents and teachers.

Nine-year-olds take the values of their peer group very seriously. They are much more interested in how other children dress than in what their parents want them to wear. This is typically the gang age because children form clubs, usually "spite clubs." This means if there are four girls on the block, three form a club and exclude the fourth. The reason for exclusion is often unclear; it might be that the fourth child has a chronic disease, that she has more or less money than the others, that she was at the dentist's the day the club was formed, or simply that the club cannot exist unless there is someone to exclude. Such clubs typically have a secret password and secret meeting place. Membership is generally all girls or all boys. If an excluded child does not react badly to being shut out, the club will probably disband after a few days because its purpose is lost. The next day, the excluded member may meet with two others and snub a different child. Parents have to be careful not to intervene with this type of play, because loyalties shift quickly: the child they defend today may be the excluded one tomorrow.

Because they are so ready for social interaction, 9-year-olds are ready for activities away from home, such as a week at camp. They can take care of their own needs and are mature enough to be separated from their parents for this length of time. Going to camp before this age usually results in homesickness and can be a negative introduction to being away from home.

Although 10-year-olds enjoy groups, they also enjoy privacy. They like having their own bedroom or at least their own dresser, where they can store a collection and know it is free from parents' or siblings' eyes. One of the best gifts for a 10-year-old is a box that locks.

Girls become increasingly interested in boys and vice versa by 11 years of age. Favorite activities are mixed-sex rather than single-sex ones. Children of this age are particularly insecure, however, and girls tend to dance with girls while boys talk together in corners. Better socialization patterns need not be rushed. Just as infants crawl before they walk, so 11-year-olds must attempt many awkward and uncomfortable social experiences before they become comfortable forming relationships with the opposite sex.

Twelve-year-olds feel more comfortable in social situations than they did the year before. Boys experience erections on small provocation so may feel uncomfortable being pushed into boy–girl situations until they know how to control their bodies better. As some children develop faster than others, every group has some members who are almost adolescent and some who are still children, making social interests sometimes difficult.

✔ Checkpoint Question 32.1

Shelly has belonged to a series of clubs for 9-year-olds. A usual characteristic of clubs for this age child is:

a. The club has formal rules and regulations.
b. It is designed to help shy children socialize.
c. It is designed to spite or exclude another child.
d. Clubs include both boys and girls.

Cognitive Development

The period from 5 to 7 years of age is a transitional stage where children undergo a shift from the preoperational thought they used as preschoolers to concrete operational thought or the ability to reason through any problem they can actually visualize (Piaget, 1969) (Fig. 32.6).

Children can use concrete operational thought because they learn several new concepts, such as:

- **Decentering,** the ability to project oneself into other people's situations and see the world from their viewpoint rather than focusing only on their own view.
- **Accommodation,** the ability to adapt thought processes to fit what is perceived such as understanding that there can be more than one reason for other people's actions. A preschooler might expect to see the same nurse in the morning who was there the evening before; a school-age child can understand that different nurses work different shifts.
- **Conservation,** the ability to appreciate that a change in shape does not necessarily mean a change in size. If you pour 30 mL of cough medicine from a thin glass into a wide one, the preschooler will say that one glass holds more than the other; a school-age child will say both glasses hold an equal amount.
- **Class inclusion,** the ability to understand that objects can belong to more than one classification. A preschooler can categorize items in only one way, for example, such as stones and shells are found at the beach; a school-age child can categorize them in many ways such as stones and shells are both found at the beach but are made of different materials, are different in sizes, etc.

FIGURE 32.6 School-age children learn concrete operational thought or concentrate on phenomena they can actually see occurring.

These cognitive developments lead to some of the typical changes and characteristics of the school-age period. Decentering enables a school-age child to feel compassion for others, which was not possible in younger years. Because understanding conservation is possible, a school-age child is not fooled by perceptions as often as before; because of this, sibling arguments over food (your piece of pie is bigger than mine, his glass of cola is bigger than mine) decrease during the school-age years. The ability to classify objects leads to the collecting activities of the school-age period. Class inclusion is also necessary for learning mathematics and reading, systems that categorize numbers and words.

What if... You make a child's hospital bed one day and then give him an injection. What if the next day the child starts to cry while you're making the bed? The lack of what cognitive process led him to believe your action would be the same the second day?

Moral and Spiritual Development

School-age children begin to mature in terms of moral development as they enter a stage of *preconventional reasoning*, sometimes as early as 5 years of age (Kohlberg, 1984). During this stage, if asked, "Why is it wrong to steal from your neighbor?" school-age children will answer, "The police say it's wrong," or "Because if you do, you'll go to jail." They concentrate on "niceness" or "fairness" and cannot see yet that stealing hurts their neighbor, the highest level of moral reasoning.

School-age children begin to learn about the rituals and meaning behind their religious practices, so the distinction between right and wrong becomes more important to them than it was when they were preschoolers. Parent role modeling is also important. Remember that school-age children are rule-oriented; when they pray, they may expect their God to follow rules also (if you are good and pray for something, you should receive it). This makes children of this age confused if a prayer is not immediately answered. Because they are still limited in their ability to understand others' views, they may interpret something as being right because it is good for them, not because it is right for humanity as a whole.

What if... Shelly understands stealing from a neighbor is wrong? Will she also understand that stealing from a large department store or taking things from a health clinic is wrong?

HEALTH PROMOTION FOR A SCHOOL-AGE CHILD AND FAMILY

Because of still limited judgment, school children need guidelines in reference to safety, nutrition, and daily care. These are always excellent topics for discussion at health care visits (Box 32.3).

Promoting School-Age Safety

School-age children are ready for time on their own without direct adult supervision. Many children as young as 8 or 9 stay by themselves after school (see the section on latchkey children later in this chapter). Children are generally ready for this type of experience if they can reliably follow instructions (don't use the fireplace; don't open the door) and can occupy themselves for an hour's time. Be certain school-age children know to use seatbelts in cars and bicycle safety around cars (AAP, 2009). As with adults, accidents tend to occur when children are under stress. Box 32.4 lists common measures helpful in preventing accidents in this age group.

School age is not too early for parents to look at the effect of carrying heavy backpacks on children's posture. A backpack that weighs more than 10% of the child's body weight is enough to cause a child to have to lean forward chronically to bear the weight. This can lead to chronic back pain (Shilt & Barnett, 2007).

Sexual abuse is an unfortunate and all-too-common hazard for children. Teaching points to help children avoid sexual abuse are summarized in Box 32.5 (see also Chapter 55).

BOX 32.3 * Focus on Evidence-Based Practice

Does family structure make a difference in how much health care children receive?

Single-father families have increased in recent years to now represent 6% of American families with children. Families headed by single fathers are less likely to be poor, are more likely to be employed, and are better off overall economically than families with single mothers but they are worse off economically, measured both by poverty status and labor force participation, than married couples with children. To investigate whether single-father parents are as conscientious in obtaining health care for children, researchers studied a total of 62,193 children. Three percent of sample children lived in single-father families and 22% of sample children lived in single-mother families. Single-father families had significantly better health care coverage than single-mother families as health insurance is associated with employment and single fathers held more full-time jobs than single mothers in this survey. Despite the difference in insurance coverage, 86% of children in single-mother and 87% of two-parent families had had a health provider visit in the past year while children in single-father households had a rate of 80 percent. Children living in single-father households had lower overall rates of well-child care (57% compared with 69% for children in single-mother households and 67% for children in two-parent households) and a lower likelihood of having a usual source of care (87% compared with 91% for children in single-mother households and 95% for children in two-parent households).

Would the above study influence how closely you assessed a child for up-to-date immunizations?

Source: Leininger, L. J., & Ziol-Guest, K. M. (2008). Reexamining the effects of family structure on children's access to care: the single-father family. *Health Services Research, 43*(1.1), 117–133.

Promoting Nutritional Health of a School-Age Child

Most school-age children have good appetites, although any meal is influenced by the day's activity. If children have had a full day of activities, they may come to the dinner table ready to eat anything. If a day was filled with frustration—a child received a poor mark in school, had an argument with a friend, or has a big game to think about—the child may pick and poke at food. This is no different from the way adults feel at times, so should be respected.

Establishing Healthy Eating Patterns

School-age children need breakfast to provide enough energy to get them through active mornings at school. They eat best if parents get up in the morning and eat some themselves. Children react badly to the instruction, "Do as I say, not as I do."

If children take a packed lunch to school, urge parents to allow them some say in the meal, because packed lunches become tedious for everyone after a while. Whether they take lunch or buy it at school, school-age children should know some elementary facts of nutrition so they do not trade a sandwich for cake or choose only desserts from the cafeteria. Ideally, children should receive guidance from school personnel, but this often is impossible in a busy lunchroom. Health care personnel, therefore, should play an active role in nutrition education at health maintenance visits.

Many children qualify for a free or reduced-price school lunch and breakfast (Kristjansson et al., 2009). A government-regulated school lunch (type A) provides milk (8 oz), protein (2 oz), one starch serving, vegetable (¾ cup), and fruit (¾ cup). Serving sizes vary according to age to provide one third of a child's nutrition requirements for a day (Fig. 32.7). Check that children are actually eating school lunches, not trading items they do not want, so they receive the full benefit of the program.

Most children are hungry after school and enjoy a snack when they arrive home. Because sugary foods may dull a child's appetite for dinner, urge parents to make the snack nutritious: fruit, cheese, or milk, rather than cookies and a soft drink.

BOX 32.4 ✻ Focus on Family Teaching

Common Safety Measures to Prevent Accidents During the School Years

Q. Shelly's mother tells you, "My school-ager is constantly on the go. How can I keep her free from accidents when I'm not always with her?"

A. Putting preventive steps in place is the key.

Accident	Preventive Measure
Motor vehicle accidents	Insist children use seat belts in a car; role model their use. Teach street-crossing safety; stress that streets are no place for rough-housing, pushing, or shoving. Teach bicycle safety, including advice not to take "passengers" on a bicycle and to use a helmet. Teach parking lot and school bus safety (do not walk in back of parked cars, wait for crossing guard, etc.).
Community	Avoid unsafe areas, such as train yards, grain silos, back alleys. Do not go with strangers (parents can establish a code word with child; child does not leave school with anyone who does not know the word). Children should say "no" to anyone who touches them if they do not wish it, including family members (most sexual abuse is by a family member, not a stranger). For late school-age, teach rules of safer sex (use of condoms; inspecting partner, etc.).
Burns	Teach safety with candles, matches, campfires—fire is not fun. Teach safety with beginning cooking skills (remember to include microwave oven safety, such as closing firmly before turning on oven; not using metal containers). Teach safety with sun exposure—use sun block. Do not climb electric poles.
Falls	Teach that rough-housing on fences, climbing on roofs, etc., is hazardous. Teach skateboard, scooter, and skating safety.
Sports injuries	Teach that wearing appropriate equipment for sports (face masks for hockey; mouthpiece and cup for football; helmet for bicycle riding, skateboarding, or in-line skating; batting helmets for baseball) is not babyish but smart. Stress not to play to a point of exhaustion or in a sport beyond physical capability (no pitching baseball or toe ballet for an early grade-school child). Use trampolines only with adult supervision to avoid serious neck injury.
Drowning	Teach how to swim; dares and rough-housing when diving or swimming are not appropriate. Do not swim beyond limits of capabilities.
Drugs	Help your child avoid all recreational drugs and take prescription medicine only as directed. Avoid tobacco and alcohol.
Firearms	Teach safe firearm use. Keep firearms in locked cabinets with bullets separate from gun.
General	School-age children should keep adults informed regarding where they are and what they are doing. Be aware that the frequency of accidents increases when parents are under stress and therefore less attentive. Special precautions must be taken at these times. Some children are more active, curious, and impulsive and therefore more vulnerable to accidents than others.

Early school age is not too young to put in place preventive measures against cardiovascular changes later in life. Limiting salty foods, for example, can help prevent hypertension (He, Marrero, & Macgregor, 2008). Excessive saturated fat can lead to the formation of artery plaques and cardiovascular disease.

Teach parents to make every attempt to make mealtime a happy and enjoyable part of the day for everyone. Some school-age children learn to eat as quickly as possible (and so incompletely) to escape from the table before something unpleasant happens, such as an argument they can sense is brewing.

Fostering Industry

As a part of fostering industry, school-age children usually enjoy helping to plan meals. They can prepare foods such as instant pudding, Jell-O, salads, scrambled eggs, and sandwiches. They may eat meals they have planned or prepared more willingly than ones that are just set in front of them.

Most parents would like children to develop better table manners. Because they are in a hurry to finish eating, school-age children tend to gulp their food. Many meals are interrupted by spilled milk. As children become teenagers and are more aware of the impression they make on others, manners often improve dramatically. It is often comforting for parents to know that children typically display better table manners in other people's homes than in their own.

Recommended Dietary Reference Intakes

Although parents may have less to say about what a school-age child eats, it is important that the increasing energy requirements that come with this age (often in spurts) are met daily with foods of high nutritional value.

BOX 32.5 ✻ Focus on Family Teaching

Teaching Points to Help Children Avoid Sexual Abuse

Q. Shelly's mother wants to protect her daughter from sexual abuse. She asks you, "What are good rules to teach children without scaring them?"

A. A number of common rules are:

1. Your body is your property and you can decide who looks at it or touches it.
2. Secrets are fun things to keep. If a person asks you not to tell about something that was done to you that you did not like, it is not a secret. It is all right to tell about it.
3. Do not go anywhere with a stranger (a stranger is someone you do not know, not someone "strange"). Do not be fooled by people asking you to give them directions or to go with them because your mother is sick or hurt or they have lost a pet.
4. Being touched by someone you like is a good feeling. You do not have to allow anyone to touch you in a way you do not like. Do not allow yourself to be left alone with a person you are uncomfortable with because that person touches you in a way you do not like.
5. A "private part" is the part of you a bathing suit touches. If anyone asks you to show them a private part or touches a private part, tell them to stop, and tell someone else.
6. If the person you tell does not believe you, keep telling people until someone does believe you.

During the late school years, the recommended dietary intakes for children begin to be separated into categories for girls and boys because boys require more calories and other nutrients at this time. Because school-age children typically dislike vegetables, their intake may be deficient in fiber. Both girls and boys require more iron in prepuberty than they did between the ages of 7 and 10. Adequate calcium and fluoride intake remains important to ensure good teeth and bone growth.

Promoting Nutritional Health With a Vegetarian Diet

School-age children who are raised in vegetarian homes need to learn aspects of vegetarian nutrition if they are going to eat in a school cafeteria. Unfortunately, many school lunch programs offer mainly milk and meat or cheese foods, such as sloppy Joe sandwiches, macaroni and cheese, or pizza. This forces children who are vegetarians to carry packed lunches. Vegetarian packed lunches can be varied with foods such as cucumber, tomato, or peanut butter sandwiches on whole-grain bread; hot soups; salads; vegetable sticks; and fruit. When eating at a friend's house, children need to learn to notify the host that they eat a special diet or know how to choose correctly from foods they are served.

A potential problem to assess with vegetarian school-age children is whether they are obtaining enough protein and calcium to be prepared for the rapid growth spurt of puberty. Foods high in calcium are green, leafy vegetables such as spinach and turnip greens, prunes, nuts, enriched bread, and cereals. Soybeans, legumes, nuts, grains, and immature seeds like green beans, lima beans, and corn are relatively high in protein. As with any individual on a vegetarian diet, children may need a vitamin B_{12} supplement. Encourage outside activities for sun exposure to increase vitamin D. Iron may need to be supplemented, especially in girls with heavy menstrual flows (Rolfes, Pinna, & Whitney, 2009).

FIGURE 32.7 School lunch programs provide nutritious meals to help school-age children meet nutrition requirements.

Promoting Development of a School-Age Child in Daily Activities

With life centered on school activities and friends, a school-age child still needs parental guidance for most daily activities, because the habits and lifestyle patterns gained during this period will form the basis for the patterns of living later in life. Figure 32.8 shows a day in the life of a family with school-age children. Along with nutritional needs, areas of concern for a school-age child and family include dressing, sleep needs, exercise, hygiene, and dental care.

Dress

Although school-age children can fully dress themselves, they are not good at taking care of their clothes until later in the school-age years. This is the right age, however (if not started already), to teach children the importance of caring for their own belongings. School-age children have definite opinions about clothing styles, often based on the likes of their friends or a popular sports or rock star rather than the preferences of their parents. Help parents be aware that a child who wears different clothing than others may become the object of exclusion from a school club or group. In schools with a gang culture, children may not be able to wear a certain color or style lest they be mistaken for a gang member. Many schools have begun requiring school uniforms to avoid this problem.

Sleep

Sleep needs vary among individual children. Younger school-age children typically require 10 to 12 hours of sleep each night, and older ones require about 8 to 10 hours. Most 6-year-olds are too old for naps but do require a quiet time after school to get them through the remainder of the day. Nighttime terrors may continue during the early school years

7:00 AM: The family sits down to a healthy breakfast. Claudia helps Laura with the butter.

7:30 AM: John walks Marc to school, emphasizing safety when crossing the street.

10:00 AM: Claudia and Laura bake a cake for the night's dessert. Four-year-old Laura enjoys practicing adult roles.

3:00 PM: Marc and Laura play together after Marc gets home from school. Their cooperative play is punctuated by an occasional argument.

FIGURE 32.8 A day in the life of a family with young children.

4:00 PM: Claudia helps Marc with his homework. Laura likes to draw alongside her big brother.

5:00 PM: The family greets John as he comes home from work.

5:30 PM: John and Marc go rollerblading before dinner. John makes sure Marc's protective gear is in place.

7:00 PM: After dinner, Marc helps with the dishes; then the family spends time together playing a game.

8:30 PM: Time to get ready for bed! Claudia helps the kids clean up and brush their teeth. And there's always time to read them a story.

9:00 PM: John and Claudia relax together at the end of the day.

FIGURE 32.8 *(continued)*

and may actually increase during the first-grade year as a child reacts to the stress of beginning school.

During early school years, many children enjoy a quiet talk or a reading time at bedtime. At about age 9, when friends become more important, children generally are ready to give up pre-bedtime talks with parents in preference to calling or text messaging a friend. Some parents react strongly to this change and feel rejected. They may need some help to take at face value their child's statement, "I'm tired. I'd rather go to sleep."

Exercise

School-age children need daily exercise. Although they go to school all day, they do not automatically receive much exercise because school is basically a sit-down activity. Children who are bussed or driven by a parent to school may therefore return home without having spent much time in active exercise.

Exercise need not involve organized sports. It can come from neighborhood games, walking with parents or a dog, or bicycle riding. As children enter preadolescence, those with poor coordination may become reluctant to exercise. Urge them to participate in some daily exercise, or else obesity, or osteoporosis later in life, can result.

Hygiene

Children of 6 or 7 years of age still need help in regulating bath water temperature and in cleaning their ears and fingernails. By age 8, children are generally capable of bathing themselves but may not do it well because they are too busy to take the time or because they do not find bathing as important as do their parents.

Both boys and girls become interested in showering as they approach their teens. This can be encouraged as perspiration increases with puberty, along with sebaceous gland activity. When girls begin to menstruate, they may be afraid to take baths or wash their hair during their period if they have heard this is not safe. They need information on the importance and safety of good hygiene during their menses. Boys who are uncircumcised may develop inflammation under the foreskin from increased secretions if they do not wash regularly.

Care of Teeth

With proper dental care, the average child today can expect to grow up cavity free. To ensure this happening, school-age children should visit a dentist at least twice yearly for a checkup, cleaning, and possibly a fluoride treatment to strengthen and harden the tooth enamel (Marinho et al., 2009) (Fig. 32.9). Some children develop a fear of dentists and, if a dentist visit is painful, want to avoid going at all. The advantage of frequent visits is that if cavities are filled when they are small, the drilling required is minimal and little pain is involved. If cavities are not treated promptly in this way but are allowed to grow large, the drilling hurts, causing these children to refuse to go back to the dentist. More large cavities then grow, and a vicious circle develops. Pedodontists specialize in caring for children's teeth and understand the developmental level of their patients. Children who tend to develop caries (cavities) might be encouraged to visit a pedodontist if one is available and affordable.

School-age children have to be reminded to brush their teeth daily. If brushing becomes an area of conflict for the family, brushing well once a day may be more effective than brushing more often but doing an inadequate job. For effective brushing, a child should use a soft toothbrush, fluoride-based toothpaste, and dental floss to clean between teeth to help remove plaque.

FIGURE 32.9 Dental caries are the number one health problem in school-age children. Teach children good dental health and encourage them to visit a dentist twice a year.

Snacks are best limited to high-protein foods such as chicken and cheese rather than candy. Fruits, vegetables, and cereals fortified with minerals and vitamins can all be fun afterschool snacks for school-age children. If the child does eat candy, a type that is eaten quickly and dissolves quickly is better than slowly dissolving or sticky candy, which stays in contact with the teeth longer.

Promoting Healthy Family Functioning

At 6 years of age, most children have passed through a preschool phase of attraction for the parent of the opposite sex and identify again with the parent of the same sex (Freud, 1962). Children from single-parent homes, or those with a parent who has difficulty being a good role model, may need help in finding a suitable adult to serve as this important person in their life.

To their parents' annoyance, many 6-year-olds often quote their teacher as the final authority on all subjects. This may be the first time the parents see someone surpassing them in their child's eyes, and accepting the situation can be painful. Children also cite their friends as guides for behavior: "Mary Jane doesn't have to go to bed until 10 o'clock," or "Carlos' mother lets him go to the movies every Saturday." Parents may require help to realize these remarks are a normal consequence of being exposed to other adults and children. A simple statement such as, "There are all kinds of ways

to do things, but in our house, the rule is this," shows no criticism of Carlos' or Mary Jane's family, yet conveys a special "our house" feeling and offers security to a child.

Parents often must be reminded that even the simplest tasks of everyday life require repeated practice before they can be accomplished well. The way parents correct children as they learn these tasks can influence children's opinions of themselves and their ability to continue learning. "Putting all the silverware in a pile is one way of putting it away; another way would be to divide spoons, forks, and knives separately" is always preferable to "What a silly way to put away silverware!" Comments such as, "Can't you do anything right?" or "Why don't you ever do what I say?" should always be avoided because children will rise only to the level expected of them. Children who are constantly told they are stupid, thoughtless, bad, or ill-behaved may begin to act that way to conform to their parents' expectations.

If parents have difficulty telling what a child's completed project is supposed to be, the time-honored "Tell me about it" is preferable to "What is it?" It is good for parents to find a redeeming characteristic in a project, no matter how shakily put together it is: "I like the bright color you painted it" or "That must have been fun to make." Displaying and using children's gifts are part of having school-age children in a family. A finger painting hung on the refrigerator door will enhance, not detract from, the most elegant home. The best-dressed woman looks even more radiant wearing her child's necklace made of macaroni on a string. Both examples are gestures of love, which goes well with everything.

In talking to parents of school-age children, good questions to ask to estimate the degree of interaction that occurs in the home and whether parents are strengthening a child's sense of accomplishment are:

- How do you correct John when he does something wrong?
- Do you display his school projects?
- Does he have chores that are his to accomplish?

Common Health Problems of the School-Age Period

Children in their early school years have one of the lowest rates of death and serious illness of any age group. The two leading causes of death are accidents and cancer. Minor illnesses are largely because of dental caries, gastrointestinal disturbances, and upper respiratory infections.

Table 32.3 shows the usual health maintenance pattern for a school-age child (AAP, 2009). Table 32.4 lists problems that parents may have in evaluating illness in school-age children. Many communities are establishing school-based community health care clinics to improve the health care available for school-age children.

Dental Caries

Caries (cavities) are progressive, destructive lesions or decalcification of the tooth enamel and dentin. When the pH of the tooth surface drops to 5.6 or below (which happens after children eat readily fermented carbohydrates, such as table sugar), acid microorganisms (acidogenic lactobacilli and aciduric streptococci) found in dental plaque attack the organic cementing medium of teeth and destroy it. Plaque tends to accumulate in deep grooves of the teeth and contact areas between teeth, making these areas most susceptible to dental decay. The enamel on primary teeth is thinner than that on permanent teeth, so they are even more susceptible to destruction than permanent teeth. The distance from the enamel to the pulp is shorter, too, so invasion of the tooth nerve can occur quickly. Neglected caries result in poor chewing and therefore poor digestion, abscess and pain, and sometimes osteomyelitis (bone infection).

As stated earlier, dental caries are largely preventable with proper brushing and use of fluoridated water or fluoride application. When caries do occur, it is important they be treated quickly and the child's dental hygiene practices be evaluated and improved if necessary. Most important, children must believe they have a stake in the health or disease of their teeth so they willingly undertake the self-care measures necessary to ensure healthy teeth, with parental support rather than parental command.

Malocclusion

The upper jaw in children matures rapidly in early childhood along with skull growth; the lower jaw forms more slowly, forcing teeth to make a prolonged series of changes until they reach their final adult alignment and position. Good tooth occlusion, in which the upper teeth overlap the lower teeth by a small amount and teeth are evenly spaced and in good alignment, is necessary for optimal formation of teeth, health of the supporting tissue, optimal speech development, and what most people view as a pleasant physical appearance. *Malocclusion* (a deviation from the normal) may be congenital and related to conditions such as cleft palate, a small lower jaw, or familial traits tending toward malocclusion. The condition can result from constant mouth breathing or abnormal tongue position (tongue thrusting). Thumb-sucking appears to have little role in malocclusion as long as this does not persist past the time of eruption of the permanent front teeth (6 to 7 years). The loss of teeth because of extraction or accident may lead to malocclusion if not properly treated to maintain alignment.

Malocclusion may be either crossbite (sideways) or anterior or posterior. Children with a malocclusion should be evaluated by an orthodontist to see if orthodontic braces or other therapy is necessary. The time to begin correction varies with the extent of the malocclusion and the jaw size. Braces are expensive and painful when they are first applied and at periodic visits when they are tightened to maintain pressure for further straightening. Some children develop mild, shallow ulcerations (canker sores) on the buccal membrane from friction of metal wires. Rubbing the offending wire with dental wax dulls the surface and gives relief. Oral acetaminophen or an agent such as Ora-Jel (an over-the-counter drug) rubbed on the ulceration also gives relief. Children who wear braces need to have their teeth assessed frequently to see they are brushing properly around the braces (a Water Pik is often recommended for thorough cleaning) and that they are using dental floss to remove plaque from around wires (Harrison, O'Brien, & Worthington, 2009).

After removal of braces, many children must wear retainers to maintain the correction the braces achieved. Although braces are wired into place, retainers are not. Wearing a retainer can prove troublesome for a child as it

TABLE 32.3 ✻ Health Maintenance Schedule, School-Age Period

Area of Focus	Methods	Frequency
Assessment		
Developmental milestones	History, observation	Every visit
Growth milestones	Height, weight plotted on standard growth chart; physical examination	Every visit
Hypertension	Blood pressure	Every visit
Nutrition	History, observation; height/weight information	Every visit
Parent–child relationship	History, observation	Every visit
Behavior or school problems	History, observation	Every visit
Vision and hearing disorders	History, observation	Every visit
	Formal Snellen or Titmus testing	At 7–8 and 10–12 years
	Audiometer testing	At 6 and 10–12 years
Dental health	History, physical examination	Every visit
Scoliosis	Physical examination	Yearly after age 8 years
Thyroid	Physical examination, history	Every visit after age 10 years
Tuberculosis	PPD skin test	Depending on prevalence of tuberculosis in community
Bacteriuria	Clean-catch urine	At 6–7 years
Anemia	Hematocrit/hemoglobin	At 11–12 years
Immunizations		
Diphtheria and tetanus (Tdap) vaccine	Check history and past records; inform caregiver about any risks and side-effects; administer immunization in accordance with health care agency policies.	11–12 years
Hepatitis A vaccine		If not previously administered
Hepatitis B vaccine		If not administered in infancy or three injections were not completed
Human papillomavirus vaccine (HPV or Gardasil) in girls		11 or 12 years; 2nd injection 2 months later; 3rd injection 6 months after 1st dose
Influenza vaccine		Yearly
Meningococcal vaccine		11–12 years
Pneumococcal vaccine		To children at high risk
Varicella vaccine		At any age after 1 year if not previously immunized or at 11–12 years if lacking reliable history of chickenpox
Anticipatory Guidance		
School-age care	Active listening and health teaching	Every visit
Expected growth and developmental milestones before next visit	Active listening and health teaching	Every visit
Accident prevention	Counseling about street and personal safety	Every visit
Problem Solving		
Any problems expressed by caregiver during course of the visit	Active listening and health teaching regarding cigarette smoking, drug abuse, sex education, school adjustment	Every visit

must be removed when eating such as in the school cafeteria or in a restaurant. Show appropriate sympathy and help children problem-solve if they are bothered by the appearance of braces or wearing a retainer. For instance, if removing the retainer in front of friends is embarrassing for a child, perhaps it could be removed in the bathroom before going to the cafeteria each day. Braces and retainers, once thought of as implements to be made fun of, have become such a common feature of life for schoolchildren today that most children who wear them find comfort in not being the only one to suffer this indignity and, once used to their own appliances, experience little reluctance in letting their classmates see them. Some even view them as a mark of pride or badge of courage.

TABLE 32.4 ✻ Parental Difficulties Evaluating Illness in the School-Age Child

Difficulty	Helpful Suggestions for Parents
Evaluating seriousness of illness	For the first time, a school-age child may view illness as a way to avoid unpleasant activities (school, a coach who asks too much, household chores). Evaluating whether the child has symptoms when he is asked to do something he likes to do often reveals the difference between exaggeration and an ill child (too sick to eat spinach, not too sick to eat ice cream; too sick to go to school, not too sick to go ice skating). If the child uses symptoms of illness as a means of avoiding situations, parents must evaluate what it is that the child wants so badly to avoid and see if some change should be made in expectations.
Evaluating nutritional intake	Many school-age children eat lunch at school; they may spend weekends away from home and weeks away at camp. As with all ages, noting whether they are growing and active is better than monitoring any one day's food intake.
Evaluating puberty changes	There is a wide variation in the time that secondary sex characteristics occur (9–17 years for girls; 10–18 years for boys). Children should be examined if and when they or their parents are concerned that pubertal changes are delayed.
Age-specific diseases to be aware of	School age is a time to evaluate vision; children normally develop vision changes as maturity of the eye globe increases. Squinting, rubbing eyes, or poor marks in school may be signs of poor vision. Streptococcal sore throats occur frequently in early-school-age children. Those with sore throats should be examined by a health care provider to prevent complications, such as glomerulonephritis or rheumatic fever, from developing. Girls, in particular, must be evaluated for scoliosis (curvature of the spine). Parents detect this by noticing that the girl's skirts hang unevenly or bra straps are uneven. Parents may need to be cautioned that vomiting or headache in the morning that passes fairly quickly (at about the same time the school bus leaves) may be a symptom of school phobia, but physical examination is in order because these are also symptoms of other conditions. Absence seizures, a neurologic condition that typically arises in school-age years, can be confused with behavior problems if observation is not thorough (see Chap. 49). Attention-deficit/hyperactivity disorder (ADHD) (see Chap. 54) can also lead to behavior or inattention disorders.

✔ Checkpoint Question 32.2

If Shelly eats candy, what is the best type in terms of preventing caries?

a. Saltwater taffy
b. A chocolate bar
c. Chewy caramels
d. Hard candy

Concerns and Problems of the School-Age Period

One of the most important disorders of the school-age period is attention-deficit/hyperactivity disorder (ADHD) because it interferes so dramatically with school progress (see Chapter 54). Other problems concern language, fears, and responsibility.

Nursing Diagnoses and Related Interventions

✻

Nursing Diagnosis: Parental anxiety related to behavior of school-age child

Outcome Evaluation: Parent states undesired behavior has decreased in frequency; parent feels less stress about child's health or future.

Problems Associated With Language Development

The common speech problem of the preschool years is broken fluency; the most common problem of a school-age child is articulation. The child has difficulty pronouncing *s, z, th, l, r,* and *w* or substitutes *w* for *r* ("westroom" instead of "restroom") or *r* for *l* ("radies' room" instead of "ladies' room"). This is most noticeable during the first and second grades; it usually disappears by the third grade. Unless it persists, speech therapy for this normal developmental stage is not necessary.

Common Fears and Anxieties of a School-Age Child

School-age children are old enough to experience adult reactions to problems at home or school.

Anxiety Related to Beginning School. Adjusting to grade school is a big task for 6-year-olds. Even if they attended preschool, grade school is different: the rules are firmer, and

BOX 32.6 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a School-Age Child Starting Middle School

Shelly Lewis is a 12-year-old girl who recently started middle school. Her mother tells you that although Shelly, who is overweight, says she likes school, she has developed a lot of nervous habits such as nail biting since school started.

Family Assessment ✻ Child lives with mother, stepfather, and 3 younger stepsisters in 4-bedroom home. Family owns a boarding kennel for dogs; both parents work full time at business. Mother describes finances as "Okay. It's hard with a big family."

Client Assessment ✻ Child has been "chubby" since preschool. States she likes to read rather than play sports. Has just started middle school (seventh grade). Observed to be restless in chair during conversation with mother about the new school. Mother states, "Her sisters have no trouble with change; she always does. Don't you think if she lost weight she'd fit in better?"

Nursing Diagnosis ✻ Anxiety related to beginning a new school.

Outcome Criteria ✻ Child states she feels more comfortable with new school setting; nail biting has decreased in intensity; agrees to begin weight-reduction program.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Assess what activities client enjoys.	Review with client advantage of participating in activities that involve more exercise than reading. Suggest listening to taped books while walking with a friend.	Effective weight reduction calls for increased exercise. Taped books still supply reading enjoyment.	Child states she will try some active activity for at least 20 minutes each day.
		Consultations		
Nurse	Assess if child would like to be referred to a weight-reduction class at health center.	Suggest different options available such as weight-loss group or commercial weight-reduction program.	Children respond well to group activities. Other group members supply friendship as well as increase motivation.	Child states whether she would like to join a weight-reduction group.
		Procedures/Medications		
Nurse	Ask child to try to identify if she feels something is upsetting about the new school; if so, what is that thing?	Help child "walk through" a day at school and discuss how small changes could affect her fitting into school.	Talking with the child allows her to share feelings and concerns openly and safely, possibly increasing the child's awareness of them and their impact on her.	Child describes a typical day and points she would like to see changed.
		Nutrition		
Nurse/nutritionist	Assess child's intake by 24-hour recall history.	Review with child changes that would reduce calories yet maintain her lifestyle.	Twelve-year-old children are old enough to take responsibility for what and when they eat.	Client reviews her dietary intake; makes at least three suggestions on things she will attempt to change.

		Patient/Family Education		
Nurse	Assess if family members appreciate the stress a new school setting can create.	Review with mother and child ways to reduce stress when encountering new situations, such as equating them with something already known.	It is easy for parents to view 12-year-olds as able to handle new situations better than they can because of pseudo-maturity.	Mother states she may have been taking the change in school too lightly; needs to offer more support.
		Psychosocial/Spiritual/Emotional Needs		
Nurse/nurse practitioner	Assess family functioning with child's mother.	Stress that all children are individuals and what works for stepsisters may not work for client.	Being constantly compared to siblings can create feelings of low self-esteem, which can lead to difficulty solving problems.	Mother states she will try to reduce comparisons to stepsisters, to help reduce stress at home.
		Discharge Planning		
Nurse	Assess if child or mother thinks an early follow-up appointment would be helpful.	Arrange for a follow-up clinic appointment within 1 month with the mother and daughter if desired.	It is difficult for a family to make internal changes if they are too emotionally involved to be objective.	Mother and child express their preferences based on their future plans.

the elective feeling ("If I don't like it, I can quit") is gone. School is for keeps until age 16 or longer, a time span too long for a young child to even imagine. Whereas preschool learning was carried out through fun activities, part of every day in grade school involves obvious work (see Focus on Nursing Care Planning Box 32.6).

Because school is an adjustment, a health assessment of all school-age children should include an inquiry about progress in school. You can obtain information by asking a parent, "How is Susan doing in school?" followed by a second question, "How does her teacher say she is doing?" If there is a discrepancy between the answers, the situation bears study. The answer to the first question reveals the parent's attitude toward the child's progress. The answer to the second may indicate a child who is having trouble adjusting to a structured school environment. Some parents have to alter their expectations of how much their child should be achieving to conform to their child's actual ability. This can be difficult.

One of the biggest tasks of the first year of school is learning to read. It is best if parents have prepared children for this by reading to them since infancy, pointing to the words and pictures as they go along. This helps children realize sentences flow from left to right and the words, not the pictures, tell the story. Box 32.7 offers some useful hints to help parents encourage reading in their young school-age child.

Many first-graders are capable of mature action at school but appear less mature when they return home. Their pseudo-sophistication of the day is gone. They may bite their nails, suck their thumb, or talk baby talk. Some develop tics (irregular movements of isolated muscle groups), such as wrinkling the forehead, shrugging the shoulders, twisting the mouth, coughing, clearing the throat, or frequently blinking

BOX 32.7 * Focus on Family Teaching

Tips to Help Make Reading More Enjoyable for a Child

Q. Shelly's grandmother says to you, "I want my grandchild to enjoy reading more. How can I encourage this?"

A. Integrating reading into a total lifestyle is the best approach.

- Read yourself to set an example, so your child associates learning to read with adult activity. If you spend most of your free time watching television, your child will think reading is mainly for children and assume that it is not important.
- Make reading more fun by encouraging your child to make practical use of reading. Ask her to read recipes while you cook or to read road signs during a car trip.
- Play a treasure hunt game in which you hide a small object, such as a favorite toy, then write simple clues on slips of paper—"Look under a lamp," then, under the lamp, "Look in a book," and so on until your child has been led to the hidden object. Such games help your child see reading as an important means of obtaining information. Your child can develop writing skills by playing the same game for you to follow.
- Suggest to relatives that a gift certificate from a bookstore would be a good present. Let your child browse the store to select the book.
- Talk about books the child has read—what was good, what was bad, or what the child learned.
- Read a book together as a pre-bedtime family activity.

or rolling the eyes. Such movements may occasionally be confused with seizure activity. Tics, however, disappear during sleep and occur mainly when the child is subjected to stress or anxiety. Scolding, nagging, threatening, or punishing does not stop either tics or nail biting; it invariably makes these problems worse. Methods such as using bad-flavored nail polish and restraining the child's hands to prevent nail biting are also ineffective.

These behaviors stop when the underlying stress is discovered and alleviated. Urge parents to spend some time with a child after school or in the evening so the child continues to feel secure in the family and does not feel pushed out by being sent to school. If such behavior manifestations persist despite attempts to eliminate their cause, the family might benefit from formal counseling.

School Refusal or Phobia. School refusal is fear of attending school. It is a type of "social phobia" similar to agoraphobia (fear of going outside the home). Children who resist attending school this way may develop physical signs of illness, such as vomiting, diarrhea, headache, or abdominal pain on school days (Tyrrell, 2007). This lasts until after the school bus has left or the child is allowed to stay home for the day.

A particular child may be reacting to a situation such as a harsh teacher, having to shower in gym class, or facing a class bully every day. In these instances, the child's fear may be well grounded. Counseling may help the child manage the situation better. If not, parents can attempt to have the child transferred to another classroom or perhaps excused from a disliked situation such as showering to stop the school resistance.

School refusal may occur from fear of separation from parents. The child may be overly dependent on the parents or may be reluctant to leave home because of worry that younger siblings will usurp the parents' affection. The anxiety of separation may also result because the parent is overprotective of the child or is the one having the most difficulty separating.

Because the problem of school refusal is usually only partly the child's, the entire family generally requires counseling to resolve the issue. As a rule, once it has been established the child is free of any illness and the resistance stems from separation anxiety or phobia, the child should be made to attend school. Reinforcement by parents to go to school this way helps to prevent problems such as school failure, peer ridicule, or a pattern of avoiding difficulties. Some children may benefit from a gradual program of school involvement, such as walking to school but not going in for one day, then going to school but staying for only 1 hour the next day, then staying for half a day, and so on, until the child can stay all day every day. Give support to parents so they can treat the child's illness symptoms matter-of-factly (a great deal of reassurance that these symptoms are not major will be necessary) so they can take the child firmly to the bus or to the classroom.

Managing school refusal requires coordination among the school, school nurse, and health care provider who diagnoses the problem. A nurse is the ideal person to coordinate such efforts and to help parents allow the child some independence not only in going to school but in other activities. A few children have such difficulty they require psychiatric therapy to resolve their difficulties with school.

Home Schooling

Because of religious or personal preference or because of disillusionment with the school system, a growing number of children are home schooled today (Gaither, 2008). It is important to identify these children at a health care visit because with their less extensive experience with peers than other children, they may not be as comfortable with peer interaction. As their main contact has been with parents at home, their vocabulary may be advanced or can suggest they are older than their real age. They may be experts at computer searching but know less than other children about health prevention measures as they have not had contact with school nurses or health courses. When discussing home schooling with parents, assess if children do have peer experiences, perhaps through participation in community sports teams. Ask if they receive exposure to other cultures or families so they can better adjust to people different from themselves at college or a first work position.

Latchkey Children

Latchkey children are schoolchildren who are without adult supervision for part of each weekday. The term alludes to the fact they generally carry a key so they can let themselves into their home after school.

Latchkey children have become a prominent concern because in as many as 90% of families today in the United States, both parents work at least part-time outside the home. Few parents have work hours so flexible they can always be at home when a child leaves for or returns from school. Extended family members who once watched children after school are often working as well or may no longer be close at hand; many communities are no longer close-knit enough to have neighbors who can be depended on to help out with informal child care.

A major concern of children staying alone is that they will develop an increased tendency toward accidents, delinquent behavior, alcohol or beginning drug abuse, or decreased school performance from lack of adult supervision. For children who feel safe in their community, however, a short period of independence every day may actually be beneficial; it encourages problem solving in self-care.

Suggestions for parents whose children must spend time alone before or after school are given in Box 32.8. Many communities offer special afterschool programs so children do not have to be home alone. Nurses are in a position to educate parents about such services so their children can feel both safe and stimulated creatively during this time. Boy Scouts and Campfire Girls are examples of organizations that offer programs to help children adjust to being home alone. Many communities are organizing hotline numbers a child who is alone can call if a problem arises. At health visits, assess whether parents and a child appear to have a problem with or are uncomfortable about afterschool arrangements. For a child who is extremely fearful or impulsive or who finds problem solving difficult, time alone after school may not be appropriate. Determine the individual circumstances, and recommend changes when appropriate.

Sex Education

It is important that school-age children be educated about pubertal changes and responsible sexual practices so they are

BOX 32.8 * Focus on Family Teaching

Tips for Latchkey Children and Parents

Q. Shelly stays by herself after school for a half-hour. Her father asks you, "What are good tips for being sure it's safe to let her do this?"

A. Think of several areas:

Safety Teaching for Children

- Always lock doors and never show keys to others or indicate that you stay home alone.
- When answering the telephone, say a parent is busy, not absent from home.
- Have a plan in event you lose your key (stay with a neighbor, etc.).
- Do not go into the house if the door is open or a window is broken.
- Learn fire safety (practice a fire drill from all rooms of the house).
- Check in with parents by telephone when you first arrive home from school.
- Identify a caller before opening the door. Agree on a secret code word; you should not open the door or go with a person unless the person knows the word.
- Learn how to change light bulbs safely if it will be dark before parents return home. If appropriate, learn how to change fuses or reset circuit-breaker switches.
- Learn how to report a fire and telephone police (practice this with your parents).

Safety Responsibilities for Parents

- Prepare a safety kit and keep it filled; include a flashlight in case of a power failure so children do not need to light candles.
- Plan afterschool snacks that do not require cooking to prevent burns.
- Keep firearms locked, with the key in a place unknown to child.
- Keep a list of emergency telephone numbers (including parents' work numbers) by the telephone.
- Arrange with a neighbor who is usually home during the late afternoon for child to stay with in an emergency.
- If an older child will be watching a younger one, be certain both children understand the rules laid down and the degree of responsibility expected.
- Be certain child understands that rules that apply during other times (never swim alone; do not play by the railroad tracks) also apply during independent time.

Parental Actions to Prevent Loneliness

- Be certain to make additional time available after work so children can describe their day.
- Each morning help children plan an activity for that day so they have something purposeful to look forward to during time alone.
- Allow special privileges such as listening to music that other members of the family do not like as well; allow extra television hours during this time.
- Consider a pet. Even a caged animal, such as a hamster or a bird, offers companionship in a quiet house.
- Call children if there will be a delay in arriving home; unexpected time alone is very frightening.
- Leave messages on the refrigerator or in the bathroom that just say hi.
- Leave a tape- or video-recorded message for children to play (make sure it is not full of tasks to do, but is a welcoming message).
- Encourage children to read; fictional characters serve as friends as well as help to pass time.
- Urge children to network with other latchkey children regarding how they use time effectively; talking on the telephone or e-mailing another child reduces loneliness for both.

Parental Actions to Increase Socialization

- Help children plan afterschool activities such as joining a science club for one afternoon a week.
- Explore sports programs at school or in the community, as these often are held after school.
- Explore child care programs at the school the child attends, a public library, or a church or synagogue.
- Network with other parents or ask for flex time so child supervision can be alternated after school.
- Be sure children have opportunities to socialize with friends on weekends or on days when either parent is home.

Parental Actions to Increase Self-Esteem

- Praise children for the ability to take care of themselves for short time intervals (rather than scold that there are cracker crumbs on the carpet).
- Walk with children through the empty house and together identify sounds (the click of the furnace turning on, the refrigerator starting to defrost, etc.), so they can determine the cause of sounds when home alone and not be frightened.
- Help children to view quiet time as beneficial time in which they can do some things more efficiently than at noisy times such as homework.
- Do not allow child to use the latchkey role to provoke parental guilt. Allow children to have some say in family spending so they can see how their time alone (which allows both parents to work) contributes to family unity and progress.

well prepared for these. Also, preteens should have adults to whom they can turn for answers to questions about sex. Ideally, these should be their parents, but because sex is an emotionally charged topic, some parents may be extremely uncomfortable discussing it with their children. As a result, health care personnel often become resource persons.

Sex education should be incorporated into health education throughout the school years in a manner that is appropriate to age and development. Topics to teach and discuss in a sex education course for both preadolescent boys and girls include:

- Reproductive organ function
- Secondary sexual characteristics, so children will know what is going on in their bodies
- Physiology of reproduction, so they understand what menstruation is and why it occurs
- Male sexual functioning, including why the production of increased amounts of seminal fluid leads to nocturnal emissions
- Explanation of the physiology of pregnancy and the possibility that comes with sexual maturity for unplanned or unwanted pregnancies
- Social and moral implications of sexual maturity
- Birth control measures and the principles of safer sex if appropriate to the cultural setting (see Chapters 5 and 6)

A sex education course that includes films and discussions is helpful but never answers all of a preteen's questions (most youngsters would rather avoid asking a question than risk appearing ignorant in front of their peers in such a setting). Handing children booklets or showing films with the words, "If you have any questions after you've read (or watched) this, come and ask me" is equally ineffective because it implies they should have no questions. Urge parents or other health educators to watch films or read booklets with children to show they are truly available to answer questions.

Stealing

During early school age, most children go through a period during which they steal loose change from their mother's purse or father's dresser. This usually happens at around 7 years of age, when children first learn how to make change and also discover the importance of money. Stealing occurs because, although a child is gaining an appreciation for money, this appreciation is not yet balanced by strong moral principles.

Parents should explore the reason for the stealing:

- Do other children on the block receive an allowance and so have money for small items?
- Did their child make a bet that must be paid?
- Is a child buying a bully's friendship by purchasing gum or candy for that child?
- Does a child need more security and view money as security?

As a rule, early childhood stealing is best handled without a great deal of emotion. A parent should tell the child the money is missing. The importance of property rights should be reviewed: mother's and father's money is theirs; the child's money is the child's; they are not interchangeable. Youngsters who continue to steal past 9 years of age may require counseling because they should have progressed beyond this normal developmental step by this age.

Some shoplifting occurs with early school-age children, but the major problem with this arises during preadolescence. Some of this happens for the same reason that past generations tipped over outhouses or untied the preacher's horse and buggy: it is a public act of rebellion against authority, a "coming of age" ritual. It usually occurs because of peer pressure such as when children believe they must have a certain type of clothing to belong to the "in" crowd. It can also be an initiation ritual for gang membership.

Shoplifting must be taken seriously by parents because it is a punishable crime, not a prank. Just as money missing from a purse should not be ignored, shoplifting should be confronted immediately to prevent children who succeed once from taking something even bigger the second time. Children should be asked how they came to possess the article and should not be allowed to use it. Children should then be denied access to stores until they demonstrate more responsibility. A child who shoplifts more than once may need counseling; it reflects more than simple confusion about property rights.

As an overall principle, parents should set good examples if they expect their child to be honest. If one parent takes money from the other without permission, neither should be surprised to find their child attempting to do the same. If a parent changes price tags or unwraps items and eats them without paying for them in the supermarket, a parent cannot expect a child to do otherwise.

Violence or Terrorism

Children basically view their world as safe, so it is a shock when violence such as a school shooting or reports of terrorists enter their lives (Gaffney, 2008). Common recommendations for parents to help children feel safe are:

- Assure children they are safe; the violence is isolated to another part of the world and they are out of danger.
- Assure children their parents are actively involved in keeping them safe.
- Observe for signs of stress such as sleep disturbances, fatigue, lack of pleasure in activities, or signs of beginning substance abuse.
- Not allow children or adolescents to view footage of traumatic events over and over, as this decreases their ability to feel safe.
- Watch news programs with children so they can explain that the situation portrayed is not near them and that their child is safe.
- Explain there are bad people in the world, and bad people do bad things, but help children appreciate not all people in a particular group or who look a particular way are bad. Lashing out at people who resemble them only causes more harm.
- Prepare a family disaster plan, including such things as bottled water, blankets, toiletries, pet supplies, appropriate clothing, flashlights, and information such as what immunizations their children have had (particularly tetanus) and, if a child is ill, a history of medical needs or care so that in an emergency, these items are ready.
- Designate a "rally point" where the family will meet if ever separated by a disaster or evacuation.

Some parents may be reluctant to talk to their children about a disaster plan for the family, believing that these

preparations will frighten children unnecessarily, but such preparations should have the major effect of increasing a feeling of safety, not decreasing it. Fear of the unknown is always more intense than fear of something tangible.

Bullying

A frequent reason school-age children cite for feeling so unhappy that they turn guns on classmates is that they were ridiculed or bullied to the point they could no longer take such abuse (Fitzpatrick, Dulin, & Piko, 2007). Why do some children become bullies and some become victims? Traits commonly associated with school-age bullies are:

- Advanced physical size and strength for their age
- Aggressive temperament (both male and female)
- Parents who are indifferent
- Parents who are permissive with an aggressive child
- Parents who typically resort to physical punishment
- Presence of a child who is a "natural victim" (underweight, small, anxious, insecure, cautious, or sensitive, with low self-esteem)

Suggestions for school personnel to deal with bullies are:

- Supervise recreation periods closely.
- Intervene immediately to stop bullying.
- Insist that if such behavior does not stop, both school and parents will become involved.
- Therapy may be needed to correct bullying behavior if it is ingrained.

Advise parents to discuss bullying with their school-age child and tell them how it should be reported, so that adults can intervene. School bullying has long-term effects on mental health from the view of both the bully and the victim (Sourander et al., 2007).

Recreational Drug Use

Once considered a college or high school problem, illegal drugs such as marijuana are now available to children as early as elementary school and certainly by the time they reach the seventh and eighth grades (Reboussin, Hubbard, & Ialongo, 2007). Cocaine and amphetamines are also becoming increasingly easy for children to obtain. Because alcohol is available in so many homes and often can be purchased in small stores without proof of age, this is yet another commonly abused drug of this age group (Wright, 2007).

The use of hard drugs and alcohol and ways to encourage children to avoid their use are discussed in Chapter 33. Inhalants that are easily available to school-age children, and so may be abused by them, are airplane glue (toluene) and aerosolized cooking oil (Ding et al., 2007). Children do not become physically addicted to glue but do become psychologically dependent on it. To achieve the desired effect, they drop quantities of the glue into a paper bag, then sniff the fumes and experience a feeling of exhilaration or giddiness. This may seem a harmless procedure, but in high concentrations glue fumes can cause extensive liver damage or pulmonary edema that can be fatal. Inhalants such as cooking spray or computer keyboard cleaner give this same effect. Because these products contain Freon, they can cause severe respiratory and cardiac irregularity.

Parents should suspect glue sniffing or some other form of recreational drug use if their child regularly appears irritable, inattentive, or drowsy. School health personnel should be aware of the increase in this practice among students and look for warning signs as substance abuse in middle school children may be associated with suicide attempts (Dunn et al., 2008).

Abuse of steroids to improve muscle mass can be found in children as young as sixth grade, particularly those interested in weight-lifting. Counsel children against this because abuse of steroids leads to cardiovascular irregularities, uncontrollable aggressiveness, and possible cancer in later life (Vertalino et al., 2007).

Cigarette smoking also begins in school-age children. With the sure knowledge that cigarette smoking plays a large part in the development of lung cancer and other serious respiratory illnesses, many parents assume their children will know not to start. Smoking is considered by children to be an adult activity, however, so adopting the habit can be considered a giant step on the road to adulthood. Although the amount of cigarette advertising targeting young people as consumers has decreased, school-age children should be taught to recognize advertising manipulation aimed at them. Caution children against experimenting with smokeless tobacco as well as this can lead to mouth and throat cancer. Children may try this after seeing professional athletes using it.

To discourage use of tobacco by school-age children, health care professionals and parents need to be role models of excellent health behaviors in hopes children will follow their good examples.

Children of Alcoholic Parents

As many as one in five children live with an alcoholic parent (Hussong et al., 2007). Such children are at greater risk for having emotional problems than are others because of the frequent disruption in their lives. Alcoholism may have a genetic cause, so children of alcoholics may be more likely to become alcoholics. They also can learn poor coping behavior. Immediate problems that can occur with children of alcoholics are:

- A feeling of guilt that they are the cause of the parent's drinking
- Constant worry that the alcoholic parent will become sick or die, leaving the child; at the same time, fear of violence from the alcoholic parent and a wish the parent would leave
- A feeling of shame that prevents the child from inviting friends home or asking for help
- Decreased ability to trust adults because the parent has been unreliable so many times
- Concern because the alcoholic parent's behavior is so erratic that no regular schedule of bedtime and meals exists
- Anger at the alcoholic parent for drinking and at the nonalcoholic parent for not doing more to correct things
- Helplessness to change the situation

Such fears may be revealed by failing marks in school, withdrawal from friends or social activities, and delinquent behavior such as stealing. With adolescence may come depression, suicidal thoughts, or abuse of drugs or alcohol. School nurses are in an excellent position to identify such children, monitor their school progress, and refer them to organizations such as Al-Anon or Alateen (http://www.al-anon-alateen.org) for support.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Altered family dynamics related to lack of motivation to reduce weight

Outcome Evaluation: Child states reasonable weight loss and exercise goals; discusses feelings about being overweight and reactions from schoolmates; expresses positive feelings about self-worth.

Motivating preteens to lose weight can be difficult because they often have little regard for what will happen to them in the future. They are not upset when told obese people do not live as long as slimmer persons and have more heart attacks, because this will happen far in the future. They do, however, have a great respect for adults who are sympathetic to their problems. They are also aware slim children are usually the most popular, and they wish they could look that way. They follow better dietary regimens, therefore, if they are asked to do so by a respected adult, such as a nurse, or if they fear being left out of social interactions

Obesity

As many as 50% of school-age children are obese by body mass index guidelines for ideal weight. Some of these children have been overweight since infancy; their prepubertal natural weight gain makes them obese. Children with an endomorphic build (a natural tendency to accumulate body fat) are more likely to be obese at any time of life than those with a mesomorphic (normal) or ectomorphic (slender) build. Many families rely on fast-food meals several times a week, and such foods tend to be high in calories and fat and can lead to obesity. Soft drink machines in grade schools add to the problem (LaRowe, Moeller, & Adams, 2007). Children of obese parents are also inclined to obesity; perhaps genetic influences have some bearing. If parents ingest a diet full of excessive calories, the child is encouraged to eat similarly; this makes environmental factors also play a role.

Obese children begin to develop many of the same health problems as obese adults, such as hypertension, type 2 diabetes, and an elevated total cholesterol level, with possible atherosclerosis. They also may be ridiculed for their size and be unable to participate on sports teams. This is strong evidence for the need for active measures to help preteens regulate their weight.

Those who become so obese that friends leave them out of activities or who cannot play sports because they tire so quickly may develop such a poor self-image that they have little motivation for self-improvement. A weight-reduction program for school-age children that emphasizes long-term lifestyle changes is best. It should contain features such as:

- Intake of about 1200 calories (no more than 30% as fat), with lifestyle changes such as a structured family meal, eliminating eating or snacking in front of the television, decreased portion sizes, and elimination of sugar-rich drinks
- An active exercise program, including such things as monitoring and limiting time spent in physical inactivity (watching television, playing computer and video games, surfing the Internet, and talking on the telephone)
- A counseling program to discuss aspects such as self-image and motivation to reduce weight (Haines & Neumark-Sztainer, 2007).

Total caloric intake cannot be reduced too drastically because children need calories to form new body tissue for continued growth. If carbohydrate intake is restricted too greatly, protein is broken down for body energy and a negative nitrogen balance is produced. Caution children not to try faddish high-protein diets (as most adults should not), because such diets do not supply enough carbohydrates and may produce a heavy renal solute load (the breakdown product of proteins) for the kidneys. It helps if children aim to lose 5 lb over a short time rather than 50 lb over a year. This short-term goal coincides better with the task of developing industry.

Surgical techniques such as stomach banding are obviously extreme measures and inappropriate for children. Obese children might request one, however, in an attempt to avoid the not insignificant difficulty of long-term weight loss.

Overweight school-age children often do well if a dieters' club is formed. They are not too young to participate in formal weight-control organizations. Having tangible support from other group members helps them follow tedious and monotonous nutrition patterns. Behavior modification can also be useful in teaching children how to eat in a healthier manner.

As a way of increasing daily activity, preadolescents do well with formal exercise classes because they enjoy the support from other children. In addition, encourage them to increase informal exercise, such as walking to and from school. Encourage coaches of childhood sports to accept obese children as part of a team, not because the child will necessarily benefit the team, but because the exercise will benefit the child. Exercise burns up calories, and if children's daylight hours are filled with activities and friends, they have less time to eat.

Lifestyle change is the ultimate goal for the entire family, because obesity is usually a family problem. Rather than preparing special meals for just the obese child, the entire family probably needs to eat in a healthier manner. Because preadolescents do not generally prepare their own food, the person in the home who prepares meals requires as much information on the planned weight loss as the child. The old concepts that used to hold ("A clean plate is good; how can you leave food when people in other countries are starving?") may have to be changed so children and other family members reduce their intake appropriately. The importance of exercise should also be reflected in the home. Family members should not only encourage the obese child to exercise but also should partake in some form of daily activity themselves.

There is some danger in pointing out to preadolescents that they are terribly overweight because some children become so obsessed with losing weight that they become bulimic or anorexic (Honey & Halsle, 2007) (see Chapter 54). Stressing that children "become healthier" or "improve stamina" may be better advice than talking about dieting.

Concerns of the Physically Challenged or Chronically Ill School-Age Child

One of the biggest problems facing school-age children with long-term illness or physical challenge is time lost from school. This threatens not only academic achievement but also children's relationships with peers. It may make a child the "odd person out" with respect to making friends or joining gangs. Whether children are confined to the home or

hospitalized, helping them to keep in contact with friends by telephone, e-mail, or letters can help foster the socialization that is important for continued development. Encourage parents (or school friends) to obtain schoolwork and help these children with their homework so they can progress with learning at a usual pace and continue to build self-esteem.

Most children with physical or cognitive challenges attend regular schools and classes (**inclusion**) because federal law (PL 99-457) stipulates all children must receive equal education in the least restrictive situation possible. Placement in classrooms is determined by a committee in each school system. You may need to advocate for a child with such a committee to demonstrate, for example, that although children use wheelchairs or need continuous oxygen, they can participate in regular classroom settings; or that a particular child would benefit from a period each day with a special resource teacher. It may be necessary to meet with a school nurse, teacher, or the child's classmates (with the parents' permission) to increase their understanding and acceptance of a child's illness.

Urge parents of children with physical or cognitive challenges to assign them household chores just like other children their age and to allow them to participate in activities, such as Girl or Boy Scouts, in which accomplishment is encouraged. It is important for such children to develop a sense of industry or accomplishment so they can persevere in measures that will help them to be as independent as possible (Fig. 32.10).

When you are caring for a school-age child who is chronically ill or physically challenged, choose short-term activities that can be completed independently, as with all school-age children. Conversely, be careful not to insult a child with tasks that are obviously not age-appropriate. Table 32.5 describes some nursing actions to help foster a sense of industry in children who are physically challenged or chronically ill.

FIGURE 32.10 A school-age child who is physically challenged is elated at a finish line. This accomplishment can go far toward her developing a sense of industry. (© Jose Carillo/Stock Boston.)

Nutrition and the Challenged School-Age Child

Food preparation and dishwashing are times for socializing in most households. A school-age child who cannot be involved in these activities because of a physical challenge needs extra time during the day to make up for these lost socializing experiences, such as a specific hour set aside for talking or sharing a project that can be accomplished in one sitting.

TABLE 32.5 ✻ Nursing Actions That Encourage a Sense of Industry in a Physically Challenged or Chronically Ill School-Age Child

Category	Actions
Nutrition	Allow choices of food and respect food preferences. Provide small food servings that child can finish, encouraging sense of accomplishment.
Dressing	Allow child to make out requisitions for supplies. Ask for suggestions regarding how bulky the child wants dressing, where to apply tape.
Medicine	Teach child name and action of medicine. Encourage child to keep track of medication times by clock or record. Child may feel more in control of injections or intravenous insertions if allowed to choose the site from among options offered. Allow child to choose oral medicine form (capsules or liquid) if possible.
Rest	Establish clear rules for rest periods (reading or watching television is all right; playing a game is not, etc.).
Hygiene	Respect modesty of school-age child at an adult level. Allow as much choice as possible such as own clothing, timing of self-care.
Pain	Encourage child to express and rate pain. Encourage child to use distraction techniques, such as counting backward from 100 or imagery, during episodes of pain. Explain source and cause of pain to give child sense of mastery.
Stimulation	Encourage school work. Encourage activity that ends in a product (putting together a picture puzzle rather than listening to a CD). Encourage paper-and-pencil games, such as connect the dots, tic tac toe. Card games provide social interaction and also encourage simple addition skills (make a deck from paper if one is not available). Do not suggest competitive games for children less than age 10 years. Encourage using playroom for socialization. Encourage child to keep in contact with school friends by telephoning or text messaging.

When eating in cafeterias or at a friend's home, children who must eat special diets are usually tempted to select the same food as everyone else rather than limit what they choose. They may decline invitations rather than admit to requiring a special diet or needing help with eating. Ask at health care visits if any of these problems are present. Help children with special diets to plan ways they could be comfortable in social food-based settings such as bringing a party snack that is easily eaten and appropriate for the child, or politely declining particular foods. Help children who are hospitalized to select a diet that is enjoyable as well as nutritious.

✔ Checkpoint Question 32.3

School-agers can begin drug abuse. What is a common household product frequently abused by school-agers?

a. Grated orange peel
b. Laundry bleach
c. Aerosol cooking oil
d. Shredded cabbage

Key Points for Review

- School-age children mature slowly but steadily. Their average annual weight gain is 3 to 5 lb; their increase in height is 1 to 2 inches.
- At about age 10, children begin to develop secondary sex characteristics. Preparation for this helps them accept these changes positively.
- Deciduous teeth are lost and permanent teeth erupt during the school-age period.
- Erikson's developmental task for the school-age period is to gain a sense of industry, or how to do things well.
- Common health problems during the school-age period include minor respiratory and gastrointestinal infections as well as dental caries and malocclusion.
- Common parental concerns during this period are language development, fears and anxieties, and behavior problems such as stealing and using recreational drugs.
- As many as 90% of parents of school-age children are dual-earner families. This means many school-age children return home before their parents. Counseling families on ways to turn this independent time alone into a positive experience is a nursing responsibility.
- Children in a concrete stage of operational thought are limited to understanding concepts they can actually see. When health teaching, use concrete examples (actually let them hold a syringe, do not just talk about it) to increase their understanding.
- School-age children thrive on rules. It is confusing for them when rules are changed (medicine will now be taken four rather than three times a day) unless they have a clear explanation of why the change is occurring.
- School-age children are looking for good adult role models; it is hard for them to feel confidence in an adult who is not honest with them or who fails to live up to their expectations by not following through on promises.
- School-age children with a family tendency toward obesity may become overweight. Helping the family learn a healthier lifestyle is important.

CRITICAL THINKING EXERCISES

1. Shelly is the 12-year-old you met at the beginning of the chapter. Her mother told you that she has developed many nervous habits since she started middle school. She asks you if this is normal. How would you answer? What suggestions would you make to her mother regarding this?
2. Shelly has become obese in the last year. School-age children develop obesity because of excessive nutritional intake, lack of exercise, and inheritance or family factors. What are suggestions you could make to help prevent Shelly from gaining more weight? What is a possible consequence of telling school-age children they are overweight?
3. Shelly's best friend is a 12-year-old boy who is confined to a wheelchair because of muscular dystrophy. Why might developing a sense of industry be particularly difficult for him? What suggestions could you make to encourage this?
4. Examine the National Health Goals related to school-age children. Most government-sponsored funds for nursing research are allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to the Lewis family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to school-age growth and development. Confirm your answers are correct by reading the rationales.

Chapter 33

Nursing Care of a Family With an Adolescent

KEY TERMS

- adolescence
- comedones
- formal operational thought
- glycogen loading
- identity
- puberty
- role confusion
- stalking
- substance abuse

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe normal growth and development and common parental concerns of the adolescent period.
2. Identify National Health Goals related to adolescents that nurses could help the nation achieve.
3. Use critical thinking to analyze ways in which care of an adolescent could be more family centered.
4. Assess an adolescent for normal growth and development milestones.
5. Formulate nursing diagnoses for the family of an adolescent.
6. Identify expected outcomes for nursing care of an adolescent.
7. Plan nursing care related to growth and development concerns of an adolescent, such as planning health teaching necessary to accept pubertal changes.
8. Implement nursing care related to growth and development or special needs of an adolescent, such as organizing a discussion group on ways to prevent drug abuse.
9. Evaluate expected outcomes for achievement and effectiveness of care.
10. Identify areas related to care of adolescents that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of adolescent growth and development with nursing process to achieve quality maternal and child health nursing care.

Raul is a 15-year-old teenager you see at an adolescent clinic. His chief concern is a head cold. He has numerous acne lesions on his forehead and cheeks. His parents tell you Raul seemed depressed for a long time after his girlfriend broke up with him but now seems happy again. They are pleased to see him maturing so much that he recently gave away his collection of baseball cards to a young neighbor. You mention to Raul that a decongestant would probably make him feel better. He asks you how many pills it would take to kill someone, then jokes he was kidding. The physician in the clinic prescribes a decongestant and suggests Raul return in 6 months.

The previous chapter discussed school-age children and the capabilities children develop during that time period. This chapter adds information about the changes, both physical and psychosocial, that occur during adolescence. Such information builds a base for care and health teaching for this age group.

Did Raul have some needs that were not met by his clinic visit?

Adolescence is generally defined as the period between 13 and 18 or 20 years, a time that serves as a transition between childhood and young adulthood. It can be divided into an early period (13 to 14 years), a middle period (15 to 16 years), and a late period (17 to 20 years). During all periods, adolescence is defined not so much by chronologic age as by physiologic, psychological, and sociologic changes. The drastic change in physical appearance and the change in expectations of others (especially parents) that occur during the period can lead to both emotional and physical health problems.

Adolescents invariably feel a sense of pressure throughout this period because they are mature in some respects but still young in others. For example, an adolescent's sexual interests are awakening, yet personal or parental pressures discourage sexual exploration. An adolescent may not feel mature enough to live away from home yet parents and teachers are urging the adolescent to apply for an out-of-town college. This duality causes a major dilemma for an adolescent, leading to many of the growth and developmental concerns of the age (Lovato et al., 2009).

There is such a strong adolescent subculture today parents may feel from the minute their child enters the teenage years that they will have difficulty guiding their child or understanding teenage values, as though entering this period locks their adolescent into a shell or pulls down a curtain between child and parents. This can become a self-fulfilling prophecy, whereby the parents actually cause the communication breakdown. At other times, communication problems can begin when a teenager refuses to respect parents' opinions or stops asking for them. Many of the problems adolescents bring to health care personnel arise from this communication impasse, no matter how it started. They also often come to health care facilities with many misconceptions, seeking adult help and guidance. National Health Goals related to adolescence are shown in Box 33.1.

BOX 33.1 * Focus on National Health Goals

Health teaching in the adolescent years is important, because healthy habits begun at this time can influence health over a lifetime. For this reason, a number of National Health Goals relate to adolescent health:

- Reduce the number of adolescents who are overweight or obese to a prevalence of no more than 5% from a baseline of 11%.
- Reduce tobacco use by adolescents to a rate of 16% from a baseline of 35%.
- Reduce the rate of smokeless tobacco use by adolescents to no more than 1% from a baseline of 8%.
- Reduce the rate of deaths caused by alcohol-related motor vehicle accidents among people ages 15 to 24 to no more than 9.2% from a baseline of 13.5%.
- Reduce the rate of suicide attempts by adolescents to no more than 1% from a baseline of 2.6%.
- Increase to 35% the proportion of adolescents who exercise at least 30 minutes a day, 5 days a week, from a baseline of 27% (http://www.nih.gov).

Nurses can help the nation achieve these goals by educating adolescents against the use of cigarettes, smokeless tobacco, alcohol, drug abuse, and acts of violence and by acting as support people for adolescents during times of crisis to help prevent suicide. Areas that could benefit from additional nursing research are identifying effective programs that reduce the use of smokeless tobacco or cigarette smoking, documenting the best actions for nurses to take in emergency rooms when adolescents are admitted after suicide attempts, and constructing rapid surveys to identify adolescents who are abusing drugs.

Nursing Process Overview

For Healthy Development of an Adolescent

Assessment

Parents rarely bring adolescents for routine health maintenance visits the way they did when their children were younger, and adolescents generally do not come to health care facilities on their own unless they are ill. Unless adolescents need a physical examination for athletic clearance, therefore, they are often not seen for health assessments. When adolescents are accompanied by their parents at health visits, it is best to obtain a health history separately from parents to promote independence and responsibility for self-care. When performing physical examinations on adolescents, be aware they may be very self-conscious. They also need health assurance and appreciate comments such as "Your hair has a nice, healthy feel," or "This is an accessory nipple. Have you ever wondered about it?" so they can learn more about their rapidly changing bodies.

Nursing Diagnosis

Nursing diagnoses for adolescents cover a wide range. Frequently used diagnoses related to adolescents and their families are:

- Health-seeking behaviors related to normal growth and development
- Low self-esteem related to facial acne
- Anxiety related to concerns about normal growth and development
- Risk for injury related to peer pressure to use alcohol and drugs
- Readiness for enhanced parenting related to increased knowledge of teenage years

Outcome Identification and Planning

When planning care with adolescents, respect the fact they have a strong desire to exert independence or do things their own way. This means they are not likely to adhere to a plan of care that disrupts their lifestyle or makes them appear different from others their age. Including them in planning is essential so the plan will be agreeable and accepted. Establishing a contract such as asking an adolescent to agree to take medication daily may be the most effective means to reach a mutual understanding.

Adolescents are very present oriented, so a program that provides immediate results, such as increased respiratory function, will usually be carried out well. In contrast, a regimen oriented toward the future, with long-term

goals such as preventing hypertension, may not be as successful. This does not mean it is not important to teach adolescents about the necessity of reducing future health risks—by eating well, *not* smoking, and generally taking care of their bodies—but that information will be best accepted if geared as much as possible to specific, short-term benefits to their health.

Teaching by peers is another effective way to motivate teens. Organizing peer support groups this way can be a major contribution of school nurses. Helpful Web sites for teenage referral are Mothers Against School Hazing (http://www.mashinc.org) and Mothers Against Drunk Driving (http://www.madd.org). Other organizations that address some of the concerns of adolescence are the American Association of Suicidology (http://www.suicidology.org), Partnership for a Drug-Free America (http://www.drugfreeamerica.org), Al-Anon/Alateen (http://www.alateen.com), Planned Parenthood Federation of America, Inc. (http://www.plannedparenthood.org), and Sexual Information and Education Council of the United States (SIECUS) (http://www.siecus.org).

Implementation

Adolescents do poorly with tasks that someone tells them they *must* do. If they help to plan tasks, however, they can typically carry them out successfully. Adolescents have little patience with adults who do not demonstrate the behavior they are being asked to achieve; a parent or nurse who smokes and asks an adolescent not to smoke, for example, will probably not be successful. For best results, evaluate how an intervention appears from an adolescent's standpoint before beginning teaching.

Outcome Evaluation

Evaluation of expected outcomes should include not only whether desired outcomes have been achieved but whether adolescents are pleased with their success. Individuals will have difficulty accomplishing desired goals as adults unless they have high self-esteem that includes feeling secure in their new body image.

Examples of outcome criteria that might be established are:

- Client states she is able to feel good about herself even though she is the shortest girl in her class.
- Client states he has not consumed alcohol in 2 weeks.
- Parents state they feel more confident about their ability to parent an adolescent.
- Client states she feels high self-esteem despite persistent facial acne.

GROWTH AND DEVELOPMENT OF AN ADOLESCENT

Adolescents grow both rapidly and mature dramatically during this period. In the United States, as in most developed countries, adolescence covers a long time span. In developing countries, in contrast, adolescence tends to be much shorter because children must take full-time jobs early in life to help support their families. Socioeconomic factors definitely influence the length of adolescence across all cultures. Recognizing that adolescents may have differing responsibilities and life experiences based on cultural expectations can be useful when making an assessment. In a family in which an adolescent is expected to begin working full-time or to marry at an early age, you may need to include factors such as occupational hazards or the effects of job, family, and financial stress on an adolescent. Readiness for early childbearing may also be important.

Physical Growth

The major milestones of development in the adolescent period are the onset of puberty at 9 to 12 years of age, and the cessation of body growth at 16 to 20 years. Between these milestones, physiologic growth and development of adult coordination occur. At first, the gain in physical growth is mostly in weight, leading to the stocky, slightly obese appearance of prepubescence; later comes the thin, gangly appearance of late adolescence.

Most girls are 1 to 2 in (2.4 to 5 cm) taller than boys coming into adolescence but generally stop growing within 3 years from menarche. Those girls who started menstruating at 10 years of age, therefore, may reach their adult height by age 13.

Boys grow about 4 to 12 in (10 to 30 cm) in height and gain about 15 to 65 lb (7 to 30 kg) during adolescence. Girls grow 2 to 8 in (5 to 20 cm) in height and gain 15 to 55 lb (7 to 25 kg). Growth stops with closure of the epiphyseal lines of long bones. This occurs at about 16 or 17 years of age in females and about 18 to 20 years of age in males.

The increase in body size does not occur in all organ systems at the same rate. For example, adolescents' skeletal system grows faster than muscles, and muscle mass increases more rapidly than heart size. These differences in growth rates make adolescents appear long-legged and awkward during a rapid growth spurt because their extremities elongate first, followed by trunk growth. Both sexes may lack coordination during these times. A 13-year-old child, for example, typically reaches to pick up a glass of milk at the dinner table and spills it, having reached beyond it because an arm is longer than the child realized.

Because the heart and lungs increase in size more slowly than the rest of the body, blood flow and oxygen availability are reduced. This means adolescents may have insufficient energy and become fatigued trying to finish the various activities that interest them. Pulse rate and respiratory rate decrease slightly (to 70 beats per minute and 20 breaths per minute, respectively), and blood pressure increases slightly (to 120/70 mm Hg), reaching adult levels by late adolescence. With adulthood, blood pressure becomes slightly higher in males than females because more force is necessary to distribute blood to the larger male body mass.

All during adolescence, androgen stimulates sebaceous glands to extreme activity, sometimes resulting in acne, a common adolescent skin problem. Apocrine sweat glands (glands present in the axillae and genital area) form shortly after puberty. Apocrine sweat glands produce a strong odor in response to emotional stimulation. Therefore, adolescents begin to notice they must shower or bathe more frequently than when they were younger in order to be free of body odor.

Teeth

Adolescents gain their second molars at about 13 years of age and their third molars (wisdom teeth) between 18 and 21 years of age. Third molars may erupt as early as 14 to 15 years of age. The jaw reaches adult size only toward the end of adolescence, however. As a result, adolescents whose third molars erupt before the lengthening of the jaw is complete may experience pain and may need these molars extracted because they do not fit their jawline (Mettes et al., 2009).

Puberty

Puberty is the time at which an individual first becomes capable of sexual reproduction. A girl has entered puberty when she begins to menstruate; a boy enters puberty when he begins to produce spermatozoa. These events usually occur between ages 11 and 14 years. The age of first menstruation in girls is gradually decreasing from a mean of 13 years to 12.4 years, probably related to more weight gain in girls (Lee et al., 2007; McDowell, Brody, & Hughes, 2007). Puberty creates many questions for early teenagers about what is normal and what is not (Cousineau et al., 2007).

Secondary Sex Changes

Secondary sex characteristics such as body hair configuration and breast growth are those characteristics which distinguish the sexes from each other but play no direct part in reproduction. The secondary sex characteristics that began in the late school-age period (see Chapter 32) continue to develop during adolescence. Typical stages of sexual maturation are shown in Table 33.1.

Sexual maturity in males and females is classified according to Tanner stages, named after the original researcher on sexual maturity (Tanner, 1962). Tanner stages of female sexual development are shown in Figure 33.1; stages of male genital growth are shown in Figure 33.2.

✔ Checkpoint Question 33.1

Raul is concerned about developing body odor. What body glands are responsible for this?

a. Adipose glands
b. Apocrine glands
c. Sebaceous glands
d. Dermal pod glands

Developmental Milestones

The same assessment categories of younger children continue to apply to adolescents.

Play or Recreation

Thirteen-year-old children change from school-age activities of active games to more adult forms of recreation such as listening to music, chatting on computers, or following a sports team's wins and losses. Team (or school) loyalty is intense, and following a coach's instructions becomes mandatory. This attitude is similar to the loyalty 6-year-old children show toward their first-grade teacher.

Young adolescents who do not have the physical ability to compete successfully in sports do their best to avoid these activities. Urge parents to encourage youngsters to play sports for their own health and well-being and the companionship involved, however, even though they do not excel. If adolescents thought they would be successful at a sport but then are not, they need a sympathetic person to listen to the frustration they feel and to be encouraged to try other activities in which they can excel, such as science, music, or art. Overuse injuries from athletics occur in early adolescence until adolescents learn more about their limits and begin to respect the advice of adults on being well prepared and trained for sports participation.

TABLE 33.1 ✻ Sexual Maturation in Adolescents

Age (yr)	Males	Females
13–15	Growth spurt continuing; pubic hair abundant and curly; testes, scrotum, and penis enlarging further; axillary hair present; facial hair fine and downy; voice changes happening with annoying frequency	Pubic hair thick and curly, triangular in distribution, breast areola and papilla form secondary mound; menstruation is ovulatory, making pregnancy possible
15–16	Genitalia adult; pubic hair abundant and curly; scrotum dark and heavily rugated; facial and body hair present; sperm production mature	Pubic hair curly and abundant (adult); may extend onto medial aspect of thighs; breast tissue adult and nipples protrude; areolas no longer project as separate ridges from breasts; may have some degree of facial acne
16–17	Pubic hair curly and abundant (adult), may	End of skeletal growth
	scrotum, and penis adult in size; may have some degree of facial acne; gynecomastia (enlarged breast tissue), if present, fades	extend along medial aspect of thighs; testes,
17–18	End of skeletal growth	

Source: Tanner, J. M. (1962). *Growth at adolescence* (2nd ed.). Oxford: Blackwell.

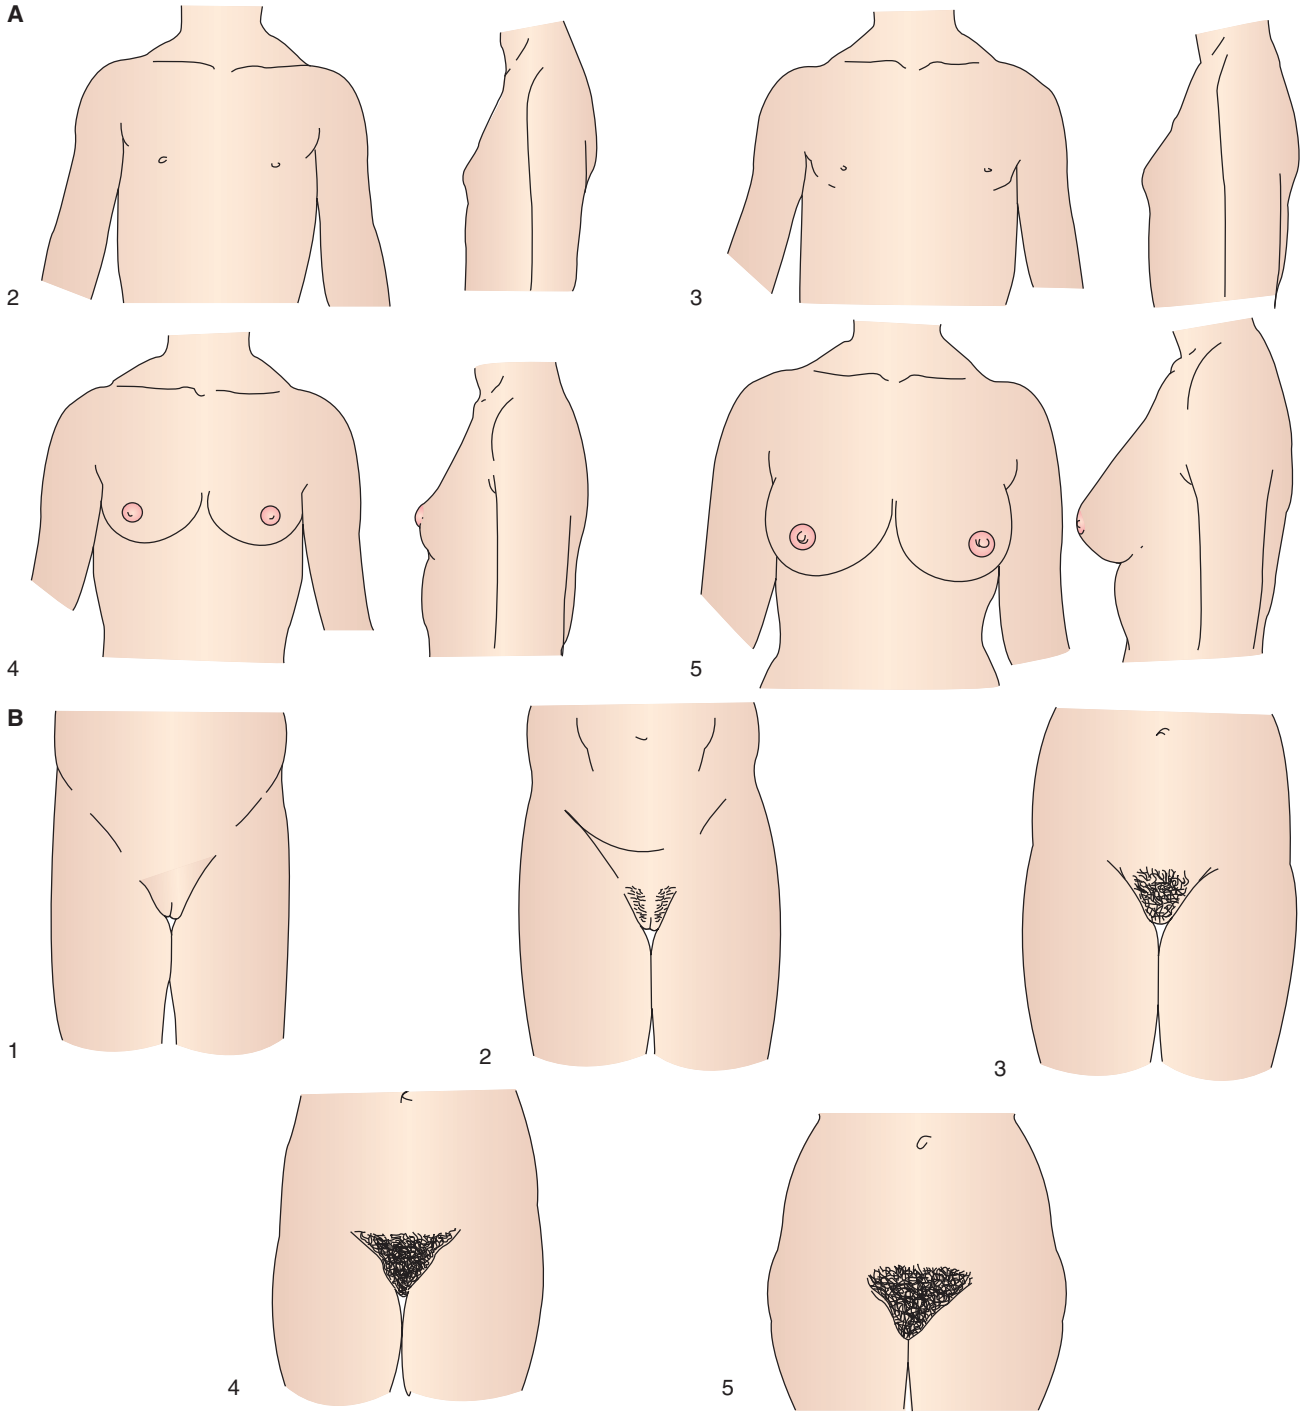

FIGURE 33.1 (**A**) Female breast development. *Sex maturity rating 1* (not shown), prepubertal; elevation of papilla only. *Sex maturity rating 2:* breast buds appear; areola is slightly widened and projects as small mound. *Sex maturity rating 3:* enlargement of the entire breast with no protrusion of the papilla or the nipple. *Sex maturity rating 4:* enlargement of the breast and projection of areola and papilla as a secondary mound. *Sex maturity rating 5:* adult configuration of the breast with protrusion of the nipple; areola no longer projects separately from remainder of breast. (**B**) Female pubic hair development. *Sex maturity rating 1:* prepubertal; no pubic hair. *Sex maturity rating 2:* straight hair extends along the labia and, between rating 2 and 3, begins on the pubis. *Sex maturity rating 3:* Pubic hair increased in quantity, darker, and present in the typical female triangle but in smaller quantity. *Sex maturity rating 4:* pubic hair more dense, curled, and adult in distribution but less abundant. *Sex maturity rating 5:* abundant, adult-type pattern; hair may extend onto the medial part of the thighs. (Adapted from Tanner, J. M. [1962]. *Growth at adolescence* [2nd ed.]. Oxford: Blackwell.)

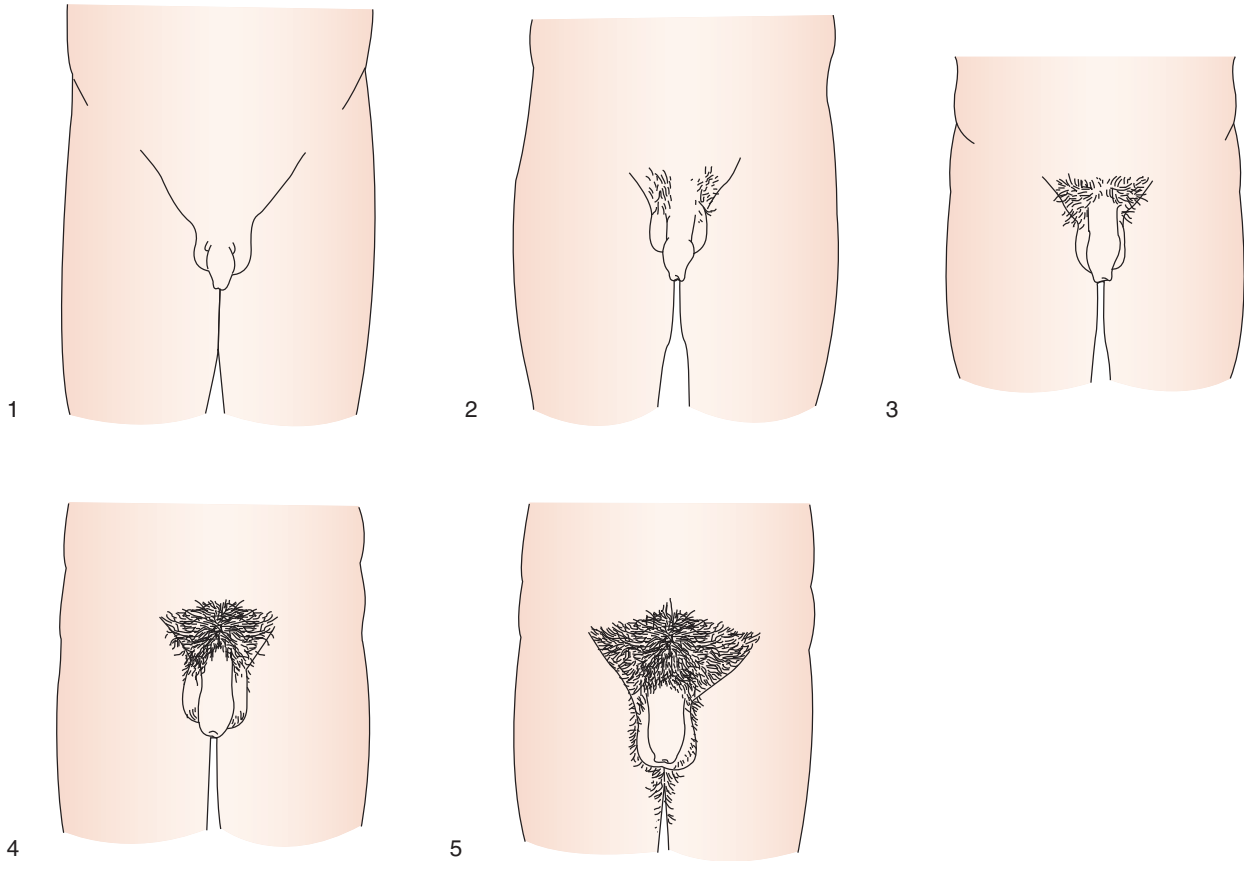

FIGURE 33.2 Male genital and pubic hair development. Ratings for pubic hair and for genital development can differ in a typical boy at any given time, since pubic hair and genitalia do not necessarily develop at the same rate. *Sex maturity rating 1:* prepubertal; no pubic hair; genitalia unchanged from early childhood. *Sex maturity rating 2;* light, downy hair develops laterally and later becomes dark; penis and testes may be slightly larger; scrotum becoming more textured. *Sex maturity rating 3:* pubic hair has extended across the pubis, testes and scrotum are further enlarged; penis is larger, especially in length. *Sex maturity rating 4:* more abundant pubic hair with curling; genitalia resemble those of an adult; glans has become larger and broader, scrotum is darker. *Sex maturity rating 5:* adult quantity and pattern of pubic hair, with hair present along inner borders of thighs; testes and scrotum are adult in size. (Adapted from Tanner, J. M. [1962]. *Growth at adolescence* [2nd ed.]. Oxford: Blackwell.)

Most adolescents spend a great deal of time just talking with peers as social interaction. Some parents disapprove of the number of hours spent in this activity, afraid their children are wasting important time, or at least exchanging a great deal of trivial conversation. For an adolescent, however, talking is no more a waste of time than was imaginative play as a preschooler. It is a major way to learn about the world.

Fifteen-year-old children may spend a great deal of time in their room or, if they do not have a room of their own, in a quiet corner of the home away from traffic and conversation areas. If they cannot find privacy somewhere in the house, they tend to spend time elsewhere.

Beginning at age 16, most adolescents want part-time jobs to earn money. Such jobs can teach young people how to work with others, accept responsibility, and spend money wisely.

When families were larger, each older child had responsibility for a younger sibling and baby care was a natural activity. With small nuclear families, many adolescents have never had the responsibility of caring for anyone younger than themselves. For their own sake and that of the children they will care for, adolescents who plan to babysit should learn some basic rules of child care and safety. Many schools or Red Cross organizations offer courses in babysitting just for the teenager.

Many adolescents engage in charitable endeavors during middle to late adolescence. They learn they are strong and capable enough not only to take care of themselves but also to help less fortunate people in their community. Adolescents do well organizing and supervising swimming or gym programs for physically challenged children, cooking and delivering food to older shut-ins, or raising money to purchase equipment for a hospital. High school clubs may be organized to send money to children overseas. These activities fulfill an adolescent's need for satisfying interaction with others and are indications of maturity and willingness to accept adult roles.

Emotional Development

Developmental Task: Identity Versus Role Confusion

According to Erikson (1993), the developmental task in early and mid-adolescence is to form a sense of **identity** or decide who they are and what kind of person they will be.

In late adolescence, the task is to form a sense of intimacy or form close relationships with persons of the opposite as well as the same sex. It is the concentration on these two tasks that leads to typical adolescent behavior. The four main areas in which adolescents must make gains to achieve a sense of identity are:

1. Accepting their changed body image
2. Establishing a value system or what kind of person they want to be
3. Making a career decision
4. Becoming emancipated from their parents

If young people do not achieve a sense of identity, they develop a sense of **role confusion** or can have little idea what kind of person they are (Erikson, 1993). This can lead to their having difficulty functioning effectively as adults, because they are unable, for example, to decide what stand to take on a particular issue or how to approach new challenges or situations. Some adolescents may become delinquent or exhibit acting-out (attention-getting) behavior because they believe it is better to have a negative image than to be nobody at all. Those who do not develop a sense of intimacy at the end of adolescence can have difficulty forming long-term or intimate relationships.

Body Image. Adolescents who developed a strong sense of industry during their school-age years have learned to solve problems and are best equipped to adjust to their new body image. Nurses can do much to educate adolescents about their bodies and help them to accept the changes that mark maturity. Some adolescents, for example, are disappointed with their final height; they had hoped to be 6 ft tall and are only 5 ft 6 in tall. In other instances, they have seen themselves as "ugly ducklings" and dreamed they would emerge as beautiful swans. They are depressed to find, at the end of adolescence, they still look much like ducks.

Adolescents are usually their own worst critics, never pleased with any aspect of their bodies. Those with low self-esteem may need parental or health care provider support to understand that a person's worth is based on more than physical appearance. They may need help to realize the characteristics that make someone creative, compassionate, and fun to be with are the qualities on which lasting relationships are built.

Self-Esteem. Like body image, self-esteem may undergo major changes during the adolescent years and can be challenged by *all* the changes that occur during adolescence, including:

- Changes in one's body and physiologic functioning
- Changes in feelings and emotional focus
- Changes in social relationships (including relationships with both family and friends)
- Changes in family and school expectations

All of these factors can have an effect on adolescents' feelings about themselves, sometimes resulting in crisis.

Help parents understand how important it is for adolescents to have immediate successes such as making the high school basketball team or having a date for the senior prom. Parental comments, such as "When you're older, these things won't be so important," are not likely to erase the hurt that comes from being 16 years old and not being included in such major events. Compassionate understanding ("It's hard to be left out") is a better communication technique.

In recent years, a number of researchers have looked at the differences in the way boys and girls handle these emotional crises of adolescence. Several researchers have proposed that adolescence is a period of particular crisis for girls who are trying to find a place in a male-dominated society. The sociologist Carol Gilligan and her colleagues interviewed more than 500 girls between the ages of 7 and 16 over a 5-year period and found many girls who, at age 11, were feisty, confident, and eager to speak their minds became, by early adolescence, hesitant to voice their opinions aloud, having pushed their earlier resistance "underground" (Gilligan, 1982). Gilligan tied this change to a growing realization among girls during adolescence that their forthrightness may not be appealing to boys; they begin to self-censor, hoping to become more popular. At the same time, girls are expected to grow up and to value independent and academic (or athletic) success over close relationships, a situation that conflicts with a girl's need to maintain personal connections. This scenario presents a double-edged sword for the developing adolescent whose concern with relationships is not valued by others and who can no longer necessarily rely on her former outspokenness to get across her concerns and opinions.

Although the turmoil of adolescence can be just as confusing to boys as it is to girls, Gilligan hypothesized there may be less pressure on boys, who may have already learned to be competitive, independent, and separated from feelings. Gilligan describes the rearing of boys as including separation from emotions and feelings at an earlier age, whereas girls are encouraged to maintain their concern for people throughout their childhood. This makes girls at risk for more conflicting feelings throughout adolescence.

Parents can help adolescent girls deal with these conflicts by encouraging them to maintain their honesty and forthrightness. According to Gilligan, however, this option puts adolescents at risk for criticism from other adults. The cost of going underground, by repressing one's views and feelings, may, however, be higher. Long-term psychological problems, notably eating disorders, which by some statistics are said to affect as many as one in five women in the United States, may be one unfortunate result of such repression.

Value System. Adolescents develop values through talking to peers. They also need an attentive adult ear, someone who will listen to their fears, hopes, dreams, and the pressure they feel to be somebody, the pressure of wanting to do something and yet not knowing what or how.

In early adolescence, girls tend to band together with girls and boys with boys. They dress identically with other members of their group: jeans and sweatshirts, special jackets, or whatever the fashion may be. On the surface, this makes adolescents appear to be losing their identities rather than finding them (Fig. 33.3). Adolescents who are different for any reason such as overweight or from a different socioeconomic, racial, or cultural background often are excluded from groups in the same way they were from clubs as 9-year-olds. This behavior may seem immature, but, like banding together, it is a necessary way for adolescents to establish a sense of identity. They know they are like the rest of the group because they dress, talk, and think the same way and go to the same places. They know they are not like the excluded member. Knowing who they are *not* is one step in discovering who

FIGURE 33.3 Adolescents have a need to interact with peers to learn more about themselves and others.

they are. Helping adolescents to appreciate that it is not fair to exclude others on the basis of superficial characteristics helps them move more quickly through this stage.

Some parents may be concerned about an early adolescent's lack of interest in the opposite sex. Occasionally, they worry about an intensely close girl–girl or boy–boy relationship. You can assure parents that adolescents must feel secure and pleased with their own sex before they can relate comfortably to the opposite sex.

Career Decisions. Part of the feeling of knowing what kind of person you are is knowing what kind of occupation will be a fit. Because of the thousands of opportunities available today, making a career decision becomes more and more difficult.

Many adolescents are encouraged to wait until they have been in college for 2 years before choosing a major. This delay may be an advantage because of the wide range of available options. It delays settling on a concrete goal until about 20 years of age, however, and therefore puts off a choice that strengthens an adolescent's sense of identity. Some school-age children do poorly in school during preadolescence but, as adolescents, show increased interest in learning as they select a job field and come to see education as relevant to their future.

Emancipation From Parents. Emancipation from parents can become a major issue during the middle and late adolescent years for two reasons. Some parents may not yet be ready for their child to be totally independent, and some adolescents may not yet be sure they want to be on their own. They may fight bitterly for a right—for example, to stay out until midnight or later on a weekend—then never use the privilege once they have gained it. Winning the battle was more important than exercising the newly won right.

In some instances, the closer the tie adolescents feel with their parents, the more severe can be their struggle. Because they love and feel loved, severing bonds is difficult. As long as parents are reasonable in their restrictions, the amount of noise being made may be proof the ties are strong and separation or emancipation is not easy.

Encourage parents to give adolescents more freedom such as allowing them to buy their own clothes, use their own judgment about allotting time for studying, choose their friends, join clubs, or choose afterschool activities; at the same time, help parents continue to place some restrictions on adolescent behavior ("You must drive the car safely or you can't use it," "You must continue to take responsibility for household chores," "We must know where you go after school"). These are not unreasonable rules and actually help adolescents accept the responsibility that must come with independence.

Help parents also make emancipation a gradual reeling-out process. Some parents err on one side or the other, either by neglecting to let out the line at all until adolescents, feeling trapped, have no other choice but to break free and swim away; or letting it all out at once, leaving adolescents to flounder because they cannot yet swim effectively on their own.

In some instances, friction and misunderstandings arise because parents had such traumatic experiences as adolescents themselves that they fear seeing their children reach this stage. Their own experiences may cause them to react so strongly that they are unable to discuss anything with their children. This makes adolescents feel they have offended their parents in some way. They do not understand that the parental attitudes are based not on anything they may have done, but on old, unresolved conflicts being brought to the surface. In other instances, parents may view adolescent growth as threatening. Seeing their adolescent grow up may make them feel old or, if a marriage is not strong, fear that once their child becomes independent their marriage may dissolve. They may strive to keep their child immature (producing conflict) in an effort to keep these thoughts from entering the corners of their minds.

Both parents and adolescents may need help to understand that emancipation does not mean severance but a change in a relationship. People who are independent of one another can have even better relationships than those who are dependent on one another. This step is actually no different from the one children accomplished when they grew from infants to toddlers, when they changed from wanting to be held and rocked to wanting to run. If parents can think of it in this light, they will gain a better perspective and may realize they will not lose their children because they become adults. There are ex-wives and ex-husbands. There are no ex-children.

By the time children are 18 years of age, they have survived leaving high school. They are in college or have found a beginning job and have begun to manage their own lives, perhaps even their own apartment. They are like swimmers who have discovered the water is not as cold as they thought it would be.

Many 18-year-olds so enjoy their new independence they find it difficult to understand why adulthood is thought to be challenging. A little more maturity will help them realize that initial success as an independent young adult does not necessarily guarantee additional success, that beginning adult life may be far easier than continuing it in the years ahead.

Sense of Intimacy. Once adolescents have achieved a sense of identity in early or mid-adolescence, they are ready to work on a second developmental task, that of achieving a sense of intimacy (Erikson, 1993). The ability to form intimate relationships is strongly correlated with the sense of trust, the first developmental task in infancy. Infants who are unable to form a sense of trust may be unable to relate to others on a

deep enough level to form lasting and close relationships as adults. Conversely, adults unable to gain a sense of intimacy may be unable to foster a sense of trust in an infant.

Some adolescents require help from parents or other adults to differentiate between sound relationships and those that are based only on sexual attraction. Never do adolescents need an adult to listen to them more than when they are struggling with the heart-rending feelings of young love or wondering whether a particular love relationship is temporary or lasting. It helps to put this into perspective if parents or health care personnel who counsel adolescents remember that first love is such an intense emotion, it physically hurts.

Some parents may not be able simply to listen without interjecting their own opinions, because they worry that love between adolescents will lead to a sexual relationship. Parents should feel an obligation to inform their children of their feelings about early sexual relationships. They also should be realistically aware some adolescents will not follow their advice. Rates of teenage pregnancy and sexually transmitted diseases, including human immunodeficiency virus (HIV) infection, are high and still rising. If parents suspect their adolescent is sexually active, counsel them to be sure their child is knowledgeable about safer sex practices (see Chapter 5, Box 5.4, for guidelines regarding safer sex; see Chapter 22 for a discussion of adolescent pregnancy).

Some adolescents may believe that intense sexual yearnings or peer pressure can be alleviated only by a sexual act. They can be reassured they are pleasant people to be with because of the many fine qualities they possess and that sexual intercourse can be delayed until two persons have come to know these qualities in each other and have made a mutual commitment based on a deeper level than simply physical passion.

Intimacy involves this deeper level of relationships or developing a sense of compassion or concern for people of both sexes. It means being able to discern when words will hurt, when a companion is unhappy and needs encouragement, or when a friend is floundering and needs support.

In our busy modern society in which adolescents can engage in such a variety of activities, they may need help learning how to project themselves into another person's situation and to ask themselves how the world looks from that position. This ability, *empathy,* is feeling for another or a developed sense of intimacy in its finest form.

Socialization

Early teenagers may feel more self-doubt than self-confidence. They want to look grown up, but they still look like children. The voices of most boys have not yet dependably deepened; this makes them unable to trust their voices to carry the serious tone they wish to convey. Most girls' bodies have not yet fully developed; they may look at themselves in a mirror and compare their profiles with those of models in popular magazines and feel inadequate.

Both male and female 13-year-olds tend to be loud and boisterous, particularly when peers of the opposite sex whose attention they would like to attract are nearby. They are impulsive and very much like 2-year-old children in that they want what they want immediately, not when it is convenient for others.

Many 13-year-olds fall "in love." At this age, however, they may spend more time longing for someone than they do instituting an in-depth and rewarding relationship. They have too little experience with life, too limited a frame of reference yet to know how to offer a deep commitment to another or accept one from that person.

Fourteen-year-olds are often quieter and more introspective than they were the year before. They are becoming used to their changing bodies, have more confidence in themselves, and feel more self-esteem.

Adolescents watch adults carefully during this period, searching for good role models with whom they can identify. They usually have a hero—a film star, writer, scientist, doctor, or athlete—whom they want to grow up to be like. Fourteen-year-olds often form a friendship with an older adolescent of the same sex, trying to imitate that person in everything from thoughts to clothing. If the older adolescent has dropped out of school or plays a particular sport, the younger person may express a wish to drop out or train for that sport, too.

Idolization of famous people or older adolescents fades as adolescents become more interested in forming reciprocal friendships. Attachments to older adolescents are often severed abruptly and painfully as older teenagers make it clear they are more interested in being with people their own age. Rejection by an older member of a pair this way forces the younger member to turn to own-age friends and ends the intense hero worship so typical of early adolescence.

Most 15-year-olds fall in love five or six times a year. However, many of these relationships are based on attraction because of physical appearance, not because of inner qualities or characteristics that are necessarily compatible with their own. Because infatuation is fleeting, it can lead to extremely intense but brief attachments that fade once the two young people discover they really have little in common. Falling in love this often, however, does not mean their feelings are any less strong or they feel any less pain when the relationship ends (Fig. 33.4).

FIGURE 33.4 Although love can be fleeting, adolescents feel intensely for another.

By age 16, boys are becoming sexually mature (although they continue to grow taller until about 18 years of age). Both sexes are better able to trust their bodies than they were the year before. By age 17, they tend to be quieter and thoughtful about interactions. They have left behind the childish behaviors they used in early adolescence—shoving and punching—to get the attention of the opposite sex.

Cognitive Development

The final stage of cognitive development, the stage of **formal operational thought,** begins at age 12 or 13 years and grows in depth over the adolescent years (Piaget, 1969). This step involves the ability to think in abstract terms and use the scientific method to arrive at conclusions. The problems that adolescents are asked to solve in school depend on this type of thought such as a boy rowing upstream at 5 miles per hour against a current of 2 miles per hour will go how far in 1 hour? Problem solving in any situation depends on the ability to think abstractly and logically.

With the ability to use scientific reasoning, adolescents can plan their future. They can create a hypothesis (What if I go to college? What if I don't go to college?) and think through the probable consequences. Thinking abstractly is what allows adolescents to project themselves into the minds of others and imagine how others view them or their actions (display compassion).

Moral and Spiritual Development

Because adolescents enlarge their thought processes to include formal reasoning, they are able to respond to the question, "Why is it wrong to steal from your neighbor's house?" with "It would hurt my neighbor by requiring him to spend money to replace what I stole," rather than with the immature response of the school-age child, "The police will punish me." Some adolescents, however, may have difficulty envisioning a department store or a large corporation as capable of suffering economic loss from stealing, a concept that can contribute to the frequent practice of petty shoplifting at this age.

Almost all adolescents question the existence of God and any religious practices they have been taught (Kohlberg, 1984). This questioning is a natural part of forming a sense of identity and establishing a value system at a time in life when they draw away from their families.

✔ Checkpoint Question 33.2

Raul is entering the final stage of cognitive development. This stage is termed:

a. Formal operational thought.
b. Cognitive attainment.
c. Concrete operational thought.
d. Scientific formulating.

HEALTH PROMOTION FOR AN ADOLESCENT AND FAMILY

Because of still limited judgment, adolescents still need guidelines in reference to safety, nutrition, and daily care. These are always excellent topics for discussion at health care visits.

Promoting Adolescent Safety

Accidents, most commonly those involving motor vehicles, are the leading cause of death among adolescents. Although teenagers are at the peak of physical and sensorimotor functioning, their need to rebel against authority or to gain attention leads them to take foolish chances while driving, such as speeding or driving while intoxicated.

In the interest of an adolescent's safety and that of others, parents need to have the courage to insist on emotional maturity rather than age as the qualification for obtaining a driver's license. Because there is a worry that driver education classes lead to more teenage drivers on the road and there is little proof that they actually reduce traffic accidents, many schools no longer offer these courses (Roberts, 2009). Encourage adolescents to seek out a community-sponsored course not only to learn the techniques of safe driving but also to learn a sense of responsibility toward others. Some adolescents dismiss seat belts as childish, and they need convincing that it is only sensible to use every safety precaution available when in a motor vehicle.

Equally dangerous for adolescents are motorcycles, motorbikes, and motor scooters, which are appealing because of their low cost and convenience in parking. Both drivers and riders should wear safety helmets to prevent head injury; long pants to prevent leg burns from exhaust pipes; and full body covering to prevent abrasions in case of an accident. Advise adolescents who choose these forms of transportation to be as familiar with safety rules as automobile drivers. They need to wait to drive motorcycles or scooters until they are emotionally mature enough to use sound driving judgment.

Drowning is another chief accident of adolescence, even though it is largely preventable. Teaching all children to swim is not the only preventive measure, because some drownings occur when good swimmers go beyond their capabilities on dares or in hopes of impressing friends. Teaching water safety, such as not swimming alone or when tired, is as important as teaching the mechanics of swimming.

Other common causes of death in adolescents are homicide and suicide, related to the easy accessibility of guns to teenagers. Gang violence and the desire to protect themselves from this can add to this problem. Accidental gunshot injuries increase in early adolescence, often for the same reason that drowning increases: youngsters want to impress friends. Some teenagers play gunshot Russian roulette to prove to friends they are courageous. It is important that both water and firearm safety be taught creatively to adolescents by encouraging problem solving rather than by lecturing, because they tend to rebel against such lectures or claim that they have heard it all before.

Athletic injuries tend to increase in number during adolescence because of the vigorous level of competition that occurs in organized sports. These are often overuse injuries because of poor conditioning. Types of athletic injuries are discussed in Chapter 51. Health teaching measures to prevent accidents and athletic injuries are summarized in Box 33.2.

Promoting Nutritional Health for an Adolescent

Adolescents are experiencing so much growth they may always feel hungry (Fig. 33.5). If adolescents' eating habits are unsupervised, they tend to eat faddish or quick snack foods rather than more nutritionally sound ones because of both

BOX 33.2 ✻ Focus on Family Teaching

Measures to Prevent Accidents in Adolescents

Q. Raul's mother tells you, "My son doesn't always use mature judgment. How can I keep him safe from accidents?"

A. Teach the following points:

Accident	Health Teaching Measure
Motor vehicle	Use a seat belt whether as a driver or passenger. Do not drink alcohol while driving, and refuse to ride with anyone who has been drinking. Wear helmet and long trousers as driver or passenger on a motorcycle. Accepting dares has no place in safe driving. Take a driver education course to learn safe driving habits for both two-wheel and four-wheel vehicles.
Firearms	Always consider all guns loaded and potentially lethal. Learn safe gun handling before attempting to clean a gun or hunt.
Drowning	Learn how to swim. Follow safe water rules, such as never swimming alone, no diving into shallow end of swimming pools, no hyperventilating before swimming under water, no swimming beyond own limit. Taking dares has no place in water safety.
Sports	Use protective equipment, such as face masks for hockey, pads for football. Do not attempt participation beyond physical limits. Careful preparation for sports through training is essential to safety. Recognize and set own limit for sports participation.

hunger and peer pressure. Some adolescents turn away from the five pyramid food groups to eat great quantities of sweets, soft drinks, or empty-calorie snacks so they are left poorly nourished despite their large intake. One form of adolescent rebellion is to refuse to eat foods that parents stress are good for them. Parents who stock their kitchens with more nutritious foods, always keep plenty of milk and healthy snacks such as fruit and vegetables on hand, and are willing to meet their adolescents halfway in terms of food preferences such as serving pizza once a week can be more certain their child is eating nutritious foods during the day. Giving an adolescent some responsibility for food planning or meals such as making dinner every Wednesday night can teach some important lessons about nutrition without conflict.

Adolescents who are slightly obese because of prepubertal changes may begin low-calorie or starvation diets to lose excess weight. Some develop eating disorders such as bulimia or anorexia nervosa (see Chapter 54). A weight-loss diet may be appropriate during adolescence, but it must be supervised to ensure that an adolescent consumes sufficient calories and

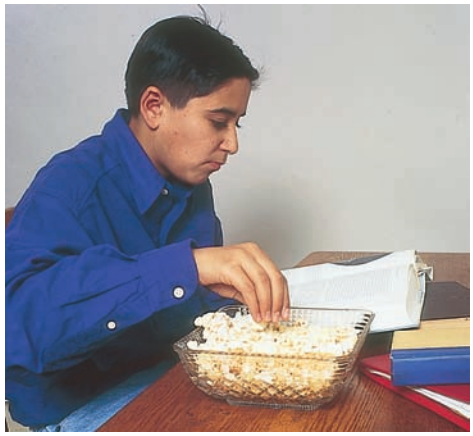

FIGURE 33.5 Adolescents experience rapid physical growth, so typically, they are always hungry. (© Billy Barnes/Stock Boston.)

nutrients for growth. For example, many adolescents omit breads and cereals entirely to lose weight rather than just reducing the amounts they consume. Diets such as these may be deficient in thiamine and riboflavin.

Recommended Dietary Reference Intakes

An adolescent needs an increased number of calories to support the rapid body growth that occurs. As shown in Appendix E, males grow more than females during this period. One of the most important things adolescents can learn is that just filling their stomachs will not provide adequate nutrition. Foods that supply the necessary carbohydrates, vitamins, protein, and minerals are essential.

The nutrients that are most apt to be deficient in both male and female adolescent diets are iron, calcium, and zinc. Large amounts of iron are necessary to meet expanding blood volume requirements. Females require a high iron intake not only because of increasing blood volume but also because iron begins to be lost with menstruation. Girls with a heavy menstrual flow (menorrhagia) may need to take an additional iron supplement to prevent iron-deficiency anemia (Selby, 2007) (see Chapter 44). Increased calcium plus physical exercise is necessary for rapid skeletal growth as well as to "stockpile" calcium to prevent osteoporosis later in life (Ondrak & Morgan, 2007). Zinc is necessary for sexual maturation and final body growth. Good sources of iron are meat and green vegetables; calcium is abundant in milk and milk products; meat and milk are also high in zinc.

Promoting Nutritional Health With a Varied Diet

Vegetarian Diets. Because vegetables generally contain fewer calories than meat, adolescents need to consume large amounts of them to achieve an adequate caloric intake with a vegetarian diet. Textured vegetable protein such as tofu or Quom can be added to meals to increase the amount of protein supplied and to help meet adolescent growth needs (Theobald, 2007). Some adolescents may find it difficult to follow a vegetarian diet because it makes them different from their peers and limits the foods they can eat at parties or at school, such as pizza, meat tortillas, or hot dogs. Whether to continue to follow this type of diet is a decision an adolescent must make as part of achieving a sense of identity. Well-balanced vegetarian diets

can supply enough energy for an active athlete (Rolfes, Pinna, & Whitney, 2009). Be certain all adolescent vegetarians are following a diet and not eating only fruits and vegetables as a method to lose weight.

Glycogen Loading. Athletes need more carbohydrate or energy than do people who do not engage in strenuous activity, and the source of carbohydrate that best sustains athletes comes from the breakdown of glycogen because this supplies a slow steady release of glucose. **Glycogen loading** is a procedure used to ensure there is adequate glycogen to sustain energy through an athletic event. Several days before a sports event, athletes lower their carbohydrate intake and exercise heavily to deplete muscle glycogen stores. They then switch to a diet high in carbohydrate. With the renewed carbohydrate intake, muscle glycogen is stored at approximately twice the usual level, ready to supply twice the glucose for sustained energy. The effects of frequent glycogen loading are unknown, however, so the practice is not recommended for adolescents. As a rule, the goals of nutrition that are best for everyone, such as eating a well-balanced diet, are also the best rules for athletes, rather than diets that interfere with carbohydrate, fluid, or fat intake (Griffin, 2007).

Promoting Development of an Adolescent in Daily Activities

Maintaining adequate nutrition to support rapid adolescent growth is essential to continued healthy development, as discussed earlier. Adequate sleep, hygiene, and exercise are also important and should become an adolescent's responsibility rather than the parents'. Parents can, however, encourage adolescents to engage in healthy patterns of living—primarily through role modeling.

Dress and Hygiene

Adolescents are capable of total self-care and, because of their body awareness, may even be overly conscientious about personal hygiene and appearance. They often wash their hair every day but then grow dissatisfied because their hair has lost so much natural oil it is dull and stringy. Both sexes try many types of shampoo, deodorant, breath fresheners, and toothpaste. They may take seriously (without admitting it) the content of ads showing toothpastes or deodorants can help win an attractive person or gain instant success. Remember this when caring for hospitalized adolescents. Providing time for self-care, such as shampooing hair, is important to include in an adolescent's nursing care plan.

Adolescents are acutely aware of what their peers are wearing. When adolescents cannot trust or are disappointed in their bodies, it is very reassuring to be dressed exactly like everyone else. When they first begin to work, many adolescents spend their first paychecks entirely on clothing. This seems inappropriate to many parents; they want their child to learn to spend money on more lasting items or to show an interest in saving. Adolescents may have to mature fully, however, before they discover their real person shows through their clothing.

Remembering how important clothing is for adolescents also helps you plan care for them during a hospitalization. Most teenagers seem to improve markedly when allowed to wear their own clothing rather than a hospital gown.

Care of Teeth

Adolescents are generally very conscientious about toothbrushing because of a fear of developing bad breath. They should continue to use a fluoride paste rather than a brand advertised as providing white teeth. They should continue to drink fluoridated water to ensure firm enamel growth (Armfield & Spencer, 2007). They tend to snack a great deal, so their teeth are always exposed to bacterial erosion, and so some may develop cavities for the first time during this period. Teens with braces must be extremely conscientious about toothbrushing to prevent plaque buildup on hidden tooth surfaces.

Sleep

Although it is widely believed that everyone needs 8 hours of sleep a night, some need more and others can adjust to considerably less. Because protein synthesis occurs most readily during sleep and adolescents are building so many new cells, adolescents may need proportionately more sleep than any other age group. In addition, because this is a stress period similar to first grade, adolescents may sleep restlessly as their mind reworks the day's tensions; even long periods of sleep, therefore, may not leave them feeling refreshed (Brand et al., 2007).

Many adolescents attempt to get by with too little sleep, because they are constantly busy and because staying up late is a symbol of the adult status they long for. Frequent lack of sleep can lead to chronic fatigue or depression, however. This is why adolescents, admitted to a hospital for even a minor illness, may sleep as if exhausted as they make up for a chronic lack of sleep.

Exercise

Just as with younger children, adolescents need exercise every day both to maintain muscle tone and to provide an outlet for tension. Unlike younger children, although they are constantly on the go, adolescents often receive little real exercise. They ride a bus to school, sit for classes, sit at a mall after school and talk to friends, sit and watch a basketball game in the evening. They have put in a full day from 7 in the morning until 11 at night, yet they have had little exercise compared with the amount they used to get when they came home from school and played tag or hide-and-seek for several hours before dinner. Because of this, adolescents who have had an injury and must learn an activity such as crutch walking need to do muscle-strengthening exercises at first, just as adults must.

Adolescents who are involved in structured athletic activities do receive daily exercise. If they have not participated in competitive sports before, however, they may need advice on increasing exercise gradually so they do not overdo and consequently develop muscle sprains or other overuse injuries.

Promoting Healthy Family Functioning

Early adolescents may have many disagreements with parents that stem partly from wanting more independence and partly from being so disappointed in their bodies. It is frustrating for children to be told by parents they are too old to behave in a certain manner when they still do not feel or look older. At other times, just when they begin to accept their maturing appearance, parents tell them they are too young to do something. It may be helpful to counsel parents to appreciate that

although it is not easy to live with a teenager, it is equally difficult to be the teenager.

When a child reaches about age 15, parent–child friction tends to peak. By this age, adolescents have discovered from careful observation that most adults are far from perfect. Teachers they previously thought of as all-knowing are revealed to have very human shortcomings: they are not able to answer every question asked; some may make it clear they do not have the time or interest for questions. Even a favorite coach may be discovered to be imperfect. School marks may slump as a reflection of this "fallen angel" syndrome.

Adolescents find even more fault in their parents and wonder how they can exist with their outdated ideas. They have trouble respecting parents who are so obviously imperfect. These adolescents may follow health advice poorly because they view health care personnel in the same light.

By the time they are 16 years old, adolescents generally become more willing to listen and to talk about problems. As a result, they may learn that adults are not as inadequate as they previously thought. Their parents, for example, may not be exactly the kind of persons these adolescents might wish they were, but, generally, 16-year-old children can understand adults are only human. This changed perception does not mean an adolescent of 16 is calm and quiet, free of parent–child discord. Adolescents may comprehend how hard it was for parents to get where they are, but they may not understand, for example, why they themselves are not allowed to stay out beyond midnight on weekends.

Seventeen-year-old adolescents who have stayed in school are usually high school seniors; for most of them, this year is likely to be stormy. Looking ahead to leaving a school system with which they have been involved since they were very young may give some 17-year-old adolescents a feeling of losing security. Even if going away to college or beginning a full-time job seems exciting, it can also be an unwelcome change from the people and routines they feel so comfortable with to new contacts and new regulations that appear strange and even hostile.

The ambivalence that such feelings create makes 17-year-olds difficult to understand. They like to see parents perpetuating family traditions: a vacation in an old familiar place, the house decorated for a holiday in the same way, or the traditional birthday meal. Parents should appreciate that clinging to security this way is not the step backward it may seem. Instead, this behavior may be the preliminary working through to a time of separation that will be a major milestone in growing up.

Unfortunately, to prove they are old enough to leave high school and to enter into a more mature college or work world, adolescents this age may begin to experiment with drugs or alcohol, interpreting their use as the mark of being an adult.

Common Health Problems of an Adolescent

A health maintenance schedule for the adolescent period and the assessments to be included at visits are shown in Table 33.2.

Hypertension

Hypertension is present if blood pressure is above the 95th percentile, or 127/81 mm Hg for 16-year-old girls and 131/81 for 16-year-old boys for two consecutive readings in different settings (see Appendix G). Adolescents who are obese, who are African American, who eat a diet high in salt, or who have a family history of hypertension are those most susceptible to developing this disease. Prevention and management of hypertension are discussed in Chapter 41. All children over 3 years of age should have their blood pressure taken routinely at health assessments to detect this (AAP, 2009). This is particularly true for adolescents as new medication plus education in risk factors makes treatment at this age successful (Seikaly, 2007).

Poor Posture

Many adolescents demonstrate poor posture, a tendency to round shoulders, and a shambling, slouchy walk. This is due in part to the imbalance of growth that arises from the skeletal system growing a little more rapidly than the muscles attached to it. Poor posture particularly seems to develop in adolescents who reach adult height before their peers. They slouch to appear no taller than anyone around them. Girls, especially, may slouch so as not to appear taller than boys in the belief that boys only like girls shorter than themselves. Girls may also slouch to diminish the appearance of their breast size if they are developing more rapidly than their friends. This also can occur from carrying backpacks that are too heavy (Moore, White, & Moore, 2007).

Urge children of both sexes to use good posture during these rapid-growth years. Tall adolescents of both sexes are generally picked out by basketball or track coaches and so may have the incentive, if properly guided, to maintain good posture. Assess posture at all adolescent health appraisals to detect the difference between simple poor posture and the beginning of scoliosis (lateral curvature of the spine; see Chapters 34 and 51).

Body Piercing and Tattoos

Body piercing and tattoos are a strong mark of adolescence (Armstrong, 2007). Both sexes have ears, lips, chins, navels, and breasts pierced and filled with studs, or tattoos applied to arms, legs, or their central body. These acts have become a way for adolescents to make a statement that they are different from their parents. Be certain they know the symptoms of infection at a piercing or tattoo site (redness, warmness, drainage, swelling, mild pain) and to report these to a health care provider if they occur as serious staphylococcal or streptococcal infections can occur at piercing sites. Caution adolescents that sharing needles for piercing or tattooing carries the same risk as sharing needles for intravenous drug use.

Fatigue

So many adolescents comment they feel fatigued to some degree that this can be considered normal for the age group. Because fatigue may be a beginning symptom of disease, however, it is important it be investigated as a legitimate concern and not underestimated. Assess an adolescent's diet, sleep patterns, and activity schedules, because all can contribute greatly to fatigue. Note when the fatigue began. A short period of extreme tiredness is more likely to suggest disease than a long, ill-defined report of always feeling tired.

If an adolescent's sleep and diet appear to be adequate, the activity schedule is reasonable (in an attempt to be popular, some adolescents take on a schedule that would exhaust three

TABLE 33.2 ✻ Health Maintenance Schedule, Adolescent Period

Area of Focus	Methods	Frequency
Assessment		
Developmental milestones	History, observation	Every visit
Growth milestones	Height, weight plotted on standard growth chart; physical examination	Every visit
Hypertension	Blood pressure	Every visit
Nutrition	History, observation; height/weight information	Every visit
Hypercholesterolemia	Total cholesterol and triglycerides	During adolescence for children with family members with the disorder
Parent–child relationship	History, observation	Every visit
Behavior or school problems	History, observation	Every visit
Vision and hearing disorders	History, observation	Every visit
	Formal Snellen or Titmus testing	At 15 and 18 years
	Audiometer testing	At 15 and 18 years
Dental health	History, physical examination	Every visit
Scoliosis	Physical examination	Every visit to 16 years
Thyroid disease	Physical examination, history	Every visit
Tuberculosis	PPD test	Depending on prevalence of tuberculosis in community
Bacteriuria	Dipstick	Annually if sexually active
Anemia	Hematocrit or hemoglobin	Annually for menstruating females
Cervical or vaginal cancer	Pap test, pelvic examination	Every 1 to 3 years for sexually active females
Sexually transmitted diseases	History, observation	Every visit if sexually active
Immunizations		
Hepatitis A vaccine	Check history and past records; inform caregiver about any risks and side effects; administer vaccine in accordance with health care agency policies	If not previously immunized
Hepatitis B vaccine		If not previously immunized
Human papillomavirus vaccine (HPV; Gardasil)		Females if not previously vaccinated
Influenza vaccine		Yearly
Measles, mumps, and rubella vaccine		If not previously vaccinated; not to pregnant adolescents.
Meningococcal vaccine		If not previously vaccinated
Pneumococcal vaccine		To high-risk groups if not previously vaccinated
Tetanus and diphtheria vaccine (Tdap)		If 5 years since last booster
Varicella vaccine		If not previously vaccinated
Anticipatory Guidance		
Adolescent care including violence and nutrition counseling	Active listening and health teaching	Every visit
Expected growth and developmental milestones before next visit	Active listening and health teaching	Every visit
Injury prevention	Counseling about street and personal safety	Every visit
Problem Solving		
Any problems expressed by caregiver or adolescent during visit	Active listening and health teaching regarding cigarette smoking, drug abuse, school adjustment	Every visit

Source: American Academy of Pediatrics. (2009). *Recommendations for preventive pediatric health care*. Washington, DC: Author.

people), and physical assessment suggests no illness, then the fatigue may be of emotional origin. It can be a means of avoiding school, avoiding conflict with parents (when children appear ill, parents are more sympathetic), or avoiding social situations. Those who are understimulated by school may develop fatigue as a sign of boredom.

Blood tests may be indicated to rule out anemia and the infection that is so common in adolescents—infectious mononucleosis (see Chapter 43). Chronic fatigue syndrome may need to also be ruled out (Knoop et al., 2008). If it is determined that teenagers do not have these conditions, they can be assured they are healthy and offered guidance to solve the problem

with better diet, more sleep, fewer activities, and development of better problem-solving techniques to relieve tensions.

Menstrual Irregularities

Menstrual irregularities can be a major health concern of adolescent girls as they learn to adjust to their individual body cycles. Chapter 47 discusses these problems in detail.

Acne

Acne is a self-limiting inflammatory disease that involves the sebaceous glands that empty into hair shafts (the pilosebaceous unit). It is the most common skin disorder of adolescence, occurring in as many as 80% to 95% of adolescents (Knox, 2008). It occurs slightly more frequently in boys than in girls. The peak age for the lesions to occur in girls is 14 to 17 years; for boys, 16 to 19 years. Although not proved, genetic factors may play a part in their development. Cigarette smoking may also increase the number of inflammatory lesions.

Before the rapid increase in androgen secretion occurs with puberty, the sebaceous glands that enter into hair follicles are small and relatively inactive, so acne is nonexistent. Changes associated with puberty cause acne to develop:

- As androgen levels rise in both sexes, sebaceous glands become active.
- Abnormal keratinization (cell growth) of the lining of the ducts occurs; this overgrowth obstructs the ducts.
- The output of sebum increases. Sebum is largely composed of lipids, mainly triglycerides.
- If all of the material formed cannot be eliminated to the skin surface because of the narrow gland ducts, the glands enlarge, and trapped sebum causes whiteheads, or closed **comedones.**
- As trapped sebum darkens from accumulation of melanin and oxidation of the fatty acid component on exposure to air, blackheads, or open comedones, form.
- Bacteria (generally, *Propionibacterium acnes*) lodge and thrive in the retained secretions, forming papules.
- Leakage of free fatty acid causes a dermal inflammatory reaction.
- If glands rupture, sebum is extruded into adjacent skin, which produces reddened inflammatory cysts.

Acne is categorized as mild (comedones are present), moderate (papules and pustules are also present), or severe (cysts are present). The most common locations of acne lesions are the face, neck, back, upper arms, and chest (Fig. 33.6). Flare-ups are associated with emotional stress, menstrual periods, or the use of greasy hair creams or makeup that can further plug gland ducts. Lesions are less noticeable in summer months, probably because of increased exposure to the sun, which increases epidermic peeling, or the reduction in stress as a result of being out of school.

Assessment. Always ask adolescents at health assessments if they are troubled with acne and to what extent it interferes with their self-image as this can be a major cause of stress in adolescents (Reich et al., 2007). Inspect for facial, chest, and back lesions on physical examination.

Therapeutic Management. The goal of therapy for acne is threefold: (a) decrease sebum formation, (b) prevent comedones, and (c) control bacterial proliferation.

FIGURE 33.6 Facial acne in an adolescent.

External Medication. Medications that are applied externally peel away the superficial skin layer to prevent sebum plugs from forming and are sufficient if only comedones are present. The most frequently used over-the-counter medications contain benzoyl peroxide. A common prescription medication is tretinoin (Retin-A cream). This reduces keratin formation and plugging of ducts. Caution adolescents using a vitamin A cream to avoid prolonged sun exposure or to use a sunblock of SPF 15 or higher, because the preparation makes their skin more susceptible than usual to ultraviolet rays. Caution adolescents also that, for the first week or two of therapy, peeling or oxidizing may make the complexion actually appear worse rather than better. Topical antibiotic creams such as erythromycin and clindamycin may be prescribed to reduce the bacterial level on skin, but usually only after oxidizing agents have not succeeded; these creams may sensitize adolescents unnecessarily to antibiotics (Karch, 2009).

Systemic Medication. Isotretinoin (Accutane), a form of vitamin A, is an extremely effective oral drug for reducing sebum production and abnormal keratinization of gland ducts; it is prescribed for cystic acne (Box 33.3).

In pustular and cystic acne, systemic (oral) antibiotics are also helpful. Tetracycline (500 mg twice daily the first week, then tapered to 250 mg daily for maintenance) is effective against the anaerobic bacteria that break down sebum to form irritating acids. Improvement is not generally seen for 2 weeks, so you may need to support adolescents to continue to take the medication during the waiting period. Without noticeable improvement, adolescents have a tendency to continue taking the higher dose or even increase the dose, hoping to initiate a faster effect. Tetracycline is not prescribed for children under age 12, because it can cause permanent staining of teeth and possibly interfere with growth of long bones. Likewise, tetracycline should not be given to females who may be pregnant, because it causes faulty bone growth in a fetus (Karch, 2009). Because tetracycline may interfere with oral contraceptives, adolescent girls should use another method of birth control while taking the antibiotic.

Food impairs the absorption of tetracycline so the drug should be taken on an empty stomach (2 hours before or after eating). Adolescents must be certain of the date of expiration of the drug; outdated tetracycline breaks down into an

BOX 33.3 ✻ Focus on Pharmacology

Isotretinoin (Accutane)

Classification Isotretinoin is a vitamin A metabolite.
Action: Reduces sebum secretion
Pregnancy Risk Category: X
Dosage: 0.5–2 mg/kg PO per day for 15 to 20 weeks
Possible adverse effects: Nausea, vomiting, dry skin, pruritus, fatigue, headache, epistaxis, dry nose, dry mouth, eye irritation, elevated sedimentation rate, hypertriglyceridemia, proteinuria, hematuria (Karch, 2009)

Nursing Implications

- Drug may be associated with an increased risk of suicide.
- Drug is highly teratogenic (destructive to fetal growth). Girls should have a pregnancy test before treatment and before prescription renewal to be certain they are not pregnant. Suggest girls use a form of birth control to prevent pregnancy while on the drug and for 1 month afterward.
- Serum levels of both triglycerides and cholesterol and liver function studies should be obtained, both baseline and monitoring, because both triglycerides and cholesterol serum are raised by the drug.
- Drug is extremely drying to skin; caution adolescents to discontinue all other acne medications during therapy to reduce this effect.
- Caution adolescents to continue to avoid sunlight or use a sunblock. If eyes become too dry, patient may need to discontinue the use of contact lenses.
- Advise adolescents to take drug with meals, to avoid gastric irritation.
- Adolescents with severe headache or visual disturbances should report these symptoms, and the medication should be discontinued.
- Advise adolescents not to donate blood while taking the drug, because of potential damage to the fetus of a recipient.

extremely toxic composition. Females taking systemic antibiotics for long periods of time become susceptible to developing candidal vaginitis and need to be instructed about the symptoms of this: a white, pruritic vaginal discharge. Alternative antibiotics prescribed are erythromycin, minocycline, or clindamycin. Although these drugs avoid the complications of tetracycline, they may not produce the same effective results.

Other Treatment Methods. If inflammatory reactions from acne are extreme, a corticosteroid such as prednisone or a nonsteroidal anti-inflammatory drug (NSAID) may be prescribed. Steroids must be used with caution in growing adolescents, because they can lead to stunted growth. Cortisone may be injected directly into cystic lesions to reduce inflammation. This type of injection may reduce keloid formation, which is why it is usually reserved for adolescents who are prone to this permanent form of scarring.

Estrogen, alone or in combination with progesterone, suppresses sebaceous gland activity and is therefore useful therapy in some girls. However, isotretinoin is more often prescribed instead of estrogen for two reasons: (a) high estrogen levels tend to close epiphyseal centers of long bones, causing bone growth to stop; and (b) long-term therapy does have potential side effects, including embolism and thrombophlebitis and possibly breast and uterine cancer.

Some degree of scarring may result from acne lesions. Laser therapy is a follow-up possibility to reduce the effect of scarring.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for low self-esteem related to development of acne during adolescence and lack of knowledge regarding treatment possibilities

Outcome Evaluation: Adolescent verbalizes positive aspects of self; states acne does not affect self-image; or, if client admits to feelings of negative self-esteem, is able to discuss feelings and concerns about condition; describes ways to prevent or reduce acne outbreaks and states realistic short- and long-term goals of treatment.

It is important to respect how devastating acne can be to an adolescent. The actual extent of the condition often is not as important as an adolescent's feelings about it. With a face constantly covered by red marks, it is extremely difficult for adolescents to feel good about themselves (see Focus on Nursing Care Planning Box 33.4).

When carrying out interventions, remember that acne is a potentially destructive disease; if left untreated, it can cause irreparable physical and emotional scarring. Therefore, advise parents and adolescents to seek medical treatment rather than self-medicate if the condition is severe. At the same time, overconcern may lead to undue self-consciousness that affects performance in school and establishment of social relationships. Common health teaching measures for the prevention and treatment of acne are summarized in Box 33.5.

Obesity

Most overweight adolescents have obese parents, suggesting that both inheritance and environment play a part in the development of adolescent obesity. It can be difficult for adolescents to learn to like themselves (achieve a sense of identity) if they do not like their reflection in a mirror. It is equally difficult if they are always excluded from groups because of their weight. This has led to the suicide rate for obese adolescents being higher than for non-obese adolescents (Whetstone, Morrissey, & Cummings, 2007). Some adolescents may be unaware their food intake is excessive, because they have been told they need excess nutrients for healthy adolescent growth and everyone in their family eats large portions. They may state that their friends are

BOX 33.4 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for an Adolescent With Acne

Raul is a 15-year-old boy you see at an adolescent clinic. His chief concern is a head cold. He has numerous acne lesions on his forehead and cheeks. His parents tell you Raul seemed depressed for a long time after his girlfriend broke up with him but now seems happy again. They are pleased to see him maturing so much that he recently gave away his collection of baseball cards to a young neighbor. You mention to Raul that a decongestant would probably make him feel better. He asks you how many pills it would take to kill someone, then jokes he was kidding.

Family Assessment ✻ Client lives with two parents and two younger siblings. Father manages a funeral parlor; mother works as a beautician for funeral parlor. Client describes finances as "all right, if you think burying people is a good way to earn money."

Client Assessment ✻ 15-year-old male with history of acne for the last 6 months. Reports washing his face approximately 5 or 6 times a day with abrasive soap and covering lesions with cocoa butter cream twice a day. He states, "Look at my skin. It's horrible! I don't eat chocolate. But no matter how much I wash it, my skin is getting worse instead of better. I dread going to school, and forget about getting my picture taken. My mom says to just wait it out." Physical examination reveals scattered pustules and comedones on forehead and face, very prominent on nose and both cheeks. Two lesions on right cheek with large erythematous base and tender to touch. Remainder of physical examination unremarkable.

Nursing Diagnosis ✻ Knowledge deficit related to cause and treatment for acne

Outcome Criteria ✻ Adolescent states causes of acne; identifies measures for prevention and treatment; demonstrates appropriate skin care measures.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse/nurse practitioner	Assess adolescent's understanding of acne and its causes.	Instruct adolescent in measures to prevent and control acne, including twice-daily washing with mild soap and water; avoidance of picking or squeezing lesions; and avoidance of greasy or oily skin preparations.	Daily washing removes irritating fatty acids; excessive washing can rupture glands and exacerbate acne. Picking or squeezing lesions ruptures glands and spreads sebum. Greasy or oily skin preparations can plug gland ducts, increasing comedone formation.	Client states intent to follow recommendations to decrease acne symptoms.
		Consultations		
Physician	Evaluate if client requires a psychiatric referral for depression.	Arrange for consultation if assessment suggests client may be contemplating suicide.	Client shows typical signs of pre-suicide behavior.	Psychiatric case worker meets with client at end of clinic visit and makes recommendations.
		Procedures/Medications		
Nurse/nurse practitioner	Assess what measures client has been using to self-treat acne.	Discuss treatment options available.	Discussion provides the adolescent with information about the numerous treatment options available for acne.	Client describes full range of therapies he has been using for self-treatment.
Physician	Determine if a topical or oral medication will be best to treat acne.	Prescribe medications to reduce acne symptoms. Caution results will not be immediate.	Vitamin A preparations and antibiotics are both effective in reducing inflammation of acne.	Client states he will follow medication regimen although results will not occur instantaneously.

		Nutrition		
Nurse/ nutritionist	Assess client's understanding of the effect of nutrition on acne.	Counsel client to follow a well-balanced diet.	No particular food is associated with development of acne, despite old beliefs.	Client states he understands food intake is not the major cause of acne.
		Patient/Family Education		
Nurse	Assess family's communication level, overall coping techniques, and abilities.	Discuss how better communication can aid in helping adolescent cope with life changes.	Parents seem unaware they are discussing a child potentially at serious risk.	Parents discuss family communication pattern; make suggestions for better patterns.
		Psychosocial/Spiritual/Emotional Needs		
Nurse	Assess how acne affects client's self esteem.	Review and reinforce with adolescent positive attributes about self.	Positive attributes provide a foundation for rebuilding self-esteem.	Client states he knows others value his friendship above his appearance.
		Discharge Planning		
Nurse	Review if any additional teaching is necessary regarding acne, self-esteem, or pre-suicide behavior.	Clarify any misconceptions about acne. Review and reinforce positive attributes about self.	Misconceptions can negatively affect self-esteem. Positive attributes provide a foundation for rebuilding self-esteem.	Client agrees he will telephone if sadness increases.
Nurse/nurse practitioner	Assess if client can safely return home.	Give client hotline telephone number; instruct to use as needed.	Knowing a support source is available can be as valuable as actually contacting the source.	Client assures staff that he has the hotline number available and will call if necessary.

overweight but their own weight seems all right, even though they are considerably overweight. Health teaching with these adolescents needs to begin with a discussion of "normal" weight. If they do not begin this as adolescents, they will become obese adults.

A reducing diet of fewer than 1400 to 1600 calories per day can rarely be tolerated by adolescents. Such a diet would not provide sufficient protein and could be deficient in vitamins. If adolescents eat a diet that is too low in protein for any length of time, they can develop a faulty nitrogen balance, which can lead to seriously impaired growth. They generally can adhere to a diet closer to 1800 calories per day.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Ineffective individual coping by overeating related to stresses of adolescent period that has led to obesity

Outcome Evaluation: Adolescent identifies stressful situations in life that lead to overeating; describes ways to avoid those situations or methods that would help coping with them.

Adolescents who are overweight because of stress need support until their pleasure in eating diminishes and their satisfaction with themselves as a "new" person or their friends' satisfaction with them can sustain them. They may need to visit a health care facility once or twice a week for encouragement and praise for their efforts. National weight-control organizations are good if other adolescents also attend the meetings. They are ineffective if all the other members are adults because adolescents generally cannot relate to adult problems. It is important that adolescent self-esteem is maintained or an adolescent may switch to binge eating or such severe dieting that the opposite—extreme weight loss—occurs.

In addition to reducing calories consumed, encourage activities that use up calories, such as swimming or participation in gym classes and other school activities (Stephens, 2008).

Adolescents could perhaps walk to school rather than ride, or walk the dog for three blocks rather than one. These activities are generally preferable to formal exercises, such as sit-ups and push-ups, which can be viewed as punishment.

BOX 33.5 ✻ Focus on Family Teaching

Guidelines for the Prevention and Treatment of Acne

Q. Raul says to you, "I've had acne for the last 3 months. How can I make this go away?"

A. Most adolescents have some acne. Try the following suggestions:

1. Do not pick or squeeze acne lesions, which ruptures glands and spreads sebum into the skin, increasing symptoms. The times you are most likely to do this are during periods of stress, such as when you are taking a test. When you find your hand on your face, distract yourself with some other motion, such as interlocking your fingers.
2. Makeup, greasy hair preparations, or tight sweatbands can plug ducts of glands and increase comedone formation. Avoid these, if possible. Using medicated makeup both covers and helps lesions heal.
3. Topical acne preparations work by unplugging glands. You must use them consistently to make them effective. Plan enough time in the morning before school and a time in the evening to apply these. Post a chart by your bathroom mirror to remind yourself.
4. Washing daily to remove irritating fatty acids is helpful. Excessive washing is not necessary to prevent lesion formation. In fact, excessive washing can actually harm healing by rupturing glands.
5. Oral medications work by reducing sebum secretions or preventing bacterial invasion. These work only if you take them conscientiously. Make a chart to post in your bathroom or kitchen to remind yourself to take these, also. Remember that tetracycline must be taken on an empty stomach or it is not effective.
6. If you are taking oral vitamin A (Accutane), do not take another source of vitamin A in a tablet. Accutane is very harmful to fetal growth. Girls taking Accutane should take measures to prevent pregnancy while taking the drug and for 1 month afterward. If a girl does become pregnant while taking the drug, she should stop taking it immediately and notify her physician.
7. Both topical and oral vitamin A make your skin very sensitive to sunlight. Avoid long exposures to sunlight, or you will sunburn readily.
8. No acne medication works immediately. While you are waiting for lesions to heal, keep yourself occupied with a new activity (join a school club, try dancing lessons). When your skin is clear once more, these experiences will help make you an interesting person as well as one with clear skin.
9. Although diet does not influence the development of acne lesions, you should eat a healthy, well-balanced diet for good general health.

Adolescents who use overeating as their main reaction to stress may require psychological counseling rather than diet counseling if they are to develop a more mature emotional response. Behavior modification is sometimes successful with adolescents as a means of helping them lose weight, but it is rarely recommended for obesity alone. If the obesity is causing serious body image problems, lowered self-esteem, and depression, behavior modification might be suggested (see Chapter 35).

General measures to help adolescents decrease overeating include:

- Making a detailed log of the amount they eat, the time, and the circumstances (including how they felt while they were eating), and then changing those circumstances
- Always eating in one place (the kitchen table) instead of while walking home from school or watching television
- Slowing the process of eating by counting mouthfuls and putting the fork down beside the plate between bites, and being served food on small plates so helpings look larger

These measures may be of little use, however, unless they are combined with a suitable diet and adequate exercise. Despite all these interventions, weight reduction may not always be effective with adolescents. For some, a more realistic goal might be to prevent additional weight gain until they reach adulthood.

Concerns Regarding Sexuality and Sexual Activity

Because of increasing exposure to and acceptance of premarital sexual relations in society, more adolescents than ever before engage in high-risk sexual behaviors exposing them to sexually transmitted infections or conception (Fergus, Zimmerman, & Caldwell, 2007). Because of this, as part of routine health assessment of adolescents and preadolescents, ask if they are sexually active or are concerned about sexual risk behaviors (Hornor, 2007).

Adolescents are usually interested in discussing sexuality concerns with a health care provider because they are concerned they are exposing themselves to HIV infection or other sexually transmitted diseases and to pregnancy. At the same time, it is a difficult topic for them to discuss. Some adolescents may feel trapped into engaging in sex even though they are unwilling, because they perceive it as a way of having friends. For adolescents who want to have intercourse, the primary reasons given are sexual curiosity (50% of boys; 24% of girls) and affection for their partner (25% of boys; 48% of girls). For adolescents who agree to have intercourse but do not really want to, the primary reasons given are peer pressure (about 30%), curiosity (50% of boys; 25% of girls), and affection for their partner (> 33%) (Nusbaum & Katsufrakis, 2008).

Counseling can help adolescents improve their perspective and learn how to say no. In contrast, some adolescents would like to be sexually active but are not because they

believe myths: early sexual relations will drain their strength and make them poor athletes; having sex too early in life will stretch the vagina and make sexual relations later on unenjoyable. Unless these falsehoods are explored through discussion, adolescents who believe them may never be comfortable with sexual relationships.

Adolescence is also the time when teenagers deal with the realization they are gay or lesbian. Although this orientation is something they have been aware of for years, actually facing it and accepting it is another step—and for many families, a difficult one (Benson et al., 2007). Offer support to adolescents who are having difficulty telling their parents about their perceived sexual orientation. To their surprise, they often discover their parents already know what they are going to say before it is voiced.

Sometimes adolescents use a mild cold or a mild acne condition as a reason to come to a health care facility, where they hope that someone will stumble onto their real concern about sexual activity. After asking adolescents at health maintenance visits if they are sexually active, ask if they have any questions or problems they want to discuss with you about this. Ask if they are interested in learning more about contraception. Be certain they are practicing safer sex measures (see Chapter 5, Box 5.4). Overall guidelines on counseling an adolescent with respect to sexual activity are summarized in Box 33.6.

Be certain to provide information on date rape and rape prevention as well when discussing sexual behaviors, because adolescents are in a high-risk age group for date rape (Yamawaki, 2007) (Box 33.7; see also Chapter 55).

BOX 33.6 ✻ Focus on Family Teaching

Health Teaching Guidelines for Adolescents Regarding Sexuality

Q. Raul asks you, "How does a guy know when he's ready for sex?"

A. Here are a few common guidelines:

1. It is your choice whether to participate in sexual relations. Do not be influenced by friends who may be exaggerating stories to impress you or who ask you for involvement you do not want. When you say no, be firm and clear about your wishes.
2. Pregnancy can occur with *any* sexual encounter unless you use some prevention to avoid it. Be direct with a sexual partner in discussing abstinence or birth control measures.
3. Sexual relations neither add to nor detract from your physical strength or general wellness.
4. The mark of an adult sexual relationship is that the activity is pleasurable to both partners. If sexual partners are not interested in your enjoyment as well as their own, you should reconsider the relationship.
5. There is no "normal" mode of sexual expression. Any activity that is pleasurable to both partners is normal.
6. Learn about safer sex techniques. Practice them (see Box 5.4, Chapter 5).

Caution adolescents about the dangers of flunitrazepam (Rohypnol), the "date-rape drug," a colorless, odorless, and flavorless benzodiazepine drug that, if dropped into a drink, can remain undetected but cause drowsiness, impaired motor skills, and amnesia (Karch, 2009). Adolescents who are seen for sexual assault who appear intoxicated or have amnesia for the event should be suspected of unknowingly ingesting flunitrazepam. In these instances, a urine specimen analysis will reveal the drug's metabolites. If a clinic does not have the ability to do this type of test, the manufacturer of the drug (Hoffmann-LaRoche Inc.) will assess for the presence of the drug.

Stalking

Stalking refers to repetitive, intrusive, and unwanted actions directed at an individual to gain the individual's attention or evoke fear. The usual stalker is a male who stalks a female who has rejected him. Stalkers instill fear into their victims by constant and threatening pursuit. In some instances, the stalker can resort to attacking a victim and even murder if further rejected.

Stalking behavior begins as early as adolescence; either males or females can become stalkers or victims (Dietz & Martin, 2007). It is difficult to prevent stalking because no one can evaluate when they begin a relationship that it will end so badly. Stalking may take place as mainly Internet correspondence (cyberstalking), but sending unwanted e-mails or instant messages is still stalking. Measures to help avoid being stalked are the same as those for avoiding rape, such as advising adolescents not to put themselves in positions where they will be vulnerable to being alone with a stalker, and report stalking to law enforcement officers so they can obtain a restraining order to prevent the stalker from coming near them any longer.

Concerns Regarding Hazing

Hazing refers to demeaning or humiliating rituals that prospective members have to undergo to join sororities, fraternities, adolescent gangs, or sports teams (MASH, 2008). Most rituals are secret and in the past were accepted as "rites of passage." In recent years, hazing has become so extreme that the practice has moved out of the "just fun" category into activities that can cause physical and certainly psychological harm. Rituals may be as subtle as being called names, forced to wear ridiculous clothing, or engage in crude or lewd skits. Unfortunately, they also can be played to an extreme where adolescents are punched or kicked, asked to pretend to perform a sexual act towards another, sodomized, left out in the cold so long, frostbite develops, or forced to drink alcohol until they vomit or pass out or even die from alcohol intoxication. Many of the rituals found in this last category constitute criminal acts which will hold up in court if the evidence is available (Sodl et al., 2008). Initiation for street gangs can require prospective members to steal or destroy property or even kill. Parents need to be aware of what clubs or organizations their adolescent is attempting to join and what the requirements for membership will be. Health care providers can help adolescents make sound decisions about what type of hazing their organization advocates by asking teenagers about the subject at health assessments.

BOX 33.7 * Focus on Family Teaching

Health Teaching Guidelines for the Prevention of Rape in Adolescents

Q. Raul's sister asks you, "Are there rules for how to avoid rape?"

A. Several suggestions are:

Home

1. Do not advertise that you stay alone while a parent works or is on vacation.
2. Ask for identification from meter readers or repairmen before admitting them into the home.
3. Insist on adequate lighting for hallways in an apartment building or around your own home.
4. Have your house key in your hand when you approach your door; do not stand fumbling for it by the doorway.
5. Keep your doors and windows locked when you are alone at home.

Car

1. Avoid isolated parking places; park near a building or in a lot with a parking attendant.
2. Lock your car when waiting in it and after parking it.
3. Look in the back seat before unlocking and entering your car.
4. Have your car key ready when you approach your car; do not stand fumbling for it.

Work or School

1. Do not enter an elevator with a stranger.
2. Lock the outside door, and do not admit people you do not know when working alone at night.
3. Ask for security protection to walk out to your car after hours.
4. When going to and from school or work after dark, walk in the street rather than next to shrubs or dark buildings.

Dates

1. Be clear with your date that when you say no, you mean no.
2. Limit alcohol use, because it can lead to risk-taking behavior.
3. Make it clear that you consider date rape the same as any rape and you will press charges.
4. Rohypnol is a sedative, known as a "date rape" drug. Do not date any individual who brags that he knows how to obtain it or use it.

Personal Actions

1. Do not wear chains around your neck that could be used to strangle you.
2. Learn self-defense; scratch the attacker to obtain skin and blood specimens under fingernails.
3. Be aware that an attacker could take any weapon away and use it on you; use caution carrying a weapon or Mace.
4. Fight or struggle cautiously to prevent harm to you beyond the rape itself. Actions such as kicking or gouging eyes may not be effective and may cause more violence.
5. If an attack occurs, observe the attacker's appearance as carefully as possible. Note identifying characteristics, such as a birthmark, scar, tattoo, words, or manner of speech, to be able to identify the individual later.
6. Press charges in court to make rape a crime of extreme magnitude and as an opportunity to fight back.
7. Work to provide rape prevention information and a united front against rape in your community.

Concerns Regarding Substance Abuse

Substance abuse refers to the use of chemicals to improve a mental state or induce euphoria. This is so common among adolescents that as many as 50% of high school seniors report having experimented with some form of drug (CDC, 2008a). Drug use occurs in adolescence from a desire to expand consciousness or to feel more confident and mature; it also can be a response to peer pressure or a form of adolescent rebellion (Box 33.8). This type of rebellion is more emotionally charged than acts such as staying out late or wearing clothing other than those approved by parents, because it is not only harmful but also illegal. Usual stages of substance abuse are shown in Table 33.3.

Types of Abused Substances

Drugs that adolescents abuse are those they can obtain on limited budgets and through limited contacts.

Prescription and Over-the-Counter Drugs. Adolescents may begin drug experimentation by taking sedatives, pain medication, or cough syrup containing dextromethorphan, abbreviated DXM, prescribed for another family member or a pet. A small amount of DXM causes lightheadedness. In larger doses, it can resort in distortions of color and sound, visual hallucinations, or "out-of-body" experiences. This is called "pharming"; unaware of usual dosages, adolescents who use drugs this way can easily overdose (Levine et al., 2007). Methylphenidate (Ritalin) is a drug frequently prescribed for attention-deficit/hyperactivity disorder. When oral Ritalin tablets are crushed and injected intravenously, they offer a feeling of giddiness and extreme well-being. Unfortunately, because they do not completely dissolve, the resultant small particles remaining in the bloodstream can result in pulmonary embolus or emphysema. Ketamine is an anesthetic used in veterinary medicine that is also frequently abused. Every house has a number of inhalants, such as a spray-type oil for cooking or gas, butane, or lighter fluid, that can also be abused by adolescents. Screening for abuse of

BOX 33.8 ✻ Focus on Evidence-Based Practice

Do adolescents who are religiously active engage in more or less substance abuse?

It is usually assumed that adolescents who attend their religious center at least once weekly abuse substances less than others. To establish whether this is true, researchers surveyed a large number (33,007) of adolescents in grades 9 through 12 as to their religious attendance and substance abuse. The results of this survey showed tobacco, marijuana, and alcohol were used regularly by 11% to 13% of all students. There were marked differences in alcohol, marijuana, and cigarette use, however, among adolescents who never, occasionally, or regularly participated in religious activity. Weekly religious attendance was consistently associated with less substance use whereas occasional religious participation sometimes was associated with greater use compared to those students who had no religious activity.

Based on the above study, would you ask an adolescent who you know attends church at least monthly if he abuses any substance such as alcohol and marijuana or could you safely assume that he would not be abusing these substances?

Source: Steinman, K. J., Ferketich, A. K., & Sahr, T. (2008). The dose-response relationship of adolescent religious activity and substance use: variation across demographic groups. *Health Education and Behavior, 35*(1), 22–43.

inhalants or readiness to abuse such substances is important, as inhalants can lead to cardiac failure even on a first-time use (Williams & Storck, 2007).

Tobacco. Although it is well documented that cigarette smoking leads to increased cardiovascular and respiratory illnesses by middle age, every day approximately 4000 American youth aged 12 to 17 years try their first cigarette. About 23% of high school students report current cigarette use and 14% report current cigar use. Eight percent of high school students and 18% of white male high school students report current smokeless tobacco use (CDC, 2008b). Adolescents usually begin smoking because the habit conveys a stamp of maturity; smoking may be viewed as especially desirable by those who are having difficulty demonstrating maturity in other areas. One of the strongest determinants of whether adolescents will begin smoking is whether their friends smoke. Although at one time proportionately more males than females smoked, adolescent girls now are the population most likely to begin smoking. As cigar smoking becomes more popular with adults, it also is becoming more popular with adolescents.

It is well documented that adolescents are influenced to begin smoking by advertising (Lovato et al., 2009). Most school systems have extensive programs as early as grade school to caution children against cigarette smoking and advertising. Unfortunately, the ultimate danger of illness or death in middle age is not a strong threat to young persons who are interested only in the present.

More effective, therefore, might be campaigns that point out cigarette smoking causes foul-smelling hair, clothes, and breath and this detracts from physical appearance. Helping adolescents find other methods to demonstrate their maturity, such as allowing them opportunities for increased decision making, and emphasizing that being able *not* to smoke is a sign of true maturity, may also be effective.

Adolescents can be urged to quit cigarette smoking through enrolling in a formal cigarette withdrawal program. Nicotine gum and nicotine patches have both been successfully used with adolescents.

Remember that adolescents are very reluctant to follow instructions that are given from a "do as I say, not as I do" standpoint. Nurses who smoke, therefore, can have extreme difficulty launching an effective campaign against the habit with adolescents.

TABLE 33.3 ✻ Stages of Substance Abuse

Stage	Name	Characteristics
0	Preabuse	Curious about drugs, need for peer acceptance; anger or boredom
1	Experimentation	Learning the high; little behavior change except lying; commonly used drugs: tobacco, alcohol, and marijuana; use is confined to social situations on weekends in the company of others, with others supplying the drugs.
2	Early regular use	Adolescent actively seeks the drug-induced mood swing; drugs are no longer just on social occasion but to relieve everyday stress. Use is frequent and may be solitary, regularly on weekends and occasionally on weekdays. Adolescents have their own supply. Drugs used include stimulants, sedatives, and inhalants. Behavior changes include change in dress, friends, deteriorating school performance, mood swings, lying, and stealing.
3	Late regular use	Dependent on substance of abuse; deteriorating behavior, fighting, lying, stealing, prostitution; often depressed, suicidal ideation, self-destructive or risk-taking behaviors
4	End stage	Substance use to avoid dysphoria; withdrawal; continued deterioration of behavior and mental state

Source: Muramoto, M. L., & Leshan, L. (1993). Adolescent substance abuse. *Primary Care, 20*(3), 141–144.

Stopping smoking is especially difficult during periods of stress or inactivity. Trying to introduce such an action during exam week, for example, is not good planning. During an illness is also a bad time, unless not feeling well has reduced the urge to smoke. A return visit for follow-up and health maintenance care might be a better time to introduce the topic.

Another source of nicotine that school-age children and adolescents may abuse is "smokeless tobacco," or chewing tobacco (Percy, 2008). Many baseball players use this form of tobacco, and adolescents who admire them may be particularly drawn to this tobacco source. Although chewing tobacco does not have the potential dangers of smoking tobacco in relation to lung disease, it can cause gingival recession and lip and mouth cancer and can be just as habit-forming as cigarettes.

Alcohol. As many as 90% of high school seniors report having used alcohol. As many as 25% of high school students report having engaged in episodic heavy or binge drinking. At least 10% of high school students report driving a car or other vehicle when they had been drinking alcohol. Twenty-nine percent of students report having ridden in a car or other vehicle driven by someone who had been drinking alcohol (CDC, 2008a). Although its use is correlated with motor vehicle accidents, homicide, and suicide in adolescents, alcohol has never carried the stigma of other drugs. Some parents are actually relieved when they realize their child's strange behavior on returning home from a party is caused by drunkenness and not illegal drugs. Alcohol use cannot be taken lightly, however, because it is linked to diseases such as cirrhosis, cognitive challenge, and destructive behaviors such as addiction, depression, and vulnerability to date rape.

Environment has a definite role in the use of alcohol, but heredity may play a part in whether an adolescent becomes addicted. Remind parents they have a responsibility to set good examples for adolescents in the use of alcohol or not drink indiscriminantly.

Most adolescents will admit they use alcohol if asked two specific questions: (a) Do you think you have a drinking problem? and (b) When was your last drink? Adolescents who answer yes to the first and "within the last 24 hours" to the second are candidates for further assessment.

Athletes tend to drink more than nonathletes probably due to their greater exposure to social situations (Wetherill & Fromme, 2007). Once adolescents face the fact that they have become alcohol dependent, an organization such as Alcoholics Anonymous can be invaluable to help them stop drinking. Encourage the remainder of their family to join Al-Anon, the organization for families of alcoholics, so both children and families can restructure their lives to find satisfaction without the use of this drug.

Many adolescents are not primary alcohol abusers but are the children of alcoholic parents. Make an effort to identify this group of children as well, not only to prevent them from becoming users of alcohol but also to help them build self-esteem and coping abilities for the difficulties they face living in a possibly disorganized household.

Performance-Enhancing Drug Abuse. Anabolic steroids are derivatives of the natural hormone testosterone. Common names are stanozolol, an oral compound, and testosterone propionate, an injectable form. Adolescents take steroids (obtained illegally) to enhance lean body mass and muscular development and so improve their athletic ability or appearance (Van den Berg et al., 2007). Anabolic steroids also have the side effects of euphoria and lessened fatigue, which make them doubly appealing (Vertalino et al., 2007).

To obtain maximum effects, teenagers may be taking up to 30 times the therapeutic dose. This can lead to adverse effects, such as early closure of the epiphyseal line of long bones, acne, elevated triglyceride levels, hypertension, aggressiveness, possibly psychosis, abnormal liver function, and, perhaps, liver cancer.

Students using anabolic steroids need to be identified so they can be cautioned that the use of such drugs is illegal in sports competition as well as being detrimental to their health. There is also concern that the use of such drugs serves as a gateway to additional drug use (Wagner & Anthony, 2007). If needles are shared, this can lead to hepatitis B or HIV infection. Human growth hormone has the ability to increase muscle strength and stamina and is more difficult to detect so is also becoming a commonly abused substance in athletes (Gibney, Healy, & Sonksen, 2007).

Marijuana. Marijuana (widely known as *pot* or *grass*) is derived from the leaves and stems of the Indian hemp plant, *Cannabis sativa.* It is generally rolled into cigarettes ("joints" or "reefers") and smoked, although it can be mixed with food or sniffed. Scraping the resin from the flowering leaves produces a much stronger substance called hashish. *Sinsemilla* is a seedless form that is even more potent.

Breakdown products of marijuana are not readily eliminated from the body but remain in the fatty cells of the brain. This residue results in synaptic gaps that can delay electrical brain waves and memory storage, especially for short-term memory. Physical and psychological effects of all forms of marijuana are euphoria and a sense of well-being, temporary impairment of coordination or motor activities, altered sensory perceptions, rapid mood swings, altered self-image, decreased attention span, and loss of memory for recent events (up to 1 hour time). Withdrawal symptoms include irritability, drowsiness, and cravings for high-carbohydrate snacks (Mendelson & Mello, 2008).

Long-term side effects can include disorders such as sinusitis, bronchitis, emphysema, and perhaps lung cancer (these can develop after only 1 year of use compared with 20 years of use for cigarette smoking), and lack of sperm formation or testicular cancer in males (Daling et al., 2009).

Despite its known dangers, marijuana is the most common illicit substance, next to alcohol, used by adolescents. Help adolescents realize that marijuana is more than an amusing leisure activity or a way to relieve stress so they can put its use into long-term perspective. Because it is used medically to relieve nausea and vomiting, adolescents may view it as harmless.

Amphetamines. The amphetamines are a group of drugs sometimes used in the treatment of hyperactivity and narcolepsy, among other central nervous system disorders. They are easily manufactured in "meth labs" in people's homes and so are readily available to adolescents. Amphetamines are called *uppers* or *speed* because they give the user a false sense of well-being, alertness, or self-esteem (Degenhardt et al., 2007). A newer, stronger form that produces intense symptoms is known as *ice.* Some of the side effects that can occur

are aggressive or demanding behavior, paranoia, and extreme restlessness. Chronic methamphetamine abuse results in severe blackened, crumbling teeth. Because amphetamines suppress the appetite, adolescents may lose weight or eat only sporadically while taking them. Their use without a prescription is illegal.

Cocaine. Cocaine is one of the most popular drugs of abuse for young adults and its use may begin in adolescents. The drug may be sniffed into the nose (snorted), smoked, or injected intravenously. Occasionally it is combined with heroin and injected (termed a speedball). Common street names for cocaine are *snow* and *white lady,* because of its fine, white powder. A stronger form, called *crack,* is manufactured by heating cocaine powder with baking soda and water. This preparation process is dangerous in itself because it involves using volatile solvents that can ignite or explode. The resulting drug, often called *freebase* or *rock,* is so strong it can cause immediate cardiac and respiratory arrhythmias (Murphy & Benowitz, 2007).

It is difficult to document how many adolescents use cocaine, but estimates range from 3% to 9%. Cocaine that is either inhaled or smoked is absorbed through the mucous membrane into the bloodstream. After absorption, blood levels rise rapidly for the first 20 minutes, peak at 60 minutes, and then decline over the next 3 hours. Although a toxic dose of cocaine is usually considered to be 600 to 700 mg, toxicity has been reported with doses as low as 20 mg (a single line).

Cocaine produces the physical effects of increased pulse and respiration rates, increased temperature, increased blood pressure, and decreased appetite. Psychological effects produced are euphoria, excitement and restlessness, increased sociability, and possible hallucinations.

Toxic symptoms include seizures, tachyarrhythmias, tachypnea, hypertension, increased deep tendon reflexes, decreased response to stimuli, nausea and vomiting, abdominal pain, headaches, and chills and fever. It is a major cause of cardiovascular arrest in young adults (Kaul & Stevens-Simon, 2008).

Cocaine is rarely ingested orally, but occasionally adolescents swallow it when trying to hide a supply from parents or school personnel. Gastric acid destroys the action of cocaine, so it is potentially harmless when swallowed in this way. Cocaine has been swallowed in plastic pouches with the idea this will allow it to pass harmlessly through the gastrointestinal tract and also allow it to be recovered later in stool. If peristaltic action in the intestine causes the bag to break, this amount of cocaine is absorbed into the bloodstream at toxic levels. This can lead to sudden cardiac and respiratory arrest.

Teach adolescents that although cocaine sniffing may be fascinating and offer temporary pleasure and relief from stress, it also causes psychological dependency and is potentially extremely dangerous because of its cardiac and respiratory effects. Chronic inhalation of cocaine can cause ulceration in the mucous membrane of the nose, and injection of the substance exposes an adolescent to the risk of HIV/acquired immunodeficiency syndrome (AIDS), hepatitis, and other diseases contracted through contaminated equipment. Cocaine taken during pregnancy can cause separation of the placenta with potential fetal and maternal death.

Hallucinogens. Examples of hallucinogenic drugs used by adolescents are lysergic acid diethylamide (LSD), dimethyltryptamine (DMT), 2,5-dimethoxy-4-methamphetamine (STP), phencyclidine hydrochloride (PCP), and methaqualone (Quaalude). The use of LSD has increased in popularity substantially since the 1960s when it first became available, because it is a drug that can be manufactured by an informed adolescent in a "kitchen lab."

All of these drugs cause bizarre mind reactions such as distortion in vision, smell, or hearing. Adolescents report seeing colors more vividly than they have ever seen before, hearing sounds so clear they cause physical pain, and perceiving themselves as being totally impervious to harm.

The effect of such drugs can be extremely pleasurable (described as a "good trip") or extremely terrifying (a "bad trip"). Recurrences or flashbacks of drug-induced experiences may, unfortunately, recur at unpredictable times and in unexpected places. Such flashbacks are not only disconcerting but can be dangerous, especially if they occur while a person is driving a motor vehicle. They can be so frightening that some users believe they are becoming mentally deranged.

It is illegal to produce, sell, or possess hallucinogens in the United States. A hallucinogen related to mescaline, methylenedioxymethamphetamine (MDMA, or known as *ecstasy*), was previously used by some psychotherapists to make patients more receptive to therapy. It has been added to Schedule I of the Controlled Substances Act because it was found to cause brain damage. Chronic use destroys the serotonin system of the brain so it is associated with progressive decline of immediate and delayed memory and with alterations in mood (Medina & Shear, 2007).

Opiates. Opiates are drugs such as heroin, meperidine (Demerol), and morphine. At one time, these were not typically used by adolescents because they are expensive, but they now are gaining popularity among teens.

Opiates can be extremely dangerous because of their tendency to decrease respiratory rate. Addiction to opiates can cause such a physiologic craving that adolescents, like adults, will steal, defraud, turn to prostitution, or resort to whatever method is available to secure enough money to buy a day's supply. In addition to the direct danger of opiates, adolescents who use them risk the danger of contracting HIV/AIDS and hepatitis B infection if they share contaminated needles. "Snorting" heroin can lead to acute cerebral vascular accident and death.

Methadone or LAAM (Levomethadyl acetate) programs may be prescribed to help adolescents wean themselves from opiates (Maremmani et al., 2007). The users report to a center every day and receive an oral dose of methadone, which fulfills the same physiologic need as heroin. Although methadone is a narcotic itself, because adolescents do not have to pay for it, they no longer have to steal or prostitute themselves to obtain it. It allows them to continue in school or hold a job and become productive citizens. Caution them that a methadone overdose can occur the same as with any narcotic. After a time, LAAM is gradually substituted. The advantage of LAAM over methadone is that its effect lasts longer—72 rather than 24 hours—so less frequent administration is necessary. If a methadone program is not available, teenagers may be treated with buprenorphine (Levy et al., 2007).

Assessment of Substance Abuse

If adolescents trust health care personnel, they will generally admit they have engaged in drug experimentation (Box 33.9). Some common findings on the health history that suggest an adolescent is abusing some substance are:

- Failure to complete assignments in school
- Demonstration of poor reasoning ability
- Decreased school attendance
- Frequent mood swings
- Deteriorating physical appearance
- Recent change in peer group
- Expressed negative perceptions of parents

These are not necessarily diagnostic findings, however, because they can also be part of an adolescent's search for identity. Substance abuse can be strongly suspected in an adolescent who is hospitalized for hepatitis B or who is HIV positive, as well as one who appears overly anxious to leave a health care facility or who receives no benefit from usual analgesic agents. General physical symptoms that indicate drug abuse are summarized in Table 33.4.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for injury related to the use of alcohol or illegal chemical substances

BOX 33.9 ✻ Focus on Communication

You talk to Raul, 15, in an adolescent clinic.

Less Effective Communication

Nurse: Here's a pamphlet about adolescents and drug use. I hope you haven't been using any.
Raul: No problem.
Nurse: Drugs can be really harmful. It takes an absolutely stupid person to use them.
Raul: No problem.
Nurse: Have you been doing any?
Raul: No problem.

More Effective Communication

Nurse: Here's a pamphlet about adolescents and drug use. I hope you haven't been using any.
Raul: No problem.
Nurse: Sometimes it's difficult for children to talk to parents or other adults about such things.
Raul: No problem.
Nurse: Have you been doing any?
Raul: No problem.

Raul answered with the same response in both conversations. Do you think he meant the same thing in both conversations? Was the nurse wise to announce that only stupid people use drugs and then ask if Raul was using any?

Outcome Evaluation: Adolescent states he is not experimenting with drugs; can describe a way to respond to peers who encourage such use; shows no evidence of drug use such as lethargy, confusion, positive urine drug screen, or parental suspicion.

In addition to any physical damage that substance abuse may cause, one of the greatest dangers of early drug experimentation is it affects an adolescent's ability to solve problems, with a consequent delay in maturity. Adolescents may cling to peers to shield drug use and stay away from adults they are afraid might detect it, removing themselves from exposure to adult role models. It is important to help adolescents plan ways they can feel satisfaction in life without substance use, such as how to feel secure enough to interact with others without relying on cocaine or marijuana, or how to accomplish activities to increase self-esteem so alcohol is not needed.

When establishing expected outcomes with adolescents who are chemically dependent, remember it is difficult for them to appreciate how much they depend on a drug until they try to stop using it. A goal of not using a drug for 24 hours at a time may be the only one possible at first.

Try to caution adolescents against substance abuse in the same manner you would caution about the unwise use of motor vehicles or swimming beyond personal limits. Scare stories (soft drugs automatically lead to hard drugs, marijuana destroys your brain, drug addicts are sex perverts) cloud the issue and make adolescents dismiss all advice given them about drugs as worthless.

To maintain a realistic approach to the problem, health care personnel and parents should counsel (not lecture) that substance abuse is both illegal and harmful but also remember how difficult it is for adolescents to say no to peer pressure. Important teaching points to prevent substance abuse are summarized in Box 33.10.

Therapeutic communities or 24-hour facilities in which adolescents can live while they recover from chemical dependency may be necessary for some adolescents. The aim of all these programs is to increase adolescents' sense of self-esteem, improve problem-solving ability, realign them with society's values, and increase their self-awareness so they can function effectively without the aid of substances of abuse. Unfortunately, campaigns against substance abuse for adolescents have not been very successful, so the problem continues. Adolescents who are no longer chemically dependent should be evaluated by a history and physical examination at all health care visits because, if the circumstances that initially caused them to become chemically dependent recur, they may return to a dependency pattern. A continuing relationship with health care personnel not only allows time for this evaluation but also provides concrete role models of nonchemical, productive behavior.

Concerns Regarding Depression and Attempted Suicide

Suicide is deliberate self-injury with the intent to end one's life. Successful suicide occurs more frequently in males than in

TABLE 33.4 ✻ Symptoms to Help Identify Drug Abusers

Drugs Used	Symptoms of Use	Dangers
Glue	Violence, drunken appearance, dreamy or blank expression Glue smears on clothing or fingers; tubes of glue, paper bags in possession	Lung, brain, or liver damage; death through suffocation or choking; anemia
Heroin, morphine, codeine	Stupor, drowsiness, needle marks on body, watery eyes, loss of appetite, bloodstains on shirt sleeve, runny nose Needle or hypodermic syringe, cotton, tourniquet string, burnt bottle caps or spoons, glassine envelopes in possession	Death from overdose; addiction; liver and other infections due to unsterile needles
Cough medicine containing codeine and opium	Drunken appearance, lack of coordination, confusion, excessive itching Empty bottle of cough medicine in possession	Addiction
Marijuana	Sleepiness, wandering mind, enlarged pupils, lack of coordination Strong odor of burnt leaves, small seeds in pocket lining, cigarette paper, discolored fingers	Psychological dependence; possibly testicular cancer
Hallucinogens (LSD, DMT, PCP)	Severe hallucinations, feelings of detachment, incoherent speech, cold hands and feet, laughing and crying, vomiting Possession of cube sugar with discoloration in center, strong body odor	Suicidal tendencies, unpredictable behavior; chronic exposure may have neurologic effects
Stimulants (methamphetamine, cocaine)	Aggressive behavior, giggling, silliness, rapid speech, confused thinking, no appetite, extreme fatigue, black caries, dry mouth, shakiness, insomnia. Pills or capsules of varying colors in possession; absence of nasal hair; possession of a glass pipe	Death from overdose; hallucinations; psychosis
Depressants (barbiturates, alcohol)	Drowsiness, stupor, dullness, slurred speech, drunken appearance, vomiting Pills or capsules of varying colors in possession; odor of alcohol on breath	Death or unconsciousness from overdose; addiction; seizures from withdrawal
Steroids	Aggressive behavior; increase in muscle strength and mass	Violent actions; possibly tumor growth

females, although more females apparently attempt suicide than males (about 8:1). Adolescent suicides are attempted most often in the spring or the fall, reflecting school stress at these times of year, and between 3 PM and midnight, reflecting depression that increases with the dark. Suicide is so common in adolescents that it ranks third as a cause of death in the 15- to 19-year-old group (CDC, 2008a). This statistic may actually be underestimated, because some well-meaning coroners or physicians may report these deaths as accidents to spare the family additional pain.

Some automobile or hiking accidents may be attempts at self-destruction; in addition, some homicides may be caused by deliberately provoking another person in the hope of being killed. Incest, abuse, increased chemical dependency, marital instability in the family, and poor problem-solving ability are reasons that may lead an adolescent to decide that death may be easier than coping with overwhelming problems. A wish to "get even" over some hurt or drug and alcohol use may contribute to suicide by further impairing judgment (Kaplan & Love-Osborne, 2008).

Some degree of depression is present in most adolescents, because they are not only losing their parents at this time as they grow apart from them, but they are also losing their carefree childhood. If school failure or loss of a friend or losing a competition is superimposed on an existing depression, the pressure may be great enough to cause some adolescents to attempt suicide. Some other reasons for attempting suicide include anger with others and manipulation (psychological blackmail) as a way of having one's needs met. Loss of a parent, loss of a girlfriend or boyfriend, loss of a community, and loss of self-esteem are all significant and can trigger a suicide. Because some adolescents may be unable to believe that a parent was at fault in the case of divorce or that the death of a parent could not have been prevented, they may believe, instead, they somehow caused the parent to leave or to die. The loss of a girlfriend or boyfriend is particularly significant because it involves two types of loss: friendship and self-esteem. Rejection from a peer group, sports team, or school club may cause a similar loss of self-esteem.

Assessment

Adolescents need to have thorough physical examinations at health maintenance visits to assure them they are in good physical health. Assess for signs of depression such as anorexia, insomnia, excessive fatigue, or weight loss. In younger adolescents, depression may be manifested by behavior problems such as disobedience, temper tantrums,

Health Teaching Guidelines for the Prevention of Substance Abuse in Adolescents

Q. Raul, at 15, is very aware drugs are readily accessible in his neighborhood. He asks you, "What are guidelines to help avoid substance abuse?"

A. Below are some common suggestions:

1. All chemicals are harmful to the body, at least to some extent (alcohol, for example, causes liver disease).
2. Relying on drugs to give you courage to solve problems (or help to forget you have problems) prevents you from learning to handle life situations and maturing.
3. The bottom line of drug abuse is that you have the final say: you are the only one who can stop chemical dependency from happening.
4. Whether a drug is inhaled, swallowed, or injected, it still is absorbed and enters your body.
5. Despite their social acceptability, alcohol and nicotine are drugs. A month of daily use of either can make you addicted.

truancy, and running away from home. Self-destructive behavior or accident proneness may be noted. Difficulties in school; acting out with chemicals, alcohol, or sexual promiscuity; or trouble with legal authorities may be further clues. Occasionally, depressed adolescents find it so hard to be alone they seek constant activity as a means of escape. In contrast, others may withdraw from contact with other persons and become completely isolated. Either behavior can be detected through assessment of activity and interaction levels.

Adolescents who attempt suicide fall into no one category, although many tend to be loners or to have difficulty expressing their feelings to others and, therefore, do not receive emotional support from friends. Others are "perfect" students. The stress of trying to achieve continually at this level, however, is the trigger that provokes suicide. Gay and lesbian youths appear to have higher levels of suicide than others, reflecting the level of stress they may be experiencing. Assess for these lifestyles as well.

If another member of a family or a close friend committed suicide, the chance that an adolescent will do so is greater than usual, as adolescents then see suicide as a method of coping and use it. The anniversary of a family member's suicide is an especially vulnerable time as wishing to join the dead family member may appear attractive. When one adolescent in a high school commits suicide, there is a good chance another will take similar action soon afterward. Adolescent suicide rates may actually reach epidemic proportions after a popular student's suicide. Students who have Internet contacts may arrange a group suicide as a method of making a statement or gaining support.

Because suicide usually reflects a problem in family interaction, family assessment is helpful. A thorough family history may reveal conflict with one or both parents. A frequent comment heard is, "They'll be sorry when I'm dead." School friends may often be aware an adolescent is contemplating suicide before the parents. Caution parents not to discount reports from their child's friends who tell them they are concerned about their child. Close to the chosen time of suicide, some adolescents may demonstrate characteristic behaviors that show they are making preparations to end their life. Teach family and friends these typical danger signs (Box 33.11).

After a suicide attempt, ask enough questions on a health history so you know whether an adolescent made a detailed suicide plan. For example, a young person who took four aspirins and left the empty aspirin container conspicuously on the kitchen counter just before his mother was due to arrive home from work is more likely to be only crying for help; one who took 100 aspirins and hid the container under the bed just after his mother left for 8 hours of work is much more apt to be making a serious attempt. You may be the first person in a health care facility to realize that an adolescent talking about suicide is not "just talking" (it is a fallacy that people who talk about suicide do not attempt it) but has a definite, well-thought-out plan to accomplish it. An adolescent who has been admitted to a hospital unit after a

BOX 33.11 * Focus on Family Teaching

Suicide Warning Signs

Q. Raul's father says to you, "Our neighbor's son recently committed suicide. What are warning signs of this to look for in our son?"

A. The following are commonly seen clues:

- Giving away prized possessions
- Organ donation questions, such as "How do you leave your body to a medical school?"
- Sudden, unexplained elevation of mood. Mood elevation may indicate that the individual has reached a decision about the suicide and feels relief.
- Accident proneness, carelessness, and death wishes
- A statement such as, "This is the last time you will see me."
- Decrease in verbal communication
- Withdrawal from peer activities or previously enjoyed events
- Previous attempt (80% of all completed suicides have been preceded by a failed attempt)
- Preference for art, music, and literature with themes of death
- Recent increase in interpersonal conflict with significant others
- Running away from home
- Recent experience of a friend or famous person committing suicide
- Inquiring about the hereafter
- Asking for information (supposedly for a friend) about suicide prevention and intervention
- Almost any sustained deviation from the normal pattern of behavior

serious suicide attempt may formulate a new plan that will be successful the next time unless some action is taken and the adolescent's life can be changed in some way.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for violence, self-directed, related to symptoms of depression or expressed desire to hurt oneself

Outcome Evaluation: Client expresses feelings of depression to health care providers or other adults; states she will contact support person should the desire to commit suicide become overwhelming.

Crisis intervention for adolescents who are contemplating suicide includes trying to alleviate their pain and depression and counseling them in an effort to help them change their perspective on the value of life. Be aware that establishing expected outcomes with adolescents who are contemplating suicide or who have made an attempt will be difficult because they are often too depressed to come up with an alternative solution to their problems (their goal is to kill themselves, not solve problems).

Try to find out the things in the child's life that are still viewed as important; build a plan that will help view life as worth living enough to work through problems. Show them no one can change everything, but everyone can make one or two changes that can make a difference. After these small changes are made, a domino effect can be created to change more and more of one's circumstances.

Because adolescents resort to suicide as a method of solving problems, helping them in this area is a prime intervention strategy. Asking "what would happen if" questions such as "Suppose you did fail a course; what would happen?" "Are there ways you can reverse the finality of the problem perhaps by talking to a teacher about make-up assignments, asking a friend for help in reviewing material, or buying a review book to help in studying?" Do not count on everyone in an adolescent's life being willing to help. A high school teacher may feel that to be asked to do outside tutoring is an imposition so for you to advise adolescents to seek this kind of help will only add to their depression. You may have to make these contacts yourself (with an adolescent's permission) because, generally, persons who are depressed have difficulty initiating this type of action because they do not believe anyone cares enough about them to help.

A general measure is to help adolescents speak honestly about thoughts of suicide and the problems that have led them to think that death is a solution. Most problems begin to seem manageable if they can be put into words in this way. It is important not to underestimate adolescents' determination to end their life, however. In most instances, an adolescent at this point needs referral to a consultant well versed in suicide prevention to improve self-image and offer alternative solutions to problems.

For an adolescent's safety, a period of observation in a hospital setting is desirable after a suicide attempt to prevent the adolescent from inflicting personal injury again and to allow assessment in a neutral setting, away from the stress that precipitated the attempt. This can take place in an adolescent service rather than a psychiatric service.

Antidepressant medicine alone, a therapy used with depressed adults, may be of little value in treating depressed adolescents. Tricyclic antidepressants generally are ineffective and may cause serious adverse effects. Evidence for the effectiveness of selective serotonin reuptake inhibitors is limited. All antidepressants have a black box warning because some antidepressants have been associated with elevating the mood of depressed children enough to allow them to formulate a plan and commit suicide after taking them (Bhatia & Bhatia, 2007). Fluoxetine is an example of a drug approved for the treatment of depression in children 8 to 17 years of age.

Continuing evaluation by both history taking and physical examination is necessary, because the young person who has attempted suicide may attempt it again if support people and better problem-solving ability are not available at another time.

What if... Raul seems unusually happy at a clinic visit, when usually he is sad? Would you worry that this change in mood is a warning sign that he might be contemplating suicide?

Concerns Regarding Runaways

A *runaway* is commonly defined as a child between the ages of 10 and 17 years who has been absent from home at least overnight without permission of a parent or guardian. The frequency of running away for adolescents may be as high as one in eight. Fortunately, most do not go far or stay away long (less than 1 week) (Milburn et al., 2007); about 1 in 20 adolescent runaways stays away as long as 1 year; some never return home. Runaway adolescents are most likely to be from low- or high-income families. Unemployment, alcoholism, sexual abuse, attempted suicide, and poverty are frequent characteristics (Chen et al., 2007). They are slightly more likely to be male than female. Events they encounter may be so traumatic they develop a posttraumatic syndrome (Thompson et al., 2007).

Assessment

Running away is usually preceded by an argument with parents that is often the last straw after a number of long-term disagreements. Other reasons may be personal concerns such as loneliness, pregnancy, and problems with friends, school, or the police. Incest can also be a precipitating cause, as can other parental abuse. A school history often reveals frequent truancy, failing grades, possible drug use, and runaway behavior by friends. It is a sad fact that some adolescents are "throwaways" or cannot remain at home because they have been rejected by their families.

Common health reasons for which runaway adolescents are seen at health care facilities are sexually transmitted

diseases, including HIV/AIDS, rape, pregnancy, substance abuse, hepatitis, and vaginitis. They also have a high incidence of suicide attempts. When caring for adolescents with these concerns, be certain to secure a thorough history so the fact they are no longer living at home will not be missed. Be sure to be nonjudgmental in questioning. Revealing you are shocked by a report an adolescent has been sleeping on a park bench for 2 months, has been robbed, or steals to obtain money could prevent you from learning even greater concerns, such as having a sexually transmitted disease, being pregnant, or using drugs. Ask if the adolescent wants to return home. Even though being homeless is high stress, and many adolescent runaways want to take the first step back toward their parents, they may not know how to begin the process.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Ineffective individual coping related to stress of adolescent period and inadequate family resources

Outcome Evaluation: Adolescent states stress level at home is manageable; is able to describe how he can use family and community resources to help solve problems and aid in a crisis.

Adolescents may run away because they cannot solve a problem in any other way; therefore, setting goals with them may be difficult. A short-term goal to stay home through a holiday rather than a long-term one of finishing high school may be all you can achieve.

Because adolescent runaways lack references for jobs and do not necessarily qualify for public assistance programs, they generally have no secure source of income. This can cause both males and females to resort to prostitution to support themselves, or they may resort to stealing. Police consider them to be juvenile delinquents and are required to return them to their homes if discovered. If they leave home again, they may be sentenced to an institution for care; unfortunately, these facilities are often crowded and may not have the means to meet adolescent needs other than food and clothing.

Try to imagine yourself in adolescent runaways' circumstances to determine whether your health instructions are sensible for their lifestyle. Giving them instructions to eat a high-protein diet or iron-rich foods, for example, may be ludicrous. If they do not have a source of running water, soaking a lesion or changing a dressing may be difficult. They may have no way to pay for health care, making it impossible to obtain a prescription medication, so giving them a sample of a drug is often more practical. If they do not have a means of transportation, they may be unable to return to the health care facility for frequent follow-up visits. Try to meet as many of the runaway's needs as possible, therefore, at one visit. Remember that many runaways have associated school failure so may be poor readers; discuss the information with them when giving them a pamphlet.

Be certain runaway adolescents are familiar with the national Youth Crisis Hotline, which they can call day or night when they want to return home. The telephone number is 1-800-448-4663 (1-800-HIT HOME). Remember also that they are runaways because, for some reason, their home was intolerable. Although they agree to return home, they may not remain there unless circumstances have been or can be changed.

Nursing Diagnosis: Impaired parenting related to inability of family to adjust to adolescent needs

Outcome Evaluation: Parents list definite changes they have made in family life to better accommodate an adolescent, such as providing increased privacy or using "contracting" with adolescent.

In some instances, it is impossible for a family to reestablish itself after a child has run away because the family is dysfunctional (incest or abuse has occurred). In other instances, family life can be modified to welcome the runaway adolescent back home.

So that parents and an adolescent can learn to communicate better, it is helpful to urge them to establish ground rules for communication (shouting or threats are not allowed; no subject is too difficult to be discussed calmly; no emotion or feeling is to be called "foolish"). Once ground rules are laid, parents and the adolescent should meet to discuss how difficult it is to be an adolescent and how equally difficult it is to be the parent of an adolescent; in the past, they became so engaged in arguing that they did not appreciate the other side of the controversy.

Helping parents and adolescents establish a contract for behavior can be effective (for the right to have her own private room, an adolescent cannot do drugs; for the right to stay overnight at a friend's house on Friday, she must eat with the family all other nights, for example). Contracting is effective with adolescents, but it does carry the responsibility for parents to be certain they are abiding by their half of the contract (not invading the private room) and of being prepared to enforce the contract. Some families benefit by calling on a mediator (a relative, a close friend, a minister or rabbi) to listen to both sides of an issue and make a ruling.

What if... After a fair trial of trying to make adjustments, an adolescent's parents are still unable to maintain a functional home life for him? What other arrangements would you suggest to them to arrange for safe care of their adolescent?

Unique Concerns of the Family With a Physically Challenged or Chronically Ill Adolescent

Achieving a sense of identity may be difficult for adolescents who have a chronic illness or other challenge. It is vital, however, for such individuals to learn to look past their particular condition to their real selves. For example, a 16-year-old girl in a wheelchair must learn to perceive herself as a teenager who is normal intellectually, is a good conversationalist, has a good sense of humor, enjoys watching football, and only incidentally uses a wheelchair to ambulate.

TABLE 33.5 ✻ Nursing Actions That Encourage a Sense of Identity in the Physically Challenged or Chronically Ill Adolescent

Category	Actions
Nutrition	If adolescent is on special diet, discuss role of food preferences with dietitian (hot dogs, pizza, etc.).
	Respect food preferences.
Dressing change	Allow adolescent to order supplies.
	Ask for suggestions as to final appearance of dressing.
	If soaks are included, have adolescent time the treatment.
	Allow adolescent to choose time for dressing change.
Medicine	Offering the adolescent a choice of site for injection or intravenous insertion encourages a sense of control.
	Teach name, action, and possible side effects of medicine.
Rest	Contract with adolescent for time and length of rest periods.
Hygiene	Respect modesty of the adolescent as being at adult level.
	Contract with adolescent for extent of self-care (will give own bath and make bed, not medicate self).
Pain	Encourage adolescent to express pain; teach distraction technique for sharp pain, such as deep breathing, counting backward from 100.
	Encourage adolescent to ask for analgesics as needed.
Stimulation	Provide tapes of favorite music with earphones.
	Provide a radio for adolescent to listen to talk show to foster active involvement.
	Encourage school work, crossword puzzles (you may need to help adolescents divide school assignments so they do not become overly fatigued and frustrated).
	Provide cards for games to increase socialization (make or have the adolescent make a card deck from pieces of paper if one is not available).
	Encourage adolescents to network with one another.
	Encourage adolescents to keep in contact with friends through telephoning, e-mail, or writing notes.

Some of the biggest problems of chronically ill adolescents are likely to be difficulties in being as independent as they would like to be, achieving in school, and establishing intimate relationships. Those who cannot learn to drive when their friends are learning to do so, who are not invited to dances and parties because of a disability, or who are too hesitant to ask someone to go with them, may feel acute losses of self-esteem. Moreover, the loss of many hours of school because of illness or frequent hospitalization may result in the inability to pursue a desired career, at least without a delay. Adolescence may be the first time these children realize that certain occupations or opportunities, such as a military career, may be closed to them. As they prepare to leave the security of a familiar school system, it may be the first time they examine just how they will be able to function on their own. Some may come to realize they will never be able to do so with complete independence.

Chronic hospitalization or the realization they will never be free of symptoms can cause depression in adolescents, placing them at high risk for substance abuse or suicide. Helping these adolescents realize that even completely well people must compromise life decisions for other reasons such as lack of money, lack of ability or qualifications, or extra personal responsibilities helps them feel they are not so different from others. This type of guidance can be time consuming, but sometimes the fact that an adult is willing to make this time commitment with them is enough to give these adolescents the self-esteem they need to alter aspirations and plans and find a future role consistent with their capabilities. Nursing actions that encourage a sense of identity in an adolescent with a long-term illness or who is physically challenged are summarized in Table 33.5.

Nutrition and the Chronically Ill Adolescent

Adolescents who are not fully mobile must be aware of their total calorie intake, or as growth needs decline at the end of adolescence they can become obese. They should also be knowledgeable about good nutrition, so they can participate in meal planning, an action that helps them feel a sense of control over this area of their life. Assess how often they have a chance to eat at fast-food restaurants; although this is not a source of excellent nutrition, eating there occasionally provides an important social experience and a chance to be like their peers.

✔ Checkpoint Question 33.3

Raul admits he has experimented with cocaine. A typical change in facial appearance that occurs with cocaine use is:

a. Frown lines in the forehead.
b. Thin, fissured lips.
c. Loss of eyebrow hair.
d. Absent nasal hair.

Key Points for Review

- The major milestones of development in the adolescent period are the onset of puberty and the cessation of body growth. Between these milestones, physical growth is rapid, although the development of adult coordination and thought processes is slow.

- The development of secondary sex characteristics is completed during adolescence. These are rated according to Tanner stages.
- The developmental task of an adolescent according to Erikson is to establish independence from parents by gaining a sense of identity versus role confusion. Adolescents, therefore, usually respond best to health care personnel who respect their attempts at independence and allow them as many choices as possible in care.
- Adolescents reach a point of cognitive development termed *formal operational thought.* With this gained, they are able to think in abstract terms and use the scientific method to arrive at conclusions.
- Adolescents need to consume adequate calories and especially protein, iron, calcium, and zinc to meet their increased growth needs.
- To appear older than they are, some adolescents present an assured, "I know that" attitude. To be effective, health teaching may have to be introduced with "I know you know this, so I'll just review it" approach that allows an adolescent to maintain a mature front, while gaining additional information.
- Being an adolescent is difficult in today's world. Be aware that, to reduce stress, some adolescents begin to use substances of abuse. Asking about an adolescent's drug experiences, if any, during a health assessment is not intruding on privacy; it is conducting safe health interviewing.
- Promoting adolescent safety is an important nursing role. Motor vehicle accidents, homicide, drowning, and suicide are leading causes of death in this age group.
- Common health problems in an adolescent are sometimes minor and include poor posture, fatigue, or acne; they can also be serious, such as beginning hypertension, substance abuse, and scoliosis. Identifying these problems and referring an adolescent for help are important nursing actions.

CRITICAL THINKING EXERCISES

1. Raul is the 15-year-old teenager you met at the beginning of the chapter. His parents tell you he was depressed after the loss of a girlfriend but now is suddenly happy. He has been collecting baseball cards since he was 8. Recently, he gave his collection away to a neighborhood boy because "I won't need them where I'm going." Why might you be concerned about him? What additional questions might you ask him? If you learned he is about to leave to be an exchange student in England, how would this affect your assessment of the situation?
2. Suppose Raul tells you during history taking he does not smoke, but you smell cigarette smoke on his clothing. Although he says he does not use drugs, a number of blue-and-white capsules fall out of his shirt pocket when he unbuttons his shirt. What questions would you ask to determine if he is smoking cigarettes or using drugs? Describe your next action if he does admit he is not only heavily into drugs but does not intend to stop using them.
3. A shy, quiet, 14-year-old girl you care for in a hospital setting tells you she is concerned because she has not menstruated yet. This is making her feel "left out" at school. How would you counsel her? What if she were 16 and had the same concern?
4. Examine the National Health Goals related to growth and development of adolescents. Most government-sponsored funds for nursing research are allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to Raul's family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to adolescent growth and development. Confirm your answers are correct by reading the rationales.

- toxoid
- turgor
- varicocele

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. State the purposes of health assessment in children of all ages.
2. Identify National Health Goals related to health assessment of children nurses can help the nation achieve.
3. Use critical thinking to analyze ways health assessment skills can be incorporated into nursing care procedures to maintain family centered care.
4. Assess a child and family by health interview, physical examination, and development screening.
5. Formulate nursing diagnoses based on health assessment findings.
6. Identify expected outcomes based on health assessment findings.
7. Plan nursing care based on health assessment findings such as informing parents of health deviations.
8. Implement nursing care such as conducting an age-appropriate health interview or physical examination by modifying techniques based on the child's age.
9. Evaluate expected outcomes for achievement and effectiveness of care.
10. Identify areas related to health assessment of children that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate nursing process with knowledge of health assessment to achieve quality maternal and child health nursing care.

Keoto Wiser is a 13-year-old you meet in an ambulatory clinic. Her father has brought both her and her 2-year-old sister, Candy, for health assessments before Keoto begins seventh grade. Her father is worried Keoto does not see well because she always sits close to the television set. Keoto's mother did not want to bring her for a preschool assessment because she is worried that if glasses are prescribed, her daughter will not be able to play on a school soccer team.

Previous chapters described the normal growth and development of children. This chapter adds information about techniques for assessing the health of children, including history taking, physical examination, related screening procedures for hearing, vision, and development, and immunizations. This information builds a base for care and health teaching for differing age groups throughout childhood.

What questions would you want to ask Keoto? What screening tests for vision would be best for this 13-year-old child? What could you do to help her adjust to wearing glasses, if they are prescribed?

Nursing assessment is not only the first step in the nursing process but also the fundamental means by which health care personnel establish and maintain contact with children and their families. Child health assessment is especially important as an opportunity to provide families with information about health promotion, signs of health and illness, and expected developmental progress in their children. This anticipatory guidance can have a long-lasting positive impact on the health of children and their families.

Effective assessment for the maternal–child population first requires you to be familiar with health maintenance standards and usual findings, because this knowledge is essential to the ability to recognize illness. Most health screening procedures are performed in ambulatory settings such as pediatric clinics, physicians' offices, health maintenance organizations, community clinics, and schools, but they can be used to evaluate children in all settings (Sleeper, Ariza, & Binns, 2009).

Sometimes it is necessary to complete just a partial history or a partial physical examination, such as when a child is referred for vision examination. This chapter, however, covers all aspects of physical examination so that, when necessary, a complete examination can be performed. Assessment procedures specific to particular illnesses are discussed in later chapters with the illness they detect.

Findings and techniques in children differ depending on racial and ethnic characteristics. Whether people establish eye contact with an interviewer, for example, is a characteristic that is culturally determined. Assessing for cyanosis, as another example, is more difficult in dark-skinned than in fair-skinned children (mucous membrane is the best place to detect this). Because height and weight charts are standardized on middle-class white children, measurements of children who do not fit this description may not plot well on these charts. In Vietnam, touching the head of a child during physical assessment is thought to be harmful because the head is considered to be the seat of the soul.

Recognizing that people hold differing cultural expectations and characteristics such as these can help in establishing rapport with children and their families and help make health assessment more meaningful.

Some cultures are much more aware of the role of communicable disease in childhood illnesses than others and so advocate for all children to be immunized against these disorders. Even if awareness about the danger of disease spread exists, however, it does not mean all people in a community are conscientious about having their children immunized. Other factors such as cost and convenience and ethical beliefs are also important.

Some religious groups, such as the Amish, do not encourage immunizations. In these communities, the prevalence of illnesses such as measles can rise to high numbers. Being aware that immunization rates are not consistent from place to place aids in understanding the importance of planning health education and health surveillance based on individual community needs. Box 34.1 lists National Health Goals related to health assessment in children.

BOX 34.1 * Focus on National Health Goals

A number of National Health Goals relate directly to health assessment of children. These are:

- Increase the proportion of territories and states that have service systems for children with special health care needs from a baseline of 15% to a target of 100%.
- Increase the proportion of children and youth, 17 years of age and younger, who have a specific source of ongoing care from a baseline of 93% to a target of 97%.
- Achieve and maintain effective vaccination coverage levels for universally recommended vaccines among young children from baselines of 84% (DTaP); 87% (hepatitis B); 91% (polio); 43% (varicella); and 92% (MMR) to an overall target level of 90% (http://www.nih.gov).

Nurses can help the nation achieve these goals by participating actively in health assessment and conscientiously screening for and administering vaccines. Nursing research that might add more information in this area would include techniques that can be used to orient preschoolers quickly to a health care setting, effective techniques for eliciting health interview information from adolescents, and methods to help parents better record or remember what immunizations their children have received.

Nursing Process Overview

For Health Assessment of the Child and Family

Assessment

Health assessment of children can be a positive, educational experience for a child and family if time is taken to listen carefully to the family's concerns and responses to questions. Never rush either an interview or a physical examination. Be sure children have time to familiarize themselves with the environment and equipment that will be used.

Obtaining health histories and performing physical examinations can be done independently or as part of a total preventive health care program for a child. The recommendations for standard preventive pediatric health care for the United States are shown in Table 34.1.

Nursing Diagnosis

Health assessment provides the data used to identify potential problems and serves as the basis for the establishment of nursing diagnoses. Be certain not to overlook diagnoses that accentuate the healthy functioning of a child and family, even when diagnoses that address specific problems have been identified. These wellness diagnoses are crucial components of the entire assessment picture and often provide an avenue for addressing identified problems. For instance, the nursing diagnosis of "Impaired social interaction related to lack of self-esteem secondary to disability" would be appropriate for a 4-year-old child who ambulates by wheelchair who, according to the parents, feels uncomfortable around other children.

If the parents have difficulty adapting to their child's disability but are eager to accept advice from health care experts on how to provide the most stimulating environment for their child, the diagnosis "Readiness for enhanced family coping" would also be appropriate. Using both these diagnoses allows the development of a plan of care that takes the best advantage of this family's strengths.

Outcome Identification and Planning

Health promotion and illness prevention are vital parts of outcome identification following health assessment. Helping parents plan for their child's next developmental stage or keeping them aware of important safety measures and other ways to keep children well are also important. Remind them about immunizations needed in the future and be certain they know when to schedule the next health visit. A current immunization schedule is always available at the Centers for Disease Control and Prevention (CDC) Web site (http://www.CDC.gov). Growth charts for children are available at both the CDC (http://www.CDC.gov/growthcharts) and the World Health Organization (http://www.WHO.int/childgrowth) Web sites.

Implementation

Health interviewing and physical examination both require a great deal of skill, skill that can be perfected only through practice. To perfect skills and judgment with children of different ages, take advantage of every opportunity to practice interviewing and physical examination techniques.

Outcome Evaluation

Health assessment of children is an ongoing process that does not end when the first database is obtained. Data must be added at all future interactions so the database remains current and meaningful. Examples suggesting that expected outcomes have been achieved would include:

- Parents state after health examination that they are satisfied with child's motor development.
- Child states after Snellen test that she is aware her vision needs correction.
- Parents state they will continue to assess child's growth by weighing child weekly.

HEALTH HISTORY: ESTABLISHING A DATABASE

The assessment of a young child begins with an interview of the child's parents. An adolescent or preadolescent may choose to be interviewed without the parents present, although many preadolescents and adolescents still prefer to have a parent with them for support.

The purpose of a health interview is to gather information that will direct physical or laboratory examinations to complete a thorough health evaluation. An extensive interview elicits facts such as parental problems in childrearing or detection of future health problems. It lays a foundation for health education and health promotion. Important principles of child health interviewing include the interview setting, the types of questions asked, and the type of information collected.

Interview Setting

An interview is best conducted in a private room with all parties seated comfortably; if not seated, a health care provider appears rushed and cannot interact at eye level. During the interview, call the parents by their names. This lets them know their input and opinions about how their child is developing are valued. A question such as, "Does Candy speak in sentences yet, Mr. Wiser?" is far more personal and a better form than, "Does your baby sit up yet?" As children grow, they are able to answer questions directly.

Types of Questions Asked

The phrasing of questions varies depending on the type of answer desired. Closed-ended and open-ended questions are two types of effective questions; compound, expansive, and leading questions, on the other hand, are three types of questions to avoid.

Closed-Ended Question

This simplest form of question asks directly for a fact: "Does Candy walk yet?" "Did you take Candy's temperature?" This is an effective type of question if a particular point is being sought. It is limited in scope, however, because the response usually will be only a yes or no, with no further elaboration.

Open-Ended Question

An open-ended question allows a parent to elaborate. In contrast to a closed-ended question like "Did you take Candy's temperature?" the question "What did you do for Candy?" is open-ended. The parent answers with a listing of all the things he did: took Candy's temperature, had her lie on the couch, gave her extra fluid, and so on. It is important to ask open-ended questions with school-age children and adolescents so they are encouraged to describe a problem fully.

Compound Question

Compound questions are confusing and should be avoided because the information they elicit is often inaccurate and must be followed by a clarifying question. An example is, "Did Candy have nausea and vomiting?" The parent answers yes, but it still is not known whether Candy had vomiting and nausea, just vomiting, or just nausea.

Expansive Question

This is an open-ended question gone wrong because it is too vague to answer. "What can you tell me about Candy?" leaves a parent wondering where to start. "How has Candy been since her last visit?" limits the question and makes it answerable.

Leading Question

A leading question supplies its own answer so also should be avoided. "Candy has had all her immunizations, hasn't she?" implies that Candy should have had them and perhaps the parent is a poor caregiver if he answers that question any way

(text continues on page 953)

TABLE 34.1 ✻ Recommendations for Preventive Pediatric Health Care

Each child and family is unique; therefore, these **Recommendations for Preventive Pediatric Health Care** are designed for the care of children who are receiving competent parenting, have no manifestations of any important health problems, and are growing and developing in satisfactory fashion. **Additional visits may become necessary** if circumstances suggest variations from normal.

Developmental, psychosocial, and chronic disease issues for children and adolescents may require frequent counseling and treatment visits separate from preventive care visits.

These guidelines represent a consensus by the American Academy of Pediatrics (AAP) and Bright Futures. The AAP continues to emphasize the great importance of **continuity of care** in comprehensive health supervision and the need to avoid **fragmentation of care.**

The recommendations in this statement do not indicate an exclusive course of treatment or standard of medical care. Variations, taking into account individual circumstances, may be appropriate.

•= to be performed ★ = risk assessment to be performed, with appropriate action to follow, if positive ← • → = range during which a service may be provided, with the symbol indicating the preferred age

[a] If a child comes under care for the first time at any point on the schedule, or if any items are not accomplished at the suggested age, the schedule should be brought up to date at the earliest possible time.

[b] A prenatal visit is recommended for parents who are at high risk, for first-time parents, and for those who request a conference. The prenatal visit should include anticipatory guidance, pertinent medical history, and a discussion of benefits of breastfeeding and planned method of feeding per AAP statement "The Prenatal Visit" (2001) [URL: http://aappolicy.aappublications.org/cgi/content/full/pediatrics;107/6/1456].

[c] Every infant should have a newborn evaluation after birth, breastfeeding encouraged, and instruction and support offered.

[d] Every infant should have an evaluation within 3 to 5 days of birth and within 48 to 72 hours after discharge from the hospital, to include evaluation for feeding and jaundice. Breastfeeding infants should receive formal breastfeeding evaluation, encouragement, and instruction as recommended in AAP statement "Breastfeeding and the Use of Human Milk" (2005) [URL: http://aappolicy.aappublications.org/cgi/content/full/pediatrics;115/2/496]. For newborns discharged in less than 48 hours after delivery, the infant must be examined within 48 hours of discharge per AAP statement "Hospital Stay for Healthy Term Newborns" (2004) [URL: http://aappolicy.aappublications.org/cgi/ content/full/pediatrics;113/5/1434].

[e] Blood pressure measurement in infants and children with specific risk conditions should be performed at visits before age 3 years.

[f] If the patient is uncooperative, rescreen within 6 months per AAP statement "Eye Examination and Vision Screening in Infants, Children, and Young Adults" (1996) [URL: http://aappolicy.aappublications.org/ cgi/reprint/pediatrics;98/1/153.pdf].

(continued)

TABLE 34.1 ✻ Recommendations for Preventive Pediatric Health Care (continued)

[g] All newborns should be screened per AAP statement "Year 2000 Position Statement: Principles and Guidelines for Early Hearing Detection and Intervention Programs" (2000) [URL: http://aappolicy.aappublications.org/cgi/content/full/pediatrics;106/4/798]. Joint Committee on Infant Hearing. Year 2007 position statement: principles and guidelines for early hearing detection and intervention programs. *Pediatrics.* 2007;120:898–921.

[h] AAP Council on Children With Disabilities, AAP Section on Developmental Behavioral Pediatrics, AAP Bright Futures Steering Committee, AAP Medical Home Initiatives for Children With Special Needs Project Advisory Committee. Identifying infants and young children with developmental disorders in the medical home: an algorithm for developmental surveillance and screening. *Pediatrics.* 2006;118:405–420 [URL: http://aappolicy.aappublications.org/cgi/content/full/pediatrics;118/1/405].

[i] Gupta VB, Hyman SL, Johnson CP, et al. Identifying children with autism early? *Pediatrics.* 2007;119:152–153 [URL: http://pediatrics.aappublications.org/cgi/content/full/119/1/152].

[j] At each visit, age-appropriate physical examination is essential, with infant totally unclothed, older child undressed and suitably draped.

[k] These may be modified, depending on entry point into schedule and individual need.

[l] Newborn metabolic and hemoglobinopathy screening should be done according to state law. Results should be reviewed at visits and appropriate retesting or referral done as needed.

[m] Schedules per the Committee on Infectious Diseases, published annually in the January issue of *Pediatrics.* Every visit should be an opportunity to update and complete a child's immunizations.

[n] See AAP *Pediatric Nutrition Handbook,* 5th Edition (2003) for a discussion of universal and selective screening options. See also Recommendations to prevent and control iron deficiency in the United States. *MMWR Recomm Rep.* 1998;47(RR-3):1–36.

[o] For children at risk of lead exposure, consult the AAP statement "Lead Exposure in Children: Prevention, Detection, and Management" (2005) [URL: http://aappolicy.aappublications.org/cgi/content/full/pediatrics;116/4/1036]. Additionally, screening should be done in accordance with state law where applicable.

[p] Perform risk assessments or screens as appropriate, based on universal screening requirements for patients with Medicaid or high prevalence areas.

[q] Tuberculosis testing per recommendations of the Committee on Infectious Diseases, published in the current edition of *Red Book: Report of the Committee on Infectious Diseases.* Testing should be done on recognition of high-risk factors.

[r] "Third Report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III) Final Report" (2002) [URL: http://circ.ahajournals.org/cgi/content/full/106/25/3143] and "The Expert Committee Recommendations on the Assessment, Prevention, and Treatment of Child and Adolescent Overweight and Obesity." Supplement to *Pediatrics.* In press.

[s] All sexually active patients should be screened for sexually transmitted infections (STIs).

[t] All sexually active girls should have screening for cervical dysplasia as part of a pelvic examination beginning within 3 years of onset of sexual activity or age 21 (whichever comes first).

[u] Referral to dental home, if available. Otherwise, administer oral health risk assessment. If the primary water source is deficient in fluoride, consider oral fluoride supplementation.

[v] At the visits for 3 years and 6 years of age, it should be determined whether the patient has a dental home. If the patient does not have a dental home, a referral should be made to one. If the primary water source is deficient in fluoride, consider oral fluoride supplementation.

[w] Refer to the specific guidance by age as listed in Bright Futures Guidelines. (Hagan JF, Shaw JS, Duncan PM, eds. *Bright Futures: Guidelines for Health Supervision of Infants, Children, and Adolescents.* 3rd ed. Elk Grove Village, IL: American Academy of Pediatrics; 2008.)

but yes. The penalty for such an exchange could be a child left vulnerable to disease.

Categories of a Health Interview

Data gathering for an initial health assessment can be divided into nine categories, which are all discussed later and in sequence. At return visits, the categories used generally include only introduction and explanation, chief concern, health and family profile, interval history, and day history.

While conducting a health interview, be certain to make a transition statement before shifting from one section of an interview to another. Without a transition, a parent can be left wondering what is the importance of the next question, possibly misinterpreting its significance. For instance, if a parent has been providing information on the family's hospital insurance policy and, without a transition statement, is asked whether the child has been vomiting, a parent may think the interviewer believes the child needs hospitalization when that is not the intent at all. A statement such as, "Before we talk about Candy's current symptoms, let me ask you some general questions about your family as a whole," is an example of a good transition statement.

Introduction and Explanation

As a matter of courtesy, parents and a child should be told to whom they are talking and what topics they will be discussing. "Hello, Ms. Wiser, I'm Janet Dickson, a nurse here in the One-Day Surgery Department. I'd like to talk to you about Candy" is an example of a suitable introduction. Because some families have never had the benefit of in-depth health care, it is also helpful to include a statement about the subjects that will be discussed during the interview. For example, "So that I can get a picture of Candy's overall health, I'd like to ask you questions about why you've brought her here today, your pregnancy with her, concerns you've had in the past, and questions about your typical day with Candy," would be appropriate. Hearing that, parents begin to concentrate on those areas because they realize health care providers in this setting are interested not just in Candy's health this particular day but in her total health.

Demographic Data

To begin collecting demographic data, obtain a child's name, address, gender, and the name of the person who will be providing information. To provide culturally competent care and make provisions for special needs, a child's culture, ethnicity, place of birth, religious or spiritual practices, and primary and secondary language should also be identified. Ask if the child has a Social Security number.

Be certain to identify the child's primary caregiver. If the parents are divorced or deceased, it is especially important to identify who has custody of the child and who has the right to sign a consent for health care.

Chief Concern

After gathering demographic data, begin data collection with the reason the parents have brought the child to the health care agency: the **chief concern.** This is what parents are most anxious to discuss, so it is important they get this immediate concern off their mind early in the interview. An effective way to elicit this information is to ask an open-ended question such as, "Why did you bring Candy to the clinic today, Ms. Wiser?" Such an opening allows the parent freedom to answer in a number of areas of concern: physical, emotional, nutritional, and developmental. If asked, "How is Candy feeling today?" or "Is Candy ill?" a parent is left to think about only physical aspects and may not voice the biggest concern: Candy's teething difficulty or frequent temper tantrums. For more details on eliciting information about children's chief concern, see Box 34.2. Record a Chief Concern in the child's record exactly as it is stated ("He has constant headaches," not, "Headache") as the parent's description often reveals not only information about a disease condition but also the depth of the parent's concern about the symptom (Geller, 2007).

History of Chief Concern

Once a parent has voiced a chief concern, ask him or her to describe at least six aspects of the problem, including duration, intensity, frequency, description, associated symptoms, and actions taken.

In discussing *duration,* determine when children were last well to determine when they became ill. For example, on Saturday morning, Candy began having long crying periods. On Monday night, she developed a fever. On Tuesday afternoon, her mother brought her into the clinic for a checkup. The parent states Candy vomited three times Monday morning and thinks this was caused by teething. Unless the parent is asked when Candy was last well, she may pinpoint Monday as the beginning of the illness (the vomiting) when actually it was Saturday (the crying).

In this example, the *intensity* of the illness refers to the kind of vomiting the child is having. Is it drooling, spitting up, or actual vomiting? *Frequency* refers to how often the vomiting occurs throughout the duration of the illness. The *description* is the amount (a cupful? a mouthful?) and color (whether it contains blood, bile, or mucus). *Associated symptoms* might include fever, abdominal pain, difficulty eating, or signs of respiratory illness. A good question to use to obtain this information is, "Is Candy ill in any other way?"

Knowing the parent's *actions* can be important for a number of reasons. First, it helps to know whether anything a parent has been doing such as offering a great deal of fluid to replace that vomited and by doing so causing more vomiting or using a home remedy or alternative therapy that actually induces vomiting could have made the illness worse. The parent's actions also reveal what the parent has previously tried but found ineffective. Telling a parent to give a child 2 tablets of acetaminophen (Tylenol) every 4 hours for fever if the parent has already done that and the fever has not improved would be unproductive. This information also reveals the parent's response to caring for an ill child. A parent who says, "I tucked her into bed and gave her a little tea to drink" is different from one who replies, "Nothing. I fall apart when my child is ill." If the child is going to return home under the parents' care, the second set of parents in the example need more instructions and support before they leave the health care setting than the first parent.

Obtaining information about the chief concern also puts the parent's observations in proper perspective. In the previous example, the parent is probably not describing

BOX 34.2 ✻ Focus on Communication

You see Keoto at another time at an ambulatory clinic because she has frequency and burning on urination. Her mother accompanies her for the visit.

Less Effective Communication

Nurse: Hello, Keoto. What's the reason you've come into the clinic today?
Mrs. Wiser: It hurts when she urinates.
Nurse: How long ago did that start, Keoto?
Mrs. Wiser: She started complaining about it yesterday.
Nurse: Has she had any blood in her urine?
Mrs. Wiser: She hasn't said anything about that. The important thing is the pain.
Nurse: Okay. I'm sure we need a urine specimen for culture. Let's get that to get started here.

More Effective Communication

Nurse: Hello, Keoto. What's the reason you've come into the clinic today?
Mrs. Wiser: It hurts when she urinates.
Nurse: Let's let Keoto answer for herself, Mrs. Wiser. Tell me what you think is the problem, Keoto.
Keoto: It hurts when I go to the bathroom.
Nurse: How long ago did that start, Keoto?
Mrs. Wiser: She started complaining about it yesterday.
Nurse: Keoto, when do *you* think it started?
Keoto: About an hour after I came in from my date last night.
Nurse: Have you had any blood in your urine?
Mrs. Wiser: She hasn't said anything about that.
Nurse: Keoto, have you noticed your urine is red or dark brown?
Keoto: I had bright blood last night.
Nurse: Let me take you down to the lavatory and explain about a urine specimen. While we're there, I'd like to ask you some more questions about last night.

At about 10 years of age, children are able to supply much of a health history by themselves. As children become teenagers, it is increasingly important for them to do this because they may not have shared a total history with a parent. In the above scenario, for example, when the child is asked directly for information, she supplied more than when her history was given by the mother. Some urinary tract infections occur in girls after their first sexual relations. It would be important to ask Keoto if she is sexually active (what her date last night included), not only to document the probable cause of the urinary tract infection but also to be certain she is knowledgeable about pregnancy prevention and safer sex practices.

teething difficulty (teething does not cause vomiting); more likely, the child has a viral gastroenteritis. Unless the problem is investigated, it is easy to accept the parent's statement at face value as a teething problem without appreciating its full significance.

During this phase of the interview, it is also important to gather information about related or other health concerns. After the chief concern is documented, ask another open-ended question to elicit additional information: "Is there anything else that worries you about Candy?" Now the parent might want to talk about Candy's temper tantrums. Unless asked about a second problem, a parent can go home with the first problem cared for but the second one still not addressed. When the parent arrives home and Candy begins stomping her feet in the car, unwilling to go into the house, the parent will feel that the health care Candy received was less than adequate because she did not receive help with this concern.

Do not assume parents will always reveal their most important concern in the initial minute of an interview: discussing certain symptoms such as constipation can be embarrassing for parents (Bisanz, 2007). It also can be frightening to put a fear a child has a serious illness into words. As long as a concern hangs as a nebulous thought in the mind, it is easy to tell oneself it may not be true. Only when a parent voices the thought ("Do you think Candy is retarded?" "Do you think this is leukemia?" "Could this be inherited?") does the fear become real. Before parents dare to speak openly this way, they must trust health care providers not to treat their statement lightly. For this reason, it is helpful to repeat the question about a second concern once more at the very end of the interview.

Health and Family Profile

Before pursuing the past history or development of a child, document the circumstances in which the child lives. A good introduction to a health and family profile is a sentence such as, "Before we talk about any past illnesses or happenings with Candy, let me ask you some questions about her health and your family as a whole."

Important information concerning a child's current health status includes:

- Who is the child's primary health care provider?
- How often is the child seen for routine health examinations?
- Are the child's immunizations up to date?
- What is the child's general state of health? How does it compare to the child's health 1 and 5 years ago (if appropriate)?
- Does the child have any known allergies?
- Does the child have a chronic illness or disability?
- Is the child taking any prescription medications? Over-the-counter medications? Home or folk remedies, such as herbal remedies?
- Is the child undergoing any treatments?

Important information concerning the family includes:

- Is the parent married, single, or divorced?
- Is the family nuclear or extended?
- How many children are in the family?
- What are the family's current living arrangements?
- What are the parents' occupations? (This helps establish the family's socioeconomic level, and time available for child care.)
- If both parents work, how do they manage child care?

Obtaining a health and family profile is sometimes delayed by medical interviewers until the end of the interview, when, theoretically, a parent or child is more comfortable and will answer these personal questions more readily. However, by following a nursing model and obtaining the information earlier in the interview, the health care practitioner can better assess the child and evaluate data.

Day History

The child's current skills, sleep patterns, hygiene practices, eating habits, and interactions with the family can all be elicited by asking a parent to describe a typical day. Day histories are fun to obtain because most parents are eager to describe their day with their child and information gained this way is surprisingly rich and pertinent, much more so than if parents are just asked how their child sleeps, eats, or plays.

Begin by asking, "Was yesterday a fairly typical day for Candy?" (The parent says yes, it was.) "Describe for me everything Candy did yesterday, beginning with when she first woke up." Some parents offer this information in great detail; with others, it is necessary to backtrack for particular details: "What did she eat for breakfast? Does she use a fork and spoon? Does she sit in a high chair or on your lap?"

Play. Play, the work of children, reveals a great deal about the child's development and overall well-being. Important questions to ask about play include:

- Is Candy kept in a playpen or given room to run?
- What is Candy's favorite toy?
- Does she play active, chasing games or engage in quiet, pretending types of activities?
- Do you (the parent) spend time reading to the child?
- Do you (the parent) play with the child or let the child play alone? (This allows for an estimation of the quality of interaction during the day.)

Sleep. Every child needs adequate rest for healthy growth and development. Poor sleep patterns can often reveal a psychosocial or physical health problem. Important questions regarding sleep include:

- When the child sleeps, how long does she sleep?
- Is falling asleep a problem?
- Where does she sleep? Does she have night terrors?
- Does she sleepwalk?
- Does she wet her bed (depending on whether the child is toilet-trained)?

Hygiene. Good hygiene practices promote healthy teeth, gums, and skin, prevent infections, and improve self-esteem. Poor hygiene may reflect neglect, depression, drug abuse, or poor living conditions. Important questions regarding hygiene include:

- How much self-care does the child do?
- Does the child take baths or showers?
- Does the child brush her teeth? How often? Does she floss regularly? (Responses depend on the age of the child.)
- Does the child wash her hands before snacks and meals?
- Has there been a recent change in hygiene practices?

Nutrition. Nutritional assessment is an important portion of a health assessment because it influences health so strongly (Rolfes, Pinna, & Whitney, 2009). Characteristics of a nutritionally healthy child that can be revealed by assessment are summarized in Table 34.2. Food and nutrient intake risk factors are summarized in Box 34.3.

TABLE 34.2 ✻ Physical Signs of Adequate Nutrition

Assessment	Finding
Overall impression	Alert, with good energy level; positive mood
Hair	Shiny, strong, with good body
Eyes	Good eyesight, particularly at night; conjunctiva moist and pink
Mouth	No cavities in teeth; no swollen or inflamed gingivae; no cracks or fissures at corners of mouth; mucous membrane moist and pink; tongue smooth and nontender
Neck	Normal contour of thyroid gland
Skin	Smooth; normal color and turgor; no ecchymotic or petechial areas present
Extremities	Normal muscle mass and circumference; normal strength and mobility; no edema present; no tender joints; normal reflexes; legs not bowed
Gastrointestinal	No diarrhea or constipation present
Finger and toenails	Smooth, pink; not cracked or broken
Height and weight	Within normal limits on growth chart
Blood pressure	Normal for age

Taking a history of a child's food intake can help determine whether there are any foods missing in a typical meal plan or whether any quantities seem inadequate or excessive. Be certain to assess not only the quantity of food eaten but the quality as well; for example, for the infant, cereal should be iron fortified.

Food intake is best obtained by asking a parent to describe a typical day (24-hour recall), listing what the child ate for each meal and between meals as well. With an older child, the 24-hour recall can be a joint parent–child venture. Providing this history can be difficult when the child consumes some meals at home and others at day care or school. It may be necessary to ask for a weekend history to get a complete picture.

When assessing the adolescent, take a 24-hour recall nutritional history without a parent present, if possible. In front of a parent, adolescents may add nutritional foods to a food intake history or leave out foods they have eaten, such as milkshakes, potato chips, or pizza, to avoid a lecture later; on the other hand, they may leave out healthy items or add less desirable ones because they may enjoy the obvious parental disapproval, indicative of their rebellion against adult authority.

BOX 34.3 ✻ Food and Nutrient Intake Risk Factors

History or evidence of any of the following may pose a potential nutritional risk:

- Intake less or greater than standard for age, calories, protein, or activity
- Intake less or greater than standard for nutrients such as vitamins and minerals
- Unusual food habits, such as pica, faddism, and meal skipping
- Inappropriate use of supplements (vitamins, minerals, fortified food products)
- A physician's order for NPO or a clear liquid diet for more than 3 days without enteral or parenteral nutrition
- Inadequate transitional feeding, enteral support, or parenteral support
- Minimal or no intake from a major food group
- Fluid intake less than output
- Eating or feeding disorders such as bulimia
- Food allergies
- Restricted diet

After taking a history of a child's food intake, determine whether the child is receiving foods that comply with the recommendations of the food guide pyramid (see Appendix K). If whole food groups are absent or grossly inadequate, follow-up evaluation should include a food frequency record as a double-check to see if the 24-hour recall was truly representative of a usual day. Remember that children do not have to eat food from all groups at every meal, as long as they eat from them every day. If parents think in terms of days rather than meals, it allows them to exert less pressure on a child to eat at each meal.

Be sure to consider the role of food preferences and cultural, lifestyle, and financial variations when assessing food intake. The number of meals eaten at home versus outside the home, the form and content of traditional meals cooked at home, and the pattern of meals should all be considered. Any religious dietary restrictions should also be obtained. Do not appear critical of a child's diet. If you convey dismay at erratic eating habits, parents or older children (especially adolescents) may begin to fabricate a food history to make it seem more acceptable.

Past Health History

For a past health history, ask whether a child has ever had any serious illnesses. Parents do not generally think of childhood diseases such as measles, chickenpox, and mumps as serious illnesses; inquire about these separately. Also inquire about the child's immunization history and whether the immunizations are up to date for the child's age. (See the discussion of immunizations later in this chapter.) Has a child had any accidents (unintentional injuries)? Any surgery? Parents may not think of a tonsillectomy as surgery because there were no stitches; ask about that separately. Did a child ever ingest anything that was inedible or harmful? Has a child been hospitalized for any reason? How many times has a child been seen in an emergency department? These last questions provide information about the degree of adult supervision, and possibly clues to abuse (Riley, 2007).

Information about the outcome of past illnesses is as important to obtain as information about the illnesses themselves. If the child had otitis media (middle ear infection) at age 2 years and received an antibiotic and recovered without complications, the parent has every reason to be confident that the child will get better from a present illness also; the parent has confidence in health care personnel. If the child had an allergic reaction to the antibiotic or was left with a hearing difficulty from the previous illness, parents may distrust the care being given to their child now; they may not follow instructions well, thinking nothing works anyway. Or the parents may need extra support to follow instructions. This is important information for planning care.

When parents report a past health concern or illness, be sure to ask for details of the illness. This can help to minimize inaccurate data and ensure that the present and future care of the child is appropriate. For example, parents might believe their child is allergic to an antibiotic because while the child was taking the drug he developed diarrhea. There is a strong possibility the diarrhea was associated with the reason for taking the antibiotic, not with the drug itself. In this example, you would want to ask about specific symptoms and record what the parent says about allergies so the person who prescribes medication for the child can decide whether a true allergy exists.

The health of children is affected by their mother's health during pregnancy. For children under age 5 years, therefore, a pregnancy history is usually obtained.

Pregnancy History. For a pregnancy history, document which pregnancy this was for the mother. Were there complications in any past pregnancies? Abortions or miscarriages? Stillbirths? Children born prematurely? A history of the pregnancy of the child being assessed can begin with a question such as, "How was your pregnancy with Candy?" This allows the mother to answer in both physical and emotional areas. After exploring details mentioned by the mother, ask about specific events that are known to occur with pregnancy that may have had an effect on a fetus, such as:

- Did the mother have any complications such as bleeding, falls, swelling of hands and feet, high blood pressure, or unusual weight gain?
- Did she take any medication?
- Were any radiographs taken?
- Did she smoke cigarettes, drink alcohol, or use recreational drugs?
- Did the pregnancy end early or late?

Because life contingencies such as loss of finances or illness in the family during a pregnancy may affect a parent's ability to form a bond with a child, the emotional experiences of a woman during pregnancy are also important to obtain. Ask if the parents planned the pregnancy. A question such as, "A lot of pregnancies come as a sort of surprise. Is that how it was with Candy?" or "Some unmarried women want to have children and some don't. How was it with you?" lets parents know you will nonjudgmentally accept any answer they give.

Next, review labor and birth. Questions to ask include:

- How long was labor? Was it what you expected it to be?
- Were there any complications? Was the birth vaginal or cesarean?
- Was anesthesia used for birth?
- Was the baby born vertex (head-first) or breech?

Ask about the health of the child at birth as well. Questions to ask include:

- Did the baby cry right away?
- Did the infant room in or need care in a special nursery?
- Did the infant need special procedures or equipment at birth?
- Was there cyanosis or jaundice?
- Was the infant discharged from the birth setting with the mother?
- How did the parents feel about having a boy or girl?
- How did it feel for them to be new parents?

Family Health History

Because some diseases are inherited or familial, it is important to know which ones occur in a family. Ask if any family member has heart disease (childhood or adult type), kidney disease, a congenital anomaly, seizures, diabetes (type 1 or 2), tuberculosis, a sexually transmitted infection, or allergies or is cognitively challenged.

Review of Systems

The last step in a health interview is a summary of body symptoms or a **review of systems.** Again, make certain to introduce this part of the history with a transition statement; otherwise, parents may think that the local problem (vomiting) they were describing suggests other problems. For example, a statement, such as, "I'd like to ask about different parts of Candy's body, from her head down to her toes, just to be certain I don't miss anything" provides a transition.

Although the important items to be covered in a review of systems differ according to the age of the child, a basic list is shown in Box 34.4.

A review of systems covers a lot of ground, but it generally takes no more than 5 minutes. However, do not rush through the questions so quickly that a parent does not have time to answer or begins to believe this part of the interview is only an unimportant exercise ("Has Candy ever had nausea/vomiting/diarrhea/painful joints/broken bones?") All the questions are important. If a child has any of the symptoms described, an entirely new area needs to be explored.

BOX 34.4 ✻ Review of Systems

The following questions provide a guide when completing a review of systems:

Neuropsychiatric symptoms: Has the child ever had seizures? Head injury? Attention problems? Depression? Aggressive behavior? Has the parent ever had such difficulty rousing the child that the parent believed the child was unconscious? Have there been any problems with suspected substance abuse?

Eyes: Has the child had difficulty with eyes not focusing? Eye infection? Does the parent have any reason to believe that the child does not see well? Does the child wear eyeglasses? Contacts?

Ears: Ear infections? Drainage from the ears? Ear aches? Tubes in ears? Any infection from piercing? Reason to believe the child does not hear well?

Nose: Frequent drainage or cold symptoms? Difficulty breathing? Nosebleeds?

Mouth: Difficulty with teeth or teething? Mouth infections? Has the child seen a dentist (if older than age 2 years)? Does the child chew tobacco?

Throat: Throat infections? Difficulty swallowing?

Neck: Masses or swelling? Stiffness? Does the child hold the head and neck straight? (Torticollis or wry neck will make the child hold the head crookedly; children with poor vision also may cock their heads to the side to try to see better.)

Chest: Is breast development in girls appropriate for age? For adolescent girls over 14 years and Tanner stage V, ask about yearly breast examination.

Lungs: Breathing problems? Infections? Pneumonia? Asthma? Does the child smoke any substance?

Heart: Has a physician ever said there was difficulty? What exactly was said?

GI system: Has there been an eating problem? Frequent nausea? Vomiting? (Ask separately from nausea; children with pyloric stenosis [obstruction of the pyloric opening of the stomach] have vomiting but no nausea; children with a brain tumor may also have vomiting but no nausea; pregnant teenagers may have nausea but not vomiting.) Diarrhea? Any constipation? Is the child toilet-trained? Any difficulty with this?

Genitourinary system: Pain or burning on urination? Blood in urine? Does the child have a good urine stream? If a girl is age 10 years or older, has she started menstruation? Any problems with menstruation? If an adolescent male, has he begun testicular self-examination? If an adolescent, is the child sexually active? Using contraception? Want more information on contraception? Ever had an STI? (To protect privacy, it is essential to ask the adolescent, not the parents, questions regarding sexuality.)

Extremities: Painful or swollen joints? Broken bones? Muscle sprains? Is the parent pleased with the child's coordination?

Skin: Rashes? Lesions such as warts?

Immunizations: What immunizations has the child received to date?

Conclusion

A health history should close with one last open-ended question: "Is there anything more about Candy we should know?" or "Is there anything I didn't mention you want to ask about?" A parent may have been reluctant to bring up something earlier. Asking this final question gives a parent a final opportunity to do this.

✔ Checkpoint Question 34.1

You take a health history on Keoto from her father. What question should you ask at the end of every interview?

a. Do you have a ride so you can get home?
b. Is there anything else you'd like to discuss?
c. Am I a good interviewer? I'm trying hard.
d. Do you have another child who also needs care?

PHYSICAL ASSESSMENT

Mastery of physical examination technique is essential to incorporating physical assessment data into the assessment step of the nursing process, so physical assessment, along with health interviewing, is one of the most frequently practiced skills of a nurse. The scope and extent of pediatric physical assessment vary, like health interviewing, depending on the circumstances of each health visit. Sometimes only a single segment is required to obtain the information needed. For example, if a child has a gastrointestinal disorder, assessment might be only a brief, multisystem examination concentrating on the gastrointestinal system such as mouth, abdomen, and rectum and fluid status (condition of skin turgor, lips, and mucous membranes). At a first health care encounter, however, children usually receive a complete physical examination.

Purpose and Techniques

The actual process of physical examination involves four separate techniques (see also Box 34.5):

Inspection is used to determine whether there is redness or swelling or any break in the skin.
Palpation yields information on warmth and edema.
Percussion helps determine the consistency of tissue beneath the surface.
Auscultation reveals the presence of sound.

These techniques are usually carried out in the above order in each area of the body except the abdomen (auscultation should follow inspection and precede palpation of the abdomen, because handling the abdomen may obliterate bowel sounds). Findings from performing these techniques strengthen or validate history findings and help determine whether a problem requires immediate action (Askin, 2007).

Use physical examination to complement the questions asked when a parent describes some symptom a child is experiencing. If parents say they think their child has pain, for example, ask about the duration, intensity, frequency, associated symptoms, and any action or activity that precipitates the pain. Then examine the area for signs of inflammation and palpate for tenderness.

Effective use of physical assessment skills takes practice. Palpating an abdomen, for example, is a simple procedure; recognizing abdominal pathology through palpation is a more complicated skill. It is difficult to distinguish between normal liver tissue and a distended liver, for example, until both these conditions have been felt many times.

BOX 34.5 ✻ Techniques of Physical Examination

Inspection: Examining a child or adolescent initially with your eyes or nose, being alert to visual indications or odors that may point to a health problem.

Palpation: Examining by touch and can be either light or deep touch. Use light palpation before deep palpation so the child or adolescent does not tense muscles and make light palpation difficult. The tips of your fingers are most sensitive to texture, vibration, consistency, and contour; the back of your hand is most sensitive to warmth. *If a child has a sensitive or painful body part, palpate that area last.* Otherwise, the child may be unwilling to allow you to touch other parts for fear of additional pain.

Percussion: The assessment of a body structure by determining the sound you hear in response to striking the part with an examining finger and then interpreting the sound. Dense body areas such as bone have a dull, flat sound; those filled with air, such as lungs, are resonant. If an organ is stretched (a distended bladder), it has a hyperresonant or low and hollow sound. An organ stretched to an even greater point of distention has a tympanic or extremely hollow, ringing sound.

Auscultation: Listening to sounds that are either discernible to the ear (wheezing or heavy breathing) or, as in most cases, made louder by means of a stethoscope. Always listen for four qualities of sound: duration, frequency, intensity (loudness), and pitch (high or low).

Equipment, Setting, and Approach

When performing a complete physical assessment, you will need the following equipment: a thermometer, a stethoscope, a tongue depressor, an ophthalmoscope, an otoscope, a sphygmomanometer, a tape measure, a tuning fork, a reflex (percussion) hammer, rubber gloves, and perhaps a client drape or gown. Nurses who work in community settings or clients' homes must be sure to carry any equipment that may be needed with them.

Be certain the temperature in an examining room is comfortable, and provide privacy. Change paper table covers between children to avoid possible spread of illness.

During a complete physical examination, every part of the child's body should be exposed for inspection. To protect against chilling and to provide for modesty, expose body parts individually and only for the amount of time necessary for the examination. As examining body parts such as the mouth or an open lesion exposes your hands to body fluids, as part of infection control precautions, wear gloves as appropriate during an examination.

People have the right not to have another person touch their body unless they permit them to do so. It is essential, therefore, to inform children it is necessary to touch them for a physical examination, and tell them what is happening at each step during the examination so they know when they will be touched such as saying, "Next I want to look at your throat." If some action will cause discomfort, such as deep palpation of the abdomen, offer fair warning: "You'll feel pressure for a minute." Such explanations are also psychologically reassuring because they prevent surprises.

Assume that adolescents will cooperate in placing themselves in whatever position is required to inspect body parts unless they are short of breath or in some other way unable to cooperate. Small children may not cooperate as readily and may need to be restrained during an examination of body parts such as the nose, throat, and ears. Proper restraint enables an examiner to see well and also to ensure that the instrument used will not accidentally injure a child. As a rule, do not ask parents to restrain during any procedure in which a child will feel threatened or feel pain; parents are best used as protectors and comforters. Some procedures, such as ear examination, do require a strong restraining hand, and this can be frightening to children. Urge parents to do this with a positive approach such as, "I'll help you keep your head still."

Variations for Age and Developmental Stage

Techniques of physical examination should be tailored to the age and developmental stage of the individual being assessed (Table 34.3). Expected findings also depend on the child's age and developmental stage.

TABLE 34.3 ✻ Techniques of Physical Examination Based on Child's Age

Age	Techniques
Newborn	Undress only the body part being examined or use a radiant heat warmer to conserve heat (be certain all body parts are exposed during examination). Examine heart and respiratory systems first before the newborn cries, then follow head-to-toe procedure, performing all manipulative procedures such as throat and eyes last. Examine newborn with parents present, using this assessment time to teach them about normal appearance and development.
Infant	As with newborns, begin examination with heart and respiratory assessment, then follow head-to-toe procedure, performing all manipulative procedures such as throat and ears last. Begin examination while parent holds infant in arms or lap to calm the child. Talk to the infant as you proceed; infants calm to sound of your voice or the feeling tone that you radiate as much as they do to what you actually say. A positive tone ("This is like a game") therefore often brings better cooperation than a strict, businesslike approach. Infants older than 3 mo like to handle tongue blades. They can be distracted by brightly colored toys while you listen to their heart or lungs. They cooperate best if a parent holds them for major portion of examination. Offering a bottle of water or pacifier may be necessary during heart assessment.
Toddler	Allow toddler to handle equipment; include games, such as blowing out otoscope light, to relax child. Ask parent to remove clothing or allow child to do it independently. Use head-to-toe procedure; leave uncomfortable procedures such as throat and ear examination for last.
Preschooler	Use games such as "Simon Says" to ease child's fright. Ask child to undress; do not remove underpants. Keep in mind that preschoolers are extremely threatened by intrusive procedures. Thus, they are frightened of examining instruments. Allow them to handle instruments before use. Assure them that instruments do not hurt. Children up to school age often need to be restrained for ear and throat examination because they grow fearful about procedures performed on a part of the body they cannot see (ears) or about a throat examination that may be uncomfortable.
School-age child	Ask whether child wants parent present or not. Proceed with head-to-toe assessment; leave genitalia for last. Allow child to undress except for underpants; supply gown. Explain equipment and reasons for procedures. Teach whys and hows of procedures.
Adolescent	Ask if the adolescent wants parent present or not. Teach adolescent about good health care during examination. Comment on body parts as you examine them: "Your heart sounds good," "Ears look fine." Sometimes adolescents are so concerned with a part of their body (a supernumerary nipple, for example) that they are unable to voice this concern. A comment such as, "This is a supernumerary (extra) nipple. Does it ever worry you that you have that?" may help the adolescent to talk about what has indeed been a concern for years. Use head-to-toe procedure; leave genitalia for last. Include health teaching on testicular self-examination.

Newborn

All newborns receive a physical examination immediately after birth and again after the first 24 hours of life. When examining newborns, remember that maintaining body temperature is one of the newborn's most difficult tasks (McCall et al., 2009). Cover body areas that are not being directly examined. Take axillary or tympanic temperatures to prevent rupture of rectal mucosa. Assess the heart rate apically because peripheral pulses may be too faint to be counted accurately. Be certain to take femoral pulses in newborns to rule out coarctation of the aorta. Include newborn reflexes, head circumference, and an assessment of gestational age (see Chapter 18) as routine parts of the examination.

Infant

Infants are usually examined most effectively if a parent holds them during most of the examination. Use an "isn't this fun?" or "this is a game" approach. As a rule, assess heart and lung function first; do intrusive procedures such as ear and throat assessment last so an infant does not cry and complicate the remainder of the examination. Blood pressure is still not taken routinely. Include assessment of newborn reflexes until 6 months of age; continue to take the heart rate apically and the temperature in the axilla or by tympanic membrane. Measure head circumference for a full year.

Toward the end of the first year, children become fearful of strangers. Taking an extra minute to become well acquainted with an infant at the beginning of an examination can help to counteract this problem.

Toddler and Preschooler

Both toddlers and preschoolers may be afraid of examining equipment. To alleviate their fears, let them handle items such as stethoscopes, otoscopes, and blood pressure cuffs before the examination (Fig. 34.1). Leave intrusive procedures such as assessment of the genitalia, ears, and throat until last. Give generous praise for cooperation (anything short of hysterical screaming or kicking is good cooperation for intrusive procedures in this age group). Box 34.6 describes ways parents can prepare children of this age for assessment.

Begin to include blood pressure as part of routine assessment at 3 years of age; taking an oral temperature by an electronic thermometer, rather than a tympanic temperature, can also begin at this age. Before beginning an examination, establish a good rapport with the child's parents, because children this age sense parental trust or suspicion.

FIGURE 34.1 Children need the opportunity to play with examining equipment so they become more familiar with it and less frightened by it.

BOX 34.6 ✻ Focus on Family Teaching

Suggestions for Preparing a Child for a Health Assessment

Q. Candy's father asks you, "How can I best prepare my 2-year-old for a preschool health exam?"

A. Here are some suggestions to help prepare a child for a health assessment:

- Promote the attitude that a health visit will be a positive experience.
- Bring a comfort item from home (favorite doll or toy).
- Never threaten the child that if she is not good, a doctor or nurse will punish her.
- Review with your daughter what she can expect during an assessment (a health care provider will ask some questions of her parent; she or he will then look at the child's head, hands, etc.).
- If she has been taught not to let strangers touch her body (as she should have been taught), reassure her that it is all right for the health care provider to examine her.
- Dress your daughter in clothing that is easy to remove and replace so you can dress her quickly after an examination. This is a way of assuring her that the examination is over.

School-Age Child and Adolescent

Some children of this age may still be unaware of what a physical examination includes and whether it will cause discomfort. Offer good explanations so they are not frightened by the unknown. Provide older children with a choice about having a parent with them during the examination. Some may enjoy having a parent with them; others may resent their presence. Adolescents are often worried about some normal physical finding such as a mole or supernumerary (extra) nipple. Make a habit of commenting on such findings—"This is a mole on your hand; that's normal"—as a means of both reassurance and health teaching. Be certain to assess height and weight as more children are obese than ever before. It is increasingly important to take blood pressure beginning in early school age also because as more children are overweight today, more have elevated blood pressure (Chiolero et al., 2007). Obesity in school-age children and adolescents is also associated with the development of type 2 diabetes mellitus and future cardiovascular disorders. There is also an association between overweight and suicide in children (Whetstone, Morrissey, & Cummings, 2007).

School-age children and adolescents are particularly modest. Respect this by careful use of gowns or drapes. Teach testicular self-examination for boys beginning at about age 13. The American Cancer Society (ACS) recommends that women should be taught to perform monthly breast self-examinations when they reach 20 years of age (ACS, 2008).

✔ Checkpoint Question 34.2

Keoto's sister is 2 years old. At what age should you include blood pressure as a routine procedure?

a. 1 year.
b. 2 years.
c. 3 years.
d. 6 years.

Components of Physical Examination

Presented here are the components of a routine or general physical assessment. Physical examination may be done in any order, but traditionally the order proceeds from head to toe, examining each body part thoroughly before moving on to the next. With infants and young children, however, it is easiest to begin with the heart and lungs; this is because if the infant cries, findings in these areas become difficult to assess over the sound of crying.

If abnormalities are discovered during an examination, further assessment will be necessary. A complete neurologic examination, for example, is not routine and so is not included here (see Chapter 49 for details on a neurologic examination). It is important to recognize what a "general" physical examination of this nature entails so you can interpret the extent of assessment a child has received when the parent states, "He had a routine physical."

Vital Sign Assessment

Vital signs refer to temperature, pulse, respiration, blood pressure, and whether the child has pain (the state of vital bodily functions including heart and lung function, metabolic rate, and comfort level). Temperature is an important assessment in children because it can reveal subtle infection that has not as yet become obvious by other signs (Sur & Bukont, 2007). Because of the important information they provide, measurements of these signs are recorded not only with complete physical examinations but in many other instances of care. Techniques of these measurements and the nursing responsibilities that accompany them are discussed in Chapter 37. Remember that blood pressure in children can be elevated if they are anxious in a medical setting the same as happens to adults (Howell et al., 2007).

FIGURE 34.2 General appearance assessment reveals that this child is well proportioned and active.

General Appearance

Physical examination begins with inspection of general appearance to form an overall impression of a child's health and well-being and to pinpoint specific body areas that will need detailed assessment (Fig. 34.2 and Box 34.7). Assess such areas as:

- Does the child appear well or ill overall?
- Is the child's height and weight proportional?

TABLE 34.4 ✻ Significant Body Odors

Source of Odor	Possible Cause
Breath	
Alcohol	Possible recent ingestion (important if coma or neurologic symptoms are present as cause of abnormal functioning)
Camphor	Mothball ingestion
Halitosis (bad breath)	Poor dental hygiene, lung infection; foreign body in respiratory tract
Burnt rope	Marijuana use
Sweet	Acidosis (seen in a child in diabetic coma)
Body	
Stale urine	Incontinence; poor kidney functioning leading to uremia; infrequently changed diapers; neglect
Sweat	May imply that child is too fatigued or stressed to maintain hygiene
"Spoiled fruit"	Wound infection
Sweet	*Pseudomonas* infection
Urine	
Maple syrup	Protein metabolic condition
Musty or mousy	Phenylketonuria or a protein metabolism disorder
Ammonia	Urinary tract infection or poor hydration leading to concentrated urine
Stool	
Putrid	Fat in stool from inadequate absorption

- Does the child appear well nourished?
- What is the child's color: pale? yellow (jaundiced)? cyanotic (blue)?
- Is posture normal? (Children who are in pain often assume an abnormal posture for relief.)
- What is the child's hygiene level (fatigue or illness can cause poor hygiene)?
- Are lesions or symptoms of a specific illness present?
- Are there any significant body odors (Table 34.4)?
- Does the child appear relaxed or distressed? Lethargic or active?
- Is breathing easy or distressed?

Mental Status Assessment

A mental status assessment is also made early in an examination as a complement to general appearance. As with general appearance, additional information is gained on mental status throughout the entire examination.

Begin by assessing a child's level of consciousness: Is the child alert? Assess children's orientation, or awareness of person, place, and time (awareness of who they are, where they are, and the date) if they are over preschool age. If an infant, does the child "attune" or look aware of surroundings? Assess the appropriateness of behavior and mood: for example, is a child hostile, frightened, or relaxed? At some point in the examination of children above preschool age, ask questions that test recent memory (what they ate for breakfast) and distant memory (who was their first-grade teacher).

Body Measurements

Body measurements are important determinants of health in children because with chronic illness the body expends so many nutrients combating the destructive process of the disease that normal height and weight cannot be maintained. Conversely, overweight (obesity) can lead to illnesses such as heart and lung disease later in life. Obesity has become such a health problem that it is considered an epidemic in many parts of the United States (Singhal, Schwenk, & Kumar, 2007).

Weight and Height. In children, both height and weight are good determinants of health and normal nutrition. Until they can stand well, infants are weighed laying or sitting on an infant scale. Because diapers can be heavy in proportion to total body weight, weigh infants nude. Always keep a protective hand over an infant on an infant scale (hovering but not touching), as infants squirm readily and there is danger of them falling. Always cover scales with scale paper before weighing to prevent spread of infection from one child to another (Fig. 34.3).

A

B

FIGURE 34.3 A nurse or caregiver should remain nearby while weighing the infant or toddler.

FIGURE 34.4 Children who can stand independently can be weighed on a regular standing balance scale.

Children older than age 2 years are weighed on standing scales, in street clothes (no shoes), or, if in a hospital, in a gown or pajamas (see Fig. 34.4). If children are going to have serial weights (weighed every day), be sure they wear the same clothing every time they are weighed so any discrepancy in weight is truly a difference in body weight and not a weight change as the result of more or less clothing. Take the weight at the same time each day (preferably before breakfast) on the same scale for greatest accuracy.

Most children and their parents want to know their weight. To convert from kilograms to pounds, multiply the kilogram amount by 2.2 (50 kg × 2.2 = 110 lb).

For accurate measurement of height for infants and older children, see Box 34.8. Plot height measurements for children on a standard graph, the same as for weight. Height and weight should follow the same percentiles. Remember that height/weight charts have been standardized for middle-class white American children, so there will be variations among children from different cultural backgrounds. The important thing to look for is consistency of measurements over time (always at the same percentile).

To assess whether weight is average for height, compare the child's weight with a standardized height/weight graph (Appendix E). In the standardized scale for children, all weights between the 10th and 90th percentiles are considered normal (statistically, a range of weights that includes two standard deviations from the mean or the 50th percentile). All children with weight below the 25th or above the 75th percentiles need close examination as they are moving close to the end points of the usual weight continuum (Chumlea, 2007).

As important as the fact that children's weight falls between the 10th and 90th percentile on growth charts is that over time the weight follows one of the percentile curves—in other words, children are not at the 80th percentile the first time they are weighed and a month later at the 40th percentile. Although both readings are within the normal range, they reflect a weight loss that would need investigation. Gaining weight in the same way could be equally serious. A child is defined as "failing to thrive" if height or weight drops below the third percentile on a standardized growth chart (Black et al., 2007). Any height or weight in this category definitely needs to be reported so its cause can be investigated.

U.S. growth charts were compiled by the CDC in the 1960s when almost all infants were formula fed, not breastfed, so breastfed infants tend to score lower on these charts (often at the 25th percentile) than might be expected. The World Health Organization has published growth charts that better reflect the weight of breastfed infants. It can be helpful to plot infant weight on these alternative growth charts to reassure parents their breastfed infant is thriving (Chumlea, 2007).

Another method to determine whether a child's weight is consistent with height is to compute the body mass index (BMI). Table 34.5 describes the formula used to calculate BMI and the implications of the values obtained (see also Appendix E).

What if... Keoto, 13 years old, weighs 93 lb? Would you be concerned? What if 6 months earlier she had weighed 110 lb and a year earlier she had weighed 105 lb?

Head Circumference. Head circumference is measured at birth and routinely on physical assessment until 1 year of age (some health care agencies measure it routinely until 2 years of age). Head growth occurs because the brain is growing, so head circumference reflects brain growth and potential neurologic function. The measurement is made by placing a tape measure around an infant's head just above the eyebrows and around the most prominent portion of the back of the head, the occipital prominence (Fig. 34.5). Babies generally push any object away from their head, so it may be difficult to carry out this otherwise simple procedure. Plot measurements on a standardized graph (see Appendix E). Head circumference should correlate with the child's length; that is, if length is in the 40th percentile, head circumference also should be. If measurements of head circumference plot at different percentiles over time, this should be reported because it implies that brain or skull growth is in some way abnormal and needs investigation.

Chest and Abdominal Circumference. Measurements of chest and abdominal circumference are not done routinely, but only when specific pathology warrants. Chest circumference is measured at the nipple line, abdominal circumference at the level of the umbilicus.

Skin

Skin is assessed in conjunction with the examination of each body region. Assess temperature, color, dryness, texture, **turgor** (amount of fluid in body tissue; Fig. 34.6), and presence of any lesions that might reveal a communicable illness of childhood.

Table 34.6 summarizes various findings that may be detected. Be certain to examine a child's total skin surface at some time during an examination. As necessary, remove and replace adhesive bandages and other dressings that could hide important findings. Be certain there is adequate lighting, especially when assessing dark-skinned children.

Box 34.8 Nursing Procedure ✻ Measuring a Child's Height

Purpose: To assess for optimal growth.

Procedure	Principle
Infant	
Until they can stand securely (at approximately age 2 years), the most accurate method for obtaining a length measurement for infants is the recumbent measuring board (Figure A).	
1. Align the infant's head snugly against the top bar of the frame and ask an assistant to secure it there. Parents can help you restrain infants for height measurements because it is a painless procedure.	**1.** Provides a starting point for measurement.
2. Straighten the infant's body.	**2.** Straightens knees to ensure accuracy. Knees are difficult to straighten in infants because they always keep them flexed.
3. Hold the infant's feet in a vertical position. Bring the foot board up snugly against the bottom of the foot.	**3.** Completes measurement.
4. If an examining table is used, mark the spots at the top of the child's head and bottom of feet and then measure between the marks.	**4.** Provides for an alternative approach.
5. Plot height measurement on a standard graph.	**5.** Allows for interpretation of findings.

A

Older Child	
For older children, a stadiometer is the most accurate method for measurement (Figure B).	
1. Have the child remove shoes.	**1.** Promotes accuracy.
2. Have the child stand straight with head held level.	**2.** Puts the child in the proper position for accurate measurement.
3. Align the measuring bar of a standing scale with the top of the head.	**3.** Determines the measurement.
4. If stadiometer is not available, place a flat object such as a clipboard on the child's head in a horizontal position and read the height at the point at which the object touches a measuring tape on the back of the scale or a flat wall surface.	**4.** Provides for an alternative approach.
5. Plot height measurement on a standard graph.	**5.** Allows for interpretation of findings.

Box 34.8 Nursing Procedure ✻ Measuring a Child's Height

B

Newborn and Infant. Newborns may appear ruddy because their layer of subcutaneous fat is thin and the intense redness of their blood circulation is visible. Erythema toxicum (newborn rash) or birthmarks (hemangiomas, mongolian spots, or nevi) may be present (see Chapter 18). After the first few days of life, a diaper rash may be present.

Toddler, Preschooler, and School-Age Child. Many children this age have minor lesions from mosquito bites or from flea bites if they own a pet. They also typically have a number of ecchymotic spots on their lower extremities from bumping into objects during active play. Ecchymotic spots on upper extremities are less common and may suggest a blood coagulation problem. In evaluating ecchymotic spots on children of all ages, though, consider the possibility of child abuse (Newton & Vandeven, 2007) (Box 34.9). Lesions, scratch marks, or excessive dryness can reveal atopic dermatitis, a common childhood disorder (Findlay, 2007).

Adolescent. At least a few acne lesions on the face or back are usually present in the adolescent. Lesions or rashes caused by allergies to cosmetics also may be seen. If a child has a tattoo or body piercing, assess the site for inflammation to be certain an infection is not beginning.

TABLE 34.5 ✻ Body Mass Index Calculation

To calculate the body mass index (BMI), divide the child's weight in kilograms by the square of the child's height in meters:

BMI (kg/m^2)	Implication
<18.5	Underweight
18.5–24.9	Normal
25.0–29.9	Overweight
>30	Obese

Head

To examine a child's head, slide a hand over the skull, assessing for irregular configurations or tenderness. Most children have a prominent occipital outgrowth; do not mistake

FIGURE 34.5 Measuring head circumference. The measuring tape passes just above the eyebrows and around the prominent posterior aspect of the head.

FIGURE 34.6 Assessing skin turgor. If the ridge of tissue does not immediately return to place, this suggests that the child is poorly hydrated.

BOX 34.9 ✻ Focus on Evidence-Based Practice

Is child abuse easy to detect from physical examination findings?

To explore this question, researchers asked 22 pediatricians, all of whom had substantial academic and clinical expertise, to evaluate and rate whether findings from child examinations indicated physical abuse. Even though the scenarios were taken from children who had been referred for abuse investigation, results showed that scenarios were rarely rated as "definite abuse" (likelihood ≥95%). Seven of 156 scenarios were rated as "no reasonable concern for abuse" (≤15% chance). Because of the wide variability in responses, the researchers recommend that health care agencies use a peer-review or multidisciplinary team approach when assessing for child abuse.

Based on the above, would you ask a colleague for a second opinion if you suspect physical abuse in a child following a physical examination?

Source: Lindberg, D. M., Lindsell, C. J., & Shapiro, R. A. (2008). Variability in expert assessments of child physical abuse likelihood. *Pediatrics, 121*(4), e945–e953.

this natural head contour for an abnormality. Assess the texture and cleanliness of hair. Children who are well nourished usually have hair of good texture; poorly nourished children tend to have dry, brittle, or limp hair. If hair is exceptionally oily, it may suggest a lack of adequate hygiene, possibly from fatigue because of an unidentified illness. If a serious protein deficiency such as **kwashiorkor** is present, the hair becomes striped with dark and light color; dark hair forms during periods of good protein intake and the light color forms during periods of protein deficit. Patches of hair loss (alopecia) suggest a fungal infection (tinea capitis), child abuse, or a possible drug reaction (chemotherapy will cause total hair loss, not patches).

Newborn and Infant. In a newborn, the head usually shows molding (an elongated shape because of pressure against the cervix before birth). A caput succedaneum or cephalhematoma from the pressure of birth may be present (see Chapter 18). Skull suture lines may be palpable. In both newborns and infants, sit the child upright and palpate the

TABLE 34.6 ✻ Skin Findings in Children That Suggest Illness

Finding	Indication
Central bluish color	Cyanosis from decreased respiratory function or cyanotic heart disease. Acrocyanosis (blue hands and feet) is normal in newborn for first 48 hours.
White color	Edema (accumulated subcutaneous fluid is stretching the skin)
Pale color	Anemia or decreased circulation to a body part
Reddened area	Local inflammation or increased systemic temperature
Linear abrasion	Scratch marks from local irritation from an insect bite, or allergic reaction
Ecchymoses (black and blue marks)	Recent injury to skin
Petechiae (pinpoint blood marks)	Blood dyscrasia (poor clotting ability)
Yellow color	Jaundice from increased bilirubin in subcutaneous tissue; carotenemia (excess carotene in skin)
Moistness	Excess perspiration from elevated temperature
Localized cold temperature	Decreased circulation to particular body part
Warm temperature	Local irritation or elevated systemic temperature
Poor turgor	Dehydration
Rash	Infectious childhood illness, excessive heat, allergy

skull for the presence of fontanelles (the places where the skull bones fuse). The anterior fontanelle is at the junction of the two parietal bones and the two fused frontal bones. It is diamond shaped and measures 2 to 3 cm (0.8 to 1.2 in) in width and 3 to 4 cm (1.2 to 1.6 in) in length. The posterior fontanelle is at the junction of the parietal bones and the occipital bone. It is triangular and measures approximately 1 cm (0.5 in) in length (see Fig. 15.2).

With the infant sitting, fontanelles should be felt as soft spots but should not appear indented (a sign of dehydration) or bulging (a sign of increased intracranial pressure). When an infant cries, cerebral pressure increases so with crying, the fontanelles may feel tense, and sometimes even the fluctuation of a pulse can be observed. The anterior fontanelle normally closes at 12 to 18 months and the posterior fontanelle by the end of 2 months. They should not be palpable after these times. The closing of fontanelles too early or too late can indicate decreased or increased brain or ventricle growth from excessive cerebral spinal fluid.

A scalp problem commonly encountered in infants is seborrhea (scaling, greasy-appearing, salmon-colored patches), or "cradle cap." Increasing the frequency of hair washing to once a day and applying baby oil to the scalp typically reduces this problem.

Toddler, Preschooler, and School-Age Child. Examine the hair of children who attend school or day care carefully for small white-yellow, sand-sized particles attached to hair strands—the eggs (nits) of pediculi (head lice). Pediculi spread easily in school-age children because of the sharing of combs and towels in school. Nits cling and cannot be readily removed from hair by running fingers the length of the hair (Sciscione & Krause-Parello, 2007). The child may have recent scratch marks on the scalp or state that the scalp feels itchy.

Also examine the scalp carefully for round circular areas (perhaps weeping in the center, crusting and scaling on the edges) that would suggest tinea capitis (ringworm, a fungal infection). Like pediculi, fungal infections can spread readily among school-age children; a prescription medication is necessary to best cure both conditions (see Chapter 43).

Adolescent. Adolescents may streak their hair with dye or arrange it in a way that requires gel, hair extensions, or use of a curling iron. Inspect to see that their scalp and hair are healthy underneath the styling.

Eyes

Observe eyes for symmetry and signs of redness (erythema), frequent blinking, crusting, squinting, or rubbing as these are signs of **conjunctivitis,** an infection of the thin conjunctiva that covers the eye globe (Patel et al., 2007). Observe lids and lashes for redness or abnormalities as well to detect a **hordeolum** or stye (an infection of the gland that lubricates an eyelash). Both conditions require an antibiotic for therapy (see Chapter 50).

Assess the location of eyes in relation to the nose (not unusually wide or narrow spaced) and the relationship of the globe to the socket (neither sunken nor protruding from the socket [exophthalmos]). Abnormalities in these areas occur in chromosomal or metabolic illnesses such as hyperthyroidism. Inspect the sclera of the eye for spots of hemorrhage (called subconjunctival hemorrhage) or yellowing. African American children often have a slight yellowing of the sclera and small black spots on the sclera; do not mistake these for abnormal findings. Assess that no sclera shows above the pupil (if it does, this is termed a sunset sign, an indication of increased intracranial pressure).

Palpate each eye globe with the eyelid closed to assess for tenseness, a finding suggesting glaucoma (rare in children). Determine whether the eyelids completely close (edema or neurologic illnesses may make eyelids too short to do this) when the child shuts the eyes. Also determine whether the lids retract far enough so they do not obscure vision when the child opens the eyes. When a lid obscures vision, a condition termed **ptosis,** it generally denotes neurologic involvement. Differences in Western and Eastern eye creases are shown in Figure 34.7.

Examine the inner lining of the lower eyelid (the conjunctiva) by pulling the lid down slightly with a fingertip. Here, the mucous membrane should appear pink and moist. In children with anemia, it often appears pale; with allergy or infection, it may appear unusually red and irritated. Do not initiate a blink reflex by touching the cornea with a wisp of cotton, as can be done in adults; this is momentarily painful and frightening to children.

In addition, observe whether the eyes appear to be in good alignment. **Strabismus** refers to eyes that are not evenly aligned. If an eye is always turning in, the condition is **esotropia;** if it always turns out, **exotropia.** Two screening procedures for straight eye alignment include a Hirschberg's test and a cover test. During a Hirschberg's test, the light of

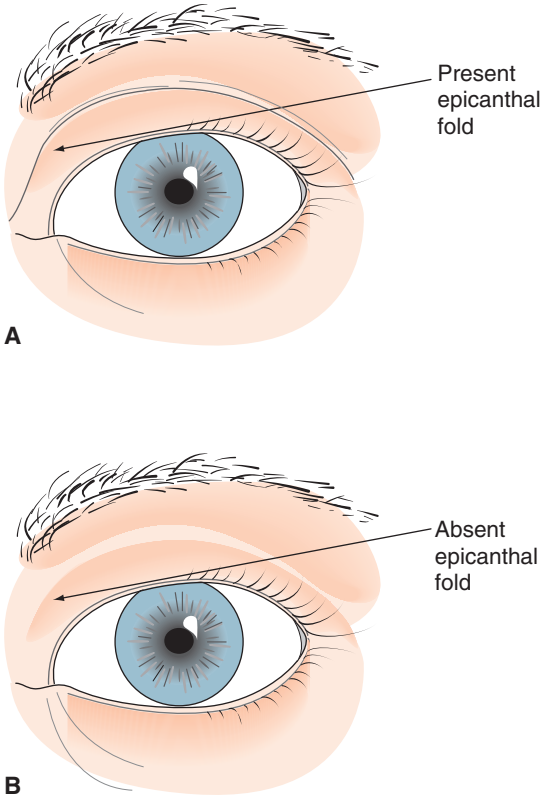

FIGURE 34.7 Differences in eye formation. (**A**) Western. (**B**) Eastern. The extra inner fold of tissue is an epicanthal fold.

FIGURE 34.8 Testing good eye alignment by Hirschberg's test. The child is asked to look directly at the light of the otoscope. The light reflex on the pupils of both eyes will be equal if the eyes are in straight alignment.

an otoscope should reflect evenly off both pupils if they are in equal alignment (Fig. 34.8).

To perform a cover test (Fig. 34.9),

- Have children look at an attractive object approximately 4 ft in front of them.
- Hold a 3 × 5-inch card over the left eye for a count of 5. If any degree of strabismus is present, the eye will wander to its misaligned position while covered.
- Remove the card and observe the eye for movement.
- As the child again fixes vision on the specified object in front, the eye will move back into line, revealing the misalignment.
- Repeat the process with the right eye. Movement after being uncovered suggests malalignment.

Some children, particularly preschoolers who have wide epicanthic folds, may appear, at a quick glance, to show misalignment. A cover test is helpful in these children. There will be no eye movement after removal of the card because there is no misalignment present, only the temporary appearance of misalignment. Reasons for true misalignment are discussed in Chapter 50.

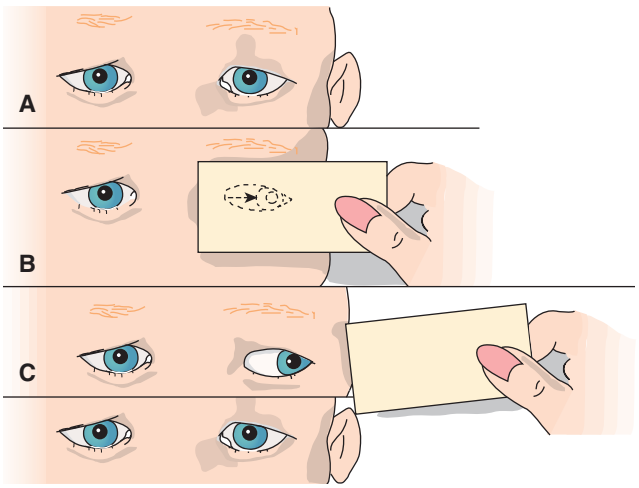

FIGURE 34.9 Cover test. (**A**) The child's eyes appear to be in good alignment. (**B**) The left eye is covered for 5 seconds. (**C**) When the card is removed, the left eye is seen to move perceptibly back to good alignment. This movement indicates that it "drifted" into a deviant position while covered, that is, that an exophoria (misalignment) is present.

Test the eyes for their ability to focus in all fields of vision also:

- Ask the child to follow a moving light (or catch the attention of an infant with a moving light) while holding the child's chin stationary.
- Move the light out to the side, then up, then down.
- Cross to the opposite side and move it up and down.
- Bring the light back to the midline and observe whether the child's eyes converge (follow the light to the nose) as the light moves in toward the nose. Infants under age 3 months cannot follow past the midline; the eyes of children under school age do not converge well.

Observe if the pupil constricts (reduces in size) in response to a light, an indication the third cranial nerve is intact. It is best to approach the child's eye from the forehead so the light suddenly appears on the pupil rather than advancing it toward the child slowly. This makes the pupil constrict more dramatically. This should occur in response to a light shining directly on a pupil (direct constriction); when one pupil constricts, constriction will also occur in the opposite eye (consensual constriction). Record that pupils are equal in size and react to light as "PERL" (pupils equivalent, react to light). If the pupil converges (moves to follow a light in toward the nose), this is charted as "PEARL" or "PERLA" (pupils equal, react to light, accommodate).

For a final step, shine a flashlight or ophthalmoscope light into the pupil. A red reflex or the red pupil that occurs with a flash photograph should appear. This is evidence that the retina is intact and the lens and cornea are clear (no tumor, cataract, scarring, or infection is present).

Newborn and Infant. Newborns often have a small, bright-red spot on the sclera (a subconjunctival hemorrhage) because the pressure of birth has ruptured a small conjunctival blood vessel. This is normal and will fade in 7 to 10 days as the blood is absorbed.

Infants can easily be tested for a red reflex, but until they are about 3 months, they cannot follow an object or light across the midline or follow a light into all six positions of gaze. Even a newborn, however, can follow a bright light to the midline. Assessing for a red reflex is important in newborns because a congenital cataract can lead to loss of central vision if not discovered early.

Toddler and Preschooler. Most young children are reluctant to let someone look into their eyes. Explaining what will happen during an eye examination is effective in reducing the child's anxiety about this part of the assessment.

School-Age Child and Adolescent. Many older children wear contact lenses (a red reflex is visible with a contact lens in place); some may be nervous about having their eyes examined because they know they should be wearing prescribed eyeglasses but are not wearing them because they do not like their appearance. Observe carefully for pupillary appearance and ability to constrict in adolescents to rule out

drug abuse. Many adolescent girls are anemic and so have pale conjunctiva.

Nose

Observe the nose for flaring of the nostrils (a sign of need for oxygen). Using an otoscope light, observe the mucous membrane of the nose for color (it should be pink; pale suggests allergies, redness suggests infection). Note and describe any discharge. Document the septum is in the midline (displaced septa such as those that occur after facial injuries can interfere with respiration and make nasal intubation in emergencies difficult). Gently press one nostril closed and ask the child to inhale; repeat on the opposite side to ensure that both sides of the nose are patent, that is, no choanal atresia or membrane obstructing the posterior nares exists. Sinuses do not fully develop until about 6 years. For children 6 or older, palpate the areas over the frontal and maxillary sinuses for tenderness, a symptom of sinus infection. Assess the sense of smell in school-age children and adolescents by asking them to identify a familiar odor such as chocolate or an orange.

Newborn and Infant. Infants are obligate nose breathers. They cannot coordinate mouth breathing, so they become disturbed when the nose is temporarily blocked to check for patency; do this only momentarily to avoid discomfort. Most newborns have milia (small white papules) on the surface of the nose.

Older Children. Many children, preschool age and older, have upper respiratory infections that cause reddened nasal mucous membranes and a purulent discharge. In contrast, allergies cause a clear discharge and pale mucous membranes. Children who have dry mucosa because of dry air (which leads to cracking and nosebleed) may be reluctant to allow inspection of their nose. Adolescents who sniff cocaine lose nasal hair and may have excoriations or abscesses in the mucous membrane. If the child has a nose piercing, inspect the site for redness or drainage.

Ears

Observe ears for proper alignment. In the average child, a line drawn from the inner canthus of the eye to the outer canthus and then to the ear will touch the top of the pinna of the ear (Fig. 34.10). Ears set lower than this are associated with chromosomal disorders such as trisomy 13. Observe the opening to the ear canal for any discharge. Touch the pinna and watch for evidence of pain (a sign of external canal infections). Observe the area immediately in front of the ear for a dermal sinus or a skin tag (a finding that is usually innocent but may be associated with kidney abnormalities). Observe the ear lobes for redness or drainage from infected piercing sites.

To examine the ear canal:

- Straighten the ear canal by pulling the pinna gently down and back in the child under 2 years of age and up and back in the older child.
- Select an otoscope tip. Otoscope tip sizes vary; use the smallest size possible that still gives adequate visibility.
- With the ear canal held straight, insert an otoscope tip into the external canal.
- Rest the instrument on a hand, not on the child's head (Fig. 34.11). In this position, the otoscope will move with a child, avoiding the danger that the plastic tip will scratch the canal if a child should move suddenly.
- Inspect the sides of the ear canal and then locate landmarks on the surface of the tympanic membrane.

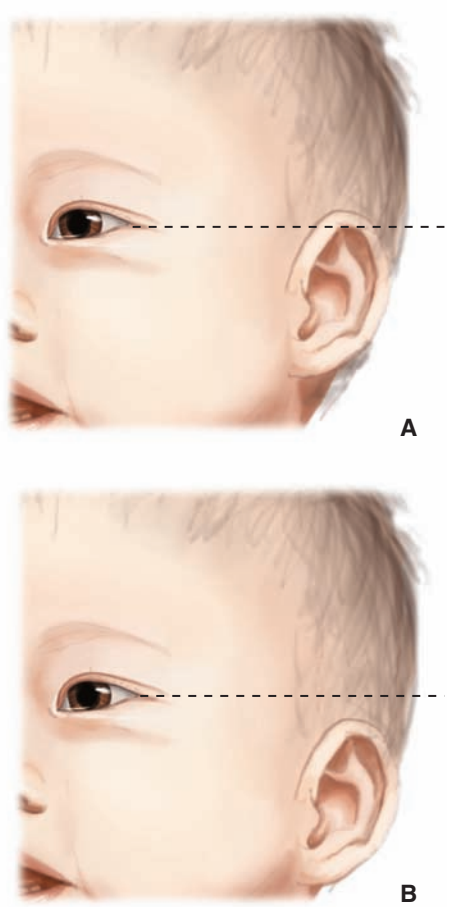

FIGURE 34.10 Normal ear alignment. When a line is drawn from the inner canthus through the outer canthus to the ear, the top of the ear pinna should meet the line (**A**). Abnormal ear alignment (**B**) is associated with certain chromosomal abnormalities.

The outline of the malleus of the inner ear through the translucent membrane is a key landmark to visualize (Fig. 34.12). The color of the membrane is pinkish gray; if the tension of the membrane is normal, a cone of light (the light reflex) should be present in one of the lower corners (at either the 5 o'clock or 7 o'clock position).

Although many children have wax (cerumen) in their ear canals, appearing as a dark-brown, glistening substance, viewing the tympanic membrane past the wax is almost always possible.

If an ear infection is present, the tympanic membrane appears reddened and often bulges forward so the malleus is no longer discernible and the cone of light is absent (Legros et al., 2008). If there is fluid in the middle ear, it may be possible to see bubbles of air through the membrane. With chronic middle ear disease (serous otitis media), the tympanic membrane may be retracted, the malleus is extremely prominent, and the cone of light is again missing. If the membrane has been torn from trauma or rupture, the jagged edge and opening to the middle ear are discernible. Inspect

FIGURE 34.11 Otoscopic examination. Note how the nurse's hand rests between the otoscope and the child's head. Should the child move suddenly, no injury to the tympanic membrane will be sustained with this technique because the otoscope will move along with the child's head.

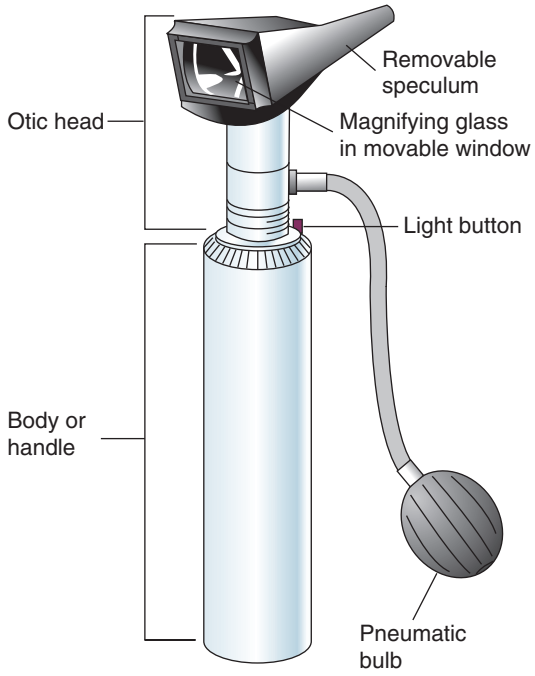

FIGURE 34.13 Otoscope with pneumatic attachment.

also for any ulcerated areas that could be a cholesteatoma or an ingrowing tumor (see Chapter 50).

Although not a routine procedure, the mobility of the eardrum can be tested by injecting a column of air into the ear canal against the drum by a pneumatic attachment on an otoscope that looks like the bulb of a blood pressure cuff (Fig. 34.13). A normal drum is freely mobile and can be seen to move with pressure on the bulb; one with fluid behind it has decreased mobility. Before introducing air, warn the child that this "tickles."

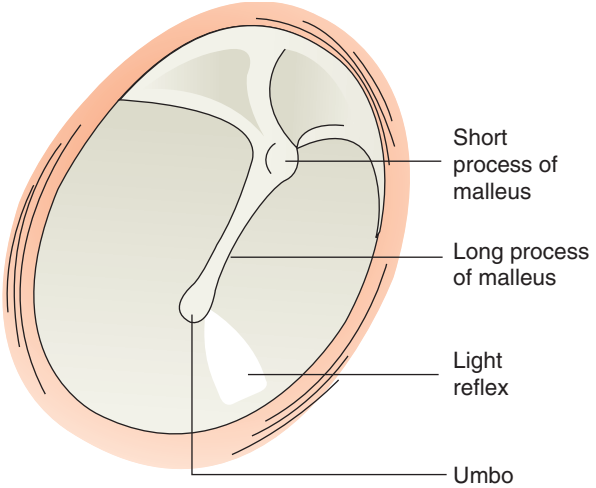

FIGURE 34.12 A tympanic membrane as viewed with an otoscope.

Finally, appraise hearing. Appraisal can be done grossly in older children by assessing their response to questions. Distract an infant with a toy; then make a sound behind the infant's back, out of peripheral vision, and watch for the response. Hearing infants will show some noticeable reaction, although they have difficulty looking directly toward or locating the sound until about 4 months of age.

Newborn and Infant. Many newborns still have amniotic fluid or vernix caseosa in their ear canal, so inspecting the ear canal is ineffective. Be certain to assess for ear level and normal pinna contour. Assess gross hearing ability—for example, by watching the infant startle to a sudden sound or quiet to the calming effect of quiet talking.

Older Children. Middle ear infection (otitis media) is a common childhood illness. This causes the ear to be painful when examined. An external ear infection (often called swimmer's ear) causes any movement of the pinna to be painful. For these reasons and because children are told many times never to put anything into their ears, they usually resist ear examinations. Explaining what is happening helps to allay any fears. Beginning with preschool age, children may have myringotomy tubes (small circular plastic tubes placed into the tympanic membrane) to relieve chronic fluid collected in the middle ear. Inspect that the area surrounding the tube is not inflamed and the tube is not merely lying in the external canal and no longer inserted into the membrane (see Chapter 50).

Mouth

Assess the external appearance of the lips, looking for symmetry and color. Ask a child to smile and frown to evaluate the mobility of facial muscles. Count the number of teeth present

FIGURE 34.14 Inspecting the pharynx in a schoolager.

and assess their condition (number missing or cavities present). Inspect the gum line (gingivae) for redness, tenderness, and edema, symptoms of periodontal disease. Inspect the buccal membrane and palate for color (pink) and the presence of any lesions. Ask a child to stick out the tongue and assess for midline position and no fasciculations (trembling). Inspect the area under the tongue for lesions in school-age children and adolescents who smoke or chew tobacco because this is the most common first site for oral cancer.

A child's tongue is normally smooth and moist. With dehydration present, it often appears roughened and dry. **Geographic tongue** is a term for the rough-appearing tongue surface that often accompanies general symptoms of illness such as fever; it may also occur normally. If a child has a pierced tongue, inspect for redness at the site. Assess that the object is secure so there is little chance of aspiration or that it is not striking tooth enamel and wearing this away.

Inspect the uvula to be certain it is in the midline. Use a tongue blade to press down and forward on the back of the tongue (Fig. 34.14). The epiglottis can usually be observed with the tongue depressed. Observe for abnormal enlargement, palatine redness, or drainage of tonsils. Although tonsillar tissue differs greatly in size, it should not be reddened or have pus in the crypts (indentations). After initiating the gag reflex in infants to view the back of their throat, always turn their head to the side so they do not choke on any saliva that accumulated in the mouth during the throat examination. Infants are less able to manage this than are adults.

Do not depress the tongue of any child who is suspected to have epiglottitis or whose glottis is inflamed. Symptoms of this condition are a sore throat, drooling, fever, difficulty with respiration, dysphagia, and a barking cough. If a swollen, inflamed epiglottis rises with the pressure of a tongue blade, it can obstruct the respiratory tract so completely the child is immediately unable to breathe.

Newborn and Infant. Many newborns have considerable mucus in their mouths because they are less able to handle swallowing because of immature muscle coordination. If a newborn has teeth, evaluate them for stability; if loose, they may need to be removed to prevent aspiration. Assess for white patches that do not scrape away from the buccal membrane or tongue (thrush), a common but abnormal finding in infants that needs antifungal therapy (see Chapter 43).

Older Children. Tonsillar tissue in children reaches its maximum growth at early school age, making many preschool children appear to be "all tonsils." As long as the tissue does not appear reddened or tender, it can be assumed to be normal for the age. Many children have irregular, pale-pink, elevated projections on the posterior pharynx as a normal finding. A stream of mucopurulent discharge in the posterior pharynx is not unusual if an upper respiratory infection and a "postnasal" flow of secretions are present. For a child with orthodontic appliances such as braces, assess carefully for pinpoint ulcers to be certain the wires are not causing undue discomfort or infection. Cavities appear as dark-brown areas on the tooth enamel. Many school-age children or adolescents have at least one present and need a dental care referral.

✔ Checkpoint Question 34.3

You typically gag children to inspect the back of their throat. When is it important *not* to elicit a gag reflex?

a. When children are under 5 years of age.
b. When a child has symptoms of epiglottitis.
c. When a boy has a possible inguinal hernia.
d. When a girl has a geographic tongue.

Neck

Assess the neck for symmetry (the trachea should be in the midline; any deviation suggests lung pathology). Observe the outline of the thyroid gland (barely noticeable before puberty because it is obscured by the sternocleidomastoid muscle) on the anterior neck. Palpate the area in front of the ear (location of the parotid gland) and smooth a hand over the location of lymph nodes at the sides of the neck and under the chin to palpate for swelling. Figure 34.15 shows the location of lymph node chains of the head and neck. Because children have so many upper respiratory infections, a few nodes that are freely movable, about the size of peas, termed "shotty" nodes because they simulate the feel of buckshot under the skin, are often present. Commonly, preauricular and postauricular nodes are palpable after ear infections, and postoccipital nodes are palpable after a scalp infection. Submental nodes generally denote a tooth abscess. Palpable submaxillary, anterior, and posterior cervical nodes follow throat infections.

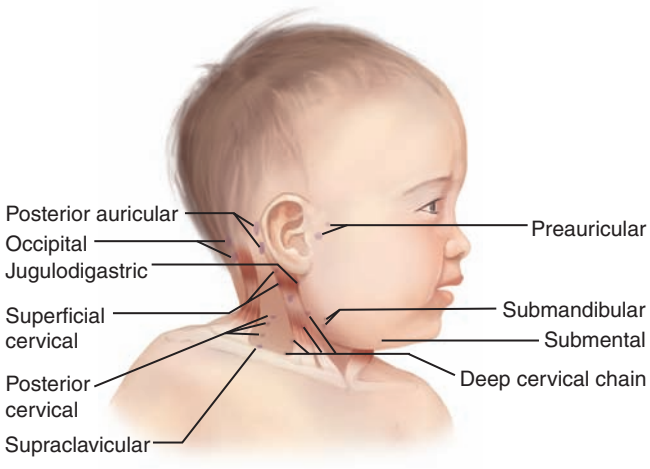

FIGURE 34.15 Location of lymph nodes.

Ask the child to move the head (or move it for the child) through flexion (touch chin to chest) and extension (raise chin as high as possible), and turn it right and left (rotation) to see that a child does this easily. Pain on forward flexion is an important sign of neurologic (meningeal) irritation.

Newborn and Infant. With infants, always assess the ability to control the head by laying the infant supine and pulling the child to a sitting position. Babies younger than 4 months of age will let their heads lag backward as they are pulled up this way; they right their heads only as they reach a sitting position. After 4 months, infants should bring their head up with them (no head lag) if their neuromuscular coordination is adequate for their age. This simple but important test yields information about overall neuromuscular control as well as neck strength.

Adolescent. In adolescents, palpate the thyroid gland for symmetry and possible nodes. To do this, press on the right side of the gland, causing it to be more prominent on the left side. Then palpate the left half to discern any irregularities (areas of hardness). Repeat on the right side. A finding of a thyroid node needs to be investigated. It may be only an innocent transient cyst, or it may be the first indication of thyroid malignancy. Many adolescents have some increase in the size of the thyroid at puberty; this hypertrophy should not be accompanied by any nodes.

Chest

For ease in specifying the location of chest pathology, the chest is divided into sections by imaginary lines drawn through the mid-clavicle, mid-mammary, and midsternum points on the front; the mid-axilla on the side; and the midscapula on the back. Pathology is described in terms of these lines such as "abnormal lung sound heard at left mid-axillary line". Other helpful means of locating pathology is by the suprasternal notch, the ribs, and the spaces between them **(intercostal spaces).** Intercostal spaces are numbered according to the ribs immediately above them (Fig. 34.16). Inspect both front and back surfaces of the chest for symmetry of appearance and motion. Inspect for **retractions** or indentation of intercostal spaces or the suprasternal and substernal areas that reflect difficult respirations. Assess the proportion of anteroposterior to lateral diameter (normally 1:2). Children with chronic lung disease develop a broad (barrel) chest or one more rounded than normal. This and other chest abnormalities are shown in Figure 34.17. An infant with a diaphragmatic hernia (intestine herniated into the chest cavity) may have a chest enlarged on that side. An infant with atelectasis (collapsed lung) may have a chest that is smaller on the affected side. If a child has an enlarged heart, the left side of the chest may appear larger.

Breasts

The degree of breast assessment depends on the child's age and development. As part of a normal breast assessment, inspect and palpate the breasts of all children to detect any abnormalities.

Newborn. Both male and female newborns may have breast edema from the influence of maternal hormones. A few drops of clear fluid may even be present from the nipples. This is normal and will fade in a few days time. Document if a supernumerary nipple is present for baseline data.

School-Age Child and Adolescent. Perform a breast examination on all girls past puberty. If a girl younger than 8 years is beginning breast development, precocious puberty (see Chapter 48) should be suspected. Many preadolescent boys develop hypertrophy of breast tissue because of increased hormonal influences (gynecomastia); they are generally concerned and need reassurance this is normal for their age and will fade as soon as androgen becomes their dominant hormone. Adolescent girls may be concerned their breast tissue is inadequate or that breast growth is uneven. They can be assured that not all women have completely symmetric breasts.

Inspection of breast tissue is easiest if a child sits on the examining table, arms at the sides, with both breasts exposed.

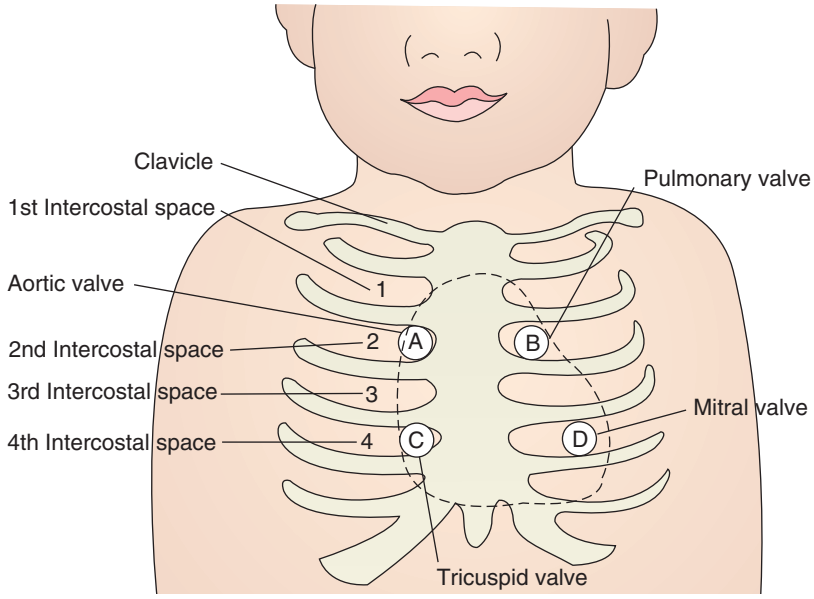

FIGURE 34.16 Intercostal (between rib) spaces are numbered according to the ribs immediately above them. The points (**A, B, C,** and **D**) to which the sounds of the heart valves radiate or where the sounds can be heard best are the listening posts of the heart.

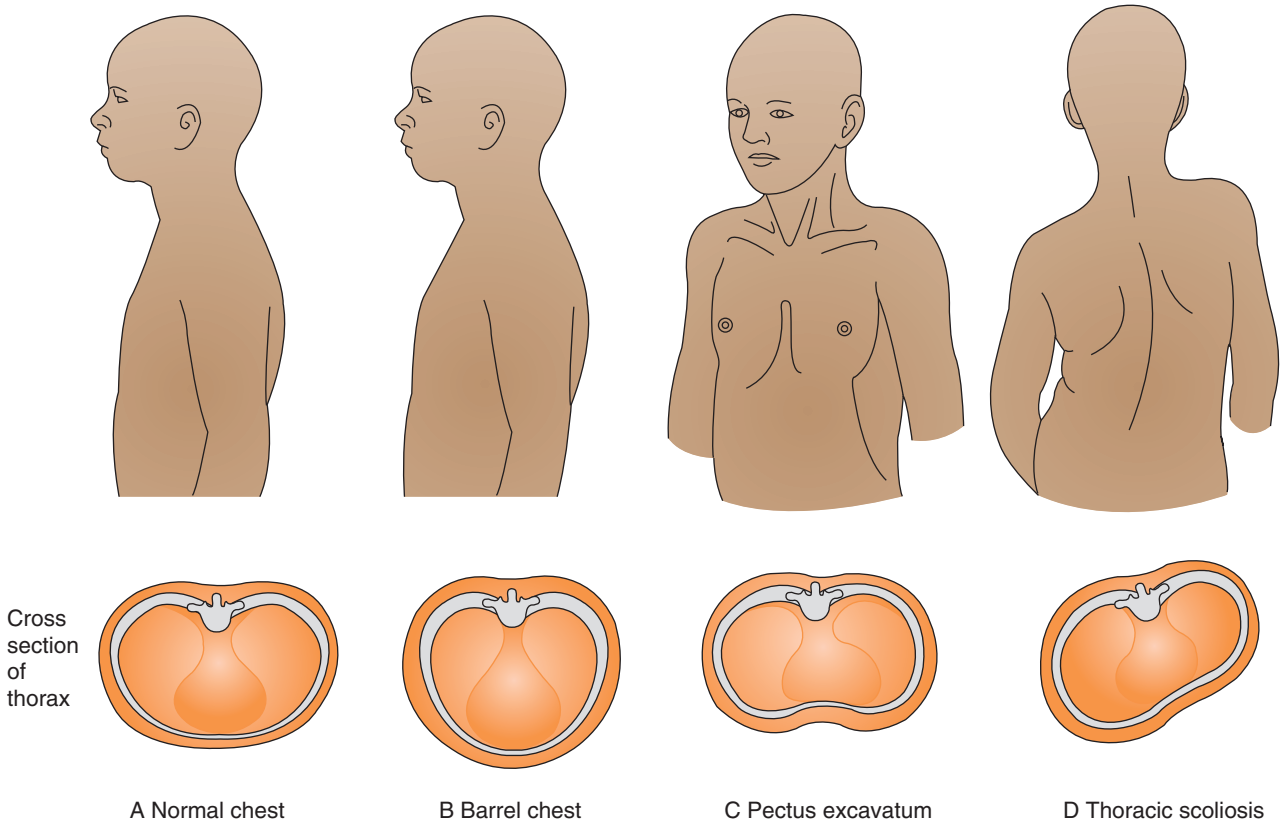

FIGURE 34.17 Chest contours that can be assessed by inspection. (**A**) Normal chest. (**B**) Barrel chest. (**C**) Funnel chest (pectus excavatum). (**D**) Thoracic kyphoscoliosis.

Inspect for symmetry. As mentioned, it is normal and not unusual for a girl to have breasts of slightly unequal size.

Inspect breasts for edema, erythema, wrinkling, retraction, or dimpling of the skin; all suggest that a tumor is growing in deeper layers of the tissue. Erythema occurs from inflammation because of abnormal, rapidly growing tissue; edema results from the blockage of lymph channels because of tumor pressure. Breast edema makes the skin appear not only swollen but also pitted (an orange-peel effect). Note any nipple discharge or "pulled" nipple placement as another way to detect edema.

With the girl's arms at her sides to take pressure off breast tissue, palpate well into each axilla (because breast tissue extends that far), and also palpate to assess axillary lymph nodes. Normally, no nodes should be felt. Ask the girl to lie down; place a folded towel under her near shoulder. Palpate the near breast with her lying down with her arm raised and placed under her head because this spreads out breast tissue; begin at the nipple and palpate outward in a circular motion. The lower edge of each breast feels hard; do not mistake this or rib prominences underneath for a tumor.

Lungs

Various findings reveal respiratory distress in children. Assess the rate of respirations and whether respirations are easy and relaxed or if accessory muscles are necessary for effective ventilation. Palpate over lung areas for vibrations that suggest air is having difficulty moving through air passages (Aylott, 2007).

On the anterior chest, lung tissue extends from above the clavicles to the sixth or eighth rib. On the posterior chest, lung tissue is as low as the 10th to 12th thoracic vertebrae. The right lung has three lobes; the left, only two. Attempt to evaluate all five lobes during lung assessment because lung disease can be specific for a lobe or involve the entire lung.

Following palpation, percuss over lung tissue. Normal lung is resonant in older children; in infants and younger children it is hyperresonant because of the thinness of the chest wall. Overexpanded lungs sound hyperresonant in older children; and lungs filled with fluid sound dull in older children and less resonant in younger children. The lower anterior lobe of the right lung will sound dull because the liver covers it on the anterior surface below the fourth or fifth intercostal space. The space over the heart will also percuss as dull.

Diaphragmatic excursion (the distance the diaphragm descends with inhalation) is an estimation of lung volume. To establish this:

- Ask the child to take in a deep breath and hold it.
- Percuss downward to locate the bottom of the lungs (the percussion note changes from resonant to flat at that point).
- Ask the child to expire fully and momentarily hold that position.
- Percuss upward to locate the expired or empty lung position (the percussion note changes from flat to resonant).

The difference between these two points is the diaphragmatic excursion. Children who have overexpanded lungs from obstructive disease will have little diaphragmatic excursion in relation to others.

Auscultate breath sounds by listening with the diaphragm of a stethoscope over each lung lobe while a child inhales and

TABLE 34.7 ✻ Breath Sounds Heard on Auscultation

Sound	Characteristics
Vesicular	Soft, low-pitched, heard over periphery of lungs, inspiration longer than expiration. Normal.
Bronchovesicular	Soft, medium-pitched, heard over major bronchi; inspiration equals expiration. Normal.
Bronchial	Loud, high-pitched, heard over trachea; expiration longer than inspiration. Normal.
Rhonchi	Snoring sound made by air moving through mucus in bronchi. Normal.
Rales (also called crackles)	Crackling or crinkling sound (like cellophane) made by air moving through fluid in alveoli. Abnormal.
Wheezing	Whistling on expiration made by air being pushed through narrowed bronchi. Abnormal; seen in children with asthma or foreign body obstruction.
Stridor	Crowing or rooster-like sound made by air being pulled through a constricted larynx. Abnormal; seen in children with upper respiratory obstruction.

exhales (preferably with the mouth open). Listen both anteriorly and posteriorly; compare the left side with the right side for equal findings. Normal breath sounds are slightly longer on inspiration than expiration. Consider whether there are any abnormal sounds. Table 34.7 describes normal breath sounds and transmitted airway sounds as well as adventitious sounds that, if heard, might reflect illness.

Newborn and Infant. Infants cannot breathe in and out on request. Try to listen to breath sounds early in an examination, because breath sounds are difficult to hear clearly over the sound of crying.

Heart and Heart Sounds

Heart assessment begins with asking children if they have ever had heart pain (Galioto, 2007). Visual inspection to see if there is a point on the chest where the heartbeat can be observed follows this. This point represents the location of the left ventricle or the point where the apical heartbeat can be heard best. In children younger than 7 years, this point is generally lateral to the nipple line and at the fourth intercostal space. In children older than 4 years, it is at the nipple line or just medial to it and at the fifth intercostal space. This point is termed the **point of maximum impulse (PMI)** and is observable in approximately 50% of children.

Percuss the left side of the chest to discern the left side of the heart. Percussing in from the axilla, the sound will become dull as the heart is identified. Normally, the percussion note changes from resonant (percussing over lung) to flat (percussing over heart) midway between the mid-axillary and mid-mammary line. A heart located farther to the left than this suggests enlargement.

To hear heart sounds, auscultate at four main points. Although these are not the anatomic locations of heart valves, they are the listening points to which the sounds of the valves radiate and can be heard best in children (see Fig. 34.18).

- The mitral valve is heard best at the fourth or fifth left intercostal space at the nipple line.
- The tricuspid valve is heard best near the base of the sternum (fourth or fifth right intercostal space).
- The pulmonary valve is heard best at the second left intercostal space.
- The aortic valve is heard best at the second right intercostal space.

Table 34.8 describes normal and abnormal heart sounds that may be heard on auscultation. Abnormal sounds are heard best if the diaphragm of the stethoscope is used first, followed by the bell of the stethoscope.

To understand heart sounds, recall heart physiology. The first sound heard (S_1) is that of the mitral and tricuspid valves closing and the ventricles contracting (described as a "lub" sound). The second sound (described as a "dub"; S_2) is made by the closure of the aortic and pulmonary valves and atrial contraction. The first sound is generally longer and lower-pitched than the second sound. It is louder than

FIGURE 34.18 Auscultating heart sounds.

TABLE 34.8 ✻ Heart Sounds Heard on Auscultation

Sound	Cause
S_1 (first heart sound)	Closure of tricuspid and mitral valves with beginning of ventricular contraction (systole)
S_2 (second heart sound)	Closure of pulmonary and aortic valves with beginning of atrial contraction (diastole)
S_3 (third heart sound)	Rapid ventricular filling
S_4 (fourth heart sound)	Abnormal filling of ventricles

TABLE 34.9 ✻ Description of Accessory Heart Sounds

Assessment	Information to be Gathered
Location	At which listening post is the sound most distinct?
Quality	Can sound be described as blowing, rubbing, rasping, musical?
Intensity	*Murmurs* are graded according to the following criteria: Grade 6: So loud it can be heard with stethoscope not touching the chest wall; has a thrill (palpable vibration). Grade 5: Very loud but must touch stethoscope to chest to hear; has a thrill. Grade 4: Loud; may or may not have a thrill. Grade 3: Moderately loud; no thrill. Grade 2: Quiet but easily discernible. Grade 1: Very quiet; difficult to hear.
Timing	When in relation to S_1 and S_2 did you hear it? A sound superimposed between S_1 and S_2 is a *systolic murmur*; one between S_2 and the next S_1 is a *diastolic murmur*. Innocent murmurs (functional, denoting no pathology) are usually systolic, although there are exceptions to this; pathologic murmurs are more likely to be diastolic.
Pitch	Can the sound be described as high- or low-pitched?
Radiation and thrills	Is there an accompanying thrill? Does sound radiate so it can be heard at another location, such as back of chest?

the second sound over the heart ventricles; otherwise, it is slightly quieter.

Note the rhythm of the heart sounds. This should be regular. **Sinus arrhythmia** is a phenomenon that most school-age and adolescent children demonstrate. With sinus arrhythmia, a marked heart rate increase occurs as a child inspires and a marked decrease in heart rate is noted as the child expires. This is a normal finding. Ask the child to take and hold a breath, and the rhythm of the heart remains the same.

With inspiration and the normal resulting increase of pressure in the lungs, the pulmonary valve tends to close slightly later than the aortic valve. This is termed **physiologic splitting** and is heard as "lub d-dub." As long as this is associated with inspiration, it is a normal finding. Fixed splitting implies there is always difficulty with the pulmonary valve closing and suggests pathology.

At times, a distinct third heart sound (S_3) may be heard because of rapid filling of the ventricles. Although this is not necessarily a serious finding, further investigation is warranted. The presence of a fourth heart sound (S_4) generally signifies heart pathology because this sound (a gallop rhythm) is caused by abnormal filling of the ventricles.

Listen to the heart in all areas; assess rate and compare this to the child's age to determine if it is a normal rate. A heart murmur is caused by the sound of blood flowing with difficulty or in an abnormal pathway within the heart (sounds like a swishing sound) and can be either innocent (functional) or pathogenic (organic). If a heart is pumping with abnormal force, there may be a palpable vibration termed a thrill on the chest wall. Palpate the precordium (area over the heart) for evidence of this (feels like a cat purring) or a heave (a definite outward chest movement), which also denotes a struggling heart. On hearing or palpating any accessory heart sounds or movements, try to describe them with reference to Table 34.9.

All unusual heart sounds need further identification and investigation of their cause. The skills of listening to and identifying normal and abnormal heart sounds require considerable practice. Determining the cause of an abnormal heart sound requires a cardiac specialist. Determining that an abnormal sound exists, however, and securing proper referral is an important nursing role.

Newborn, Infant, and Toddler. Listen to heart sounds in young children early in an examination, before a child begins to cry, because it is almost impossible to evaluate heart sounds over the sound of crying. Allowing a parent to hold a child while listening to the heart helps reduce fear.

School-Age Child and Adolescent. Listen carefully for sounds of murmurs in children of school age and older. Be particularly conscientious with student athletes; it seems paradoxical that they could have heart disease, but, if present, it can be fatal to them during athletic events (Drezner et al., 2007). Refer them to a physician for further evaluation if any abnormalities are detected. Parents are always frightened by an unusual heart sound, but unless the child has other symptoms, they can be assured that most murmurs are innocent (functional) and caused only by the normal flow of blood across valves.

✔ Checkpoint Question 34.4

Keoto has a sinus arrhythmia. This refers to:

a. A widely spaced rib cage
b. Faint, barely audible heart sounds
c. Increased heart rate on inspiration
d. An abnormal heart rate in a child

Abdomen

The abdomen is divided anatomically into four quadrants. The quadrants and the organs that lie within them are shown in Fig. 34.19. To assess an abdomen, first inspect the surface for symmetry and contour. It will be slightly protuberant in infants and scaphoid in older children. Note any skin lesions or scars.

Auscultate the abdomen for bowel sounds before palpating, because palpating may alter bowel movement (peristalsis) and therefore disturb bowel sounds. Bowel sounds can normally be heard in all quadrants of the abdomen. They are high "pinging" sounds that occur normally at intervals of approximately 5 to 10 seconds. Since these sounds are high-pitched sounds, they may be heard best with the bell of a stethoscope. If the bowel is distended, the sounds occur more frequently; if the

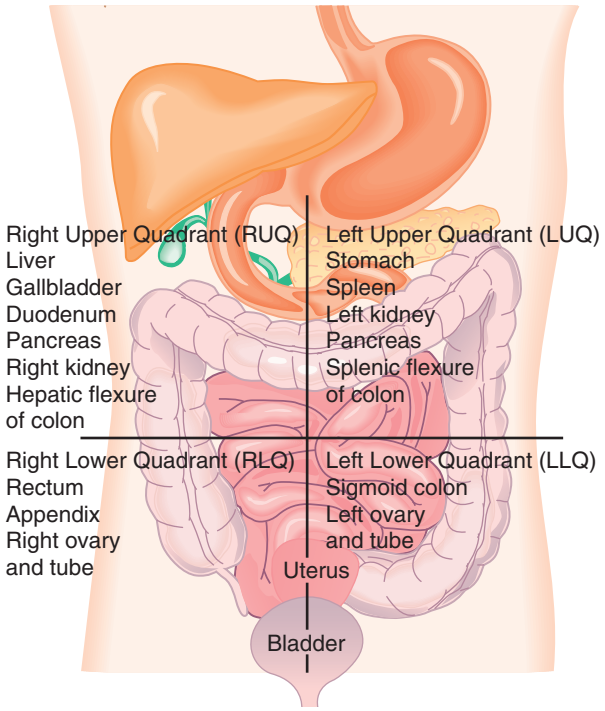

FIGURE 34.19 Quadrants of the abdomen and underlying structures.

bowel is blocked so that there is no movement of contents, the sounds will be absent below the obstruction. Listen for 3 to 5 minutes before concluding that no bowel sounds are present to be certain they are not just widely spaced.

Listen along the middle of the abdomen over the aorta for irregular sounds. A **bruit** is a swishing or blowing sound that occurs if there is an outpouching of the aorta (an aneurysm), a condition that can be congenital, although it usually occurs with aging.

Palpate the abdomen in a systematic manner to include all four quadrants. First palpate lightly, then deeply. Ascertain whether any area is tender by watching the child's face while palpating; observe for guarding or the child tensing the abdominal muscles to keep you from pressing deeply at that point. If a child indicates any portion of the abdomen is tender, begin assessment at the farthest point and work toward the tender area. If no tenderness is present, the order of palpation is unimportant as long as it is thorough. Note any hard areas or masses. If a tender area is detected, attempt to elicit rebound tenderness to determine its cause. To do this, press in on the abdomen, then lift your hand suddenly. This causes internal organs to vibrate. Although all children do not show this sign, the occurrence of more pain with the vibration than with the original pressure is one of the standard diagnostic criteria for appendicitis (Becker, Kharbanda, & Bachur, 2007).

By palpating from the right lower quadrant to the right upper quadrant, the hand will bump against the lower edge of the liver 1 to 2 cm below the right ribs. On the left side, the lower edge of the spleen may be discernible in the same way. A liver or spleen larger than this is suggestive of disease. Palpate the umbilicus to try to identify the presence of an umbilical hernia. A fascial ring at the umbilicus of more than 2 cm in diameter in an infant denotes a ring of fascia larger than will normally close spontaneously; when this is present, the child will generally need surgery to prevent an umbilical hernia. Liver, spleen, and bladder size can all be documented further by percussion.

Newborn and Infant. Kidneys may be located by deep abdominal palpation in newborns and infants. The right kidney is slightly lower than the left and so is easier to locate. The optimal time to palpate the kidney of a newborn is during the first few hours of life, before the bowel begins to fill with air and obscures palpation. To palpate the kidneys:

- Place a hand under an infant's back just below the 12th rib.
- Press upward.
- Place the other hand on that side of the abdomen just below the umbilicus.
- Press deeply.
- Locate the kidney, which can be felt as a firm mass approximately the size of a walnut between the hands.

Preschooler and School-Age Child. Children's abdomens at this age are often "ticklish," and children may tense or guard their abdominal muscles when touched, making it difficult to palpate. Distract a child by asking a question about home or school, or let a child place a hand under the examiner's to help relax (Fig. 34.20).

Genitorectal Area

In both sexes, the rectum should be inspected for any protruding hemorrhoidal tissue (rare in children) or fissures. Fissures may signify chronic constipation, intra-abdominal pressure, or sexual abuse.

Female Genitalia. Inspection of external female genitalia and assessment of femoral nodes are included in every complete health assessment (Hornor, 2007). An external examination consists of inspecting for Tanner stage of hair growth and configuration (an inverted triangle) and inspection of external genitalia (clitoris, labia majora, and labia minora) for normal contours. Look for signs of discharge or irritation. A vaginal discharge that suggests infection or a fourchette tear in a young child may be an indication of sexual abuse, in an adolescent of rape (Lewin, 2007). A pelvic examination is usually scheduled at the time the girl becomes sexually active or at age 18 (American Academy of Pediatrics [AAP], 2009). The technique for an internal pelvic examination is discussed in Chapter 11.

FIGURE 34.20 Decrease ticklishness during abdominal palpation by placing the child's hand under yours.

Male Genitalia. Inspection of male genitalia consists of observing:

- The distribution and Tanner stage of hair, which has a diamond shape
- The penis, for lesions that might suggest a sexually transmitted infection
- Appearance and placement of the urethral opening, which should be slitlike and centered at the penis tip. Children with repeated urinary tract infections develop scarring of the meatal opening, making it small and round (Hornor, 2007).
- The ability to retract the foreskin, if a boy is uncircumcised. Phimosis exists when the foreskin of a child older than 6 to 12 months is too tight to retract.

Hypospadias is a term for a urethral opening located on the inferior or ventral (under) surface of the penis; **epispadias** denotes a urethral opening on the superior or dorsal (upper) surface. Both these conditions need to be identified. If more than a slight deviation is present, repair is usually initiated before school age because such a urethral placement may interfere with self-image if not corrected. With adulthood, it can interfere with fertility.

Inspect the scrotum for size and the presence of testes. In most boys, the left testicle is slightly lower than the right, so the scrotum does not appear truly symmetric. Palpate to check that both testes are present by placing one hand over the top of the scrotum at the inguinal ring and then palpating the testis on that side (see Chapter 18, Fig. 18.17). This hand position prevents the testis from slipping up into the inguinal ring and appearing to be absent on palpation. Any swelling or mass in the scrotum needs to be identified. The most likely cause of such a condition is a **hydrocele,** or a fluid-filled sac, but it could represent a serious finding such as testicular cancer in adolescents. Hydroceles can be transilluminated: when a flashlight is held in back of the scrotum, the fluid-filled cyst glows. A **varicocele** (enlarged vein of the epididymis) may be palpated. These are not important findings in young boys, but they could possibly interfere with fertility in later life.

Assess the urethral meatus for any discharge that could reveal a sexually transmitted infection such as gonorrhea or any lesions that would suggest herpes 2 infection or syphilis (see Chapter 47). Beginning at puberty, teach boys to do testicular palpation every month. The technique for this is shown in Box 34.10.

Inguinal Hernia

To assess for the presence of an inguinal hernia in an infant, simply observe the groin area for any bulging (especially while the infant is crying). In a school-age child or adolescent, with the child standing, place a fingertip against the inguinal ring in the groin area and ask the child to cough. If the tendency for a hernia is present, coughing tightens the abdominal muscles and forces the abdominal contents to bulge against the finger. Palpate femoral nodes (located in the groin and on the inner surface of the upper thigh) for any swelling, which suggests infection.

Extremities

Observe the upper extremities for good color and warmth. Inspect the fingernails for color, contour, and shape. Normally, nails are pink, smooth, and convex. They should feel hard to the touch and not so brittle that they break readily. Signs of bitten fingernails in the school-age child may reflect a high level of stress. Darker-skinned children's nails are more deeply pigmented. A blue or purple tinge denotes cyanosis; a yellow tinge is jaundice. Children who have decreased respiratory function or heart disease develop clubbed fingers (Fig. 34.21); children with endocarditis often have characteristic linear hemorrhages under the nails. Iron-deficiency anemia may cause extremely concave surfaces (spoon-shaped). Press against a fingernail, release the pressure, and time the refilling interval (should be under 5 seconds). Count the fingers and check for webbing between fingers. Examine that fingerprints are present. Distinctive dermatoglyphics are present on fingertips from the third month of intrauterine life; these are unique to every person and show patterns of circular grooves. Abnormal fingerprints may occur with chromosomal anomalies. Check for normal palmar creases. Children with chromosomal abnormalities

BOX 34.10 ✻ Focus on Family Teaching

Testicular Self-Examination

Q. Keoto's father asks you, "What is the best technique for testicular self-examination?"

A. Starting in the adolescent years, all males need to perform testicular self-examination. Follow these guidelines:

- Select a certain day each month (first day, last day, and so forth) to perform the examination.
- Perform the examination in or immediately after a shower, because that is when scrotal skin is most relaxed.
- Gently roll each testicle between your thumb and fingers, feeling for any hard lumps or nodules, change in consistency, or difference in size.
- If you notice any of these changes, call your doctor.
- Also feel for the epididymis, found at the rear of the testes. It should feel like a strong cord.
- Remember that for most males, one testicle is slightly larger than the other and hangs a little lower in the scrotal sac.

FIGURE 34.21 Clubbed fingers are a sign of cyanosis from heart or respiratory disease. (From NMSB/Custom Medical Stock Photograph.)

may have only one central palm crease (a simian line) on each hand rather than the normal three (see Chapter 7). Check the wrist, elbow, and shoulder joints for movement and normal range of motion; palpate joints for swelling or warmth. Palpate to be certain no lymph nodes are present in the antecubital space; palpate to check the radial pulse is present.

Inspect the lower extremities for color and warmth. Count the toes and check for webbing between toes. Check the ankle, knee, and hip joints for normal range of motion. Check for developmental hip dysplasia in infants by attempting to abduct the hip fully (see Chapter 27, Box 27.9). Palpate to ensure no enlarged lymph nodes are present in the groin or popliteal areas and that femoral pulses are present and equal bilaterally. Ask the older child to walk, and observe for ease of gait, limping, or any foot displacement such as toeing in or out. Toddlers typically walk with a wide-based gait; they walk best if allowed to walk toward their parent (a safe action) rather than away. Many adolescents are self-conscious and slouch or amble rather than presenting their true, natural gait. Children who limp need further evaluation. A limp can be the result of something as simple as a blister on the foot from wearing new shoes but can also be a sign of a serious hip or bone condition (Paton, 2007).

Back

Inspect the back for symmetry and the spinal column for any deviation. Inspect the base of the spine for a dermal sinus (a pinpoint opening) or for a tuft of hair or a hemangioma that might reveal a spina bifida occulta (a defect of the bony structure of the canal). Inspect also for any dimpling that might denote a dermal cyst (pilonidal cyst). This is an innocent finding unless it becomes infected or connects to deeper tissue layers. Assess for tenderness along the spinal column by palpating each vertebra as chronic lower back pain can be present as early as school age (Shilt & Barnett, 2007).

Routine assessment of the school-age child beginning at 12 years and through adolescence should include a scoliosis (sideways curvature of the spine) screening (Sponseller, 2007). Box 34.11 details the steps to follow for a scoliosis screen. (See Chapter 51 for more details on scoliosis.)

Box 34.11 Nursing Procedure ✻ Scoliosis Screening

Purpose To assess for scoliosis (sideways curvature of the spine).

Procedure	Principle
1. Have the child remove clothing, except for undergarments. Ask the child to stand up straight, with feet together and arms at sides. Observe the child from a posterior view.	**1.** Promotes optimal view of back.
2. Inspect for unequal shoulder or hip level, prominence of one scapula, or a curved spinal column (See Fig.).	**2.** Denotes signs of spinal curvature.

Box 34.11 Nursing Procedure ✻ Scoliosis Screening

Procedure	Principle
Ask yourself the following questions: • Is one shoulder higher than the other? • Is one shoulder blade more prominent than the other? • Does one hip seem higher or more prominent than the other? • Does the child seem to lean to one side? • Does the spinal column appear curved?	
3. Compare the level of the elbows in relation to the iliac crests. Be sure the arms are hanging down at the sides. Ask yourself the following questions: • Is the distance between one arm and body greater than on the other side? • Are the elbows uneven? • Do the elbows fall at the level of the crest or closer to the crest on one side? (Normally the elbows fall above the iliac crest.)	**3.** Helps to determine uneven posture because it will affect level of elbows.
4. Ask the child to bend over and touch toes while you continue to observe the back. Ask yourself the following questions: • Is there a hump in the back? • Does the spinal column appear to curve? • Is one shoulder blade more prominent than the other?	**4.** Provides evidence of spinal rotation. As the child bends, the rotation of the spine accompanying scoliosis becomes more prominent.
5. Refer the child to a physician for further examination if the answer to any of the above questions is yes.	**5.** Provides for proper referral.
6. Educate the child to inform parents or health care providers if signs of scoliosis begin to develop, such as a skirt hanging unevenly, or bra straps that need to be adjusted.	**6.** Encourages health promotion.

Neurologic Function

A full neurologic examination takes at least 20 minutes to complete, so it is not included in a routine physical examination. It is important, however, to assess for **deep tendon reflexes** (such as triceps, biceps, patellar, and Achilles reflexes) to test for motor and sensory function and balance and coordination. Techniques for eliciting deep tendon reflexes are shown in Figure 34.22. Grade reflexes according to the scale in Table 34.10. The biceps reflex tests the fifth and sixth cervical nerves; the triceps reflex tests the seventh and eighth cervical; the patellar reflex tests the second, third, and fourth lumbar; and the Achilles reflex tests the first and second sacral. Test the sole of the foot for a Babinski reflex (see Fig. 18.8). Fanning of the toes will occur in an infant younger than 3 months; a downward reflex of the toes will occur beyond 3 months. (Some normal infants demonstrate a flaring Babinski response until they are 2; in the absence of other neurologic findings, this is not significant.)

Test for superficial reflexes: abdominal reflexes in both sexes, cremasteric reflex in boys. An abdominal reflex is elicited by lightly stroking each quadrant of the abdomen. Normally, the umbilicus moves perceptibly toward the stroke. Presence of the reflex indicates integrity of the 10th thoracic nerve and the first lumbar nerve of the spinal cord. A cremasteric reflex is elicited by stroking the medial aspect of the thigh in boys. The testes move perceptibly upward. The presence of this reflex indicates integrity of the first and second lumbar nerves.

Motor and Sensory Function

Test general facial nerve function by asking a child to make a face. The child's ability to grasp with the hands and push against a surface with the feet establishes general motor ability. Recall whether gait was adequate when the child was observed walking to assess for balance and coordination.

To test sensory function, ask children to close their eyes and identify the location where they are touched at six points (at least) on different body parts.

ASSESSING VISION, HEARING, AND SPEECH

Assessing vision, hearing, and speech is an important part of physical assessment because these are important to the development of age-appropriate skills.

FIGURE 34.22 Deep tendon reflexes. (**A**) Triceps reflex. The triceps tendon is struck. The forearm will move perceptibly if the reflex is elicited. (**B**) Biceps reflex. The examiner's thumb is placed over the biceps tendon. The reflex hammer actually strikes the examiner's thumb. The examiner will feel the child's forearm move when the reflex is elicited. (**C**) Patellar reflex. (**D**) Achilles reflex. In both **C** and **D**, the child grasps his hands together and pulls as a means of distracting him away from what the nurse is testing. This helps to decrease muscle tension, facilitate the reflex arc, and elicit more accurate results.

TABLE 34.10 ✻ Grading of Deep Tendon Reflexes

Grade	Interpretation
4+	Hyperactive; extremely marked reaction; abnormal
3+	Stronger than average but within normal range
2+	Average response
1+	Less than average response but within normal range
0	No response; abnormal

Vision Assessment

Assessing vision is an important part of physical assessment because good vision is so important to childhood development. The extent of testing depends on the age of the child.

Any child with congenital anomalies, low birth weight, or fetal alcohol syndrome is at risk for eye abnormalities, as is a child who received oxygen at birth. During an assessment, if you notice an unreported injury or infection or signs of neglected vision, make a special note. Because the average parent is careful of a child's eyes, these findings may be indicative of child neglect.

Vision Screening

Routine vision screening is usually begun at 3 years of age. Common vision screening indicators and techniques for children of different ages are summarized in Table 34.11. Parents can provide important clues to possible problems: listen carefully any time a parent expresses concern about or questions a child's ability to see well.

Newborn and Infant. Newborns should be able to focus on a moving object such as a finger and follow it to the midline.

TABLE 34.11 ✻ Common Vision Screening Indicators and Procedures

Age	Common Test
Newborn	General appearance* Ability to follow moving object to midline; focus steadily on an object at 10–12 in
Infant and toddler	General appearance* Ability to follow light past midline
3 yr–school age	General appearance* Random dot E for stereopsis (depth perception) Allen cards or preschool E chart for visual acuity Ishihara's plates for color awareness
School age–adolescent	General appearance* Snellen's test for visual acuity

* Note redness, blinking, squinting, or crusting.

Infants see black and white objects better than they do colored objects. They seem to see objects that are closest to them (a distance of about 19 cm [8 to 10 in]) best. Ask the parents if an infant's eyes follow them as they move around the room. Does an infant who is older than 6 weeks return their smile? Do the parents have any reason to think their child has difficulty seeing?

Toddler and Preschooler. Ask the parents of older infants, toddlers, or preschoolers if their children do any of the following:

- Rub their eyes, blink frequently, squint, or frown
- Cover one eye to look at objects
- Tilt the head to see things better
- Stumble over objects in their path
- Hold books and toys extremely close or extremely far away to look at them

Asking whether children sit close to a television set is meaningless because almost all children do that if allowed.

School-Age Child and Adolescent. Ask the parents if their child does any of the following:

- Reports frequent headaches
- Does poorly with classwork
- Avoids sports that require long-distance vision, such as baseball or softball
- Avoids watching movies
- Skips over words when reading aloud
- Reports blurriness or double vision
- Has reddened conjunctivae or drainage from the eyes
- Blinks at bright light

Techniques of Vision Testing

Vision is tested by asking a child to read an eye chart. All children need good orientation to such testing so they can appreciate this is not a test in the usual sense of the word; otherwise, they may be unusually anxious or try to pass it by cheating. Vision testing needs to be started in the preschool period so children with amblyopia (lazy eye; see Chapter 50), a potentially serious vision disorder, can be identified while the condition is still correctable (Wallace et al., 2007). In addition to usual testing, a Polaroid or digital photograph of a child can be used to help identify strabismus (uneven gaze).

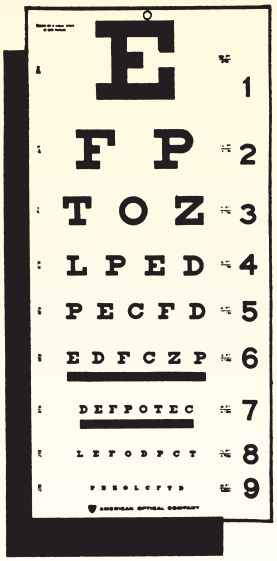
Snellen Chart. As soon as children can identify letters of the alphabet (early school age), their vision can be tested at a health checkup by using a Snellen eye chart. This chart is standardized, so set procedures must be followed when using it to test vision (Box 34.12).

Preschool E Chart. Between 3 years of age and the age they can read the alphabet, children can have their vision tested by using an LEA chart that uses symbols such as squares and circles instead of letters, or a preschool E chart (Fig. 34.23). These charts are also helpful in testing children who are cognitively challenged or those who do not speak fluent English. To test using a preschool E chart, the procedure is similar to that of the standard Snellen chart:

1. The child stands 20 ft from the chart and then should read first with the right eye, then with the left, then both eyes, as with standard testing. Young children do

Box 34.12 Nursing Procedure ✻ Snellen Eye Chart Assessment

Purpose To assess vision.



Procedure	Principle
1. Hang the chart so the 20-ft line is at the child's eye level.	**1.** The child who has to look up or down must look farther than the child who is looking straight across at the chart. A possible solution to avoid moving the chart is to have smaller children stand and taller children sit. To accommodate children in wheelchairs, the chart needs to be lowered (or else have all children sit for the test).
2. Provide a good light for the chart and place it so there is no glare. A light intensity of 20 foot-candles is recommended.	**2.** Appropriate lighting provides for optimal test conditions.
3. Measure a distance of 20 ft from the chart. Mark the floor at this point with a piece of masking tape or other similar mark. For younger children, it is helpful to cut out paper footprints and paste them to the floor with the heels of the footprints touching the 20-ft line. If the child sits in a chair, the back legs of the chair should touch the 20-ft line.	**3.** Twenty feet is the optimal distance from the chart for testing.
4. Provide an individual 3 × 5-in card (to cover the eye not being tested) for each child who is examined.	**4.** Covering the other eye allows for one eye to be tested at a time.
5. If the child wears glasses, screen while he or she is wearing the glasses. If a child has forgotten to bring glasses, defer the screening until the child can bring the glasses. Do not screen the child first without glasses and then with them, because this forces the child to strain to read the chart.	**5.** Testing with corrective lenses screens for corrected eyesight. After squinting, a child may have difficulty readjusting to reading with glasses, and this makes the prescription appear too weak or too strong.
6. To begin testing, tell the child to stand with his or her shoes on the footprints (heels against the line); keep both eyes open; and cover the left eye with the occluding card. Be certain the child does not press the card against the eye (instead, the edge of the card should rest across the child's nose).	**6.** Covering the eye not being tested provides optimal test conditions. Pressure will cause blurred vision when the child removes the card to test that eye.

Box 34.12 Nursing Procedure ✻ Snellen Eye Chart Assessment

Procedure	Principle
7. Begin at the 40-ft line of the chart and, using a pointer or pencil, point to each symbol on the line from left to right (the order in which children are taught to read). If the child reads a majority of symbols in a line, he or she sees the line satisfactorily.	**7.** Starting at the 40-ft line is the standardized testing procedure.
8. If the child "passes" the 40-ft line, have the child read the 30- and 20-ft lines or the last line the child can read. Record the last line read. If the child fails to read the 40-ft line satisfactorily, then begin at the top of the chart and move downward to identify the last line the child can read. Record this reading. Because the 200-ft, 100-ft, and 70-ft lines have so few symbols, the child must read all the symbols on them to have read satisfactorily.	**8.** Moving to the 30-ft line or less reflects use of standardized testing procedure.
9. Visual acuity is always stated as a fraction. The top number is the distance in feet the child stands from the chart (always 20). The bottom of the fraction represents the last line the child read correctly. The adult with good (average) vision can read the 20-ft line from 20 ft away and thus is said to have 20/20 vision.	**9.** Using a fraction for visual acuity is the standardized reporting procedure.
10. It is important to test the eyes separately, then together. For example, Tony reads all the symbols on the 40-ft line with his right eye; he misses three out of four on the 30-ft line. His visual acuity for his right eye is 20 (the distance from the chart) over 40 (the last line he read correctly). With his left eye, Tony reads the 40-ft, 30-ft, and 20-ft lines correctly. His vision in that eye is 20/20. With both eyes, Tony reads the 40-ft, 30-ft, and 20-ft lines correctly. His visual acuity for both eyes is 20/20.	**10.** If only this last reading were taken, the right eye weakness (a symptom of amblyopia or "lazy eye") would be missed.
11. Observe children for straining or squinting as they read the chart.	**11.** By squinting and changing the shape of the eyeball, children can improve their vision and will score higher. Children will appear to see better than they actually do in everyday situations.

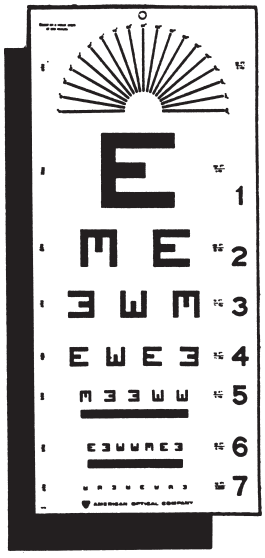


FIGURE 34.23 Astigmatic and preschool E chart. (From the American Optical Corporation, with permission.)

not understand the importance of not pressing an occluder card against their eye or of not peeking, so a second person is often needed to hold the card for children of this age. Using a pair of plastic eyeglasses with one side patched is another way to solve this problem.

2. It is helpful to compare the E with a table with three legs and ask the child which way the legs of the table point. By 3 years, children are familiar with tables, but Es are strange symbols. Tell the child to point with the entire arm and hand in the direction the legs point so you do not confuse the hand motion.
3. Begin at the 40-ft line, as with the standard Snellen chart, and work downward until the child passes all lines or cannot read the majority of symbols on a line.

Allen Cards. Preschool children may also be tested with Allen cards, which consist of pictures of common objects such as a horse and rider, car, house, and birthday cake. These are shown to the child at a 15-ft distance, and the child is asked to identify the pictures (proof the child sees them). Be certain children have time to examine the cards before the test so they know the names of the objects.

STYCAR Cards. For this test, the child is given cards with nine letters: H, C, O, L, U, T, X, V, and A. The child holds up the card that matches the one pointed to on a chart.

Titmus Vision Tester. Another useful method for testing the vision of children is the Titmus Vision Tester. This is the same instrument used by many motor vehicle licensing offices. As the child looks into the eyepieces of the machine, alphabet letters or preschool Es are projected onto a well-lighted screen for the child to identify. Closed vision testers such as the Titmus have an advantage over wall charts in that a child is less easily distracted during testing. Also, because children cannot see the vision chart beforehand, they cannot memorize the letters while waiting to be tested.

Color Vision Discrimination Testing. The inability to discern colors is a sex-linked recessive characteristic that tends to occur in males rather than in females, although females carry the gene for the disorder. All male children should be screened once for the disorder during their early school years.

To test a child for color awareness, ask the child to identify the colored stripes at the top of a Snellen eye chart or show the child a series of colored diagrams (Ishihara's plates). With the latter, a person with color vision can see hidden figures such as butterflies, but people with red-green or yellow-blue color vision deficits cannot. Detecting color vision deficit in children is important because many educational materials and some occupations depend on the ability to identify color. Even such a simple childhood pleasure as riding a bicycle safely on city streets depends on being able to distinguish colors, such as red from green on a traffic light.

Vision Referrals

Screen children twice before referring them to a physician for corrective eye care, as some children do not perform well on eye tests because they are easily distracted or do not know their alphabet as well as they pretend to know it. For example, they may say they do not see a letter when they really mean they do not know or remember its name. Testing twice helps eliminate or identify this type of misleading result.

After a second screening, the following children generally require a vision referral:

- Preschool children (3 to 5 years of age) who have 20/50 vision in one or both eyes
- Children 6 years of age or older who have 20/40 vision or worse in one or both eyes
- Any child with a two-line difference between the eyes, which might be the beginning of amblyopia
- Any child who states or shows symptoms of visual disturbance

Hearing Assessment

A thorough health assessment should also include an evaluation of hearing, including both history and observation, because good hearing is necessary for the development of age-appropriate skills. Parents and grandparents are usually attuned to hearing difficulty in children and may be suspicious of it in advance of its official detection. When taking an auditory history, be certain to ask the accompanying adult or parent an overall question such as, "Do you have any reason to believe your child doesn't hear as well as other children?"

Auditory Screening

Routine screening for adequate hearing levels is usually begun at 3 years of age. Testing requires knowledge of the technique, use of an audiometer, and a quiet, undistracted setting.

Newborn and Infant. In most hospitals, all newborns are routinely screened for hearing. Certain infants are high risk for hearing deficits so definitely should be screened. This includes infants with:

- History of childhood hearing impairment in the family
- Perinatal infection, such as cytomegalovirus, rubella, herpes, toxoplasmosis, or syphilis
- Anatomic malformations involving the head or neck
- Birth weight less than 1500 g
- Hyperbilirubinemia at a level exceeding indication for exchange transfusion
- Bacterial meningitis, especially when caused by *Haemophilus influenzae*
- Severe birth asphyxia: infants with an Apgar score of 0 to 3, those who failed to breathe spontaneously within 10 minutes of birth, or those with hypotonia persisting to 2 hours of age
- Newborns who received an antibiotic

A newborn's hearing is usually assessed through simple response testing—observing whether an infant stirs or responds to a sound delivered to the child with a commercial device (Young & Tattersall, 2007). It can also be done by brainstem auditory-evoked response (BAER) testing. For this method, an earphone is placed on the infant and an electrode is attached to the scalp. When sound is transmitted to the child's ear through the earphone, the electrical potential created as the sound is processed by the brainstem is read by the scalp electrode, processed by a microcomputer, and plotted on a graph. This type of testing may be used at any age and is successful even in children who are comatose or anesthetized. Smaller units using transient evoked otoacoustic emissions (TEOAEs) are also available. With these, a click stimulus delivered to a normal ear produces an echo from the cochlea. This can be detected by a miniature microphone to reveal even minor hearing loss. Although newborn hearing screening can lead to false-positive results because many infants of this age are still sleepy from birth analgesia and may have fluid- or vernix-filled ear canals, repeating the test usually decreases the incidence of false-positive results.

Older Children. Older children who are at risk for hearing loss are those who have been exposed to loud noises such as an explosion or loud music, were of low birth weight, have congenital anomalies, have a repaired cleft palate, or have had repeated ear infections. During history taking, ask children if they ever worry if they have difficulty hearing. Ask them how they are doing in school. Some children with a minimal hearing impairment are considered to have behavioral problems in school because they do not follow directions well or appear not to be following the teacher's discussion when in fact they may be unable to hear what is being said. Be certain not to confuse difficulty hearing with shyness or recalcitrance in answering. Children with an ear infection (otitis media) or allergies should be tested after the fluids in their ears clear because their hearing may be

temporarily affected by these conditions. Cerumen in the ear canal is not documented to substantially decrease hearing.

Principles of Audiometric Assessment

Frequency. Sound is the result of vibration; frequency is the number of vibrations a sound creates per second. When frequency is increased, the pitch of the sound increases. For audiometric testing, frequency is measured in Hertz units. Normal speech sounds fall into a narrow range, 500 to 2000 Hz, so to function adequately and speak effectively, a child must be able to hear in this range. Children are tested for a wider frequency range than this, from 500 to 6000 Hz, on a routine screening assessment.

Loudness. Decibels are an expression of the intensity of loudness of a sound (or vigor of the vibrations). A decibel level of 0 dB is the softest sound that can be heard. Normal conversation is approximately 50 to 60 dB. The sound level at which inner ear damage can occur is about 90 dB. Sound levels of 140 dB are so intense they actually cause pain. Screening audiometry is done at 25 dB.

Hearing Loss. Table 34.12 lists levels of hearing loss. The inability of a child to hear sounds softer than 30 dB indicates a child will have some difficulty hearing normal instructions and questions. If a child cannot hear sounds softer than 50 dB, the child misses most normal conversation and will have difficulty achieving in a regular classroom environment. Hearing loss at this level is so severe that the child will also be speech-challenged because normal speech sounds cannot be heard.

If children can hear all frequencies at the 25-dB level, they have passed an audiometric screening check. If a child fails to hear two or more frequencies at 25 dB, in either or both ears, the child has failed a screening audiometry test and should be referred to a physician or an otologist. An **audiogram** is a record of audiometric testing. Figure 34.24 shows an audiogram of a child with normal hearing in the right ear (the child heard all frequencies at the 20-dB level) but an inability to hear sounds softer than 45 dB in the left ear at frequencies of 1000, 2000, and 4000 Hz.

Acoustic Impedance Testing

Acoustic impedance testing is based on the principle that sound entering the ear canal meets resistance at the tympanic membrane. If the middle ear is functioning normally, there will be a symmetric pattern of resistance on a tympanogram printout. If the middle ear is functioning abnormally, the level of resistance will be greater or less than normal, so the pattern will be abnormal.

Acoustic impedance testing is performed by audiologists. For the assessment, the ear to be tested is plugged with a rubber disc. Sound is then administered to the ear through the center of the disc. The resistance met at the eardrum is registered and recorded as a graph. Tympanograms are inaccurate in children younger than 7 months because the tympanic membrane is too compliant under that age to register normal impedance.

Conduction Loss Testing

Both the Rinne and the Weber tests are helpful assessments that can be used to help determine the cause of hearing loss in older children (Box 34.13).

Speech Assessment

Speech problems are directly related to hearing problems: infants who do not hear will make preliminary babbling sounds but then will not develop intelligible speech because they cannot hear and repeat sounds. Speech difficulties may also be related to:

- Motor development such as when the child cannot control tongue and facial muscles well enough to form proper words
- Cognitive development such as when the cognitively challenged child cannot grasp the concept of speech or word use until later than normal, or possibly not at all
- Cultural influences such as when the parents speak two languages, making it difficult for a child to accurately learn and articulate either language or when parents spoke "baby talk" for so long the child mimicked that instead of pronouncing words clearly

Speech screening begins by asking children a few simple questions to determine their language pattern. Also ask parents

TABLE 34.12 ✻ Levels of Hearing Loss

Hearing Loss (DB Level)	Hearing Level Present
Slight (<30)	Inability to hear whispered words or faint speech No speech challenge present Possible lack of awareness of hearing difficulty Achievement in school and home is attained by leaning forward, speaking loudly
Mild (30–50)	Beginning speech challenge possibly present Difficulty hearing if not facing speaker; some difficulty with normal conversation
Moderate (55–70)	Speech challenge present, possibly requiring speech therapy Difficulty with normal conversation
Severe (70–90)	Difficulty with any but nearby loud voice Vowels easier to hear than consonants Speech therapy required for clear speech. Possible ability to still hear loud sounds such as jets or whistle of train.
Profound (>90)	Almost no sound heard

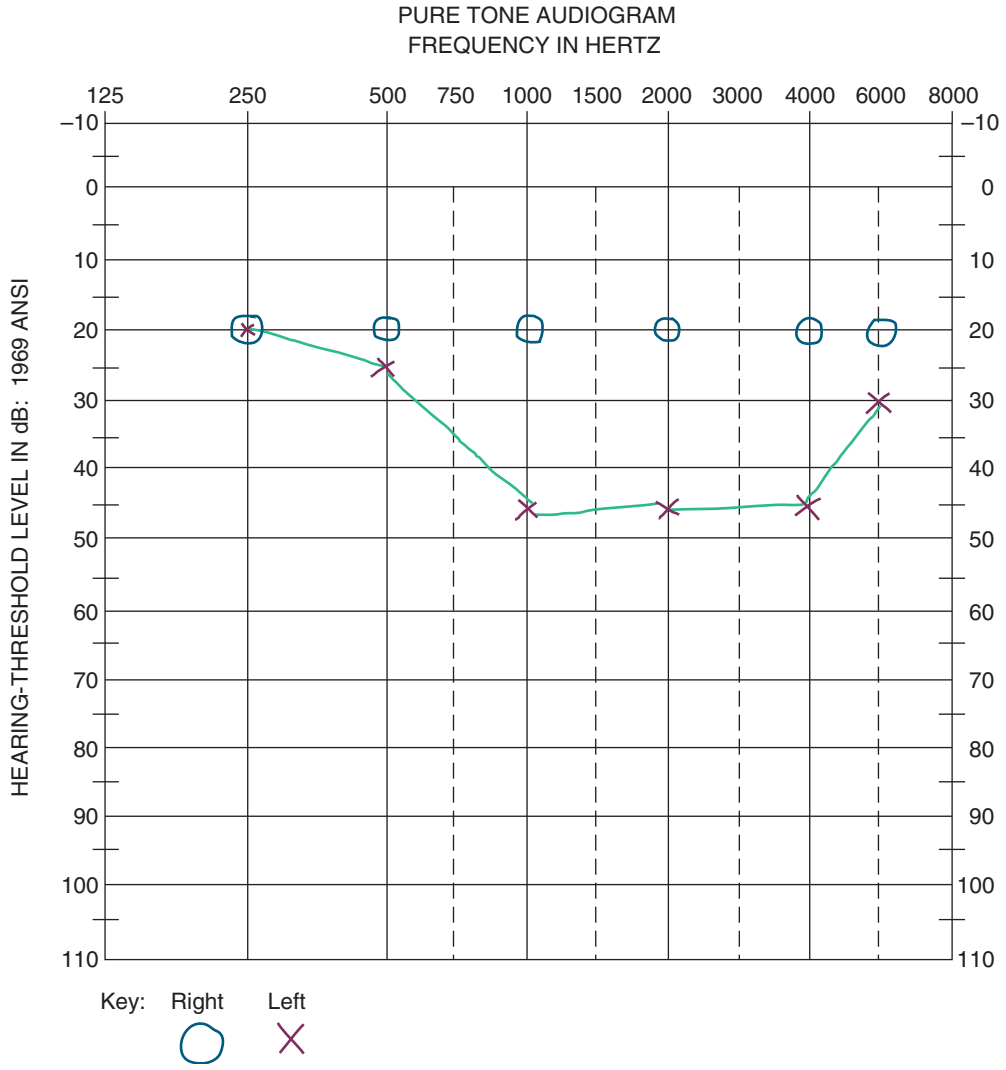

FIGURE 34.24 An audiogram done as a screening procedure. Notice that hearing is normal in the right ear (all frequencies are heard at the 20-dB level). In the left ear there is hearing loss (the frequencies 1000, 2000, and 4000 Hz are heard only at the 45-dB level). (Courtesy of Dr. H. Schill, Speech Pathology and Audiology Department, Boston University.)

if they have noticed any difficulties with their child's pronunciation or comprehension. Standardized tests, such as the Denver Articulation Screening Examination (DASE), may also be administered.

Denver Articulation Screening Examination

The DASE is designed to detect significant developmental delays and normal variations in the acquisition of speech sounds. Because it is a standardized test, its directions must be followed carefully. The test is useful only with English-speaking children.

Administration. Before the test, explain that the child will need to repeat some words she hears. Give enough examples so she will understand what she is to do: "When I say 'boat,' then you say 'boat.'" When you are certain the child understands the directions, say each of the 22 words shown on the DASE form (Fig. 34.25A). Convey the impression that there is no right or wrong answer. Give the child approval for responding and following directions correctly, no matter how inaccurately the child repeats the word.

Scoring. The DASE is designed for use with children between ages 2.5 and 6 years. In scoring, consider the child's age to be the closest previous age shown on the percentile rank chart (see Fig. 34.25B). Score the child's pronunciation of the underlined sounds or blends in each word on the test form. A perfect raw score is 30 correctly articulated sounds. Match this raw score on the percentile rank chart with the column representing the child's age. The number at which the raw score line and the age column meet is the percentile rank of the child (how the child compares with other children of that age). Percentiles shown above the heavy line are abnormal; those below the line are normal—for example, a 3-year-old who says only 12 sounds correctly ranks in the

BOX 34.13 ❇ Rinne and Weber Tests

Rinne and Weber tests are assessments for air and bone conduction.

Rinne Test

Strike a 500-Hz tuning fork and hold the stem of it against the child's mastoid bone. Ask the child to say when the tuning fork's ringing sound can no longer be heard. When the child says it is no longer audible, move the fork forward so it is at the auditory meatus (Figure A). Because air conduction is normally better than bone conduction, the child should hear it when it is held in front of the meatus, although it can no longer be heard when it was held against the bone. If the child does not hear it when it is brought forward, then the child's air conduction is probably reduced.

Weber Test

Strike a 500-Hz tuning fork and hold the stem of it against the top of the child's head (Figure B). The child with normal hearing in both ears will hear the sound equally well with both ears. If the child has an air conduction loss in one ear, the child will hear the sound better in that ear than in the good ear. The test must be used in conjunction with other evaluation tools because if the sound is intensified in one ear, it may mean that there is no hearing perception (there is nerve loss) in the opposite ear.

FIGURE 34.25 Denver Articulation Screening Exam (DASE). (**A**) Test form. *(continued)*

To score DASE words: Note Raw Score for child's performance. Match raw score line (extreme left of chart) with column representing child's age (to the closest previous age group). Where raw score line and age column meet number in that square denotes percentile rank of child's performance when compared to other children that age. Percentiles above heavy line are ABNORMAL percentiles, below heavy line are NORMAL.

PERCENTILE RANK

Raw Score	2.5 yr.	3.0	3.5	4.0	4.5	5.0	5.5	6 years

29		98	98	94	84	84	77	68
30		100	100	100	100	100	100	100

To Score intelligibility:

	NORMAL	ABNORMAL
2 1/2 years	Understandable 1/2 the time, or, "easy"	Not Understandable
3 years and older	Easy to understand	Understandable 1/2 time Not understandable

Test Result: 1. NORMAL on Dase and Intelligibility = NORMAL

2. ABNORMAL on Dase and/or Intelligibility = ABNORMAL

* If abnormal on initial screening rescreen within 2 weeks. If abnormal again child should be referred for complete speech evaluation.

B

FIGURE 34.25 *(continued)* (**B**) Percentile rank form. (Reprinted by permission. Copyright 1971 by Amelia F. Drumwright, University of Colorado Medical Center, Denver, CO.)

9th percentile (abnormal ranking), and a 3-year-old who says 20 sounds correctly ranks in the 58th percentile (normal ranking).

In addition to determining the percentile ranking, rate the child's spontaneous speech in terms of intelligibility as 1, easy to understand; 2, understandable half the time; 3, not understandable; or 4, cannot evaluate (maybe the child did not speak in sentences or phrases during your contact with the child). Score intelligibility according to the chart in Figure 34.25B. For a final score, rate the child's total test result (normal or abnormal on the DASE or intelligibility).

Children who score abnormally on this screening test should be retested in 2 weeks. If they still score abnormally, they should be referred for complete speech evaluation.

ASSESSING DEVELOPMENTAL MILESTONES

It would be ideal if children demonstrated all the developmental skills of which they are capable every time they are asked to demonstrate them. Rarely, however, do they accomplish this. Infants become hungry, sleepy, or upset during testing. Older children may become shy. A portion of developmental information on almost all health assessments, therefore, must be elicited by history taking. All previous developmental milestones must be obtained this way.

Developmental History

Many parents keep careful records of their first child's development, a less careful record of their second, a scanty record

of the third, and so on. The best information, therefore, generally depends on parents' memories.

Parents may not be able to recall the month during which a skill was first demonstrated. It is often helpful to ask them to try to remember in terms of holidays or seasons. For example, they may not know at which month their infant first used a pincer grasp (grasped cleanly with index finger and thumb) but do recall the way the child pinched the ear of the family dog at a summer picnic.

If parents seem to have no recall at all of developmental milestones that are important for the child's present evaluation, suggest they ask other family members or look through family photographs to jog their memories and then call with as much information as they can gather.

In addition to getting the parents' description of the skills a child has mastered, it is helpful to watch children perform skills and rate them according to standard criteria.

Denver II Developmental Screening Test

The Denver II Developmental Screening Test (see Appendix H) is the most widely used tool to assess childhood development (Frankenburg, 1994). The test can detect delays during infancy and the preschool years. Four main categories of development are rated:

1. Personal–social
2. Fine motor-adaptive
3. Language
4. Gross motor skills

Administration

The Denver II ideally should be completed when a child is approximately 3 or 4 months of age, again at about 10 months, and again at 3 years. It is a supplement to the developmental evaluation by history that should be a part of every well-child assessment.

The materials to administer the test must be purchased as a kit. They include a skein of red wool, a box of raisins, a small bottle, a bell, a rattle with a narrow handle, a tennis ball, ten 1-inch brightly colored blocks, a small plastic doll, a toy baby bottle, a plastic cup, and a pencil.

Although administration of the Denver II is not difficult, it should not be attempted except by health care providers trained specifically in its procedures and interpretation. This precaution is necessary to ensure the validity of its developmental norms. Periodic retraining and proficiency testing are recommended to sustain a high degree of accuracy in administration.

A parent should be cautioned before administration that this is not a test of intelligence but of the child's level of development. The child's inability to perform a task that most children of the same age can accomplish indicates a delay in that area. Further evaluation is then needed to determine the reason for this delay.

Scoring

The child is scored P (passed), F (failed), R (refused), or N.O. (no opportunity) on each item according to guidelines in the instruction manual. Each item is represented on the test form (see Appendix H) by a bar showing the ages by which 25%, 50%, 75%, and 90% of children normally have mastered that item. The left end of the bar is the 25% mark; the tick mark at the top of the bar, 50%; the left end of the colored (gray) area, 75%; and the right end of the bar, 90%. Looking at the form, notice, for example, the item "plays pat-a-cake" in the area of personal-social development. With this item, 25% of children show the trait at 7 months, 50% between 9 and 10 months, 75% between 10 and 11 months, and 90% by ages 11 to 12 months. Interpretation of performance is detailed in the manual.

Prescreening Test

A Denver Prescreening Developmental Questionnaire (R-PDQII) is available in addition to the Denver II. The PDQII is designed to identify children who require further testing with a full Denver II. It is a questionnaire completed by the parents addressing 10 developmental items. A child who scores 8 out of 10 or fewer should be retested in approximately 2 weeks. If the initial score is under 6 or the retest score is 8 or below, the child should have a full Denver II. Encouraging parents to complete a questionnaire this way can detect developmental delays that otherwise might be missed in a busy office or clinic (Hix-Small et al., 2007).

Cognitive Development

Children must learn many important concepts or ideas such as near, far, here, there, number sequences, how to judge time intervals, how to reason and solve problems, and how to judge weight before they can function effectively in the world.

This type of learning—gaining concepts—is cognitive learning and is measured by intelligence tests. **Intelligence** can be defined as the ability to think abstractly, to adjust to new situations, and to profit from experience. Almost everyone has had their intelligence quotient (IQ) rated at some point in a school career. Although intelligence tests are not part of routine health appraisals, it is helpful to be familiar with those that are used for childhood measurements because these findings are helpful in predicting children's school success.

The IQ is the ratio of mental age as measured by an intelligence test to chronologic age. The formula for IQ is (mental age/chronologic age) multiplied by 100. A child aged 9 years old (chronologic age) who passes all the items on an intelligence test that an average 9-year-old child passes would be (9 [mental age]/9 [chronologic age]) × 100 = 100 (child's IQ). If a child passes no more items than the average 5-year-old child would, the IQ would be (5 [mental age]/9 [chronologic age]) × 100 = 55. If a child passed all the items that a 12-year-old child normally passes, the IQ would be (12 [mental age]/9 [chronologic age]) × 100 = 133.

Intelligence scores are not always accurate because children may score poorly because of test anxiety. Cultural bias and past experience can also affect how children score. Therefore, labeling children by IQ and classifying them into divisions based on IQ is often unfair and must be done with considerable thought and study.

It is difficult to test very young children with any degree of accuracy because they lack the ability to complete tasks in the areas used for scoring intelligence tests: comprehension, imagination, reasoning, memory, and vocabulary. The most common tests used with infants include the Cattell Infant Intelligence Scale, the Bayley Mental Scale, and the Gesell

Developmental Schedule. These tests rely heavily on perceptual and motor skills as rating devices.

The two most frequently used tests for older children are the Wechsler Intelligence Scale for Children and the Stanford-Binet test. All schoolchildren take one of these tests during the primary school grades. The results are made available to child health care teams if they can demonstrate to school officials that such information is necessary for total health care or planning. If the information is unavailable, the child can be referred to a psychologist or a psychological testing clinic for assessment.

Goodenough-Harris Drawing Test

A child's drawing can reveal information on developmental or emotional problems. A Goodenough-Harris Drawing Test is a quick intelligence measurement that can be administered without special training (Goodenough, 1926). Give a child between 3 and 10 years of age a pencil and paper and tell the child to draw a person. Urge the child to draw it carefully and to take enough time to do it well.

The child receives 1 point for each of the items in the drawing listed in Box 34.14. For each 4 points scored, 1 year is added to a base age of 3 years to calculate the child's mental age. The image shown in Box 34.14 was drawn by a 4½-year-old child: it was given 8 points. The child's IQ level is therefore (5.0/4.5) times 100 = 111.

Scores on the test are reasonably reliable, correlating well with a Stanford-Binet test, although results may not be as reliable with children who are mentally ill. A child who scores significantly lower than chronologic age (after allowing for

BOX 34.14 ✻ Goodenough-Harris Drawing Test

Score one point for each characteristic listed below that is present on drawing. For every four points, 1 year is added to a base mental age of 3 years.

1. Head present
2. Legs present
3. Arms present

4a. Trunk present
b. Length of trunk greater than breadth
c. Shoulders indicated

5a. Both arms and legs attached to trunk
b. Legs attached to trunk; arms attached to trunk at correct point

6a. Neck present
b. Neck outline continuous with head, trunk, or both

7a. Eyes present
b. Nose present
c. Mouth present
d. Nose and mouth in two dimensions, two lips shown
e. Nostrils indicated

8a. Hair shown
b. Hair nontransparent, over more than circumference

9a. Clothing present
b. Two articles of clothing nontransparent
c. No transparencies, both sleeves and trousers shown
d. Four or more articles of clothing defnitely indicated
e. Costume complete, without incongruities

10a. Fingers shown
b. Correct number of fingers shown
c. Fingers in two dimensions, length greater than breadth, angle less than 180°
d. Opposition of thumb shown
e. Hand shown distinct from fingers or arms

11a. Arm joint shown, either elbow, shoulder, or both
b. Leg joint shown, either knee, hip, or both

12a. Head in proportion
b. Arms in proportion
c. Legs in proportion
d. Feet in proportion
e. Both arms and legs in two dimensions

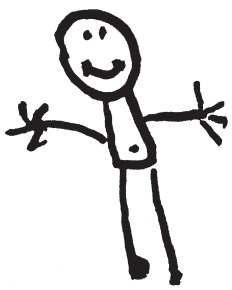
13. Heel shown

14a. Firm lines without overlapping at junctions
b. Firm lines with correct joining
c. Head outline more than circle
d. Trunk outline more than circle
e. Outline of arms and legs without narrowing at point of junction with body
f. Features symmetric, correct position

15a. Ears present
b. Ears in correct position and proportion

16a. Eye detail: brow and lashes shown
b. Eye detail: pupil shown
c. Eye detail: proportion correct
d. Eye detail: glance directed to front in profile drawing

17a. Both chin and forehead present
b. Projection of chin shown



An 8-point drawing

From Goodenough, F.L. (1926). *Measurement of intelligence by drawings.* New York: World Book Company, with permission.

fatigue, illness, strange surroundings, nervousness, physical ability to use a pencil, and previous practice using a pencil and paper) should be referred for more refined testing.

Temperament

Temperament refers to a child's innate behavioral characteristics, such as activity level, rhythmicity, tendency to approach or withdraw, and adaptability to situations (see Chapter 28). A child with an "easy" temperament is generally adaptable and easy to care for; a child with a "difficult" temperament, in contrast, will almost automatically create childrearing concerns. Helping parents assess their children's temperament helps them, in turn, recognize their children's uniqueness and so anticipate and ideally prevent personality conflicts as a child grows older and expresses identified reactions to situations. If a behavior or parent–child interaction problem is already present, a nursing assessment can be useful to determine whether temperament is a factor in the problem and to assist parents with constructive solutions (Thomas & Chess, 1977).

IMMUNIZATION STATUS

One of the most important health assessment and promotion measures for children is to establish that their immunization status is up to date (AAP, 2009; Tables 34.13 and 34.14). Routine immunization schedules call for children to receive immunity against a number of dangerous infections, including measles, mumps, rubella, diphtheria, tetanus, pertussis, hepatitis B, poliomyelitis, pneumococcal pneumonia, *H. influenzae* meningitis, varicella (chickenpox), and rotavirus. New influenza vaccines are developed yearly to help ward off influenza viruses. Human papillomavirus vaccination (HPV) is recommended for prepubertal girls. Research continues on the development of vaccines to combat other diseases, including HIV infection and West Nile virus.

Teach parents about the need for children to be immunized and the need to be able to describe the record of immunizations their child has received. If gaps occur in a child's immunizations, remind the child's primary care provider about this lack in protection and prepare to administer the necessary vaccines.

Help parents understand that although diseases such as measles and mumps are referred to as common childhood illnesses, they are serious illnesses, possibly leading to complications such as pneumonia and encephalitis. When children develop these common communicable diseases, they need to be seen by a primary health care provider to minimize the risk for these complications (see Chapter 43).

Types of Immunizations

Immunizations or vaccines are the solutions used to immunize children to provide artificially acquired active or passive immunity. Box 34.15 reviews characteristics of active and passive immunity.

Vaccines are prepared in a number of forms. Attenuated vaccines are made from live organisms that have been reduced in virulence to a point where they will not cause active disease but will ensure a good antibody response. Because they are strong and effective solutions, a single dose usually provides a good degree of active immunity.

Because some bacteria, such as diphtheria, cause disease by producing a toxin, the vaccine against such a disease, a **toxoid,** is actually an extract of the toxin with reduced virulence. The antibodies produced against toxin-producing bacteria are **antitoxins.** The solution given for passive immunity against diphtheria is an antitoxin.

Gamma globulin is serum obtained from the pooled blood of many people. Because it combines the serum of many people, it probably has antibody protection against measles, rubella, poliomyelitis, varicella, and hepatitis B, among many other infectious diseases. When administered, it offers artificially acquired passive immunity.

Immune serums are serums available against specific diseases such as diphtheria, tetanus, the pit viper snake, black widow spider, and respiratory syncytial virus. Like general immune globulin, these provide passive immunity.

Available Vaccines

The AAP and CDC issue specific recommendations for childhood immunization (see Table 34.13 and Appendix J).

Diphtheria, Tetanus, Pertussis (DTaP) Vaccines

Diphtheria, tetanus toxoid, and acellular pertussis (whooping cough) vaccines are supplied in a single vial as DTaP and given in one intramuscular injection. It is recommended that children receive a primary series of four immunizations with the vaccine (2, 4, 6, and 15 to 18 months). A booster is then given between 4 and 6 years, or before entry into school. In the past, no further pertussis vaccine was administered after this point. Now, because of whooping cough outbreaks in the teenage or young adult population, a combined injection of diphtheria, tetanus toxoid, and acellular pertussis (Tdap vaccine) is recommended at 11 to 12 years. Teenagers who did not receive the 11/12-year booster or received only diphtheria/tetanus injection at that time are encouraged to receive one dose of Tdap 5 years after the last Td/DTaP dose. It is recommended that adults continue with tetanus prophylaxis every 10 years throughout life to keep tetanus immunization current.

In the past, a great deal of controversy arose about the safety of the diphtheria-tetanus-pertussis vaccine, most of it directed at the pertussis component. Severe reactions, such as high fever, persistent crying, and even seizures, were reported. For this reason, the former DTP vaccine has been modified to DTaP or contains a less reactive pertussis component. Side effects can still include drowsiness, fretfulness, low-grade fever, and redness and pain at the injection site.

Some parents, after hearing about reactions to the former vaccine, may refuse immunizations for their children. This is their right, but children who are not immunized against pertussis (unless there is a medical or moral contraindication) may be refused admittance to preschool or beginning school programs. Parents should be informed of this when they refuse to sign consent for immunization.

Pertussis vaccination is contraindicated in children who have a progressive or unstable neurologic disorder or who have had a severe allergic reaction to pertussis in a previous DTaP vaccination. If pertussis immunization is contraindicated, the Td, or diphtheria-tetanus vaccine, is substituted.

TABLE 34.13 ✻ Recommended Immunization Schedule for Persons Aged 0 Through 6 Years—United States • 2009 (For those who fall behind or start late, see the catch-up schedule)

Vaccine ▼ / Age ►	Birth	1 month	2 months	4 months	6 months	12 months	15 months	18 months	19–23 months	2–3 years	4–6 years

Meningococcal[10]										MCV	

Range of recommended ages

Certain high-risk groups

This schedule indicates the recommended ages for routine administration of currently licensed vaccines, as of December 1, 2008, for children aged 0 through 6 years. Any dose not administered at the recommended age should be administered at a subsequent visit, when indicated and feasible. Licensed combination vaccines may be used whenever any component of the combination is indicated and other components are not contraindicated and if approved by the Food and Drug Administration for that dose of the series. Providers should consult the relevant Advisory Committee on Immunization Practices statement for detailed recommendations, including high-risk conditions: http://www.cdc.gov/vaccines/pubs/acip-list.htm. Clinically significant adverse events that follow immunization should be reported to the Vaccine Adverse Event Reporting System (VAERS). Guidance about how to obtain and complete a VAERS form is available at http://www.vaers.hhs.gov or by telephone, 800-822-7967.

1. Hepatitis B vaccine (HepB). ***(Minimum age: birth)***

At birth:

- Administer monovalent HepB to all newborns before hospital discharge.
- If mother is hepatitis B surface antigen (HBsAg)-positive, administer HepB and 0.5 mL of hepatitis B immune globulin (HBIG) within 12 hours of birth.
- If mother's HBsAg status is unknown, administer HepB within 12 hours of birth. Determine mother's HBsAg status as soon as possible and, if HBsAg-positive, administer HBIG (no later than age 1 week).

After the birth dose:

- The HepB series should be completed with either monovalent HepB or a combination vaccine containing HepB. The second dose should be administered at age 1 or 2 months. The final dose should be administered no earlier than age 24 weeks.
- Infants born to HBsAg-positive mothers should be tested for HBsAg and antibody to HBsAg (anti-HBs) after completion of at least 3 doses of the HepB series, at age 9 through 18 months (generally at the next well-child visit).

4-month dose:

- Administration of 4 doses of HepB to infants is permissible when combination vaccines containing HepB are administered after the birth dose.

2. Rotavirus vaccine (RV). ***(Minimum age: 6 weeks)***

- Administer the first dose at age 6 through 14 weeks (maximum age: 14 weeks 6 days). Vaccination should not be initiated for infants aged 15 weeks or older (i.e., 15 weeks 0 days or older).
- Administer the final dose in the series by age 8 months 0 days.
- If Rotarix® is administered at ages 2 and 4 months, a dose at 6 months is not indicated.

3. Diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP). ***(Minimum age: 6 weeks)***

- The fourth dose may be administered as early as age 12 months, provided at least 6 months have elapsed since the third dose.
- Administer the final dose in the series at age 4 through 6 years.

4. *Haemophilus influenzae* type b conjugate vaccine (Hib). ***(Minimum age: 6 weeks)***

- If PRP-OMP (PedvaxHIB® or Comvax® [HepB-Hib]) is administered at ages 2 and 4 months, a dose at age 6 months is not indicated.
- TriHiBit® (DTaP/Hib) should not be used for doses at ages 2, 4, or 6 months but can be used as the final dose in children aged 12 months or older.

5. Pneumococcal vaccine. ***(Minimum age: 6 weeks for pneumococcal conjugate vaccine [PCV]; 2 years for pneumococcal polysaccharide vaccine [PPSV])***

- PCV is recommended for all children aged younger than 5 years. Administer 1 dose of PCV to all healthy children aged 24 through 59 months who are not completely vaccinated for their age.
- Administer PPSV to children aged 2 years or older with certain underlying medical conditions (see *MMWR* 2000;49[No. RR-9]), including a cochlear implant.

6. Influenza vaccine. ***(Minimum age: 6 months for trivalent inactivated influenza vaccine [TIV]; 2 years for live, attenuated influenza vaccine [LAIV])***

- Administer annually to children aged 6 months through 18 years.
- For healthy nonpregnant persons (i.e., those who do not have underlying medical conditions that predispose them to influenza complications) aged 2 through 49 years, either LAIV or TIV may be used.
- Children receiving TIV should receive 0.25 mL if aged 6 through 35 months or 0.5 mL if aged 3 years or older.
- Administer 2 doses (separated by at least 4 weeks) to children aged younger than 9 years who are receiving influenza vaccine for the first time or who were vaccinated for the first time during the previous influenza season but only received 1 dose.

7. Measles, mumps, and rubella vaccine (MMR). ***(Minimum age: 12 months)***

- Administer the second dose at age 4 through 6 years. However, the second dose may be administered before age 4, provided at least 28 days have elapsed since the first dose.

8. Varicella vaccine. ***(Minimum age: 12 months)***

- Administer the second dose at age 4 through 6 years. However, the second dose may be administered before age 4, provided at least 3 months have elapsed since the first dose.
- For children aged 12 months through 12 years the minimum interval between doses is 3 months. However, if the second dose was administered at least 28 days after the first dose, it can be accepted as valid.

9. Hepatitis A vaccine (HepA). ***(Minimum age: 12 months)***

- Administer to all children aged 1 year (i.e., aged 12 through 23 months). Administer 2 doses at least 6 months apart.
- Children not fully vaccinated by age 2 years can be vaccinated at subsequent visits.
- HepA also is recommended for children older than 1 year who live in areas where vaccination programs target older children or who are at increased risk of infection. See *MMWR* 2006;55(No. RR-7).

10. Meningococcal vaccine. ***(Minimum age: 2 years for meningococcal conjugate vaccine [MCV] and for meningococcal polysaccharide vaccine [MPSV])***

- Administer MCV to children aged 2 through 10 years with terminal complement component deficiency, anatomic or functional asplenia, and certain other high-risk groups. See *MMWR* 2005;54(No. RR-7).
- Persons who received MPSV 3 or more years previously and who remain at increased risk for meningococcal disease should be revaccinated with MCV.

The Recommended Immunization Schedules for Persons Aged 0 Through 18 Years are approved by the Advisory Committee on Immunization Practices (www.cdc.gov/vaccines/recs/acip), the American Academy of Pediatrics (http://www.aap.org), and the American Academy of Family Physicians (http://www.aafp.org).

Human Papillomavirus[2]	*see footnote 2*	HPV (3 doses)	HPV Series
Meningococcal[3]	MCV	MCV	MCV
Influenza[4]	Influenza (Yearly)		
Pneumococcal[5]	PPSV		
Hepatitis A[6]	HepA Series		
Hepatitis B[7]	HepB Series		
Inactivated Poliovirus[8]	IPV Series		
Measles, Mumps, Rubella[9]	MMR Series		
Varicella[10]	Varicella Series		

Range of recommended ages

Catch-up immunization

Certain high-risk groups

This schedule indicates the recommended ages for routine administration of currently licensed vaccines, as of December 1, 2008, for children aged 7 through 18 years. Any dose not administered at the recommended age should be administered at a subsequent visit, when indicated and feasible. Licensed combination vaccines may be used whenever any component of the combination is indicated and other components are not contraindicated and if approved by the Food and Drug Administration for that dose of the series. Providers should consult the relevant Advisory Committee on Immunization Practices statement for detailed recommendations, including high risk conditions: http://www.cdc.gov/vaccines/pubs/acip-list.htm. Clinically significant adverse events that follow immunization should be reported to the Vaccine Adverse Event Reporting System (VAERS). Guidance about how to obtain and complete a VAERS form is available at http://www.vaers.hhs.gov or by telephone, 800-822-7967.

1. **Tetanus and diphtheria toxoids and acellular pertussis vaccine (Tdap).** ***(Minimum age: 10 years for BOOSTRIX® and 11 years for ADACEL®)***
   - Administer at age 11 or 12 years for those who have completed the recommended childhood DTP/DTaP vaccination series and have not received a tetanus and diphtheria toxoid (Td) booster dose.
   - Persons aged 13 through 18 years who have not received Tdap should receive a dose.
   - A 5-year interval from the last Td dose is encouraged when Tdap is used as a booster dose; however, a shorter interval may be used if pertussis immunity is needed.
2. **Human papillomavirus vaccine (HPV).** ***(Minimum age: 9 years)***
   - Administer the first dose to females at age 11 or 12 years.
   - Administer the second dose 2 months after the first dose and the third dose 6 months after the first dose (at least 24 weeks after the first dose).
   - Administer the series to females at age 13 through 18 years if not previously vaccinated.
3. **Meningococcal conjugate vaccine (MCV).**
   - Administer at age 11 or 12 years, or at age 13 through 18 years if not previously vaccinated.
   - Administer to previously unvaccinated college freshmen living in a dormitory.
   - MCV is recommended for children aged 2 through 10 years with terminal complement component deficiency, anatomic or functional asplenia, and certain other groups at high risk. See *MMWR* 2005;54(No. RR-7).
   - Persons who received MPSV 5 or more years previously and remain at increased risk for meningococcal disease should be revaccinated with MCV.
4. **Influenza vaccine.**
   - Administer annually to children aged 6 months through 18 years.
   - For healthy nonpregnant persons (i.e., those who do not have underlying medical conditions that predispose them to influenza complications) aged 2 through 49 years, either LAIV or TIV may be used.
   - Administer 2 doses (separated by at least 4 weeks) to children aged younger than 9 years who are receiving influenza vaccine for the first time or who were vaccinated for the first time during the previous influenza season but only received 1 dose.
5. **Pneumococcal polysaccharide vaccine (PPSV).**
   - Administer to children with certain underlying medical conditions (see *MMWR* 1997;46[No. RR-8]), including a cochlear implant. A single revaccination should be administered to children with functional or anatomic asplenia or other immunocompromising condition after 5 years.
6. **Hepatitis A vaccine (HepA).**
   - Administer 2 doses at least 6 months apart.
   - HepA is recommended for children older than 1 year who live in areas where vaccination programs target older children or who are at increased risk of infection. See *MMWR* 2006;55(No. RR-7).
7. **Hepatitis B vaccine (HepB).**
   - Administer the 3-dose series to those not previously vaccinated.
   - A 2-dose series (separated by at least 4 months) of adult formulation Recombivax HB® is licensed for children aged 11 through 15 years.
8. **Inactivated poliovirus vaccine (IPV).**
   - For children who received an all-IPV or all-oral poliovirus (OPV) series, a fourth dose is not necessary if the third dose was administered at age 4 years or older.
   - If both OPV and IPV were administered as part of a series, a total of 4 doses should be administered, regardless of the child's current age.
9. **Measles, mumps, and rubella vaccine (MMR).**
   - If not previously vaccinated, administer 2 doses or the second dose for those who have received only 1 dose, with at least 28 days between doses.
10. **Varicella vaccine.**
    - For persons aged 7 through 18 years without evidence of immunity (see *MMWR* 2007;56[No. RR-4]), administer 2 doses if not previously vaccinated or the second dose if they have received only 1 dose.
    - For persons aged 7 through 12 years, the minimum interval between doses is 3 months. However, if the second dose was administered at least 28 days after the first dose, it can be accepted as valid.
    - For persons aged 13 years and older, the minimum interval between doses is 28 days.

The Recommended Immunization Schedules for Persons Aged 0 Through 18 Years are approved by the Advisory Committee on Immunization Practices (www.cdc.gov/vaccines/recs/acip), the American Academy of Pediatrics (http://www.aap.org), and the American Academy of Family Physicians (http://www.aafp.org).

DEPARTMENT OF HEALTH AND HUMAN SERVICES • CENTERS FOR DISEASE CONTROL AND PREVENTION

BOX 34.15 ✻ Active Versus Passive Immunity

Immunity, the ability to combat a particular antigen, may be either active or passive.

Active Immunity. When a child produces antibodies after the natural invasion of a pathogen (the child has measles, for example), the child is said to have *naturally acquired active immunity.* Active antibodies (or the child's ability to produce antibodies rapidly should the specific antigen [measles] invade again) last a lifetime. When pathogens are artificially injected into the child by immunization, the child receives *artificially acquired active immunity.* If the specific antigen should enter again, antibodies are produced against the pathogen that are just as lasting as those produced in naturally acquired active immunity.

Passive Immunity. IgG antibodies that a woman possesses either through immunization or through having had a disease are transferred across the placenta to a fetus in utero. Because the fetus does not make these antibodies but merely receives them, this is termed *naturally acquired passive immunity.* Passive immunity lasts only months. Some antibodies transferred across the placenta may have slightly longer lifetimes than this. For example, measles antibodies have been isolated up to age 1 year, and that is why measles immunization must be delayed until age 15 months (AAP, 2009).

When children are exposed to a disease against which they have no antibodies, antibodies made synthetically or obtained from animal serum may be injected into the child to give rapid immunity (*artificially acquired passive immunity*). Like naturally acquired passive antibodies, these last only approximately 6 weeks. A child who is susceptible to tetanus, for example, would receive tetanus antibodies after a stab wound.

Polio Vaccines

Inactivated polio vaccine (IPV) contains all three strains of poliovirus and is the type preferred for routine immunization. IPV is administered in a primary series of three doses and given along with DTaP at 2, 4, and 6 to 18 months of age. A fourth booster dose is given between the ages of 4 and 6 years, before school entry (AAP, 2009).

Measles, Mumps, Rubella (MMR) Vaccines

Measles-mumps-rubella vaccine is furnished in one injection and routinely administered between 12 and 15 months. A second dose of MMR is generally given between the ages of 4 to 6 years or, if the child did not receive the 4- to 6-year dose, at 11 to 12 years. Although MMR may be given as early as 12 months, it is usually recommended that the vaccine not be administered to children younger than 15 months because children receive a great deal of passive immunity to measles from their mothers across the placenta. Until this passive immunity has faded, the injected vaccine will be neutralized by passive antibodies and no immunity will result. For the same reason, children who have recently received immune globulin or other blood products that contain antibodies should not receive MMR vaccination for about 3 months because the passively acquired antibodies could interfere with the child's immune response to the vaccine.

Side effects of the vaccine include transient rash and a fever, which may begin 5 to 12 days after vaccination and last several days. Adverse reactions include joint pain, low-grade fever, rash, and lymphadenopathy 5 to 12 days after vaccination.

Children should be skin-tested for tuberculosis before measles vaccine administration because measles virus can cause tuberculosis to become systemic. Tuberculosis skin tests also may show false-negative reactions if given shortly after measles immunization (a child who has active tuberculosis would be wrongly identified as not having it).

Formerly, there was a concern that the administration of the MMR vaccine was associated with the development of autism in children, as symptoms of autism often begin to be apparent during the second year or close to the time of MMR vaccine administration. Further research has shown there to be no causal relationship between the vaccine and autism, dispelling this fear (Clifton, 2007). Parents may ask about this, however, and refuse to have their child immunized against MMR for this reason.

Hepatitis B Vaccine

The vaccine for hepatitis B virus (HBV) is recommended for all infants in the United States as Hepatitis B is associated with liver cancer later in life. Three doses are required. Those born to hepatitis B surface antigen (HBsAg)-negative mothers should receive the first dose in the newborn period before hospital discharge, a second dose 1 month after the first dose, and a third dose 2 months later but not before 6 months of age. Those born to HBsAg-positive mothers should receive hepatitis B immune globulin within 12 hours of birth plus HBV. A second dose of HBV is recommended at 1 to 2 months, and a third dose at 6 months. If the mother's HBsAg status is unknown, infants should receive the vaccine within 12 hours of birth, the second dose at 1 month of age, and the third dose at 6 months of age. Children who did not receive the vaccine at birth may begin a two-injection or three-injection series, depending on the vaccine used at any well-child visit. In addition, HBV immunization is recommended for populations at increased risk for contracting hepatitis B infection, including (but not limited to) health care workers with significant exposure to blood, clients receiving hemodialysis, those with hemophilia and others receiving clotting factor concentrates, illicit injectable drug users, and sexually active individuals with multiple sexual partners.

Hepatitis A Vaccine

Two doses of hepatitis A vaccine, administered 6 months apart, are recommended for all children between 1 and 2 years of age. Children who did not receive this as toddlers can be vaccinated against hepatitis A at any time.

Rotavirus Vaccine

Rotaviruses are responsible for the majority of severe gastrointestinal disease in infants so immunization against these

viruses is important in preventing outbreaks of diarrhea in infants, particularly those who attend a day care setting. The vaccine is given at 2, 4 and 6 months. No doses should be given after children are older than 32 weeks.

H. influenzae Type B Vaccines

H. influenzae type b conjugate vaccine (Hib) protects against *H. influenzae* bacteria, a major cause of meningitis in children. You may need to explain the difference between *H. influenzae* (a bacteria) and influenza virus, so that parents do not think that a "flu shot" protects against this. Several formulations of this vaccine are available, and three of them are currently licensed for use in infancy. Depending on the individual vaccine, they are administered in a two-dose (at age 2 and 4 months) or a three-dose regimen (at 2, 4, and 6 months, with an additional booster at 12 months). Local reactions include tenderness at the injection site. Systemic reactions such as crying and fever may occur (AAP, 2009).

Varicella Vaccine

Varicella (chickenpox) vaccine was a difficult vaccine to develop because of the complex structure of the herpes-zoster virus. It is an important vaccine because once a generation of children has been successfully immunized, it should mark the end of epidemic childhood diseases. Infants may receive varicella vaccine at any visit after their first birthday (usually scheduled at 12 to 18 months) and again at 4 to 6 years. Those who did not receive the vaccine as infants and who lack a reliable history of chickenpox should be immunized during adolescence with two doses of vaccine, administered at least 1 month apart.

Pneumococcal Pneumonia Vaccine

The pneumococcal vaccine is recommended for all children between 2 and 23 months. The vaccine is administered at 2, 4, 6, and 12 months and provides protection for 6 to 10 years (AAP, 2009). It is especially recommended for children (and adults) who would be prone to a pneumococcal infection (those with pulmonary or cardiac disease, those without a spleen, those who are immunosuppressed).

Human Papillomavirus Vaccine

The human papillomavirus (HPV) is associated with the development of cervical cancer in women. To help prevent HPV, it is recommended that all girls receive three injections of this vaccine beginning at 11 to 12 years of age. The second dose should be administered 2 months after the first and the third dose 6 months after the first dose. Those who did not receive the vaccine in early adolescence can receive it at any time, respecting the proper monthly intervals for administration. Some teenagers who have taken abstinence pledges not to have sexual relations until they are married may voice that they do not need the vaccine. Counseling them about the safety of prophylaxis may be necessary.

Meningococcal Vaccine

Children who have immunologic deficiencies or have had their spleen removed because of trauma or therapy for a blood dyscrasia are prone to develop meningitis caused by meningococcal bacteria. Children in these high-risk groups are, therefore, advised to receive a meningococcal vaccine between 2 and 10 years of age. As meningitis occurs frequently on college campuses, previously unvaccinated college freshmen living in dormitories should also receive the vaccine.

Lyme Disease Vaccine

Lyme disease is a serious and debilitating infection caused by *Borrelia burgdorferi* and transmitted by the bite of a deer tick. A vaccine to guard against it is available for high-risk populations such as workers who maintain power lines and hunters. Although the initial trials are favorable, it has not yet been approved for children under 15 years of age (AAP, 2009).

Influenza Vaccine

Influenza is caused by A, B, or C retroviruses, which mutate so easily it has been impossible to design a vaccine that is effective for longer than 1 year. All children, infants through adolescents, particularly those who have chronic pulmonary or cardiovascular disorders or are immunosuppressed, should receive a yearly injection of the vaccine. As the vaccine can be supplied as a nasal spray, receiving the vaccine is painless (AAP, 2009).

Anthrax and Smallpox Vaccines

Anthrax is a potentially fatal disease caused by a gram-positive spore-forming anthracis bacillus spread by farm animal feces. It is extremely rare, but parents may ask about a vaccine for it because of the threat of biologic warfare associated with terrorism. A vaccine is available for people in high-risk occupations, such as hunters, taxidermists, or veterinarians, but it is not recommended for children yet.

Smallpox is an extremely infectious disease caused by the smallpox virus and transmitted by direct or indirect contact. Smallpox vaccination has not been required in the United States for over 30 years because the disease is theoretically extinct across the world. As with anthrax, parents may ask about vaccination for it because it is a disease associated with biologic warfare and terrorism. Both a vaccine (active artificial immunity) and passive artificial immunity are available, should a child be exposed to the virus. In some high-risk communities, health care providers are asked to be immunized to be certain that they will not contract the virus in a terrorist attack (Wiser, Balicer, & Cohen, 2007).

Administration of Immunizations

Assess well children at health maintenance visits and assess the immunization status of ill children at clinic or hospital admission to identify those who need their immunizations updated. Children who are seriously ill should not receive immunizations, but a slight upper respiratory tract infection (a stuffy nose with no fever) is not a contraindication. So many infants and preschoolers have common cold symptoms (the average toddler has 10 to 12 colds a year) that if children were not immunized at health maintenance visits when they have slight cold symptoms, many would never receive basic immunizations. Table 34.13 shows current recommended childhood immunizations, Table 34.14 displays recommended adolescent recommendations, and Table 34.15 displays immunizations for children who did not receive primary immunizations

TABLE 34.15 ✻ Catch-up Immunization Schedule for Persons Aged 4 Months Through 18 Years Who Start Late or Who Are More Than 1 Month Behind—United States • 2009

The table below provides catch-up schedules and minimum intervals between doses for children whose vaccinations have been delayed. A vaccine series does not need to be restarted, regardless of the time that has elapsed between doses. Use the section appropriate for the child's age.

CATCH-UP SCHEDULE FOR PERSONS AGED 4 MONTHS THROUGH 6 YEARS

VACCINE	Minimum Age for Dose 1	Minimum Interval Between Doses			
		Dose 1 to Dose 2	Dose 2 to Dose 3	Dose 3 to Dose 4	Dose 4 to Dose 5
Hepatitis B[1]	**Birth**	**4 weeks**	**8 weeks** (and at least 16 weeks after first dose)		
Rotavirus[2]	**6 wks**	**4 weeks**	**4 weeks**[2]		
Diphtheria, Tetanus, Pertussis[3]	**6 wks**	**4 weeks**	**4 weeks**	**6 months**	**6 months**[3]
***Haemophilus influenzae* type b**[4]	**6 wks**	**4 weeks** if first dose administered at younger than age 12 months **8 weeks (as final dose)** if first dose administered at at age 12–14 months **No further doses needed** if first dose administered at age 15 months or older	**4 weeks**[4] if current age is younger than 12 months **8 weeks (as final dose)**[4] if current age is 12 months or older and second dose administered at younger than age 15 months **No further doses needed** if previous dose administered at age 15 months or older	**8 weeks (as final dose)** This dose only necessary for children aged 12 months through 59 months who received 3 doses before age 12 months	
Pneumococcal[5]	**6 wks**	**4 weeks** if first dose administered at younger than age 12 months **8 weeks (as final dose for healthy children)** if first dose administered at age 12 months or older or current age 24 through 59 months **No further doses needed** for healthy children if first dose administered at age 24 months or older	**4 weeks** if current age is younger than 12 months **8 weeks (as final dose for healthy children)** if current age is 12 months or older **No further doses needed** for healthy children if previous dose administered at age 24 months or older	**8 weeks (as final dose)** This dose only necessary for children aged 12 months through 9 months who received 3 doses before age 12 months or for high-risk children who received 3 doses at any age	

1. **Hepatitis B vaccine (HepB).**
   - Administer the 3-dose series to those not previously vaccinated.
   - A 2-dose series (separated by at least 4 months) of adult formulation Recombivax HB® is licensed for children aged 11 through 15 years.
2. **Rotavirus vaccine (RV).**
   - The maximum age for the first dose is 14 weeks 6 days. Vaccination should not be initiated for infants aged 15 weeks or older (i.e., 15 weeks 0 days or older).
   - Administer the final dose in the series by age 8 months 0 days.
   - If Rotarix® was administered for the first and second doses, a third dose is not indicated.
3. **Diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP).**
   - The fifth dose is not necessary if the fourth dose was administered at age 4 years or older.
4. ***Haemophilus influenzae* type b conjugate vaccine (Hib).**
   - Hib vaccine is not generally recommended for persons aged 5 years or older. No efficacy data are available on which to base a recommendation concerning use of Hib vaccine for older children and adults. However, studies suggest good immunogenicity in persons who have sickle cell disease, leukemia, or HIV infection, or who have had a splenectomy; administering 1 dose of Hib vaccine to these persons is not contraindicated.
   - If the first 2 doses were PRP-OMP (PedvaxHIB® or Comvax®), and administered at age 11 months or younger, the third (and final) dose should be administered at age 12 through 15 months and at least 8 weeks after the second dose.
   - If the first dose was administered at age 7 through 11 months, administer 2 doses separated by 4 weeks and a final dose at age 12 through 15 months.
5. **Pneumococcal vaccine.**
   - Administer 1 dose of pneumococcal conjugate vaccine (PCV) to all healthy children aged 24 through 59 months who have not received at least 1 dose of PCV on or after age 12 months.

(continued)

TABLE 34.15 ✻ Catch-up Immunization Schedule for Persons Aged 4 Months Through 18 Years Who Start Late or Who Are More Than 1 Month Behind—United States • 2009 (continued)

CATCH-UP SCHEDULE FOR PERSONS AGED 4 MONTHS THROUGH 6 YEARS

VACCINE	Minimum Age for Dose 1	Minimum Interval Between Doses			
		Dose 1 to Dose 2	Dose 2 to Dose 3	Dose 3 to Dose 4	Dose 4 to Dose 5
Inactivated Poliovirus[6]	**6 wks**	**4 weeks**	**4 weeks**	**4 weeks**[6]	
Measles, Mumps, Rubella[7]	**12 mos**	**4 weeks**			
Varicella[8]	**12 mos**	**3 months**			
Hepatitis A[9]	**12 mos**	**6 months**			

CATCH-UP SCHEDULE FOR PERSONS AGED 7 THROUGH 18 YEARS

Tetanus, Diphtheria/ Tetanus, Diphtheria, Pertussis[10]	**7 yrs**[10]	**4 weeks**	**4 weeks** if first dose administered at younger than age 12 months **6 months** if first dose administered at age 12 months or older	**6 months** if first dose administered at younger than age 12 months	
Human Papillomavirus[11]	**9 yrs**	**Routine dosing intervals are recommended**[11]			
Hepatitis A[9]	**12 mos**	**6 months**			
Hepatitis B[1]	**Birth**	**4 weeks**	**8 weeks** (and at least 16 weeks after first dose)		
Inactivated Poliovirus[6]	**6 wks**	**4 weeks**	**4 weeks**	**4 weeks**[6]	
Measles, Mumps, Rubella[7]	**12 mos**	**4 weeks**			
Varicella[8]	**12 mos**	**3 months** if the person is younger than age 13 years **4 weeks** if the person is aged 13 years or older			

- For children aged 24 through 59 months with underlying medical conditions, administer 1 dose of PCV if 3 doses were received previously or administer 2 doses of PCV at least 8 weeks apart if fewer than 3 doses were received previously.
- Administer pneumococcal polysaccharide vaccine (PPSV) to children aged 2 years or older with certain underlying medical conditions (see *MMWR* 2000;49[No. RR-9]), including a cochlear implant, at least 8 weeks after the last dose of PCV.

6. Inactivated poliovirus vaccine (IPV).
- For children who received an all-IPV or all-oral poliovirus (OPV) series, a fourth dose is not necessary if the third dose was administered at age 4 years or older.
- If both OPV and IPV were administered as part of a series, a total of 4 doses should be administered, regardless of the child's current age.

7. Measles, mumps, and rubella vaccine (MMR).
- Administer the second dose at age 4 through 6 years. However, the second dose may be administered before age 4, provided at least 28 days have elapsed since the first dose.
- If not previously vaccinated, administer 2 doses with at least 28 days between doses.

8. Varicella vaccine.
- Administer the second dose at age 4 through 6 years. However, the second dose may be administered before age 4, provided at least 3 months have elapsed since the first dose.
- For persons aged 12 months through 12 years, the minimum interval between doses is 3 months. However, if the second dose was administered at least 28 days after the first dose, it can be accepted as valid.
- For persons aged 13 years and older, the minimum interval between doses is 28 days.

9. Hepatitis A vaccine (HepA).
- HepA is recommended for children older than 1 year who live in areas where vaccination programs target older children or who are at increased risk of infection. See *MMWR* 2006;55(No. RR-7).

10. Tetanus and diphtheria toxoids vaccine (Td) and tetanus and diphtheria toxoids and acellular pertussis vaccine (Tdap).
- Doses of DTaP are counted as part of the Td/Tdap series
- Tdap should be substituted for a single dose of Td in the catch-up series or as a booster for children aged 10 through 18 years; use Td for other doses.

11. Human papillomavirus vaccine (HPV).
- Administer the series to females at age 13 through 18 years if not previously vaccinated.
- Use recommended routine dosing intervals for series catch-up (i.e., the second and third doses should be administered at 2 and 6 months after the first dose). However, the minimum interval between the first and second doses is 4 weeks. The minimum interval between the second and third doses is 12 weeks, and the third dose should be given at least 24 weeks after the first dose.

Information about reporting reactions after immunization is available online at **http://www.vaers.hhs.gov** or by telephone, **800-822-7967**. Suspected cases of vaccine-preventable diseases should be reported to the state or local health department. Additional information, including precautions and contraindications for immunization, is available from the National Center for Immunization and Respiratory Diseases at **http://www.cdc.gov/vaccines** or telephone, **800-CDC-INFO (800-232-4636).**

DEPARTMENT OF HEALTH AND HUMAN SERVICES • CENTERS FOR DISEASE CONTROL AND PREVENTION

or are behind in a vaccination schedule (a catch-up schedule). Because these schedules change yearly based on the introduction of new vaccines or new potential health threats, consult the AAP web site (http://www.aap.org) for up-to-date information before immunizing a specific child.

Because children with chronic illnesses may be hospitalized when an injection is due, such children often fall behind schedule. Children who miss the scheduled time for an immunization should not have the series started over but simply continued where they left off.

Primary care providers may choose to alter the sequence of immunization schedules if specific infections are prevalent at the time. For example, measles vaccine might be given on a first health maintenance visit (providing a child is older than 12 months) if an epidemic were currently under way in the community.

Children who are immunosuppressed, receiving corticosteroids, or receiving chemotherapy or radiation therapy should not receive live virus vaccines. The live-attenuated viruses such as measles, rubella, oral polio (OPV), and mumps must not be given to girls who are pregnant because these vaccines could cross the placenta, causing actual disease in the fetus. Before traveling internationally, parents should consult their local public health service to see what additional vaccines are required for overseas travel.

When preparing to administer an immunization, be sure to follow the manufacturer's recommendations for storage and handling of vaccines such as whether to expose to light or whether to refrigerate. Failure to follow these precautions may significantly reduce the potency and effectiveness of vaccines.

Although measles, mumps, and rubella vaccines are prepared from chick embryo cultures, egg sensitivities are not likely to occur because egg albumin and yolk components of the egg are absent from the culture. Children with egg allergy should have their allergist's permission for immunization, however, to rule out the possibility of a hypersensitivity reaction.

What if... Keoto's father tells you they have moved so often he does not know what immunizations she has had, but he knows she has never received a full series of anything. What would you do? Should Keoto have everything repeated?

Providing Teaching about Immunizations

A major reason parents do not bring children for routine immunizations is they do not know what is required or have misconceptions about immunity. Fully inform parents and, when old enough, children about what immunizations are needed in childhood. When vaccines are given, be certain parents know what is being given and what side effects may be expected. Because children may develop a low-grade fever after any immunization, counsel parents they may need to give acetaminophen (Tylenol) or children's ibuprofen for a fever of greater than 101° F (38.4° C).

Unfavorable reactions are most likely to occur within a few hours or days of administration. With live attenuated virus vaccines, viruses can multiply, so reactions may occur up to 30 days later. With rubella vaccine, a reaction (serum sickness) may occur up to 60 days later. Ask parents to report any untoward symptoms of immunization such as these.

When giving a vaccine, record the date, type of vaccine, vaccine manufacturer, lot number, and name and address of the vaccine provider so that if a vaccine reaction should occur, the instance can be investigated. Make a copy of the child's immunization record and urge parents to keep such records at home as well. They will need this information to admit their child to school and to feel safe in the event of an epidemic of a particular disease. They will need to know their child's record of tetanus immunization if the child should receive a puncture wound so that the correct therapy can be given for this.

CONCLUDING A HEALTH ASSESSMENT

At every health maintenance visit, inform parents and the child (or ask the child's physician to inform them, depending on agency policy) of any available results of screening procedures performed. After learning the results, some parents may require counseling to assist them with health or behavior concerns (see Focus on Nursing Care Planning Box 34.16).

Ask parents if they have any other remaining questions. If the health assessment revealed some health concerns and follow-up procedures are planned, be certain parents understand the reason for the upcoming tests. Suggest to parents that follow-up telephone calls are welcome after they return home from a health assessment so additional questions can be answered. Provide parents with the best hours to call so someone will be available to answer questions for them.

✔ Checkpoint Question 34.5

Keoto's father wants to be sure Keoto's immunizations are up to date. When is the immunization for varicella usually given?

a. At 12 to 18 months of age.
b. At 2 and 4 months of age.
c. At 16 years of age.
d. It is not recommended for children.

Key Points for Review

- Health assessment always causes some degree of apprehension for both parents and children because of worry some illness will be detected. Giving reassurance of wellness during examinations helps to alleviate this worry.
- A health history is an important part of a health assessment. The purpose is to gather information that will supplement physical or laboratory examinations to provide a more thorough health evaluation.
- The parts of a complete health history are introduction, chief concern, present health, family profile, history of past illnesses, day history, family health history, and review of systems.
- Physical examination involves four techniques: inspection, palpation, percussion, and auscultation. Techniques and approaches must be varied according to the child's age.
- Be certain to use examining instruments safely such as supporting an otoscope base so that if a child moves, the otoscope moves with the child. Be certain young children

BOX 34.16 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Child in Need of a Presports Health Assessment

Keoto Wiser is a 13-year-old you meet in an ambulatory clinic. Her father has brought her for health assessment before Keoto begins seventh grade.

Family Assessment ✻ Child lives with two parents and 2-year-old sister, Candy. Father works as a paramedic for the fire department; mother is a notary public employed by a bank. Father rates finances as "good."

Child Assessment ✻ Keoto was born with a lung cyst that was removed by surgery at 6 months of age. Her father is concerned her lessened lung size may make her ineligible for competitive sports participation. Asking if carbohydrate loading would give her enough energy to make up for any decreased lung function. Is also concerned she needs eyeglasses, as she always sits close to the television set.

Nursing Diagnosis ✻ Anxiety related to ability to participate in school sports program

Outcome Criteria ✻ Client participates in school sports program to the degree based on physical findings.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Assess child's development by taking a 24-hour day history.	Discuss with parent and child any areas that cause concern.	Parents can "get behind" in expectations of child, as preteenage children are growing and developing rapidly.	Parent or child gives day history; discusses any areas they see as problematic.
		Consultations		
Physician	Determine which school physician determines eligibility for sports teams.	Consult with school physician to determine eligibility for sports.	Schools may have restrictions on children who do not have both pairs of duplicate organs like lungs.	Qualifications for sports participation are outlined for parents and child.
		Procedures/Medications		
Nurse practitioner	Obtain health history, particularly in regard to stamina, nutrition, and past ability to participate in structured activities.	Perform complete physical examination focusing on heart, lung, muscle, and nutrition status.	Physical examination can reveal additional findings regarding lung capacity and stamina.	Physical examination determines child's overall health.
Nurse	Assess whether child is familiar with Snellen vision testing.	Test child's eyesight using a Snellen eye chart.	A Snellen eye chart is a standardized test for vision appraisal.	Child completes eye exam. Mother agrees to any recommendations.
		Nutrition		
Nurse/ nutritionist	Assess what parent and child know about carbohydrate loading.	Counsel regarding disadvantages of carbohydrate loading and sports participation for children.	Children and parents who are well informed can make informed choices on the benefit of nutrition practices.	Parent and child state they understand carbohydrate loading is not recommended for children.
		Patient/Family Education		
Nurse	Assess past health history and recommended immunizations.	Review with parent and child the child's current immunization status and any immunizations needed.	Parents are often unfamiliar with required immunizations so need to be reminded of recommended schedules.	Parent and child agree to any immunization necessary before child returns to school.

		Psychosocial/Spiritual/Emotional Needs		
Nurse	Assess what will be child's reaction if she cannot participate in school sports program.	If child is unable to participate in school sports, review with child other options: join a club; petition school sports committee.	Planning ahead can help child adjust to less-than-desired results from health assessment.	Child lists alternate ways to participate with other children at school, if sports are not an option, or describes sensible plan for petitioning for exception to rules.
		Discharge Planning		
Nurse	Assess if parent or child has had questions answered by health assessment.	Answer remaining questions; schedule a return visit as needed.	If questions remain unanswered at a health assessment, needs are not fully met.	Parent and child state they have no further questions; describe plans for next action.

are not left unsupervised on an examining table so they do not fall.

- The components of a physical examination are vital sign assessment; general appearance; mental status assessment; body measurements; and assessment of head, eyes, nose, ears, mouth, neck, chest, breasts, lungs, heart, abdomen, rectogenital area, extremities, back, and neurologic function.
- Adolescent boys should be taught testicular self-examination at the time of a health appraisal. The American Cancer Society recommends that women should be taught to perform monthly breast self-examinations when they reach 20 years of age.
- Vision assessment consists of asking children to read a standardized chart such as a Snellen or Preschool E Chart, cover testing, or color discrimination assessment.
- Hearing assessment consists of such assessments as audiometric testing and a Rinne and Weber test.
- Development is an important part of total assessment. The Denver II Developmental Screening Test and the Denver Articulation Screening Examination are specific development tests.
- The Goodenough-Harris Drawing Test correlates well with IQ and is an easy test to administer to children between the ages of 3 and 10 years to assess intelligence.
- Temperament refers to a child's innate behavioral characteristics, such as activity level, rhythmicity, and tendency to approach or withdraw and adapt to situations. Assessing this can help parents better understand behavior in their child.
- Assessment of immunization status is included as part of health assessment. Childhood immunizations are a major safeguard for children against common illnesses.

CRITICAL THINKING EXERCISES

1. Keoto is the 13-year-old girl you met at the beginning of the chapter. Her father has brought her to your ambulatory clinic for a middle school checkup because he is worried she needs glasses (she always sits close to the television set). Her mother was reluctant to bring her because she does not want her to be prescribed glasses. What questions on history would be important to ask the father or Keoto? What type of eye chart would you use with Keoto to assess her vision?

2. Keoto's 2-year-old sister, Candy, is very resistant to being examined. What techniques would you use to help this toddler adjust better to a physical examination?

3. Children should be completely undressed for physical examinations and all body surfaces inspected. What would be your response if Candy's father said he did not want to undress his child? What if he did not want to remove a Band-Aid from Candy's back?

4. Examine the National Health Goals related to health assessment of children. Most government-sponsored funds for nursing research are allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to Keoto's family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to child health assessment. Confirm your answers are correct by reading the rationales.

Chapter

35 Communication and Teaching With Children and Families

KEY TERMS

- affective learning
- behavior therapy
- clarifying
- cognitive learning
- communication
- demonstration
- empathy
- feedback
- focusing
- nontherapeutic communication
- paraphrasing
- perception checking
- positive reinforcement
- psychomotor learning
- redemonstration
- reflecting
- teaching plan
- therapeutic communication

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe principles of effective communication and teaching and learning as they relate to health teaching with children.
2. Identify National Health Goals related to communication and teaching with children that nurses could help the nation achieve.
3. Use critical thinking to analyze ways therapeutic communication and health teaching can be further incorporated into the nursing care of children and families to make it more family centered.
4. Assess children for their ability to communicate and readiness to learn.
5. State nursing diagnoses related to communication and health teaching with children.
6. Identify expected outcomes for a specific child based on the child's age, developmental maturity, emotional needs, and communication or learning style.
7. Plan nursing care based on the use of communication and health teaching priorities.
8. Implement health teaching such as devising a puppet show using principles of effective communication and teaching–learning.
9. Evaluate expected outcomes for achievement and effectiveness of care.
10. Identify areas of care related to effective communication or health teaching of children that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of effective communication and teaching–learning with the nursing process to achieve quality maternal and child health nursing care.

You meet two patients of very different ages in an outpatient clinic. Wolf Whitefeather is a 3-year-old boy with chronic asthma who is scheduled for repair of syndactyly (webbed fingers) next week. One of his favorite activities is coloring. His mother tells you she is concerned Wolf will be hard to entertain after surgery because the large pressure bandage he will have afterward will prevent him from coloring with that hand. "I don't even want to begin to talk to him about surgery," she tells you.

What would be a good strategy for teaching about this type of surgery to a 3-year-old child?

Barry Sandoz is a 15-year-old with a recurring peptic ulcer. His mother tells you health teaching with Barry will be ineffective because he never listens to a thing adults say.

Would you try to teach Barry more about his condition? How would your communications with these children vary because of their age difference?

Previous chapters discussed normal growth and development and how children's understanding increases with age. This chapter adds information about techniques for effective communication and health teaching with children. This type of information is what builds successful bases for disease prevention and health promotion for an age group.

Communication and health teaching are independent nursing actions that accompany all nursing care. They are probably the most frequently used interventions for nurses working with childbearing and childrearing families because health promotion is such a priority for this population. Education is a prime method for empowering families to assume responsibility for their own health. It is as important as any intervention for families experiencing some type of illness or injury; it is especially important when preparing a child for surgery or some other health care procedure. New areas that require teaching are constantly arising as the health care environment continues to grow more technical.

Learning to communicate is one of the most important skills that children learn (Barlow & Parsons, 2009). Communication with children can be either formal or informal. Health teaching may be offered to an individual or to a group of children with similar learning needs. It can also be both formal, such as teaching a group of preschoolers about hospitalization, or informal, such as assuring a parent a child is getting enough nutrition, even though the child snacks rather than sits down to regular meals. The same principles of effective teaching and learning apply no matter which technique is used or whether it is offered to an individual or to a group. National Health Goals related to health teaching and children are shown in Box 35.1.

BOX 35.1 ✻ Focus on National Health Goals

Several National Health Goals address good communication or health teaching, because it is such an important mechanism of preventive health care. These goals include:

- Increase the proportion of middle, junior high, and senior high schools that provide school health education to prevent unintentional injuries, violence, suicide, tobacco use and addiction, alcohol and other drug use, unintended pregnancy, HIV infection, AIDS, and other STIs, unhealthy dietary patterns, inadequate physical activity, and environmental health problems from a baseline of 28% to 70%.
- Increase the proportion of the nation's elementary, middle, junior high, and senior high schools that have a nurse-to-student ratio of at least 1:750 from a baseline of 28% to 50%.
- Increase the proportion of local health departments that have established culturally appropriate and linguistically competent community health-promotion and disease-prevention programs, from a baseline of 35% to 50% (http://www.nih.gov).

Nurses can help the nation achieve these goals by consulting with schools and health care organizations to develop health teaching programs and by teaching such programs. Areas that could benefit from nursing research include ways in which busy health care providers can better incorporate health teaching into care; what special techniques are needed to be certain that underserved populations are addressed; and whether material with immediate application requires different teaching techniques than material necessary for long-term care.

Nursing Process Overview

For Health Teaching With Children

Assessment

Communication and health teaching are best accomplished when they are placed within the context of the nursing process. Learner needs and characteristics, teacher characteristics, available support people, and level of content are all factors that affect learning or whether communication will be received. Assessing these allows nursing diagnoses that clearly state the specific health needs to be formulated.

Nursing Diagnosis

Common examples of nursing diagnoses related to communication or health teaching are:

- Impaired verbal communication related to use of Russian as primary language
- Deficient knowledge related to importance of taking medicine daily
- Health-seeking behaviors related to ways to improve the child's nutritional intake
- Impaired verbal communication related to placement of endotracheal tube
- Anxiety related to perceived amount of material needed to be learned for home care of child

Outcome Identification and Planning

After formulation of a nursing diagnosis, an individualized plan for communication or teaching should be constructed. A plan should detail not only what is to be communicated or learned but also methods regarding how this will be accomplished and evaluated. The most effective way to ensure that expected outcomes are achieved is to ask a child or family to join in planning. Be certain outcomes are concrete and measurable (not "Child will discuss general aspects of his disease," but "Child will list three steps to help prevent disease reoccurrence"). Helpful tips for health education can be found at the American Association for Health Education Web site (http://www.aahperd.org/AAHE).

Implementation

The step of implementation involves the actual communication or teaching carried out. Teaching children is not always easy and requires practice and knowledge of each child's particular developmental level and needs.

Outcome Evaluation

As a final step of communication or teaching, what was communicated or learned must be evaluated. A new plan may need to be developed and teaching continued if communication or learning was less than optimal. Examples of outcome criteria are:

- Child demonstrates good technique in self-injection of insulin.
- Child demonstrates anger by language rather than punching wall.
- Child lists five foods to include in a high-protein diet.
- Family demonstrates improved family communication techniques by next clinic visit.
- Parents demonstrate effective cardiopulmonary resuscitation technique at home visit.

COMMUNICATION

Communication is the exchange of ideas between two or more persons. It can be verbal, using words, or nonverbal, using actions such as touch or eye contact or even a remote system such as mail or e-mail. It is an important process in the care of children because it can make or break an effective relationship. As a process, communication can be divided into two major categories: nontherapeutic (casual, everyday conversation) and therapeutic (helpful and constructive interchanges).

Nontherapeutic Communication

Nontherapeutic communication is identified by its lack of structure or planning—that is, it lacks deliberate purpose other than socializing. Dinner conversation is an example of nontherapeutic communication.

Therapeutic Communication

Therapeutic communication is an interaction between two people that is planned (you deliberately intend to determine the true way a child feels), has structure (you use specific wording techniques that will encourage the response you expect to elicit), and is helpful and constructive (at the end of the exchange you will know more about the child than you did at the beginning, and the child, ideally, also knows more about a particular problem or concern).

In some instances, there is no cure for a child you care for—no surgery, no medication, no pain relief. If you practice therapeutic communication, however, you still have something to offer this child: support by your words or nonverbal communication such as touch. This is often the most valued, most appreciated, and most helpful aspect of all the care you offer (Fig. 35.1).

Components of Good Communication

Cultural differences between a teacher and a learner can complicate techniques of health teaching and evaluation of its effectiveness. Even when language is not a barrier, the way children show that they are listening or comprehending may vary from culture to culture. Looking directly at a speaker, for example, is considered disrespectful in some Asian countries. The "OK" sign traditional in the United States can be interpreted as vulgar, not positive, in Spain. In South Africa or some Middle Eastern countries, a "thumbs up" sign is insulting. In India, the way people move their head to express "yes" and "no" can be opposite to those used in the United States.

FIGURE 35.1 Sitting at the child's level and allowing the child time for self-expression are steps that improve therapeutic communication.

Being aware of these cultural differences is important when planning health teaching for diverse cultural groups so that neither teaching nor reactions to teaching are misinterpreted. Communication can be broken down and diagrammed according to its essential components: the encoder, the code, the decoder, and response or feedback.

The Encoder

The encoder is the person who originates a message. Such a person desires to share a thought or feeling with someone else. The person molds this thought into a form suitable for transferring to another person (a code). Communication can be ineffective if a person omits cognitive processing or speaks without thinking, chooses the wrong words for the message, or accompanies the spoken words with a facial expression, tone of voice, or gesture inappropriate for the message.

The Code

The code is the message that is conveyed, as well as the medium or system used to convey it. Although this usually involves a simple spoken system, messages can also be conveyed by such methods as a painting, poem, novel, Morse code, Braille, computer, television, CD, radio, audio or videotape, DVD, camcorder, movie projector, telephone, or text messaging. Communication can be ineffective because a person chooses the wrong medium for a message such as delivering a lecture with many technical words when a drawing with carefully labeled parts would have made the message much clearer, or e-mailing when confronting a person directly would have been more effective.

The Decoder

The receiver (decoder) of the message is the person who not only receives it (hears it, reads it, views it) but interprets or decodes its meaning (cognitive processing). Messages are

interpreted in light of the receiver's previous knowledge. They may be misinterpreted if a receiver's store of knowledge is too different from that of the sender. Messages may also be misinterpreted if the receiver misses part of the transmission, such as the wink accompanying the spoken words that would have let the receiver know the sender was joking. Under stress, children tend to narrow their ability to receive information to a small area of concern (they center). When you are dealing with children who are extremely anxious, you may find, therefore, although you gave excellent instructions (both sender and message components of communication were adequate), a child did not "hear" you (did not receive or could not interpret the message because of anxiety).

Feedback or Response

Feedback is the reply the decoder returns to the sender to acknowledge the message has been received and interpreted. This could be a spoken statement, a nod of the head, a facial grimace, a return e-mail, or the sudden slamming of a telephone receiver. With feedback, the roles of sender and receiver become reversed and another communication cycle is begun. Communication can be ineffective if children do not offer feedback (the message was either not received or understood) or offer feedback before the message is fully interpreted (acting before thinking). When you are caring for children with sensory challenges such as vision or hearing problems, you may need to change your usual feedback mechanisms in order to be understood, because a nod of the head or quiet response may not be received.

The Development of Language

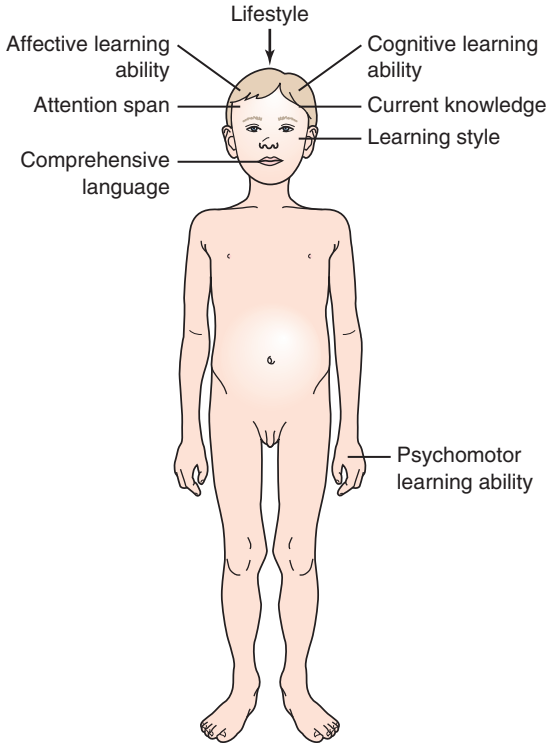
Development of language involves not only physically being able to form and voice words but also comprehension of what they mean and how they are used (Marshall, Goldbart, and Phillips, 2007) (Box 35.2). One of the first responses an infant makes at birth is to communicate. A first cry is important because it signals the infant is breathing well. It also announces to the parents the birth is real and stimulates the beginning of parent–child interaction. Early in life, when infants cry, they kick their legs and thrash their arms or react with their whole body. Some new parents comment that their newborns have bad tempers because the infant seems so angry. They are actually commenting on the way newborns respond with their total body to stimuli. Infants discontinue gesturing wildly with every need as soon as they learn the more refined communication system of language.

By age 2, children have mastered language well enough to be able to put together two-word sentences (a noun and a verb). By preschool age, they not only have a vocabulary of about 900 words but also can code them into simple jokes or stories (Goldson & Reynolds, 2008).

School-age children enlarge their ability to communicate from oral exchanges to use of e-mail or the telephone. They can write poetry and, by the end of the period, show an adult sense of humor by the jokes they create. Adolescents progress to a new phase in which they originate new words for objects or feelings ("cool" and "whatever" as responses). This form of communication helps them separate their world from adults and keeps their adolescent culture separate.

Box 35.2 Assessment

Assessing the Child's Learning and Communication Capabilities



Levels of Communication

Not every conversation you engage in has the same depth level, nor should it. Throughout a day, a person may use as many as five levels, from clichés to peak communication.

First-Level: Cliché Conversation

Cliché conversation is pleasant chatting or comments such as, "Have a nice day" between people who do not intend their relationship to extend beyond a superficial level. It is important when meeting a child for the first time that you introduce yourself not only with your name but also your position and function ("I'm a student nurse who is going to take care of you"; "I'm a nurse who will be visiting you in your home"). This information leads the family to move the conversation from the cliché level to a more meaningful one.

Second Level: Fact Reporting

Fact reporting is simply stating facts about oneself ("I'm 12; I'm in sixth grade"). Fact reporting is necessary for you to understand children, but it does not tell you anything about their feelings or needs. Children can move from this level to a higher level of communication only when they feel they can trust you with more information.

Third Level: Shared Personal Ideas and Judgments

When children know you well, they are able to share ideas such as, "I always wanted to be an astronaut" and judgments ("This is too hard for me; I need to learn a different way"). This level of communication exposes them to loss of self-esteem if their views are not respected. It is the level that is the beginning of therapeutic interactions.

Fourth Level: Shared Feelings

It is difficult to share feelings until you truly trust one another, because feelings are tenuous, fragile concepts, easily destroyed and crushed by inept or uncaring comments. Listen carefully for an expression of feeling from children such as, "I hate always being sick." These admissions are telling you much more than how a child experiences the world; they represent trust in you and the depth of the relationship the child has established with you.

Fifth Level: Peak Communication

The fifth level of communication is a sense of oneness, or being able to know what the other person is experiencing without it actually being voiced. It sometimes occurs spontaneously in high-intensity situations but generally arises out of long-term relationships. For example, you notice that a parent sits soundlessly beside her daughter's bedside for hours at a time. When she leaves, the daughter says, "She makes me feel so much better when she's here." It would be easy to view this mother as nonsupportive (she says almost nothing during the time she's there), but by using fifth-level communication, she has given her daughter more comfort than other visitors who talk the entire time they visit.

Nonverbal Communication

Nonverbal communication involves a variety of factors that are important as accomplishments to effective communication. Nonverbal communication can be especially important in areas such as intensive care units when a child may be unable to speak because of endotracheal tubes and ventilators. Nonverbal communication can be expressed in a variety of ways.

Distance

Although it is affected by cultural and personal variables, the distance at which you position yourself from the person you are talking to can indicate your feelings or the type of conversation you want to have. People generally consider the space directly surrounding them (up to 18 inches) as *intimate* space, to be crossed only by people who know them well or with whom they are comfortable having close body contact. Sometimes you will notice in a heated discussion that one person moves aggressively into this space and the other automatically steps back to protect it. People in elevators usually separate themselves from others by this much space if the car is not full.

Whenever you touch a child, you violate this space, so always ask permission to touch ("Okay if I change your bandage now?"), or with small children, announce what you are going to do ("It's time to change your bandage now"). If children agree to let you enter this space, it means they see you as safe, protective, and helpful.

The space between 18 inches to 4 feet is sensed by most people as *personal* space. This is the distance people usually stand apart from each other for casual conversation. It is a comfortable hand-shaking distance. When you stand by the side of a crib or bed or sit next to a person at home, you are within this space. It is a concerned, I-care-about-you distance but does not invade intimate space.

The distance between 4 feet and 12 feet is *social* space, the distance used to conduct business or teach a class. Conversation spoken at this distance is readily heard by others. Do not use social space to ask a personal question. If you ask a child, "How are you feeling?" as you pass in a hallway, for example, the child will probably answer, "Fine, thank you," a programmed reply almost everyone is taught in early childhood. In contrast, if you ask that same question from a personal or intimate distance, providing privacy, the answer might be, "I'm scared I'm never going home again."

Although it is carried out miles apart, most people perceive speaking on the telephone or using the mail or e-mail as either social or personal space. The tone of voice or the words used help to differentiate which area they consider it to be. A message such as, "Have I got news for you!" suggests social space. "Can you keep a secret?" brings it into intimate space.

Distance beyond 12 feet is *public* space. To communicate from this distance, you need to shout; privacy is not respected at all. Waving to a friend in a hallway or across a parking lot is an example of public space communication.

Genuineness

Genuineness is a quality of projecting sincerity or being yourself. Children will have difficulty trusting you and therefore will be unable to move to a deep relationship with you if you change your behavior from one day to the next such as from maximum patience to short-tempered, because they have to spend energy every day testing to see who you are that day. The way to achieve a feeling of genuineness is not to try to be what you are not as the insecurity that comes from pretending can manifest itself as negative feelings such as aggressiveness or a bored attitude.

Warmth

Warmth is an innate quality, and some people manifest it more spontaneously than others. Basic ways in which warmth is demonstrated are direct eye contact, use of a gentle tone of voice, listening attentively, approaching a child within a comfortable space of 1 to 4 feet (closer may be threatening; farther away may be distancing), and using touch appropriately. Warmth is a quality that you display best when you know another person well. Any action that helps you to know a person better (taking a health history, talking about school or family or how a child feels about the present situation) not only lets you plan care but also allows you to become increasingly comfortable with the child and deepen the warmth of your relationship.

Empathy

Empathy is the ability to put yourself in another person's place and experience a feeling the same as that person is experiencing. People who are capable of empathy are the best support people because they can anticipate a child's reactions or fears. At first, it seems empathy would require you to have experienced all the situations that children experience. This is not necessarily true, however, because you understand the common emotion of all situations in other ways. If you have hoped for something very strongly and then not attained it, loved someone and not had that emotion returned, lost someone or something that was so important to you that you felt actual pain, you can feel empathy for children who have received a disappointing diagnosis or who are unhappy for other reasons you have never experienced. Feeling empathy is emotionally draining because, when you assume another person's emotions, you experience them at the same depth as that person. Nurses who are capable of empathy need to surround themselves with good support people so they have refueling resources when they need them.

Gestures

Children vary a great deal in the gestures they use to accompany their spoken words. Although this is culturally influenced, it is also an individual trait. Be careful not to assess emotion only by a child's gestures; some children wave their arms wildly describing an everyday occurrence; others would use that degree of expression only when in extreme distress. Be aware also that your own gestures are always being read by children. A statement that you approve of something is contradicted by placing your arms across your chest in a disapproving, stern manner. Saying that broccoli is good to eat because it contains antioxidants but then making a sour face makes your healthy eating message ineffective.

Body Posture and Gait

Children who feel good about themselves usually assume an upright body posture and walk rapidly and surely; those who are depressed or insecure tend to slouch and move more slowly and timidly; those who are threatened tend to either draw back or act aggressively. Children who are in agreement with you usually maintain eye contact with you as you speak to them. Very depressed or insecure children do not do that (they feel too inferior), nor do children who are very angry. Children from some cultures may not meet your gaze because it is not culturally appropriate.

Facial expression is an important accompanying gesture. Clenched teeth, frowns, and smiles are easily interpreted by everyone. The degree of pain a child is experiencing may be more evident by facial expression than words.

General Appearance

Children who have good self-esteem tend to maintain good body hygiene and care about their appearance. Those who are depressed may not feel the effort involved in grooming is worthwhile. Personal hygiene varies, however, and it is difficult to assess on your first contact with a child. What you see as ill-kempt may be neat and trim for that particular child; what you think of as well groomed may be comparatively sloppy for that child.

Be aware that your impression of how children dress registers very strongly on your subconscious. Do not let an unconscious dislike for a mode of dress of some child (body piercing or a turban) cause you to draw back. Preparing to give nursing care is not the same kind of activity as evaluating whether you wish to invite someone to dinner.

Touch

Touch is the most intimate and meaningful of nonverbal techniques. When words are inadequate, touch rarely is. Learn to use touch such as clapping a child's shoulder or squeezing a hand to accompany reassuring words or in place of words as a strong support signal (I'm here; I understand; it's all right to be afraid). On the other hand, be aware that some children enjoy being touched more than others. Because of individual preferences or cultural variations, some children do not like you to use this nonverbal signal with them. Assess individually for the appropriateness of using touch.

Use of Humor

Some people have a natural knack for finding humor in any situation; others do not instinctively have this quality and must cultivate it. Those who can laugh at their own mistakes are usually enjoyable people to have around, because their laughter at themselves suggests that, when you make a mistake, they will be able to accept it the same way (or at least not be angry about it).

Be careful of the use of humor with children because they are school-age before they appreciate most adult jokes. If they are fatigued or ill, they may be looking for a firm support person to be with them more than one who is amusing. You can often measure a child's progress by noting the first time after a procedure the child responds to you with a humorous statement. Remember, though, that laughter and joking can also be signs of increasing anxiety. Evaluate the use of humor to be certain a child really finds a situation amusing.

Use of Drawings

A useful nonverbal technique to learn how children feel about a frightening experience is to ask them to draw a picture of what happened or a picture of themselves. A child hospitalized for heart surgery, for example, might draw her heart prominently. She's revealing that she realizes she cannot survive if something happens to such an important body part.

A child's use of color may be a clue regarding mood (happy children tend to use bright colors; depressed children use black or dark colors). A child with good self-esteem usually fills the full page with a drawing; one with less self-esteem crowds a drawing into a corner. These observations are quite variable, however; a child may have had only a black crayon with which to color or may be saving the rest of the paper for a second drawing.

Use of Music

The type of music to which children prefer to listen to often also conveys their mood. The better they feel about themselves, the more likely they are to choose lively music; if they are sad, they often choose a quieter, more comforting type.

Children enjoy repetition, however, and so may play the same music over and over, independent of their mood.

Techniques To Encourage Therapeutic Communication

Several techniques are effective in deepening communication patterns and relationships. These techniques can be learned if they are not a spontaneous part of your present communication pattern (Box 35.3).

Attentive Listening

No one likes to talk to someone who does not appear to be listening or responding. Good listening, therefore, like speaking, is not passive but active. Be aware that your posture reveals to a great extent whether you are listening (sitting, not standing, to convey that you are not on the run; leaning forward, not backward; stooping to meet a child's level). Nodding, maintaining eye contact, and stopping all other activities are strong indicators you are attuned to what is being said. Making it clear that you are concentrating on what another is saying by such a motion as nodding indicates you value what the other person is saying. Children who feel valued are much more likely to confide feelings and concerns than those who sense you consider them not important.

In some instances, it is necessary to repeat a part of what a child said, interject an appropriate "uh-huh" or "m-m-m," or make a direct statement ("I'm listening. Go on") to indicate you are listening. Be certain that when you are listening to the 20th child on any given day, you do not exhibit "end-of-the day" behavior. To be therapeutic, you have to give everyone's concerns the same alert attention.

BOX 35.3 * Focus on Family Teaching

Listening to Children

Q. Barry's mother says to you, "My son always tells me I don't listen to him. How can I be a better listener?"

A. Try the following tips:

1. Stop talking. You cannot listen if you are talking.
2. Look and act interested. Do not read or write while he talks. Listen to understand rather than to reply.
3. Remove distractions. Do not doodle, tap, or shuffle papers. Would it be quieter if you turned off the television?
4. Empathize. Try to put yourself in your child's place so you can see his point of view.
5. Be patient. Allow plenty of time. Do not interrupt. Do not edge toward the door or walk away.
6. Hold your temper. An angry person gets the wrong meaning from words.
7. Hold argument or criticism, which puts children on the defensive. They may stop talking or get angry.
8. Ask questions. This is proof that you have been listening.
9. Stop talking. This is the first and last suggestion, because all others depend on it.

Open-Ended Questions

A pointed or direct question used in discussing asks for a specific task; it implies all you are interested in hearing about is that one fact. An example of a direct question is, "Do you take Tylenol when you have a headache?" An open-ended question is not limited to a simple answer but invites a wide variety of responses because it is so comprehensive such as, "Tell me what you do when you have a headache." A child might answer this question by not only describing the amount of analgesic she takes but also putting a cold towel on her forehead, staying home from school, and closing her eyes to stop the pain. Three or four times more information has been elicited.

Open-ended questions are not effective if the topic is difficult for a child to describe (a preschooler has difficulty responding even yes or no; a paragraph of material would be impossible) or if the child is naturally shy or defensive about the subject (he knows he has not been doing the things you told him to do and would rather not admit it).

Most communication is a combination of direct and open-ended questions. Listen carefully the next time you ask someone to explain something to see if you make use of mostly direct (information-limiting) questions or open-ended (information-expanding) ones.

Reflecting

Reflecting is another technique, like attentive listening, that is so simple that its importance is easy to discount. **Reflecting** is restating the last word or phrase a child has said when there is a pause in the communication. A child says, "I'm worried," and then stops. You repeat the last word. "Worried?" The child, assured you are listening and interested, will generally enlarge on the first statement: "I'm worried I won't make the football team this year." Older school-age children may not respond well to reflection; they may interpret it as imitating them, not seeking information.

Clarifying

Clarifying consists of repeating statements others have made so both of you can be certain you understood them. This is particularly helpful if a child has been describing a set of symptoms or series of actions. You would clarify such a statement by saying, "Let me see if I understand this. You said you always get the pain first in your stomach. Then it spreads to your chest." If you are not quoting correctly, the child will interrupt and restate the problem: "No, the chest pain comes first."

Paraphrasing

Paraphrasing is restating what children have said not only to assure them you have heard correctly (as in clarifying) but also to help them explain what they have been trying to say in other words. In clarifying, you repeat a child's exact words; in paraphrasing, you retain the meaning of the words but repeat them in a clearer or more condensed form. The child says, for example, "I don't talk about my problems with my parents." A paraphrasing statement might be, "You're telling me you and your parents haven't discussed home care. Is that right?" When paraphrasing, ask for confirmation that your interpretation is correct; otherwise, you may find yourself putting words in children's mouths.

When the topic is embarrassing or emotionally charged (an adolescent discussing sexual orientation), the child might use such vague terms that the explanation becomes difficult to follow. Paraphrasing using basic terms would let him know not only that you understand him but that, if he can describe the problem better with such words than with medical terminology, it is acceptable to you.

Perception Checking

Perception checking documents a feeling or emotion reported to you. This makes it a step deeper than paraphrasing. In paraphrasing, you document a statement or fact; in perception checking, you document a feeling or emotion. The child says, "I'm not at all worried about surgery. I know a lot of kids have the same thing done every day. I mean, what could happen?" You say, "You're telling me you're not worried, but the number of times you've said it makes me wonder if you really are worried. Are you?"

Always ask for validation that your perception is correct so you do not make false assumptions. Perception checking is helpful because, as a rule, children are not ready to deal with emotions until they can admit they are experiencing them. When you bring an emotion out on the table this way, it allows them to confront it and deal with it for the first time. They may lose their reluctance to admit other worries because you have implied that worrying is acceptable.

Focusing

Focusing helps children to center on a subject you suspect is causing them anxiety because they comment about it indirectly or else completely avoid it. It is done by repeating something they said ("You mentioned you feel tired all the time") or by mentioning the avoided topic ("You haven't said a word about how you feel about this surgery. Is that a problem?"). Once a subject is brought up for discussion, most children respond to it. As long as it can be avoided, however, they do not have to face the problem and begin to solve it.

Supportive Statements

Supportive statements let children know you accept their behavior or at least appreciate they have dealt well with unfortunate circumstances. For example, an adolescent says, "My girlfriend dumped me while I've been here in the hospital." Such a statement deserves a supportive reply such as, "That must not feel good." The adolescent will take this response to mean you want to discuss the topic and, encouraged by your empathy, may elaborate on it as it still affects him.

Silence

If you ask a question and a child does not respond immediately, it is natural to ask another question or perhaps change the subject, assuming the child is not interested in the topic. This is a social custom that allows you not to put someone into the awkward position of having to discuss a sensitive topic. Silence, however, is an effective therapeutic technique. If you ask an emotion-laden question ("Are you worried?") and the child does not answer immediately, allow a period of silence to pass. Because you do not hurry to fill in the silence, the child is likely to respond by hurrying an answer (to fill in the silence); when this happens, the answer is usually spontaneous and often open and uninhibited. In other instances, a child may answer the question deliberately and cautiously and, because you have provided a period of time to answer, offer additional information.

Do not overdo silence, however, either by the number of times you use it or the length of time you allow it to extend. In this era of constant noise, many individuals are extremely uncomfortable with silence. Too much silence can indicate to a child you are not interested enough to maintain the conversation.

Process Recording

Process recording is a method to examine how effective you are at therapeutic communication. After your next interaction with a child, take a few minutes and write down in the left column of a sheet of paper a statement the child made to you. In the middle column, write what you thought on hearing the statement. In a third column, write your response. Try to record both statements and responses verbatim or as close to the actual words used as possible. The average person can accurately recall about 3 minutes of communication this way.

Next, examine your responses to each statement: Did I encourage the child to tell me more by my response, or did I block communication? Were my responses supportive or critical or trite? Did I use open-ended questions or closed, direct ones? Did I check perceptions or did I just assume that I understood correctly what was told to me? See Box 35.4 for an example of a process recording with an adolescent.

✔ Checkpoint Question 35.1

Barry tells you he hates school. Which response would be the best example of paraphrasing?

a. "Tell me again what you said."
b. "School?"
c. "You're telling me you're unhappy with school?"
d. "Hate is a strong emotion for a teenager to feel."

Factors That Can Interfere With Effective Communication

Because so much of nursing care is influenced by verbal communication, it is important to avoid miscalculations in communication and to recognize common situations in which meanings can easily be distorted.

Age and Developmental Level

Age and developmental levels are important to communication ability because they influence vocabulary and reading ability so greatly (Oakhill & Petrides, 2007). A 3-year-old child may not have the vocabulary to explain the way her knee feels (she has heard the word "ache" but only in connection with headache; she does not know that knees can ache as well). Early school-age children have difficulty describing the blurring they experience as they focus on a blackboard with less-than-perfect eyesight, because this is the way they have always seen. The ability to describe inner feelings such as anger, sadness, and fear comes only with adolescence.

BOX 35.4 ✻ A Process Recording

The following is a record of an interaction between a nursing student and Barry Sandoz, a 15-year-old boy who is hospitalized. Barry has been diagnosed as having a peptic ulcer.

What Client Said and Did	What I Thought and Felt	What I Said and Did
	I felt anxious meeting a new patient, although I thought he'd be friendly because he was so close to my age.	I walked into his room and said, "Good morning."
He was sitting up in bed holding his hands on his abdomen. He said, "Get me something for this pain," without even looking at me.	I felt attacked. As if he thought I should have done something sooner, but I had just arrived.	I asked, "What kind of pain are you having?"
He said, "I need a student nurse like a hole in the head. Isn't there anyone else around?"	Now, I really felt attacked.	I said, "I can get you something for pain. I just need to know what kind of pain you have."
He said, "Hydrochloric acid is carving a hole into my stomach. Is that enough explanation for you to get me something?"	I felt angry that he insisted on putting me down so.	I said, "It certainly is. And I appreciate that if I had pain like that I would not want to answer questions either." I left to find my instructor and get him something for pain. I returned in 15 minutes and said, "I have an injection for you."
He asked, "Did you have to take so long to do that?"	I was getting really angry.	I said nothing. I just checked his ID band and gave him the injection.
He asked, "Now could you get me my purple pill?"	I was angry at his demanding tone and threatened because I didn't even know what he meant by his "purple pill."	I said, "I'll have to check your medication sheet."
He said, "Any chance you could do that in a hurry?"	Even more angry.	I said, "Are you always so demanding?"
He turned on his side so his back was to me, clenched his teeth, and pushed his hands into his abdomen again.	I realized that my criticism was unfair because he was in pain. But it was too late to take it back.	I said, "I'm sorry. I know you're uncomfortable."
He shouted, "I am not uncomfortable! I am having my stomach ripped out! Could you help me out in any decent way with that?"	I realized I was in over my head. I thought I'd limit any further interaction so he couldn't make me angry again.	I said nothing. I just left to check on whether he could have any other medicine. I returned (quickly as I could) with Prilosec (his purple pill).
He asked, "Do you know if Dr. M. is still in surgery?"	Threatened again; I didn't even know how to find that out.	I said, "I can find out for you."
He said, "Hand me that book on the chair over there, before you go, will you?"	Trying to concentrate on not being angry at his demanding tone, yet I had medicine I had to give safely.	I said, "Let me see your ID band again first."
He turned his wrist over so I couldn't read his ID.	I thought: I am tired of him demanding things and getting the book was not as important as what I was doing.	I said nothing.
He said, "If I don't get to that book today, I might as well cash it in."	Getting angry again, but also "hearing" what he had said for the first time.	I said, "Cash it in?"
He said, "Don't you think I ought to? I can't go back to school with pain like this. Wouldn't dying be better than failing out?"		I was surprised how one quick response on my part had brought out so much emotion. I also knew I was in over my head again (but in a nice way).

(continued)

BOX 35.4 ✻ A Process Recording (continued)

Evaluation

My overall interaction with Barry would have been better if I hadn't been caught so off guard in the beginning by assuming that he was going to be someone who had a lot in common with me (student–student, close age group). His initial response to me seemed so much more intense because I had stereotyped him that way.

My responses to him were adequate up to the point that I became angry. I should have answered his comment, "Do you always take so long to do something?" with a supportive one such as, "I know it's hard to be in pain." (I heard a nurse answer that question for a client with, "Believe it or not, sometimes I take longer," and all of us laughed. I think the client felt good about being able to appreciate something funny, but I'm glad I didn't try humor here. Silence was inadequate but at least not irritating.)

If I had been more sensitive to what Barry was saying (and less angry), I would have noticed that after I gave the injection he became nicer to me (asking if I could get him his Prilosec, not just demanding it). I was too angry to notice his change in behavior though, so I cut off his preliminary attempt to interact with me by criticizing him ("Are you always so demanding?") My supportive statement ("I'm sorry; I know you're uncomfortable") was ineffective after the criticism.

In the final interaction, I was so concerned with my own needs (get my work done) that I completely missed what he said about why the book was important to him. Fortunately, at the last minute, I got my mind off my problem and onto his and was able to produce a therapeutic response for him. He shouldn't have had to describe something with the impact of driving a truck over me before he caught my attention, though. Better listening (and thinking while I'm listening) would make me hear better and be more helpful sooner in this type of interaction.

Intellectual Level

Intellectual level, like age, affects vocabulary and ability both to encode and decode messages. It influences the number of languages a child speaks, reading ability, and the depth of explanation a child is capable of understanding.

Physical Factors

Physical factors such as speech impairments and hearing or vision challenges interfere with the transmission and reception of messages. When children are distracted by such sensations as fatigue or pain, they also may have a reduced ability to transmit or receive messages correctly.

Technical Terminology

Adults have heard common medical words and so usually have little difficulty understanding an explanation of one. Children, in contrast, have not heard many medical words. Listen to the explanations you give them to be certain you would have understood your explanation at their age.

Showing Disapproval

Parents and children do not come for health care to be criticized; they come to learn more about how to stay well or recover from illness. If you criticize them, they may not reveal any further information to you because they do not want you to react in the same way you did to their preliminary statements.

Suppose an adolescent says, "I never drink milk. That's for babies." Knowing milk is an important source of calcium, you respond, "That's not healthy. You should drink at least two glasses a day." This discourages the adolescent from telling you any more about her eating habits (she does not eat much protein either, but you will miss this information because she will not expose herself to your criticism again).

Be aware that nonverbal disapproval (frowning, sighing) can be just as conversation stopping as spoken disapproval. On the other hand, this does not mean you should show approval of wrong actions. Merely listen to them with no action or comment and make a mental note. At the end of your interaction, introduce the change in behavior you'd like to see ("Let's plan some ways you can include more calcium with your meals without drinking milk").

Not Showing Approval When Warranted

Every student has had the experience of completing a difficult assignment and receiving only criticism from a teacher—no comment that, aside from the part that was not satisfactory, the rest of the assignment was done well. This happens because the instructor assumed the student would do a good job; no reward was given for meeting minimum criteria. From the other side of the desk, however, it would have been satisfying—and offered motivation to continue to do well—to have heard the words "good job."

When discussing health care problems with children, it is easy to forget that what you accept as standard behavior may take a great deal of effort for an ill child to accomplish (coughing and deep breathing after surgery seems simple but is actually very difficult to do because it is so painful). Giving children praise for what they do well encourages them to tell you more about themselves and to try other things. If a topic is difficult for them to talk about, saying that you realize it is a sensitive topic helps them continue to discuss it.

Being Defensive

In the same way that children who request health care do not enjoy being criticized, neither does the average health care provider. If a child makes a critical remark, therefore, it is easy to respond with a defensive or protective comment rather than a therapeutic one. An adolescent might say, "We

have to wait so long here; this is a really dumb clinic." It is easy to reply, "Don't say that. This is a good clinic." This type of response implies that any complaint is out of line. Try to respond instead with a supportive comment such as, "I know it makes a long day for you." No health care agency is so good that there is nothing to criticize.

Cliché Advice

Cliché advice (advice given from a formula, not individualized to the situation) is meaningless because it is too general to be helpful. Statements such as, "Rome wasn't built in a day" and "You have to walk before you can run" are examples of this kind of advice. Children consider their problem unique and resent being given advice that could apply to everyone.

Topping Up

"Topping up" is minimizing a child's views by telling a better story. A child tells you, for example, he has a headache; you say, "You should feel the one I have." A child says she has a problem; you say, "You want to know what problems really are? Come and work here." This implies to children their problems are inconsequential, at least in respect to yours. They will not be likely to tell you any more about themselves after such responses.

Communication Situations That Require Special Skills

Some communication situations require special skills in addition to the usual therapeutic communication techniques to promote understanding.

The Shy Child

The amount of verbal communication children use varies culturally and individually. Some children talk excessively when they are nervous; those who are shy may stop talking completely. Children who are comfortable with verbal communication reach out to secure the help they need from others by talking; shy individuals are more likely to have their needs go unrecognized. It is difficult to assess how shy children feel when they are reluctant to communicate about such things as whether they are psychologically ready for surgery or if they understand the long-term effect a disease is going to have. If they do not give you much verbal feedback, the tendency is to believe they do not have a concern. That leaves them without support people when they most need them.

Fortunately, in most instances, once children realize they know and can trust you, shyness fades. A therapeutic response, therefore, would be not to leave them alone but to maintain an active relationship despite the lack of feedback. This does not necessarily involve talking to children but may involve checking on them frequently, remaining in the room while a physician completes an examination, helping with the adhesive strip after a technician obtains a blood sample, or sitting with them for a few minutes while a medication takes effect.

The Angry Child

It is difficult to work with angry children because you feel yourself being pulled into their anger. The typical response at hearing an angry outburst is to imitate it (a child is radiating anger as tight-lipped silence, so you say nothing as well; a child shouts at you, and you shout back). This is not therapeutic, however. Make a point of not allowing yourself to be drawn into children's anger, while at the same time acknowledging it is all right to be angry (I understand that you're angry but please don't shout"). Help them to focus their anger if at all possible so they can better understand it and begin to deal with it.

To encourage focusing, ask children to detail why they are angry. An adolescent who feels angry at the entire health care delivery system is highly frustrated because he cannot begin to handle the whole bureaucracy; establishing that what he is really angry about is one nurse's action, for example, builds a base for resolving the problem. If a child uses silence as a method of maintaining anger, suggesting possible reasons for the anger may be helpful ("I know Dr. Smith was just talking to you. Are you angry about something she said?" or, "I know you were asking about crutch walking before. Does it have something to do with that?"). Once the subject is out in the open, few children can resist describing the extent of or reason for their anger. Be aware, too, that when you ask someone to explain why they are angry, you ask for the emotion and the distress that go with it to be expressed as well. Even if you are the object of the anger, you are committed to listening to the child's views.

Helping children focus anger this way moves them toward a constructive solution (focusing anger at the physical therapy department because that is where the offense occurred seems justified, but calling you names, not eating dinner, or shouting at a parent does not). If necessary, censor the way the anger is expressed, not the right to be angry. Keep anger from affecting you by reacting to the explanation, not the tone or force of it. Keep any response on your part a tone gentler and quieter than that used toward you.

The Demanding Child

Nursing has few equals in job satisfaction (provided salary and other working conditions are adequate) because the majority of people you care for are grateful for everything you do for them. It can be upsetting, therefore, to discover a particular child who is not grateful for or even satisfied with anything you do. This type of child is also easy to back away from or avoid.

Demanding behavior generally stems from insecurity or fear (so afraid that something will happen to them while you are out of the room they constantly find more for you to do to keep you in the room, or so afraid of unplanned events that they structure things so that nothing unexpected can happen). Give more of yourself, not less, to counteract this response. When you have proven you are dependably there for them, children do not feel so insecure, and the need to be demanding usually fades. Withdrawing may increase the child's insecurity and the demanding behavior. Ask instead, "Is there anything else I can do for you?" not, "Haven't I already done enough?"

The Sexually Aggressive Adolescent

Sexually aggressive behavior stems from the same cause as every other aggressive and demanding behavior: insecurity. It can be manifested as telling unwelcome jokes or inappropriate physical touching. This may be pronounced in adolescents

who worry that illness or surgery will interfere with sexual function. Adolescents with this degree of insecurity may benefit from counseling to help them channel coping responses into more socially acceptable behaviors. Be sure they have factual information regarding the extent or effect of their illness. Set limits, as necessary, to make giving care acceptable to you. Always censor the action, not the adolescent. Be aware that sexually aggressive behavior occurs in both males and females.

The Child Who Is Not Proficient in English

It is not unusual in any nursing care setting to encounter children who have a different primary language from yours; in other instances, a child's speech may be limited or difficult to understand because of an accent, dialect, or speech impairment; some children may speak your language but their use of words is so different from yours that the words have different meanings (Uccelli & Paez, 2007).

Most children who speak another language have a support person who can serve as an interpreter. Anticipate the instructions you will need to give the child (cough, deep breathe, save urine, and so forth) and ask the interpreter to write them out in the child's language for times the interpreter may not be present. Post them conspicuously in the room or the child's care plan so everyone giving care can be familiar with them.

Most health care facilities have a list of people who serve as translators as needed; many times, you can contact such a person by telephone to ask for a specific word you want to know. If you have to give instructions and no translator is present, do not be self-conscious about using hand gestures or drawing a picture to express the action you want (a child lying in bed), an arrow pointing to a chair, and a child sitting in a chair for, "I'm going to help you get out of bed." Allow children ample paper to draw pictures to show what they want to tell you. Supply pictures for preschool children so they can select the one they want.

Everyone has a tendency to shout at children who speak a different language as if loudness will increase understanding. Try to avoid doing this. When using an interpreter, be certain to speak slowly and use common words that can be translated literally. "I need to stick Mary's arm for blood" could be interpreted literally to mean putting a stick in the child's arm.

The Unconscious Child

Hearing is the last sense lost with unconsciousness and the first sense regained with consciousness. This means you always need to be aware that children who do not respond to you may be able to hear and interpret anything you say. Never say anything to unconscious children or within their hearing, therefore, that you would not say if they were fully alert. Continue to use nonverbal communication such as touch to help convey your message.

The Hearing-Challenged Child

It is difficult for hearing challenged children to enunciate words clearly because they are not aware that the voice sound they are forming is not clear (Toe, Beattie, & Barr, 2007). When communicating with hearing-challenged children, check whether they use a hearing aid; if so, be certain it is turned on. Face them when you speak so they can follow your lip movements. Use hand gestures as necessary to convey your message, or write out instructions. If you have difficulty understanding what they are trying to say, ask them to write it down if they are old enough. Use common sense about how loud to raise your voice to facilitate communication. As a rule, at the point that privacy is lost, it is time to resort to written words or sign language. Children who use sign language to communicate have a right to have an interpreter present to facilitate communication, the same as children who do not use English as their primary language.

The Vision-Challenged Child

When speaking to a child who is challenged visually, be careful not to rely on nonverbal communication techniques such as hand gestures, as these cannot be seen. A statement such as, "Take a piece of gauze about this long" is meaningless. Never touch children who cannot see you without speaking to them first so you do not startle them.

HEALTH TEACHING IN A CHANGING HEALTH CARE ENVIRONMENT

In the past, when children were admitted to hospitals well in advance of surgery and remained in the hospital after surgery or therapy until they were almost totally well, there was a wide window of time for health teaching. Today, when surgery is often a 1-day experience, the window for teaching has greatly narrowed (Cabana et al., 2008). This means nurses must use more creative approaches to achieve the same health education results. Discharge instructions may require both verbal and written approaches (Johnson, Sandford, & Tyndall, 2009).

Children's sophistication about learning techniques has also changed. Children today are exposed to such a diet of clever animation on television or in movies that a simple lecture on good nutrition can seem dull and uninteresting. Children who are adept at arcade or computer games where dexterity is the requirement may no longer find handling a syringe or a feeding tube a challenging feat. Before beginning, assess each child to find out what the child expects to learn, identify individual learning style, and determine what teaching techniques would suit the child best.

The Teacher–Learner Relationship

Effective teaching and learning depend a great deal on the teacher–learner relationship, because, as a teacher, you can only influence an individual to learn; you cannot force learning. Before teaching can be considered effective, learning has to have occurred in a way in which change in behavior is measurable. Conversely, before learning occurs, teaching must have occurred in some form. For example, a parent teaching a child about the need to brush teeth daily must not only elicit the child's statement that daily brushing is important but also see that the child is, in fact, brushing her teeth every day. If the topic is abstract, such as helping a child change a concept about a chronic illness, change can still be measured (the child not only talks about the illness but also begins to take actions to prevent complications). Common principles of teaching are summarized in Table 35.1. Principles of effective learning are summarized in Table 35.2.

TABLE 35.1 ✻ Principles of Teaching

Principle	Rationale
Know the subject.	To effectively teach children, you must be able not only to present material but also to answer questions about it. Children's questions can be as probing as an adult's and they can often be more frequent, because children are used to asking questions of a teacher or a parent.
Know the audience.	Children vary a great deal in cognitive development depending on their age group. To teach preschoolers about health, you might choose to teach how to brush teeth using puppets as a teaching aid. The same clever puppet and toothbrushing presentation likely would not be well received among adolescents.
Know yourself.	Analyze which teaching techniques (lecture, role playing, small group discussion, audiovisual aids) fit your teaching style. Using techniques that are comfortable allows teaching to be most effective.
Assess individual learning styles.	Most children respond well to visual images (seeing a demonstration or drawing) to complement learning. Assessing individual learning styles helps to meet each child's best way of learning.
Define expected outcomes.	Expected outcomes serve as guidelines to help you select from all you know about a subject that part which is most pertinent to an individual child. They should be realistic, measurable, and mutually established. Instruction on how to walk using crutches for an early school-age child would include how to carry school books while using crutches; for an adolescent, instruction might include how to board a city bus so he or she could get to and from a part-time job.
Provide an environment conducive for learning.	Children are easily distracted from learning because of so many new experiences in their world. Divide material into segments to keep teaching sessions short; avoid competing factors such as television or mealtime.
Be consistent.	Nothing is more confusing to a person learning something for the first time than to be told two different ways to do it. Choose one method that should work best for a child and then consistently stress that method. After a child has learned the one method, then suggest alternative methods if the child is interested.
Be honest.	Abstract concepts such as "little white lies" cannot be understood by children younger than adolescents.
Recognize that actions teach as much as or sometimes more than verbal statements.	Children watch facial expressions and nonverbal gestures as much as they listen. Be certain that a nonverbal statement is not contradicting a verbal one.
Teach from the simple to the complex.	Fundamentals must be grasped before extensive learning can proceed. Many children have little idea of body anatomy. Often you need to begin with the basics; when these are mastered, you can proceed to teach about a disease condition.
Teach principles.	Teaching children the principle behind why they are doing something gives them reason to do it. It expands learning in that it allows children to modify and change to an alternative method as long as the principle is fulfilled.
Emphasize what the child should do; mention, but do not emphasize what the child should not do.	Teaching from a positive standpoint makes learning more enjoyable. Because health care information should last a lifetime, thinking of it in a positive way makes it applicable to lifetime use. However, children need to know both the do's and don'ts regarding health issues.
Include evaluation as a final step.	The only way to determine the effectiveness of teaching is to test or evaluate if learning has occurred. Structure the time and method of evaluation when first establishing a teaching plan.

An equal partnership encourages learning more readily than a relationship in which a teacher maintains ultimate control and authority. A teacher–learner relationship based on mutual sharing empowers and motivates an individual to learn. To foster mutual sharing in the learning process, first negotiate with the learner to establish learning needs and goals. Allow this negotiation to continue throughout the entire learning process as needs and goals change. Next, focus on the whole person by considering the learner's cognitive and developmental abilities, values, beliefs, feelings, experiences, and learning style. Finally, the teacher–learner relationship should be interactive. The teacher and learner should both actively participate in the process and modify the teaching plan as they learn from one another.

Types of Learning

There are several different types of learning. Learning the mathematical formula necessary to change pounds to kilograms, for example, is different from learning how to fill a

TABLE 35.2 ✻ Principles of Learning

Principle	Rationale
Learning occurs best when children are ready to learn.	Interferences with learning may be physical (e.g., pain or hunger) or psychological (e.g., fear or anxiety). The first time children are told that they must inject insulin daily, for example, they may be too anxious to learn about it.
Learning occurs most quickly if children can see how the new information will benefit them.	Sixteen-year-old children learn how to drive a car quickly because they grasp readily that being able to drive will immediately enlarge their world. Children are not ready to learn insulin injections until they can see an advantage of giving them. Make a habit of including the benefit of learning in the introduction of learning.
Learning occurs best if rewards, not penalties, are offered.	Notice the amount of shoulder patting and back slapping that high school coaches engage in (rewarding by praise). Giving positive reinforcement immediately like this makes it more effective than if such reinforcement is delayed. If you must criticize the way a task was done, first compliment children on some aspect they did well and then explain the part that needs improvement. This increases self-esteem and allows children to feel good enough about themselves so that they can accept the criticism. Never be reluctant to praise in public; always criticize in private.
Children learn best by actively participating in learning.	Active participation requires involvement in learning. Ask questions to involve participation; allow children to touch and handle equipment to increase participation.
Learning occurs best in a non-stressful and accepting environment.	No one wants to take a chance redemonstrating a procedure or asking a question if they believe that actions or opinions will not be respected. People do learn from "top sergeants," but the learning experience has so many unpleasant memories attached to it that they may not retain the learning. Health teaching is too important to be presented in a way that will lead to its being quickly discarded.
Children learn best those things that hold a particular interest for them.	Everyone is more interested in some things than in others. A child with diabetes mellitus who enjoys dancing might be most interested in learning regulation of insulin for exercise; an adolescent anxious to leave for college might be most interested in selecting a diabetic diet from a cafeteria.
Learning ability plateaus.	Children learn to the point of saturation; learning and interest in learning halt at that point and do not continue until the material learned is thoroughly digested and understood. Wait until information is processed, and, at that point, the child will be interested once more.

syringe. Learning to be kind to a brother with a chronic illness is yet another type. Before you begin teaching, for best results, analyze the type of learning you want to see take place. This helps in setting goals and designing teaching strategies.

Cognitive Learning

Cognitive learning involves a change in the individual's level of understanding or knowledge. Learning the principle behind why a particular medicine must be injected into a muscle, as opposed to subcutaneous tissue, is cognitive learning. Cognitive learning requires adequate development, intelligence, and attention span. It can be gained through exposure to any teaching technique but is usually learned through lecture, reading, and audiovisual aids. Techniques for teaching when cognitive learning is the goal must be based on the learner's cognitive ability (Barlow & Parsons, 2009). During the school-age years, learning capability is concrete (children have difficulty picturing body parts functioning unless they actually see them doing this); during the adolescent years, it becomes possible to learn abstract concepts, and children at that point can accept that liver enzymes are released with liver damage even though they never see that occur (Piaget, 1969).

Psychomotor Learning

Psychomotor learning requires a change in a person's ability to perform a skill. Learning to hold a syringe, fill the syringe with medicine, and inject it into a muscle is an example of psychomotor learning. Acquiring psychomotor skills depends on muscle and neurologic coordination. It is mastered best through demonstration and redemonstration.

Affective Learning

Affective learning involves a change in a person's attitude and is the most difficult area in which to bring about change. To teach a child the reason for and the skill of giving a self-injection, for example, may be easy; teaching the child to *like* giving a self-injection may never be possible. The best goal accomplished could be that the child will *value* the procedure because it will prevent him from developing hyperglycemia. Affective learning is gained best though role modeling, role playing, or shared-experience discussion.

Influence of Age and Stage on Ability to Learn

Learning ability varies a great deal depending on a child's stage of development and the past experiences the child has had in the specific area of learning (Heard, 2008).

The Infant

Infants learn by exploring the environment with their senses (psychomotor learning). They learn best from a primary caregiver because that is whom infants most want to please. Few health care points are actually taught at this age. Any that are taught must be presented not as a structured activity but as a game or an amusing or attractive activity. You could teach an infant to exercise a leg by showing how to kick a balloon tied to a crib rail or rolling a ball and encouraging the infant to move and creep after it, for example.

The Toddler

Toddlers are developing a sense of autonomy that is, learning to be independent (Erikson, 1993). Trying to teach toddlers a new activity such as eating a new food or brushing their teeth may be met with a sharp "No!" as children this age enjoy exerting their new independence. This retort does not mean the activity is unappealing to a child, however, only that the child is aware he does not have to do everything he is told to do. Toddlers also sometimes resist a change in routine because they need rituals to feel secure. If an activity will allow children to increase a level of independent functioning, they will usually learn it rapidly. Teaching activities such as exercise or deep breathing by having children imitate the action is an effective teaching method because it presents the activity as a game (so there is nothing to be resisted). Parents can be instrumental in maintaining a new skill their child has learned by incorporating it into a daily routine or a ritual.

The Preschooler

Preschool children are interested in learning, because developing a sense of initiative is the main developmental task of the period. Provided that instructions are geared to their small vocabularies, they "soak up" new methods of doing things. Because they are so imaginative and uninhibited, they have few reservations about the "right" way to do things. They will experiment with trial-and-error methods. They will both watch eagerly and freely redemonstrate a skill. They ask many questions about equipment and procedures. Keep explanations short and words simple; a preschooler's attention span rarely exceeds 5 minutes.

In terms of cognitive development, preschool children "center" or can learn only one characteristic of an object. This can limit their ability to learn all aspects of care or more than one method of doing something on any one day (Piaget, 1969).

Preschoolers tend to be frightened of intrusive procedures such as rectal temperature taking, bladder catheterization, or nasopharyngeal suction. They typically remove adhesive bandages minutes after application to check on the condition of their skin underneath (that it has not disappeared); they worry that any blood removed may be the last they have. Teaching this type of procedure or explaining to children why it is necessary calls for clear explanations and praise for learning. Use dolls or puppets to help children visualize details whenever possible, because pointing to a place on a puppet's body is not as intrusive as pointing to the child's own body (Fig. 35.2).

FIGURE 35.2 Teaching with dolls or toys can help to make an intrusive procedure seem less frightening for a preschooler.

Parents are often most aware of the technique that will be best to motivate their preschooler. Often, this begins with reading or telling a story about the problem (Ono et al., 2008).

The School-Age Child

School-age children enjoy short projects that offer an immediate reward. Therefore, they learn best if a procedure is broken down into different stages and presented as separate short procedures rather than one long one. They enjoy games, so playing "Simon Says" may be an effective way to have school-age children learn deep breathing, for example.

School-age children are used to learning things and accept learning a new procedure or new information as just another experience in a busy day. The "staying power" of school-age children is notoriously short, however; the ability to continue to perform at the level taught tends to decrease sharply if learning is not reinforced. Be certain, therefore, that a backup person in the home knows the health care information as well as the child so that person can reinforce it or carry out a procedure if necessary.

Toward the end of the school-age period, children become interested in doing only those things their friends are also doing. Children may interpret as unreasonable, therefore, a request to do something after school (come home and take a medication) that is different from what all their friends are doing such as stopping at the playground or mall. Modify a teaching plan as necessary to help children fit what they must learn into a school and social schedule. Otherwise, the teaching may be very short-lived.

As part of moral development, school-age children thrive on rules or the "right way" to do things (Kohlberg, 1984). This means if two or more people are going to be involved in teaching, they must be consistent in their approach. It is frustrating for school-age children to be shown two ways or not have a "right way" to do something.

Parents who have been supervising their child's school learning through checking homework easily assume a role in supervising health learning also. Parents who have not been monitoring learning previously may need support to fulfill this role.

The Adolescent

Adolescents, struggling for identity, like to learn things separately from their parents. As a rule, they can be responsible for their own self-care; if they understand how the new actions they have been taught will directly benefit them, unlike school-age children, they will continue to carry those actions out conscientiously. Adolescents have a strong need to be exactly like their friends, however; they rarely continue any action that makes them different or conspicuous in front of their peers.

Remember that adolescents are present-oriented; they learn procedures and new information best if they can see how it will immediately benefit them. They also focus best on things they can do rather than on things they cannot do. They learn poorly if the only benefit of new information presented to them is something that will affect them at some future date. Rotating insulin injection sites, for example, prevents "pockmark" formations (*lipoatrophy*) in the skin when the person reaches approximately 30 years of age. Given this information, adolescents tend not to rotate injection sites because the benefit is not relevant to them at the moment. An explanation such as, "Rotating injection sites will ensure insulin absorption and allow you to play basketball this semester" (an equally true statement) is a better adolescent motivator.

For the first time, adolescents are able to think abstractly or use scientific reasoning. This means they can create hypotheses ("what if" questions) and think through what will be the consequences of an action (Piaget, 1969). This allows them to understand the principle of what they are being taught and reinforces the reason for the learning. Parents may find they are not as effective with teaching their child as they were when the child was younger. They may need to "step aside" and let you introduce the subject until the phase of adolescent rebellion passes.

✔ Checkpoint Question 35.2

You want Barry to increase his cognitive understanding of his condition. Which statement from him would best show he has increased cognitive knowledge?

a. "I feel so much better now about the care I need."
b. "I understand I have to take two types of medicine."
c. "I've finally learned how to swallow big capsules."
d. "I hate having to take medicine but I will take it."

DEVELOPING AND IMPLEMENTING A TEACHING PLAN

A **teaching plan** is a design of the content to be taught and the teaching–learning techniques to be used. The first step in developing a teaching plan consists of assessing a child's current level of knowledge, ability, and motivation to learn new knowledge.

Areas of Assessment

Important areas for assessment include a child's current level of understanding; cognitive, physical, psychosocial aspects; and how the new knowledge will meld with the child's and family's lifestyle.

Language Level

Assessing language development includes assessing both the child's spoken vocabulary (how well the child speaks) and comprehensive vocabulary (how many words the child understands). Most children have a comprehensive vocabulary well above their speaking one or can understand about three times the words they actually use. Assess also "family vocabulary" or specific words the family uses. Be aware that if English is not a child's primary language, comprehensive vocabulary may not be greater than spoken vocabulary in English. Additional pictures, drawings, or diagrams may be necessary to convey meaning (Timler, Vogler-Elias, & McGill, 2007).

Child's Current Knowledge

Assessing how much a child currently knows about the health area in question helps to establish the needs and goals for the teaching plan. Current knowledge is in part developmentally based and in part experience based. Parents can tell you if a young child has had experience with the subject area. Some school-age children have had excellent anatomy and health classes as part of their science curriculum and are well aware of body organs. Children who are home schooled may have researched the subject as an independent project. Children who have lived with a family member with an illness may already know what home care problems occur with that particular illness; on the other hand, what they know about the illness may be accompanied by so many misconceptions that they need a great deal of teaching to prevent being hampered by half-truths or unnecessary restraints. A helpful method of assessment, which promotes mutual sharing in the learning process, is asking children to list what they know about the health area on one side of a piece of paper and what they want to know more about on the opposite side. To reveal this type of information, young children can be asked to draw pictures of themselves, of someone with their illness, or of a good thing to do to keep well.

Child's Intellectual Capability

In many instances, intellectual capability can be inferred from developmental milestones such as a child spoke in two-word sentences at 2 years or from educational level such as attending the age-appropriate class in school. However, most children regress at least slightly with illness; what one would normally expect from a 10-year-old, therefore, may be impossible for an *ill* 10-year-old. Children with chronic illnesses may not have met developmental milestones because of their lack of experiences, not because they do not have the cognitive ability to learn.

Child's Physical/Cognitive Capabilities

If a procedure that requires a certain level of psychomotor skill, such as medicine injection, will be necessary for care, assess a child's physical ability to perform the procedure (Hughes, 2007). If you omit this step, the procedure will be frustrating because you will be asking a child to perform a skill above capability. Assess vision and hearing ability and right- or left-hand dominance as well; these are important considerations for determining not only whether a child can accomplish procedures but also how the material will be presented.

Child's Psychological or Emotional Capabilities

To learn best, children need some motivation to learn or at least appreciate how their life will be improved through learning this new skill. It may be difficult for young children to grasp how the new skill will make them feel better. Some children are too ill or too exhausted or have too much pain to be ready for learning until these factors can be alleviated. With early hospital discharge, a great deal of health education may have to be delayed until a particular child has returned home and feels better.

Children, like adults, may have difficulty learning about an aspect of their care if they find it distasteful. A child who uses food as comfort, for example, may have trouble learning about a restrictive diet because it conflicts with the way the child views food. Children with urinary or bowel disorders may have difficulty learning about these body parts if they view them as "dirty" or distasteful. School-age and adolescent children may have difficulty discussing and asking questions about a reproductive tract illness not only because they lack knowledge of the subject but also because they sense sexual functioning is not an "open" topic in their family.

Children with low self-esteem are less capable of learning self-care than others because they do not feel as capable as others. For some children, it may be necessary to plan ways to increase self-esteem first before planning active teaching.

Child's Sociocultural Values

Different cultures have different values related to good health. If a child from a family that values sports develops an illness that impairs the ability to run, for example, the family might consider the disability overwhelming. If the family believes that being able to write and read well are the keys to succeeding in life, the same leg impairment might be viewed as merely a minor complication. Study each family individually to determine which aspect of health will be most important to emphasize when teaching (Box 35.5).

An important aspect of culture is whether children are raised in an environment where they are urged to be active participants in learning (allowed a lot of "hands-on" experimentation) or whether they are encouraged to be "watchers." Male/female roles also are culturally determined. This means a girl from a female-passive culture might not be enthusiastic about learning a self-care procedure because self-care is not expected of her. How long children are expected to be children (carefree, no responsibility) also varies culture to culture. In a family where children are expected to be out working and contributing to the family income by age 15, a child might have a very different attitude toward learning a self-care activity than the same-age child in a family where children are expected to remain noncontributing family members until after college (at least 21 years of age).

Child's Attention Span

The attention span of children and the capability to comprehend concepts and perform psychomotor skills differ a great deal depending on individuality and age. In general, the younger the child, the shorter is the attention span (under school age, 5 minutes of attention is all that can be expected). This means you must use more "attention-getting" teaching to hold attention in younger children. Think about the clever puppet shows or animation children are exposed to today. Teaching that is not accompanied by these same attention-holding techniques needs to be very short to be effective.

BOX 35.5 * Focus on Communication

Wolf Whitefeather is the 3-year-old boy scheduled for a syndactyly (webbed fingers) repair next week. You speak with him through a puppet at a clinic visit to assess his understanding of the surgery.

Less Effective Communication

Nurse: Hello. Could you tell me what the little boy named Wolf is going to have done in surgery?
Wolf: His fingers got sick when he was born.
Nurse: When is he having them fixed?
Wolf: The day after we go to church.
Nurse: Will it hurt?
Wolf: No. His fingers are going to sleep.
Nurse: Will he have a big bandage afterward?
Wolf: So big he can't see how his fingers got cut.
Nurse: Okay. Thank you for talking to me. I'll see you Monday.

More Effective Communication

Nurse: Hello. Could you tell me what the little boy named Wolf is going to have done in surgery?
Wolf: His fingers got sick when he was born.
Nurse: When is he having them fixed?
Wolf: The day after we go to church.
Nurse: Will it hurt?
Wolf: No. His fingers are going to sleep.
Nurse: Will he have a big bandage afterward?
Wolf: So big he can't see how his fingers got cut.
Nurse: What does that mean? Cut?
Wolf: Cut so they're not there anymore.
Nurse: Why do you think that's going to happen?
Wolf: I think he's been bad.

The two scenarios above are good examples of what asking children about what they expect to happen in surgery can reveal. When asked what he means by "cut," it becomes obvious that Wolf needs additional teaching, probably using a drawing to illustrate what will be done. After surgery, when his fingers are covered by a pressure dressing so he cannot see them, he will need additional reassurance that his fingers are still intact underneath the gauze.

Child's Lifestyle

Lifestyle refers to the common pattern of a child's life. For example, a child who attends school daily and returns home every day at 3 PM has a fairly consistent lifestyle. A busy adolescent who works part-time, participates in several clubs after school, and socializes on weekends may have a varied pattern of activity every day.

Knowing family patterns helps to plan the timing of such activities as medication administration or exercise or meal times. If both parents work during the day and do not return home until 6 PM, medication may have to be administered after this time; exercises may have to be supervised in the

evening, not the morning. A family that goes camping every weekend will need to plan ways to carry out a health routine at remote camp sites.

Child's Learning Style

Some children learn well from oral descriptions. Others have to see a statement in print before they can fully comprehend it. Still others are so visually oriented that they need to see a picture or a diagram before they can grasp the explanation. These different learning styles vary from child to child; few children are aware of their own learning style, so they cannot explain what it is. After caring for them for a time, it becomes easier to detect the way children learn best. Tailor a teaching plan to a learning style for the most effective learning situation.

Formulating the Plan

Formulating a teaching plan begins with establishing expected outcomes and techniques of teaching. It may need to include communication strategies for parents as well as children.

Identifying Personal Strengths and Limitations

When formulating a teaching plan, be honest about your capabilities. If you feel uncomfortable teaching a child about surgery with clever puppets dressed in scrub suits, it might be better to avoid this approach; in the wrong hands, such a method can sound so flat or complicated a child is left feeling more frightened by the presentation than comforted. Attempting to use a teaching method that is uncomfortable can cause children to interpret your insecurity as evidence there is something wrong with them, not with the method.

Some health teaching involves giving instructions in areas of care that may be personally embarrassing such as instructing a member of the opposite sex how to obtain a clean-catch urine specimen, for example. Proceeding blindly may not result in effective teaching, because the child may be so embarrassed by your discomfort that concentrating on instructions becomes difficult. In doing this type of teaching, nothing serves you as well (as in any client contact) as honesty. Admit to children that you are not used to giving this type of instruction. This approach will probably evoke a response from children that they are not used to having anyone talk about it either. Once you have found common ground (this is not the most comfortable discussion for either of you), there is a basis for effective health teaching. Honesty also allows a child to know that your discomfort is not from lack of knowledge on the subject (the child can trust what is being said) and also not the child's fault (the subject, not the child, is the disturbing factor).

Preparing Expected Outcomes

Planning outcomes is most effective when they are planned collaboratively with a child and family. They should reflect the type of learning desired: cognitive, psychomotor, or affective. They should help to establish both content and time guidelines based on both the child's cognitive ability to learn and the time frame it will take to learn. It is unnecessary (and often overwhelming) for a child to learn everything about an illness in the first day or week after a diagnosis. Likewise, information on how to stay well does not need to be presented in one setting. In many instances, it is effective to teach only part of the information needed; another nurse in another setting such as an ambulatory clinic or in the child's home can teach the remainder. For best results, state outcomes as behavioral objectives or as the activity the child is expected to demonstrate when the child has learned the new knowledge—not "Tim understands the importance of deep-breathing exercises daily" but "Tim does deep-breathing exercises daily."

Identifying Teaching Formats

Teaching techniques vary with the content to be covered, teacher–learner characteristics, and the environment for teaching.

Formal Versus Informal Teaching. Both formal and informal teaching formats are used in health education. Careful assessment is necessary to determine which format would be the best technique for a given situation. An example of formal teaching would be conducting a class on healthy eating as part of a health education course. An example of informal teaching would be explaining to a child who refuses to eat that he needs to at least drink something because his body needs more fluids to get better. Sometimes informal teaching occurs so spontaneously that it is easy to be unaware of it. It may occur, for example, in response to a question such as, "How long will I have to take this medicine?" If you answer, "For 2 weeks," that is just answering a question. If you answer, "For 2 weeks because. . .," that is teaching.

Be careful not to equate informal teaching with disorganized, or unnecessary, teaching. It is just as important as formal teaching; it is just communicated in a less structured way. Informal teaching requires that teaching and learning principles that include knowing the subject, recognizing individual learning styles, providing an effective environment, limiting time span, and so forth are followed, just as with more formal teaching. Table 35.3 lists suggestions for incorporating informal teaching into care.

Group Versus Individual Teaching. Although most health teaching is done on an individual basis, teaching groups of children is common in some situations. Individual instruction more directly addresses a child's unique needs; group teaching can meet individual needs while adding depth to learning as children discuss information within the group. For many children, hearing that they are not the only person with their problem is comforting. Hearing another child discuss how to solve a problem may be more meaningful than hearing the same information from an adult. Peer learning in this way, therefore, not only improves knowledge but may also improve attitude and motivation to learn.

Consider the following important guidelines when group teaching:

1. Assess for common interests and goals so that the information will appeal to as many in the group as possible.
2. Be certain that all members of the group can see and hear all others.
3. Encourage all members of the group to participate in discussions by calling on them if necessary.
4. Limit any one person from dominating the group by a statement such as, "That's a good point, Reneé. Has anyone else had a similar experience?"

TABLE 35.3 ✻ Ways to Incorporate Informal Teaching Into Care

Activity	Type of Teaching
Medication administration	Children as young as early school age should know the type and action and any expected side effects of all medication they are taking. Present medicine not by saying, "Here is your pill" but "Here is your [name of medication], medicine to help your temperature come back to normal. After you take this, you might feel yourself start to sweat. That means it's working."
Vital sign measurement	When taking vital signs such as blood pressure, temperature, and pulse, tell children what normal levels are: "Your blood pressure is 100/70. That's normal." If the child is in a high-risk category for hypertension, add some prevention measures to teaching.
Any procedure	Always tell children the purpose and principle of procedures, not "You need to drink a lot of fluid," but "You need to drink a lot of fluid because . . ."
Dressing changes	Dressing changes provide an opportunity to teach the danger of introducing infection into an open wound. The parents or child may not change this dressing, but they will apply bandages to small cuts in the future and so will benefit from teaching.
Mealtime	Provide information about nutrition: "I know you're not hungry enough to eat the entire sandwich, but could you try the meat? Meat is high in protein and that's important for healing."
Hygiene	Emphasize the necessity of good perineal hygiene to decrease the possibility of urinary tract infection.
Physical assessment	Explain aspects of testicular self-examination and describe "normal" findings as both education and reassurance.
Positioning	Teach the hazards of immobility and how change of position and ambulation increase circulation and respiratory function.
Sleep	Teach that sleep is a healing therapy and should not be considered a waste of time.
Bowel elimination	Teach children that elimination patterns vary; occasional variations in their elimination patterns are normal.

5. Avoid competition in the group. No one is always right; no one is always wrong.
6. Ask group members to evaluate the experience afterward to be certain it met the group's needs.

Home Versus Institutional Teaching. Health teaching is just as important in the home as it is in a health care agency, school, or community setting. Teaching in the health care agency usually focuses on immediate acute care concerns. Teaching in the school may focus on topics such as basic health promotion and hygiene, reproductive and sex education, and drug prevention. Teaching in the home may focus on medication regimens, dressing changes, or measures to prevent complications of a particular illness. It may also involve helping a child and parents adapt a procedure to the home setting, such as accommodating a wheelchair at home. Be certain parents have obtained the supplies they will need to learn and perform the procedure in the home.

Teaching in the home offers the advantage of being able to assess a child's environment, interactions with other family members, and overall family functioning. This may yield data that prove useful for further planning and implementation of care. It may also provide an opportunity to include other family members—siblings, grandparents, and so forth—in the teaching plan, which could strengthen the impact of teaching and ensure that all family members understand the procedures in the same way.

Always include evaluation as a step of teaching in all settings so you can feel confident that learning has occurred.

What if... Barry, who is overweight, needs to begin a lower-calorie nutrition pattern as well as a lower-cholesterol one? Who would you need to teach? Barry? His mother who prepares his food? Or his father, who does the family grocery shopping?

Determining Teaching Strategies

Because children's knowledge base, capabilities, learning styles, and attention spans vary, teaching strategies are most effective when they are intermixed and when they are selected in response to the individual situation and child to be taught. The more interactive the method, the more appealing it might be to a particular child.

Lecture. Lecture (or directly explaining information) is the most efficient and time-saving method of offering information to both individual children and groups. A lecture, however, does not allow for much participation, and it is effective only in short, well-structured periods. It is rarely effective for children who are not yet school age.

Demonstration. **Demonstration** is actually performing a procedure such as a dressing change or instillation of eye drops so the child can see clearly how the procedure should be done. Do not demonstrate a procedure unless you have all the necessary equipment to do it. If you stop in the middle of a demonstration to say, "Be sure to use a sterile syringe, not what I'm using," the poor technique demon-

strated may be the lesson learned, not the good technique. The purpose of demonstration is to show how the procedure actually is done; having to imagine steps is little different than reading about it. School-age children, because of their stage of cognitive development (concrete operations), learn best by demonstration (Fig. 35.3).

Redemonstration. To determine whether a child has truly grasped a demonstration, ask the child to perform a **redemonstration,** or exact imitation of the procedure. Redemonstration is best if it immediately follows demonstration. Praise the effort to redemonstrate even if the redemonstration is not of the quality desired. No one likes to be put on the spot, and children may be unwilling to expose themselves again by a second demonstration if criticized. Be aware that there are many different ways to do almost everything. Children do not have to follow your motions exactly, as long as their technique accomplishes the same goal. An effective way to correct a wrong action is to say, "That's one way of doing that; most children, however, find it easier to. . . ." This type of criticism is nonthreatening because it acknowledges the child's effort in a positive way before offering a correction.

Discussion. Discussion is a shared learning experience in which children ask questions about particular concerns and these are answered based on their individual circumstances, or children are asked questions about some problem, such as how they anticipate managing some aspect of care, and together the problem is solved. At the beginning of health education, children tend to ask few questions because they do not know enough about an illness or health issue to anticipate concerns. As their knowledge increases, so does their ability to project and modify information to fit their own lifestyle. Remember that children tend to think in the present: a problem that will arise once tomorrow is usually more important to a child than one that can be predicted to arise repeatedly in years to come. Because it recognizes and respects their opinions, school-agers and adolescents enjoy discussion.

Role Modeling. Role modeling is demonstrating a certain attitude or behavior you want a child to learn. Be certain when health teaching not only to present facts but also to radiate a positive attitude. Showing frustration at getting a bubble out of medicine in a syringe demonstrates, for example, that giving injections is frustrating; showing a bored attitude toward nutrition instructions implies that nutrition information is boring. The child picks up the role modeling cues as readily as the spoken message. Role modeling is an important technique used to teach new parents newborn care; as they watch a nurse hold, comfort, and talk to their newborn, they quickly learn to model these behaviors.

FIGURE 35.3 A school-age child watches a demonstration of insulin injections.

Behavior Therapy. Typically, learning occurs best with **positive reinforcement** (a child tries to understand a new procedure, is praised for the effort, and tries even harder). **Behavior therapy,** also called *behavior modification,* is a term used for a system aimed at *erasing* some form of behavior that interferes with healthy functioning. It was originally designed to help people who are cognitively challenged erase socially unacceptable behavior such as poking their fingers in their eyes. Currently it has many uses, including concerns such as controlling disruptive classroom behavior. The basic premise of behavior modification is that a child is rewarded for healthful behavior, whereas unhealthful behavior is ignored or unrewarded. For example, a cognitively challenged child may have a socially unacceptable habit of constantly rocking back and forth. The child is not scolded or criticized for rocking, but the action is ignored. On the other hand, preferred behavior (sitting for 5 minutes without rocking) is praised. As another example, a child might be ignored for being a picky eater, then praised for the few bites he does eat well. Children respond best to behavior modification if, in addition to praise, they receive a tangible reward such as a star on a chart or an extra privilege of some sort for good behavior.

A behavior modification program must be discussed with the child before it is begun, because no behavior can be modified, just as no new behavior can be learned, until a child truly wants a change to occur. It might be necessary to ask older children to sign a learning contract to be certain that both teacher and learner agree on the method to be used. Many older children are able to use self-rewards to reinforce a behavior modification program such as rewarding themselves by playing a video game or going to a movie after an afternoon of efficient studying or an hour of doing breathing exercises.

Behavior modification is a technique that must be used with common sense and concern so that children are not being manipulated more than they are being helped to achieve a more healthful lifestyle. It is a legitimate device to use in helping a child with attention deficit/hyperactivity disorder sit still long enough to eat a meal or learn in school. It can be helpful in encouraging children to do as much self-care as possible or discourage disorders such as obsessive compulsive behavior (O'Kearney, Anstey, & von Sanden, 2009).

Trying to modify beliefs or values by behavior modification is unethical and is one reason why behavior modification is often criticized as a learning technique. However, some behavior changes also require a change in values to be effective and long term. For example, a child's behavior of talking back to parents can be extinguished by ignoring or not responding to the behavior and praising polite communication. This method teaches the child to value improved communication and parental approval in order to meet his or her needs.

Selecting Teaching Tools

Teaching tools are the mechanical devices used to present content. They vary based on content, teacher–learner characteristics, and environment.

Visual Aids. "A picture is worth a thousand words" is not an idle quotation but a realistic one. Because small children know little about their bodies or where body organs are located, using visual aids such as drawings or photographs of anatomy can be very helpful. Figure 35.4 shows abdominal contents as an example of such a drawing. You could use such an illustration to show a preschooler how food moves through the body. Figure 35.5 is an example of a good tool to use while naming body parts. Pointing to a figure drawing and saying, "This is the part of your tummy the doctor will fix," is less threatening than actually pointing to the child's abdomen. Clarifying body parts this way is important because young children may have no clear understanding of where a body part such as a hand ends and an arm begins.

Do not be afraid to draw a picture of a heart, a kidney, a bladder, or any other organ to make a point about anatomic structure. Children are more interested in understanding procedures or the reason for a health maintenance measure than criticizing your artwork (they likely do not know anatomy well enough to be able to tell if a drawing is distorted).

Pamphlets. Pamphlets are helpful teaching aids with school-age children and adolescents because they usually contain brief, easy to read, easily understood information and are often cleverly illustrated with cartoon characters to make them enjoyable. Be certain to read any pamphlet before offering it to a child to be certain the information included in it is accurate. Medical advances are made so quickly that a 1-year-old pamphlet may contain a gross inaccuracy in the light of subsequent knowledge.

If a pamphlet contains some statements that are inaccurate or that do not apply to a child, do not simply cross out the information that would be contradictory before offering it (most children deliberately read what they have been told not to read); take the time to explain why it does not apply. Also, do not be misled into believing that because children are given clever pamphlets, they will necessarily read them and learn from them. Sit with a school-age child and read the pamphlet together; talk with an adolescent about the pamphlet's contents later to ensure it has been read.

Learning Games. For memorizing certain kinds of information, such as what foods are high or low in potassium or sodium, flash cards are a helpful learning tool. Many children enjoy playing trivia-type board games. Instead of the usual

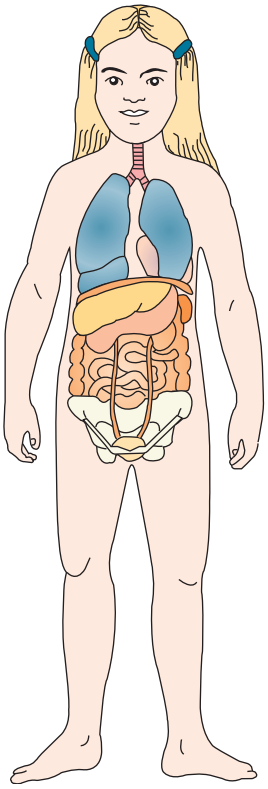


FIGURE 35.4 Anatomic drawings are helpful to illustrate basic health education topics as well as health care procedures.

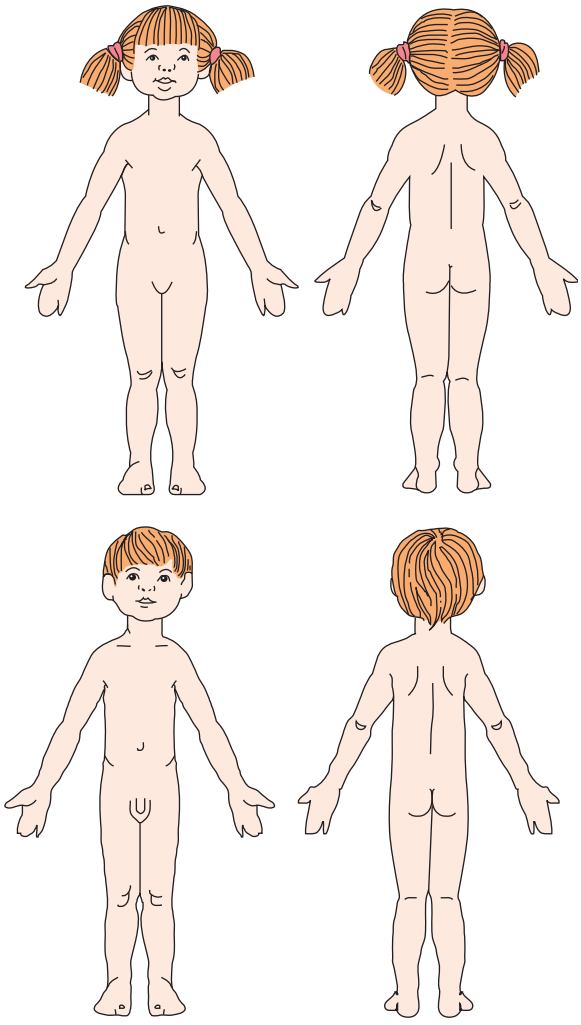

FIGURE 35.5 Simple line drawings such as these can be used to explain to a child exactly what part of his or her body will be "fixed" in surgery. For many children, having this pointed out on a drawing seems much less intrusive than having it pointed to on their own body.

categories of information, make up new cards with questions such as, "Where is insulin produced in your body?" If the child can answer the question correctly, a token is allowed to advance a designated number of spaces on the board. Children learn information quickly this way because the reward for learning is so immediate. Having parents play the game with their child educates the parents at the same time.

Word scrambles are easy games to develop. Crossword puzzles are fairly easy to design; one might be developed to address the activities that are important for a child to do after surgery such as deep breathe, exercise legs, and not eat immediately.

Videotapes, CDs, and DVDs. Many health care agencies, homes, schools, and community centers have videotape or DVD playback equipment that can be used to show a short tape or PowerPoint presentation as part of a health education program. Most households have VCRs or DVD players, so tapes or disks can be sent home for families to view. Viewing such programs can give children a sense of power in that the program seems to be talking directly to them. It can also be used over and over to refresh children's knowledge of the steps they need to take to remain well (Yoon & Godwin, 2007). As with pamphlets, view the material first before showing it; be certain to check that the vocabulary used is appropriate for an individual child or family (Bauman et al., 2007).

Puppets and Dolls. Many children are shy about talking to strangers; this shyness, in addition to their concern about what will happen to them, may make it difficult for them to discuss or explain what they know about their health, illness, or intended surgery. However, they may be able to open up to an uncritical puppet or doll (see Focus on Nursing Care Planning Box 35.6). Preschool children are particularly receptive to puppets and dolls because, with their imagination

BOX 35.6 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Preschooler Having Surgery

Wolf Whitefeather is a 3-year-old boy who is scheduled for repair of syndactyly (webbed fingers) next week.

Family Assessment ✻ Client lives with mother in two-bedroom mobile home. Parents separated. Mother works at hospital in medical billing. Grandmother does child care 4 hours a day; child attends Head Start program in afternoon. Mother describes finances as "I'm making it." Father will visit after surgery; mother has custodial authority.

Client Assessment ✻ Favorite activity: coloring. His mother tells you she is concerned Wolf will be hard to entertain after surgery because the large pressure bandage he will have afterward will prevent him from coloring with that hand. "I don't even want to begin to talk to him about surgery," she tells you. When nervous or frightened, child has a habit of biting his hand; he has done this constantly since admission.

Nursing Diagnosis ✻ Deficient knowledge related to what to expect in surgery

Outcome Criteria ✻ Child describes expected outcomes of surgery. Demonstrates a minimum of nervous behaviors such as biting hand, can play "Simon Says" for hand exercises postsurgery, and describes how pain will be relieved by "special button" (patient-controlled analgesia).

Teaching Points ✻ Child is shy with strangers; mother states that he learns best by "hands-on" experiences; "cocks head" when puzzled. Also learns better from his mother than from his father (father tends to be authoritarian).

Cognitive Learning to Be Taught ✻ Why surgery is necessary

Psychomotor Skills to Be Taught ✻ To keep hand in elevated position after surgery

Affective Aspects to Be Taught ✻ Accepts surgery as a growth experience

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Assess what child and parent understand about care necessary postoperatively.	Introduce postoperative hand exercises child will need to do by playing "Simon Says."	Games are an appealing way to keep the preschooler interested and motivated in doing exercises.	Child demonstrates opening and closing hand to help prevent contractions postprocedure.
		Consultations		
Surgeon	Assess which anesthesiologist or nurse anesthetist is available for consult.	Request anesthesia/analgesia consult.	Child is too young to be cooperative during surgery; needs pain relief afterward.	Anesthesia service meets with child and parent and determines best form of anesthesia and pain management.

		Procedures/Medications		
Nurse practitioner/ resident physician	Assess health history.	Complete physical exam.	Health assessment helps ensure readiness for surgery.	Child cooperates with history and exam.
Nurse	Assess Wolf's and parent's knowledge of surgery and postoperative procedures.	Introduce dressing and show how child's hand will be suspended postoperatively by letting Wolf dress and suspend puppet's hand.	Therapeutic play provides an excellent medium for teaching and learning with toddlers and preschoolers.	Child demonstrates he understands how hand will be positioned by showing position with puppet.
		Nutrition		
Nurse	Assess if child and parent know child will be NPO for general anesthesia for surgery.	Teach parent importance of NPO preoperatively and immediately postoperatively.	Maintaining NPO status helps prevent aspiration with anesthesia.	Child and parent state they understand necessity for NPO status and will adhere to requirement.
		Patient/Family Education		
Nurse	Assess child's cognitive level and ability to learn.	Using puppets, teach that child's hand must be washed with antiseptic wash solution before surgery.	Reducing skin bacteria prior to surgery can help prevent osteomyelitis.	Child cooperates with preprocedure washes.
Nurse	Reassess who is child's main support person.	Ask mother, as support person, to reinforce preparation.	Wolf learns best from mother; reinforcement from her could help Wolf go into the operation viewing it as a growth experience.	Mother reinforces necessity for surgery and accompanying pre- and postoperative procedures.
		Psychosocial/Spiritual/Emotional Needs		
Nurse/pain management team member	Assess what past experiences, if any, child has had with pain.	Teach that child will have pain after surgery but that it can be relieved by a "special button" on his intravenous line.	Preparing a child for postoperative procedures and explaining how pain will be relieved before surgery (when the child still feels well) can help reduce the amount of learning the child needs to accomplish after surgery, when he doesn't feel well.	Child and parent state they know there will be pain and understand method to be used for control.
		Discharge Planning		
Nurse	Assess if child and parent feel equipped to change bandages, carry out hand exercises at home.	Review with parent a schedule of care based on Head Start and grandmother involvement.	Helping a parent walk through how postprocedure activities can be managed helps ensure adherence.	Mother states that she has a plan for how to consistently arrange care given by three caregivers.
Nurse/ physician	Assess when return visit is needed and is convenient for parent.	Schedule return visit for postsurgery evaluation.	Follow-up care is necessary to evaluate success of surgery.	Parents states she understands importance of follow-up visit and will keep appointment.

at its peak, they believe the puppet or doll is actually talking to them (Wright et al., 2007).

Teaching preschool children about what to expect from a hospital experience is often taught by using a series of puppets to represent different hospital personnel such as a surgeon, a nurse, and a nurse's assistant. Children can practice giving the doll "shots" or submitting it to the procedures they will experience (see Chapter 36 for a discussion of therapeutic play).

Mass Media. Television and radio are examples of effective mass media that teach many children topics about self-help or self-care. Consulting on the topics to present or helping develop the material used in these types of health messages can be an important role for nurses. Messages originated for these media must be attention-getting and brief to compete with the programs and commercial messages that precede or follow them.

Computers. Many children learn to solve problems using computers as early as preschool age and are exposed to computers at home, child care, or school. Using a computer application to answer questions about an illness is effective because this type of activity can be both entertaining and informative (Gielen et al., 2007). Caution children that not all information posted on the web is reliable and participating in chat rooms can lead to exposure to Internet predators.

Health Fairs. Health fairs are displays presenting health-related information to large numbers of people. They are effective with children if they encourage active participation through interactive displays or computer games.

Preparing Teaching Supplies

To avoid having to reorganize equipment or instructions each time a procedure is taught, put together a basket or box containing all the information and equipment needed to teach a particular task. This helps ensure that teaching is organized and is economical in that everyone on a hospital unit is not opening new equipment for demonstrations. It also helps to ensure that everyone is teaching the same information. Nothing is more confusing to anyone learning a new skill than to be taught two different principles for doing it or two different techniques.

Implementing the Plan

Health teaching can begin immediately and flow easily if goals have been developed well and strategies for teaching have been designed carefully.

Resource People

Many health care agencies, including home care agencies, have specific people who are available for health teaching about specific subjects such as diabetes, stomal care, or respiratory exercises or drug prevention. Using such people is helpful because they know all the "tricks of the trade" for teaching that particular subject.

Some children do not learn as well from such designated teachers, however, because they see them only infrequently, where they see a primary nurse daily. Some parents react badly to the thought that it takes an expert to tell them about the care needed (if care is so complicated, how can they possibly learn it?). They also find it inconvenient to be told that their questions cannot be answered until the following day when the designated teacher is available to answer them. Be sure that if a designated teacher does teach a subject, you coordinate your teaching with that person. Make a point of introducing the person to a child so the child does not view the person as a suspicious stranger.

Parent Education

With very young children, parents as well as children need teaching. It is good practice with all children to be certain that at least one adult in the household has the necessary information or can perform the required skill as well as the child. Let the child choose this person as the individual who everyone assumes is a child's chief support person may not be the person the child perceives as the most reliable choice and, therefore, not the one the child wants as a health care backup. This person, when identified, needs as much information as the child does about why the health measure is important.

What if... Wolf, 3 years old, refuses to tell you whether he has pain because you are a "stranger" and he doesn't talk to strangers? What would you do?

Evaluating the Effectiveness of Teaching

Evaluation, or assessing whether teaching has been effective, is the final step in teaching. Evaluation occurs not only after the teaching plan has been implemented but throughout the entire learning process. This ongoing evaluation helps both teacher and learner modify the teaching plan to better meet changing needs.

There is some advantage in asking children questions before and after teaching to prove that teaching was effective and the child has safely learned a new health care measure. Demonstration of a change of behavior or attitude, however, is the real proof that learning has occurred.

HEALTH TEACHING FOR A SURGICAL EXPERIENCE

Teaching to prepare a child for surgery is an example of teaching that requires planning for several stages of learning. The child and the child's parents often feel anxious about surgery because this is always a potentially frightening experience, so teaching must first address this anxiety. Such preparation differs according to the type of surgery being performed, but certain activities apply to all surgery and all children. Psychological preparation of both child and parents is aimed at reducing a child's fears about the procedure and consists primarily of providing health teaching and opportunities for therapeutic play. Physical preparation includes providing for restrictions on food and fluid intake before surgery, preparing the incision site on the child's skin, and arranging for transportation of the child to surgery. Because many children's surgical procedures are done on an ambulatory basis, preparation must also include informing parents

about the details of the preparation techniques, the surgery, the postoperative period, and the steps they must take toward preparation. Do not downplay a family's fears, but allow the child and family opportunities to express their concerns as part of the teaching–learning process.

Assessing Current Level of Knowledge

On admission to an inpatient surgical or an ambulatory unit, discuss with parents the preparation they have made for this experience and what specifically they have told a child about what will happen. It is good to ask also whether a child's concerns about the experience seem more or less than the parents had anticipated. Is the child emotionally prepared? Ask if there has been an unpleasant surgery or hospitalization in the family that a child might have heard discussed. Has the child seen anything recently on a medical show on television that might have been upsetting?

Emotional Preparation

Preparing a child emotionally for surgery requires minimizing fears common to all children such as fear of separation, fear of mutilation, or fear of death. This can be accomplished by telling a child about the procedure and describing any specific equipment and techniques that will be used, such as anesthesia, eye bandages, nasogastric tubes, sutures, or special aftercare. Be certain all preparation is appropriate to the child's age. More children who need surgery receive a general anesthetic rather than a local or regional anesthetic, as might be used with adults, because this minimizes their fears of intrusive or mutilating procedures, and because children who are not yet adolescent are not mature enough to cooperate adequately during surgery if they are not fully anesthetized.

It is best to prepare a child for surgery or hospitalization in stages because it is difficult for a child to absorb everything at once. However, contact before surgery may be limited to only one office or clinic visit, so time constraints can force information to be more compacted.

Be certain to discuss preparations for surgery such as coming for blood work and not eating the morning of surgery. If the child will have general anesthesia, it is important to emphasize that anesthetized sleep is "special" sleep. Otherwise, toddlers or preschoolers may be reluctant to fall asleep after surgery for fear people will come and do strange things to them. Do not say a child will be "put to sleep." Dogs and cats who are "put to sleep" are not seen again. To help prepare a young child for surgery, a doll could be used: its abdomen washed, an injection given to make it sleepy, and a hospital gown put on. It could be carried to a cart made from a cardboard box. After saying goodbye to its parents, the doll could be wheeled to surgery by a puppet nurse.

The surgery procedure should be discussed but minimized. "After you're asleep, the doctor will fix your tummy. You won't feel anything because of the special sleep. When you wake up, you'll be in a room called a recovery room where you'll stay until you're wide awake." Be honest concerning pain: "Your tummy will feel sore afterward, but I'll give you something to make it feel better" is a fair statement.

It is important to alert children that nurses and doctors in surgery wear surgical masks. Assure toddlers and preschoolers that the persons behind the masks are doctors and nurses, some of whom the child has probably already met, not superheros or bandits.

It is good to mention recovery rooms in preparation, because this is often an area parents neglect to mention. In fact, parents may not be aware that, in some institutions, they will not be allowed in the recovery room and may have promised the child, "As soon as you wake up, I'll be there." Clarify the parents' misconceptions about recovery rooms, and reiterate that the child will get to see his parents back in his own room once he is fully awake. This both makes the parents' preparation correct and saves the child from feeling deceived.

Explain postsurgery items, such as the use of oxygen, monitors, bedpans, bandages, or intravenous equipment. Furnishing a doll with such equipment is especially helpful in preparing younger children (Fig. 35.6). This prevents preschoolers from feeling overwhelmed by being taken to an intensive care unit and shown actual monitors and respirators. After surgery, be certain to evaluate whether a child's preparation was adequate, both to document that the experience was as trauma free as it could be and to evaluate your expertise in teaching children (Li, Lopez, & Lee, 2007).

Physical Preparation

Most children will be placed on nothing by mouth (NPO) status for surgery. The length of the time a child will remain NPO depends on the child's age. Adolescents and school-age children may be restricted from taking food or fluid from midnight until the time of surgery the following morning; however, if infants younger than 6 months were held NPO for as long a time as this, they would be taken to surgery in dehydration. Therefore, infants younger than 6 months may be kept NPO for as little as 4 hours. At the end of the 4 hours, as the infant becomes hungry, the infant will begin to cry and fuss for fluid. Parents need an explanation that infants who vomit during surgery because of recent feedings may aspirate; therefore, even though an infant is becoming hungry, it is important that fluid not be ingested. Although a hungry child will usually not suck on one for long, a pacifier can be offered.

Preparation of surgical sites varies. In most instances, shaving of the area and final cleansing are done in a holding room adjacent to the operating room after the child is anesthetized. A povidone–iodine wash may be ordered before

FIGURE 35.6 Pretending to be a pirate helps this young child prepare for having to wear an eye patch after surgery.

transport to the operating room for some types of surgery. Washing a particular body part in this manner can be interpreted as an intrusive procedure by a preschooler. Give a great deal of assurance that the solution being used will not sting but is only cleaning.

Implementing the Plan

Check children's identification bands to ensure they are legible and secure before the child is transported to surgery. If not, replace or secure them before surgery. Immediately before transport, remove barrettes and bobby pins from a child's hair and check the mouth for loose teeth (particularly in children aged 6, 7, and 8 years, who are losing their central and lateral incisors) or for dental appliances. It is rare to find a child with full dentures but not uncommon to find a post or screw-in tooth that may have to be removed before surgery or a retainer used to maintain orthodontic correction after brace removal. Teeth braces do not need to be removed. Make certain the anesthesiologist knows about any loose teeth before an airway for surgery is inserted (a loose tooth could be knocked totally free and aspirated during the procedure).

For some children, having to give up their own pajamas or their bedroom slippers or outside shoes to change to a hospital gown is a terrifying moment. Giving up underpants is a step that many preschool and early school-age children cannot tolerate. For this reason, many children are allowed to wear their own pajamas or clothes until they are under an anesthetic.

In ambulatory settings, children may walk to surgery. If they will ride in a cart, this should have been introduced during preparation. Be sure to fasten a restraining strap for safety (presented with, "Here's your seat belt; it's just like going in a car."). Preschoolers may enjoy taking a favorite toy or blanket to surgery with them. Ideally, they should be allowed to keep this with them until they are under an anesthetic. Parents should be allowed to accompany children to the operating suite. Some parents can accompany a child into an anesthesiologist's induction room; for others, this is inappropriate or too anxiety-producing. A nurse whom the child knows should accompany the child to the operating room and remain there until the child is under the anesthetic, if possible. Even if a child has been well prepared for the surgical experience and the change in personnel on arrival to the surgical suite, saying goodbye to parents at the door of the surgical suite and the actual sight of strange personnel can lead to high levels of anxiety and fear.

Although it may not be cost-effective to have a staff nurse wait with a child until the child is under an anesthetic, the nurse's wait will probably not be long if the child has been called for surgery when the surgical suite is almost ready. The psychological benefit of a familiar nurse's comforting presence can make the difference between a positive and negative hospital experience (Box 35.7).

✔ Checkpoint Question 35.3

You want to use a board game to teach Barry more about his hypercholesterolemia. At what age are children first ready for competition and so enjoy board games?

a. 3 years.
b. 6 years.
c. 10 years.
d. 14 years.

BOX 35.7 ❊ Focus on Evidence-Based Practice

What type of information do the parents of children with head injuries want from health care providers?

To answer this question, nurse researchers mailed a questionnaire asking, "What questions did you have when your child injured his/her head?" to parents of children who were seen in a hospital emergency department for head injury. The mean age of the 24 girls and 33 boys was 5.2 years (with a range from 1 month to 15 years), with 36 (63%) of the children having been less than 5 years old at the time of their injury. The head injuries were caused by falls (76%), bicycle accidents (8%), trauma to the head (8%), or sporting accidents (8%). Despite differences in the severity of the child's head injury and requirement for hospitalization, all the families expressed the same informational needs and the need for emotional support. The concerns that parents voiced were categorized into four divisions: (1) Information about the head injury by responses such as, "Is there a brain injury?" "Is there bleeding into the brain?" (2) Need for information on everyday living by such responses as, "Are there any restrictions?" "What should we be aware of?" (3) Need for reassurance by responses such as, "Is there any risk for delayed development?" or "Will she/he recover?" and (4) Need to share the emotional burden by responses such as, "Should we have come to the hospital by ambulance?" or "Should we have come to the hospital sooner?"

Based on this study, would it be important to include emotional support for children as a part of information they need following an injury?

Source: Falk, A. C., von Wendt, L., & Klang, B. (2008). Informational needs in families after their child's mild head injury. *Patient Education and Counseling, 70*(2), 251–255.

Key Points for Review

- Communication is the exchange of ideas between two or more persons. It can be verbal or nonverbal.
- Therapeutic communication is a planned interaction, has structure, and is constructive. Nontherapeutic communication lacks deliberate purpose other than socializing.
- Successful communication requires an encoder, a code, a decoder, and feedback or response.
- Levels of communication are (a) cliché, (b) fact reporting, (c) shared ideas, (d) shared feelings, and (e) a sense of knowing what another wants without it needing to be voiced.
- Typical methods of nonverbal communication are using distance, gestures, body posture and gait, touch, use of drawings, and empathy.
- Techniques that encourage therapeutic communication are attentive listening, open-ended questions, reflecting, clarifying, paraphrasing, perception checking, focusing, supportive statements, and silence.

- Some situations require special communication techniques such as interacting with demanding or shy children, children who are visually or hearing challenged, or children who are not proficient in English.
- Establishing a teacher–learner relationship based on mutual input and setting expected outcomes are effective ways to meet the unique needs and goals of a child and family.
- There are three types of learning: cognitive, psychomotor, and affective. For something to be learned well, all of these areas may need to be involved.
- To individualize a teaching program for a child, assess the child's attention span, cognitive or intellectual capability, lifestyle, and learning style and your own teaching strengths and limitations.
- In many instances, there is a great deal of material a child must learn about an illness. If possible, divide material into lessons that must be taught immediately and lessons that can be taught at spaced return health visits.
- The format and strategies of teaching used with children vary depending on a child's age and developmental level. Various types to consider are formal versus informal, single or group teaching, lecture, discussion, and role playing.
- Behavior modification is a special technique aimed at erasing some form of behavior that interferes with good health.
- Children are learning many other things besides health information every day. This may make the retention of information not as great as you would like. You may need to schedule frequent reviews and updates to keep information current.

CRITICAL THINKING EXERCISES

1. Wolf Whitefeather is the preschooler you met at the beginning of the chapter. He will be having surgery in a week for bilateral syndactyly (webbed fingers). His mother asks you how to prepare him for this. What suggestions would you make? The child will be left with a noticeable scar and some lack of function after surgery, so he cannot be reassured that everything will be all right. How will this affect your teaching?
2. Barry Sandoz's family has hypercholesterolemia. It is recommended that Barry begin a low-cholesterol diet. He says, "Don't tell me anything about foods I can't eat. I've heard it all." You say, "Heard it all?" He says, "Don't repeat what I said. That really bugs me." You know he needs to learn more about foods to eat so he can eat safely in the school cafeteria. What would you do?
3. Wolf has to learn how to use a peak flowmeter at least once daily to monitor asthma symptoms. How would you teach this skill to so young a child? Suppose his mother says there is no reason to teach him how to read the meter because she will do it for him. Would your teaching plan be different?
4. Examine the National Health Goals related to communication and teaching with children. Most government-sponsored funds for nursing research are allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to the Whitefeather family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to communication and children. Confirm your answers by reading the rationales.

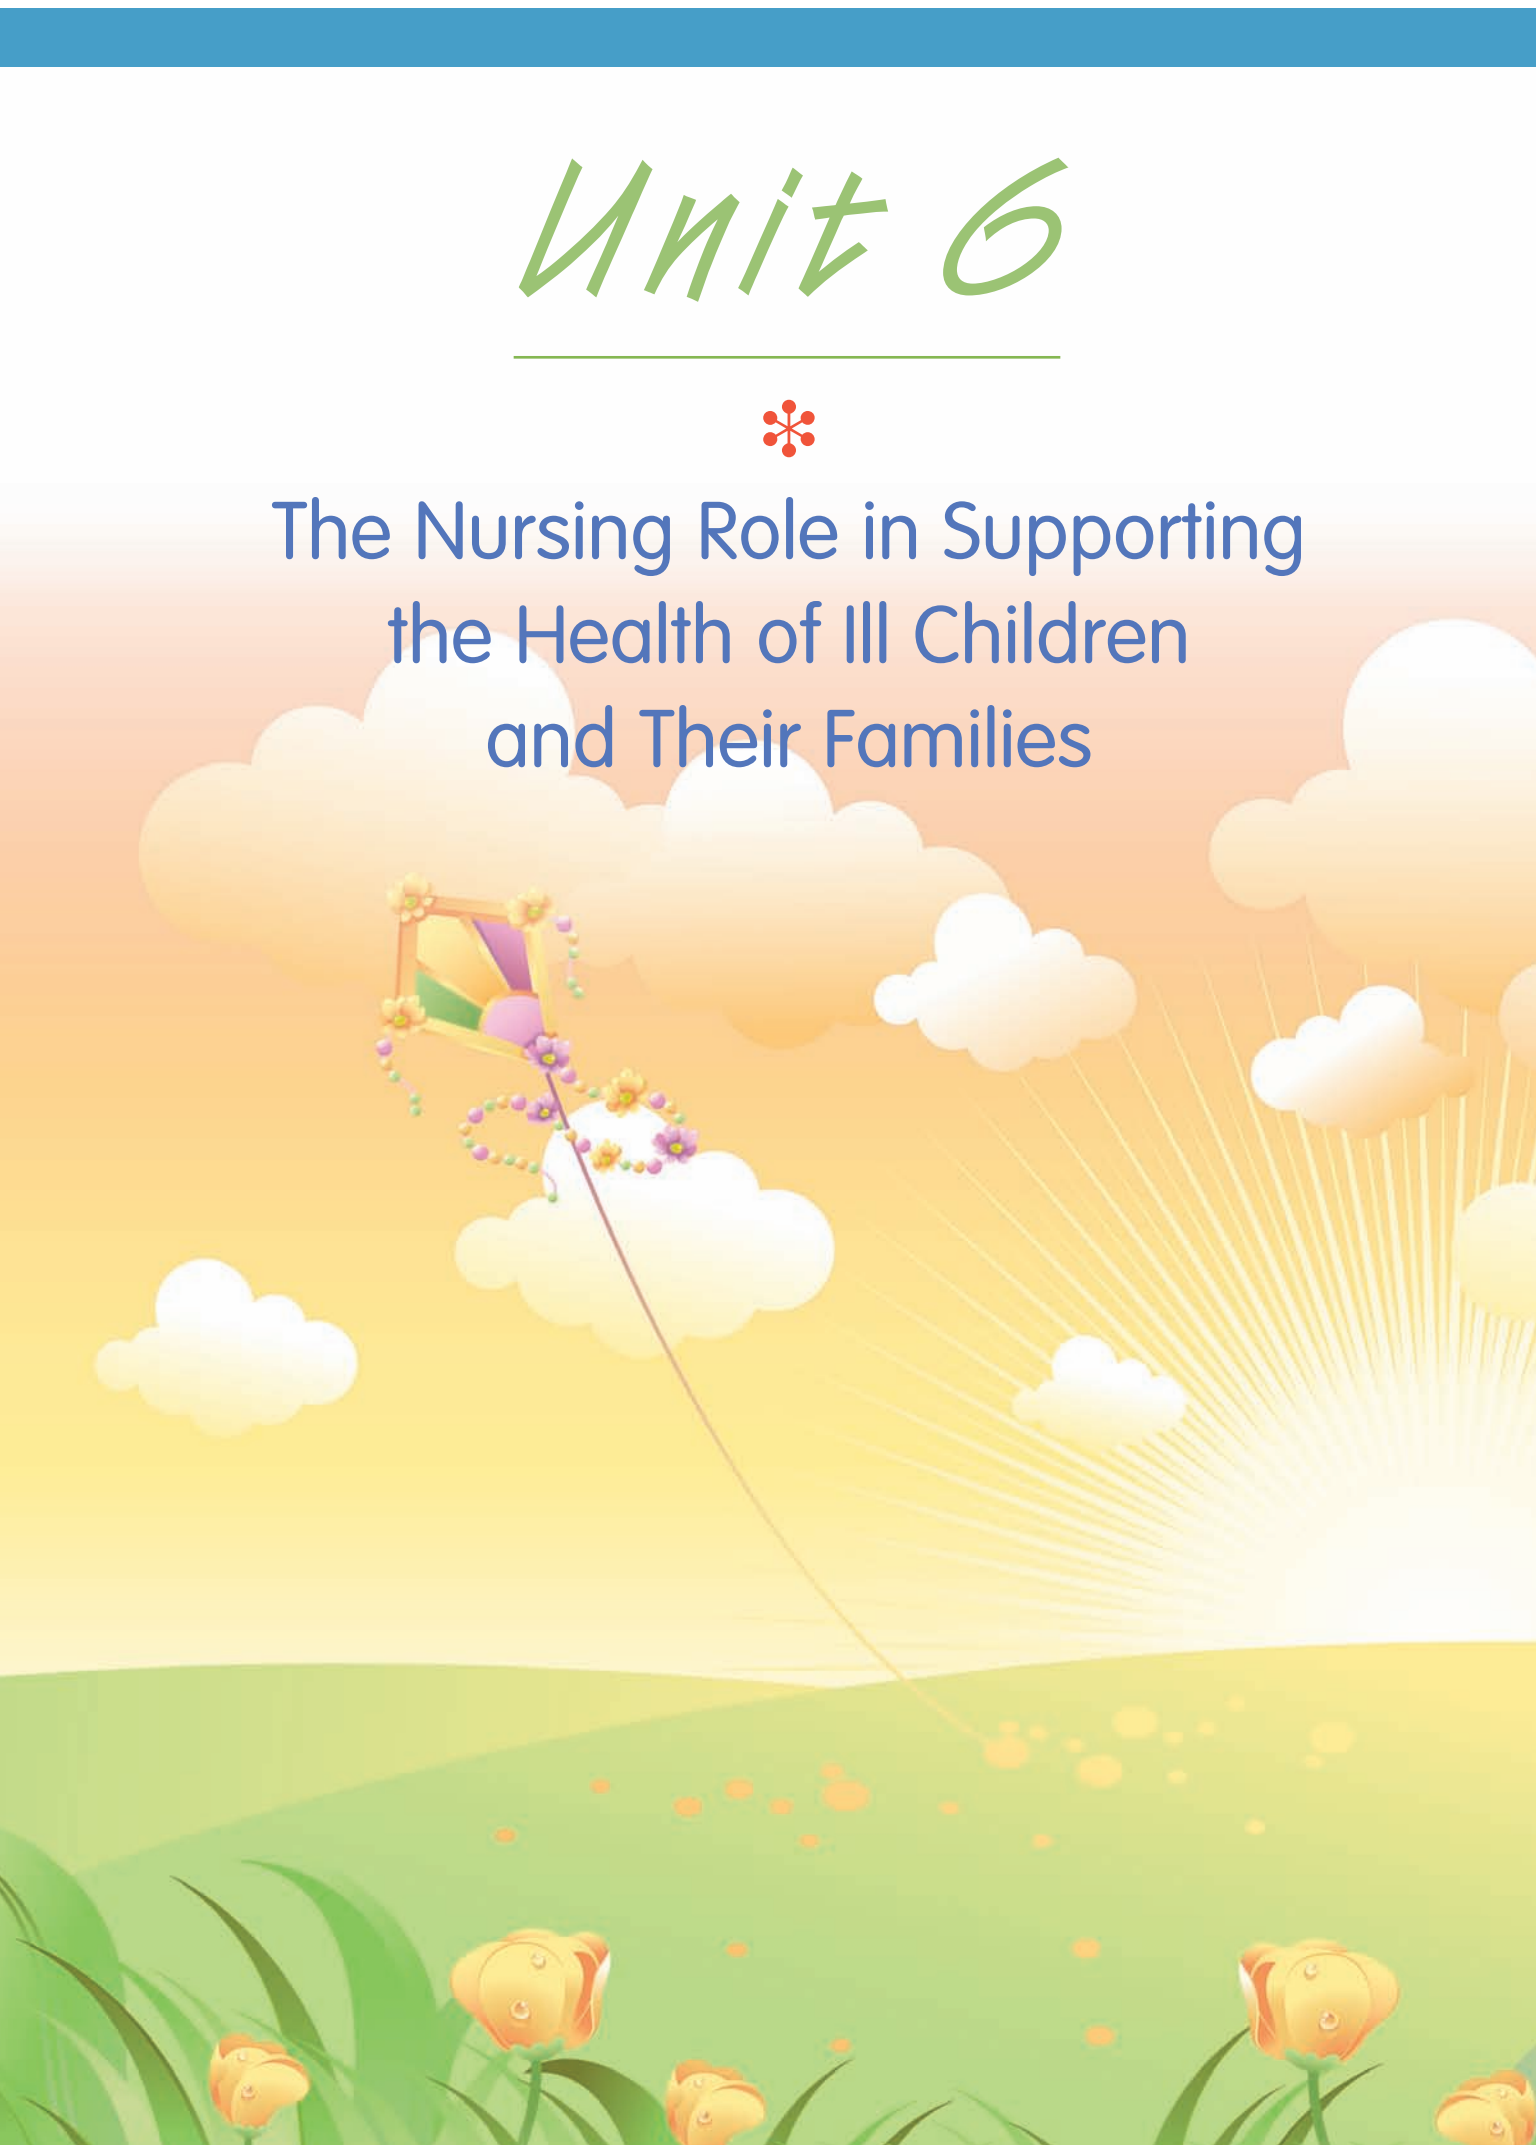
Unit 6

The Nursing Role in Supporting the Health of Ill Children and Their Families



This page intentionally left blank.

Chapter

36 Nursing Care of a Family With an Ill Child

KEY TERMS

- calorie counting
- case management nursing
- non–rapid eye movement (NREM) sleep
- play therapy
- primary nursing
- rapid eye movement (REM) sleep
- sensory deprivation
- sensory overload
- sleep deprivation
- therapeutic play

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe illness and illness experiences as they must appear to children.
2. Identify National Health Goals related to care of ill children nurses can help the nation achieve.
3. Use critical thinking to analyze ways in which illness care can be made more family centered and less traumatic for children.
4. Assess the impact of an illness, especially one requiring a hospital stay, on a child.
5. Formulate nursing diagnoses related to the stress of illness in children.
6. Establish expected outcomes for an ill child.
7. Plan nursing care to reduce the stress of illness, such as helping parents plan for ambulatory care or hospitalization.
8. Implement measures such as orientation, education, and therapeutic play to reduce the stress of illness.
9. Evaluate expected outcomes for achievement and effectiveness of care.
10. Identify areas related to illness in children that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge about a child's response to illness with the nursing process to achieve quality maternal and child health nursing care.

Becky is a 7-year-old who burned her foot in a campfire accident. She is going to be admitted to the hospital for 1-day surgery to have the wound debrided. Becky's parents tell you that Becky "hasn't been herself" since the injury. She has reverted to temper tantrums and sulking, more like a 3-year-old than one of early school age. Even though she has been told eating meat is important because it provides protein for healing, she refuses to eat anything but Jell-O or soup. In the admission suite of the hospital, she picked up a doll and twisted its leg off. "How can we get our old daughter back again?" her mother asks you.

Previous chapters described the normal growth and development of children and their special needs at each stage of development. This chapter adds information about the additional needs of children when they become ill. Such information builds a base for nursing care and health teaching.

Becky is obviously showing some effects of her accident. What type of additional explanation might be helpful to her? What advice would you give her mother to help her better prepare Becky for the upcoming debridement procedure?

Illnesses that require the attention of health care professionals are outside the usual occurrences of childhood, so most children typically have little knowledge about them. Helping a child and family prepare for or adjust to such an experience is a fundamental nursing role. This role goes well beyond just providing information on what to expect throughout an illness. It involves providing emotional support as well.

Nurses need to provide orientation programs before hospital admissions and advocate for more open parental visiting and overnight stay policies even in intensive care areas if these are not already in effect (Zelkowitz, 2009). In addition, nurses can help families establish a therapeutic environment for the care of an ill child in the home. For individual families, nurses can perform several interventions that promote comfort, safety, security, and continued growth and development. Therapeutic play is one of the more powerful tools available to a nurse working toward this objective. National Health Goals related to children and illness are shown in Box 36.1.

Nursing Process Overview

For an Ill Child

Assessment

Assessment for an ill child begins with an interview of the child and parents to identify ways they think the illness will change their lives. This could include a wide range of situations such as increased expenses, changes in schedules to visit or stay with a hospitalized child, the need for one parent to take a leave from work to care for an ill child at home, the need to schedule frequent ambulatory visits, consultation to handle body image changes, and the need to arrange for child care for other children. Because these needs change as the course of an illness changes, assessment must be ongoing.

Nursing Diagnosis

Nursing diagnoses vary greatly depending on the extent of a child's illness, the care needed, and the age of a child. Those often used with families of children seen in ambulatory and in-hospital settings include:

- Health-seeking behaviors related to lack of knowledge regarding illness
- Anxiety related to pending hospital admission
- Risk for social isolation related to hospitalization
- Fear related to being away from home for first time
- Activity intolerance realted to fatigue from illness
- Potential for injury related to high-tech therapy equipment

Outcome Identification and Planning

Planning for the care of an ill child requires consideration of all aspects of the child's and family's life: financial, social, and personal. When children become ill, many of their needs, such as those for nutrition, play, and family support, change. If a child will need long-term care or hospitalization, the entire family may find their priorities changing. Unless these changing needs are examined, recognized, and met, a child may achieve physical wellness again but not mental or emotional health. A family may be left severely disadvantaged. Identifying additional needs in this way and putting in place necessary services or interventions is an important nursing role. An organization that offers helpful information on hospitalization of children is the National Association of Child Care Professionals (http://www.naccp.org).

Implementation

Five hazards that may occur with children with all illnesses are (a) experiencing harm or injury, such as physical discomfort, pain, mutilation, and death; (b) being separated from routines, parents, peers, and respected adults; (c) facing the unknown (new and strange sights and sounds and happenings); (d) facing uncertain limits (unclear definition of acceptable and expected behavior); and (e) experiencing a loss of control (loss of competence or loss of the ability to make decisions).

Being aware of these potential problems is important to guard against those that are preventable and to reduce a child's anxiety associated with those that cannot be prevented (such as facing new sights and sounds). Discussing these hazards with older children is important so that implementations to reduce their impact can be tailored to each child. Reading to a child, role playing, and puppetry are all useful techniques for reducing the number of new experiences and easing the impact on the child. Be certain that the techniques you use are appropriate not only for a child's age but also for the child's individual learning style and level of illness. Be certain that children participate in making any decision that is age appropriate for them.

BOX 36.1 ✻ Focus on National Health Goals

Illness and hospitalization can be major stressors for children. Two National Health Goals speak directly to this:

- Increase the number of states and the District of Columbia that have implemented statewide pediatric protocols for online medical direction.
- Increase the number of states and the District of Columbia that have implemented guidelines for prehospital and hospital pediatric care (http://www.nih.gov).

Helping with assessment of children's stress level and reducing the stress of hospitalization or health care are ways that nurses can help the nation achieve these goals. Areas where additional nursing research or evidence-based practice could aid understanding are: What measures do parents need to make them feel most comfortable in a hospital setting? What are the deterrents to therapeutic play on hospital units, and how could these be removed? And are there additional contributions nurses could make to shorten hospital stays for children?

Outcome Evaluation

Evaluation of expected outcomes for ill children should include specific measures such as whether discomfort was kept to a minimum during the experience. Indicators to evaluate outcomes that are long term should include whether children were able to return to usual behaviors after the experience. The following are examples that suggest achievement of outcomes regarding a hospital experience:

- Parents state their level of anxiety regarding hospitalization of their infant is now at a tolerable level.
- Parents have effectively changed work schedules to be able to stay with their child in the hospital.
- Social isolation of toddler is minimized through case manager nursing assignment.

THE MEANING OF ILLNESS TO CHILDREN

The response of children to illness depends on their cognitive ability, past experiences, and level of knowledge. From early school age, children generally know quite a bit about the workings of their major body parts. As general guidelines, early grade-school children are usually able to name the function of the heart, lungs, and stomach. They may not be able to do that for the bowel, kidneys, or bladder; this reflects the difficulty some parents have in discussing these body parts with their children.

Younger children may think the cause of illness is magical (no one knows where it comes from) or that it occurs as a consequence of breaking a rule such as walking in the rain or eating candy after school. With this perspective, they may also think that getting well again is possible only if they follow another set of rules, such as staying in bed and taking medicine. By fourth grade, children are generally aware of the role that germs play in illness but may be fooled by thinking that all illness is caused by germs. Because of this, they may see a passive role for themselves in getting well, because illness comes from outside influences. At about eighth grade, children are able to voice an understanding that illness can occur from several causes, such as being susceptible to chickenpox because they did not get the vaccine or they carelessly caused an accident. Once they understand this, they can take an active role in getting better. These concepts parallel cognitive development (see Chapter 28).

Knowing how children of each age view illness affects the planning of nursing care, influencing how explanations should be worded. For example, saying that you are going to "stick" a child for blood work could be interpreted by young children as meaning you are actually going to put a stick in their arm. Saying a child will receive a dye for a test could be interpreted as meaning the child will "die" during the procedure. Children who think illness comes as punishment for breaking rules can interpret nursing procedures such as giving an injection as punishment. They can be confused about explanations of procedures because some words sound alike or have double meanings ("drawing" as in making a picture versus drawing blood). Because of these distorted perceptions, explanations of procedures do not always relieve children's stress.

Differences in Responses of Children and Adults to Illness

Keeping in mind that children are not just small adults is important when evaluating how children react to illness, perceive an illness, or react to health care (Fig. 36.1). Their body images, as evidenced in their drawings, are different from those of adults. They can have difficulty telling which body parts are indispensable and which are not (this is why it is wise to talk to preschool and early school-age children about "fixing" body parts, such as tonsils, rather than "taking them out").

Inability to Communicate

Very young children do not have the vocabulary to describe symptoms. Headache is an example of a symptom that children younger than 5 years have a great deal of difficulty describing. Dizziness and nausea can be equally bewildering because children this age do not know the words to express these phenomena.

By the time they reach school age, most children can describe symptoms with accuracy. They may intensify their concerns, however, if they believe someone expects symptoms to be more serious. They may minimize symptoms if they are afraid illness will interfere with an activity.

Because of this, evaluate a child's symptoms as much by observation as by a child's report. A crying, whining preschooler who is "just not herself" probably has a symptom she cannot describe. A school-age child who guards her abdomen (keeps abdominal muscles rigid) is in pain just as clearly as a child who verbalizes a source of discomfort. This makes keen, astute observations necessary to ascertain the extent of a child's illness at any given time.

Inability to Monitor Own Care and Manage Fear

Adults who are ill often ask about medications prescribed for them or procedures they are scheduled to undergo. For example, if a hospitalized man knows he is to receive a diuretic three times a day and by 10 AM has not been given it, he usually reminds someone of the oversight. School-age and younger children cannot monitor their own care this way because they may not know which medicine or procedures they

FIGURE 36.1 Illness is potentially traumatic because of the unknown and pain and discomfort that may be involved. Children need extra attention and reassurance to calm their fears.

are to receive. If they do know, they may be confused about time. In addition, children have fears that adults do not experience. The infant, for example, fears separation above all else; the toddler and preschooler fear such things as separation, the dark, the unknown, intrusive procedures, and mutilation of body parts. The school-age child and adolescent are concerned about the loss of body parts, loss of life, and loss of friends. Adults have fears also, but most have learned to cope with them. Children in a strange environment (such as a hospital) require proportionally more support and active intervention to cope with their stress and fears or hospitalization can result in a posttraumatic stress disorder (PTSD) (Pao, Ballard, & Rosenstein, 2007).

Nutritional Needs

In addition to psychological differences, there are major physiologic differences in the way illness affects children compared with adults. This is because children have different physiologic needs and respond to imbalances in different ways.

Children need more nutrients (calories, protein, minerals, and vitamins) per pound of body weight than adults, for example, because their basic metabolic rate is faster, and they must take in not only enough to maintain body tissues but also enough to allow for growth. The infant requires 120 kcal per kilogram of body weight per day; the adult requires only 30 to 35. An ill child who must limit food intake because of nausea or vomiting, therefore, may require hospitalization, even though this might be unnecessary for an adult under the same circumstances.

Fluid and Electrolyte Balance

In the adult, extracellular water (that in plasma and outside body cells) represents approximately 23% of total body water; in a newborn, extracellular water is closer to 40%. This means that an infant does not have as much water stored in the cells as an adult does and so is more likely to lose a devastating amount of body water with diarrhea or vomiting. Because of this, there is no such thing as "only diarrhea" or "simple diarrhea" in a child younger than 1 year. The full implications of both vomiting and diarrhea are discussed in Chapter 45.

Systemic Response to Illness

Because their bodies are immature, young children tend to respond to disease systemically rather than locally. The child with pneumonia, for example, may be brought to an emergency department not because of a cough (although the child has one) but because of accompanying systemic symptoms such as fever, vomiting, and diarrhea. Nausea and vomiting, in fact, occur so frequently in children with any type of illness these symptoms do not have the diagnostic value they have in adults. Systemic reactions of these kinds can delay diagnosis and therapy and cause increased fluid and nutrient loss, circumstances that compound an initial illness and can result in hospitalization.

Age-Specific Diseases

Because of their growth requirement and their immaturity, children are susceptible to some diseases that do not affect adults. For example, because infants are growing, a lack of vitamin D will cause rickets or abnormal bone growth, but this same lack does not cause these condition in adults. Most adults have achieved immunity to common infectious diseases; children, however, are susceptible to childhood diseases such as measles, mumps, and chickenpox. Children younger than 5 years who have a high temperature may respond with generalized seizures (febrile seizures), a phenomenon that rarely occurs after this age (Pavlidou, 2008). When children do not receive adequate iron, those younger than 1 year of age are subject to iron-deficiency anemia because fetal red blood cells are destroyed after birth and are replaced by mature red blood cells only very slowly.

✔ Checkpoint Question 36.1

Young children are more at risk for dehydration with vomiting than are adults. This is because:

a. They have a smaller stomach and intestines than do adults.
b. They have proportionally more extracellular water than do adults.
c. Children metabolize fluid more slowly than do most adults.
d. They maintain more fluid inside body cells than do adults.

CARE OF THE ILL CHILD AND FAMILY IN THE HOSPITAL

The parents of children admitted to intensive care or neonatal intensive care units (ICUs and NICUs) can be predicted to experience a high degree of stress during their child's hospitalization both because of the severity of their child's illness and the high-tech pediatric ICU or NICU setting (Koh et al., 2007). They can experience a second round of stress when their child is transferred from an NICU or pediatric ICU (PICU) to a regular hospital unit (Rowe & Jones, 2008). Based on this theory that hospitalization creates a high degree of stress for children, only those children who cannot be managed successfully on an ambulatory basis are now admitted to the hospital. This was not always true. For example, in the past, most children with head injuries automatically stayed overnight for observation. Currently, unless a child is unconscious or shows other signs of neurologic injury, the child is sent home to be observed by parents for signs of increased intracranial pressure. This policy requires that time be spent to teach parents skills such as how to take a pulse or evaluate consciousness. Teaching them requires patience because parents under stress can have difficulty comprehending instructions. However, because psychological trauma and excessive health care costs are prevented by allowing a child to return home, it is important teaching. Children who are seen in the emergency departments for acute gastritis and vomiting were also once automatically admitted to the hospital so they could receive intravenous fluid. Today, they are given an oral hydrating solution or probiotics so they no longer need to be admitted (Marcos & DuPont, 2007).

As yet another example, many pediatric surgery procedures such as tonsillectomy or herniorrhaphy can be done on an ambulatory or outpatient basis. This prevents the major problem of separation anxiety, but it does not necessarily reduce parents' or children's anxiety about the procedure. Some parents actually feel less confident and more anxious with ambulatory procedures than they did with in-hospital admissions because they sense their responsibility for prepa-

ration and follow-up care will be significantly greater (Heard, 2008). They often comment that modern care is not as good as when children were admitted, and that this change is a result of cost containment by insurance companies. Although it is true that short hospital stays reduce cost, it is helpful to inform parents that ambulatory or outpatient procedures are as safe as those performed with hospital admissions, and that ambulatory procedures can be helpful in preventing the detrimental effects of separation.

The Effect of Hospital Separation and Children

Decreasing Separation Anxiety

It is difficult to explain the meaning that a primary caregiver has for a child, but the intensity of the relationship can be demonstrated. As early as 4 months of age, the infant registers disapproval if a primary caregiver walks away. As early as 5 months of age, an infant registers anxiety when strangers are present or when a person other than the usual caregiver gives care. Infants fix their eyes on the stranger, become restless, perhaps thrash arms or legs, and begin to cry. This activity peaks at approximately 8 months of age, so it is commonly called "8-month anxiety." It is a developmental milestone that shows an infant is able to distinguish a primary caregiver from other persons. It also means the child has reached a vulnerable stage in emotional development and will react poorly to separation or to the threat of it (Smith, Hefley, & Anand, 2007).

Toddlers and preschoolers can be as affected by separation as infants. In many instances, they express their feelings better, louder, and longer than infants. Although many toddlers and preschoolers attend day care and have had prior experiences with separation, others may have had only limited experiences. Being hospitalized may be the first time they are away from parents in a strange setting or away from home overnight. If this is so, many preschoolers may wonder whether they will ever live with their parents again. Problems of separation are especially intense in younger children because they do not understand time. Statements such as, "Mom will visit again tomorrow" or "Dad will be here by 6 o'clock" are meaningless to children younger than 5 years because they do not know what either "tomorrow" or "6 o'clock" means.

School-age children and adolescents react better than younger children to the separation imposed by hospitalization because they have experiences they can use for comparison. They have been to school for whole days; perhaps they have stayed with a grandparent or a friend overnight; they may have been to camp. This can make hospitalization a time for developing self-esteem and confidence in their ability to be independent. Even in light of this, ill school-age children and adolescents may still feel anxious about being separated from their parents. They appreciate their parents' presence and need reassurance that their parents support and love them.

Remember that parents may have an equally difficult time being separated from children. You may need to spend time with them assuring them that their child will receive good care at all times, even if they are absent.

To appreciate why preventing separation is so important, it is helpful to review the research that provided the foundation for this method of care. Spitz (1945) was one of the first researchers who documented the effects of separation on children. He observed children in a penal nursery and in a foundling home who were separated from their mothers for both short and long periods. From this observation, he was able to document how poorly children responded to separation from their parents. Bowlby conducted additional studies after World War II (Bowlby, 1966). Building on Spitz's and Bowlby's work, Robertson (1958) studied the effect of hospitalization on children and supplied labels for separation effects (Table 36.1). Although defined over 50 years ago, these findings are still applicable to children today.

Effects of hospitalization can be so severe that they can be compared to posttraumatic stress disorder, the development of characteristic symptoms following exposure to an extremely traumatic situation (Mulvihill, 2007). Children who develop this condition demonstrate persistent symptoms of anxiety such as difficulty falling asleep, irritability, outbursts of anger, difficulty concentrating or completing tasks, or stomachaches and headaches. They re-experience the traumatic event through dreams or flashbacks.

Reducing the ill effects of separation and hospitalization to the extent possible should be a high priority for health care providers. Nurses play a major role in this on both direct care and management levels. Unfortunately, despite the best preparation by parents or nurses, not all of these effects of hospitalization can be prevented.

✔ Checkpoint Question 36.2

Suppose Becky shows signs of separation anxiety. The first stage of separation anxiety is marked by:

a. Loud, demanding crying.
b. Silent, sullen protest.
c. Quiet introspective thought.
d. Inability to respond verbally.

TABLE 36.1 ✻ Stages of Separation Anxiety

Stage	Manifestations
Protest	The child cries loudly and demandingly; rejects any attempts to be comforted by nurse or substitute primary caregivers.
Despair	The child becomes less active and cries monotonously or wails in a state of mourning; may turn away from parent's approach; often lies on abdomen, facial expression flat; may lose weight and develop insomnia; loses developmental skills; prone to minor ailments such as upper respiratory infections; IQ will measure lower than previous measurement.
Denial	The child is silent, face expressionless; represses feelings for absent caregiver to protect self; deterioration in developmental milestones is apparent; may respond quickly but superficially to all caregivers; may have difficulty forming close relationships later in life.

Preparing the Ill Child and Family for Hospitalization

Many childhood illnesses such as febrile seizures, appendicitis, poisonings, and asthma attacks strike suddenly, making advance preparation for hospital admission impossible. However, when hospitalization such as orthopedic or second-stage surgeries is scheduled, preparation is possible. As a rule, parents eagerly seek guidance from nurses on what and how much to tell their children about an anticipated admission. The preparation parents make for a child obviously varies according to the child's age and individual experience. No matter what the child's age, parents do best when they convey a positive attitude toward the hospitalization or surgery. Statements such as, "They'll make you behave in the hospital" or "Wait until you have to stay in bed all day" should be avoided.

Children can worry unnecessarily if they are told about their approaching hospitalization too far in advance. Conversely, few things are more frightening for children than to hear conversation halt as they enter a room or to hear adults spelling out unknown words. As a rule, therefore, children between 2 and 7 years of age should be told about a scheduled ambulatory or inpatient hospitalization as many days before the procedure as the child's age in years. For example, a 2-year-old should be informed 2 days before hospitalization; a 4-year-old, 4 days before; and so forth. Children older than 7 years should be told as soon as the parents are aware of it.

On the day of hospital admission, it is important for you to discuss the preparation the child has received to ensure that the child and family accurately understand the child's condition and upcoming procedures. Based on that, you can provide further health teaching and clear up any misunderstandings (Box 36.2).

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Deficient knowledge related to preparation for hospitalization

Outcome Evaluation: Parents and child both state they feel prepared for hospitalization; child has brought some personal items important to self. Child describes with accuracy and detail appropriate to age the reason for hospital stay; asks questions and expresses feelings appropriate to age about hospitalization.

Preparing Family Caregivers. Planning for hospitalization should begin as soon as parents know that hospitalization will be necessary. Some parents, however, may be so concerned about the reason for hospitalization that they cannot begin to prepare their child until they are better prepared themselves. Easing parental anxiety regarding illness and hospitalization this way is particularly important because infants and children can keenly sense a parent's stress. No amount or type of preparation for children will be effective if they react to their parents' unspoken tension. Even though parents may say, "Don't worry, everything will be all right," a child can sense if parents really do not believe that everything will be all right, a situation that can hamper recovery.

As part of preparation, urge parents to ask questions about the hospitalization so they are as familiar as possible with what will happen. If they are well informed in this way, they will (at least theoretically) have as low an anxiety level as possible.

Advise parents to ask about things such as what diagnostic procedures will be necessary, how long the hospital stay will be, and what kind of dressings or other equipment will be used. If you are practicing in a doctor's office or clinic where surgery or a hospital admission is first proposed, become familiar with these facts to serve as the parents' backup informant. Many parents ask a nurse for their main information or ask to have the physician's explanation clarified to be certain they have understood it correctly. If they arrive at a hospital unit with questions unanswered, fill in gaps immediately.

BOX 36.2 ✻ Focus on Communication

Becky is a 7-year-old you are going to admit to your hospital unit for burn debridement. Becky and her mother arrive together on the unit.

Less Effective Communication

Nurse: Hello, Becky. How are you?
Becky: Good.
Nurse: Do you know why you're coming into the hospital?
Mrs. Miller: We've talked about surgery. She knows that's why she's here.
Nurse: Did you bring a favorite toy, Becky?
Becky: I brought a book to color.
Nurse: You sound ready. Let's get you admitted.

More Effective Communication

Nurse: Hello, Becky. How are you?
Becky: Good.
Nurse: Do you know why you're coming into the hospital?
Mrs. Miller: We've talked about surgery. She knows that's why she's here.
Nurse: Tell me why you're here, Becky.
Becky: To read a book. I brought a book.
Nurse: Let's talk about everything you told her, Mrs. Miller, about surgery.
Mrs. Miller: Well, I didn't want to introduce anything scary.
Nurse: Let's take some time and talk about the whole procedure.

The above poor communication example happened because the nurse assumed that when the parent said she had prepared her daughter, she had prepared her in the same way the nurse would have prepared her. The communication improved when the nurse stopped assuming about the level of preparation and asked direct questions of the mother and child about what they knew.

Preparing an Infant. Because an infant cannot understand explanations of surgery or treatments, preparation is minimal. Special items such as a favorite toy, blanket, or pacifier should be packed. These objects provide a special kind of security for which there is no substitute.

A primary caregiver should plan to spend a great deal of time in the hospital with an infant. For rooming-in, a parent needs to make plans for older children or a spouse ahead of time. If a parent cannot arrange to room-in, make plans to have a consistent nurse assigned to the infant. This can both help decrease parental anxiety and minimize separation anxiety in the infant (Jolley, 2007).

Preparing a Toddler or Preschooler. Three chief fears of toddlers or preschoolers are fear of the unknown, fear of abandonment or separation, and fear of mutilation. Preparation for children of this age, therefore, should clearly aim at alleviating these fears. Bringing a favorite toy or personal item such as a blanket can help. Referred to as "transitional objects," these items are symbols of the longed-for return home. Some parents buy a new toy to replace a child's favorite one because they are ashamed of a teddy bear with one ear or one eye missing. A new bear may mean nothing to the child, however, and clinging to it may not offer comfort.

When making hospital beds or changing paper on examining tables, watch for ragged blankets and threadbare stuffed animals; these can cling to sheets and can be easily discarded. Throw nothing away without first asking a child or parent if it is important. What looks like a useless alphabet block to you may mean security and home to a child.

When children are admitted to a hospital in an emergency, parents rarely have time to bring toys. In these instances, suggest a parent give a child a familiar object, such as the parent's wallet (money and papers removed) or a sweater. The child will hold these in the same way as a favorite toy. The child's outside shoes can serve this same purpose as the child interprets their presence as meaning because shoes walk home, so will the child.

Several helpful books about hospitalization are available for parents to read with children and also learn more about children's health care. These can be obtained from local bookstores, libraries, or Internet book sites, or by writing directly to the publishers (Box 36.3). For preschool preparation, parents could read one of these books to a child, adapting the story to include information specific to their child. Some books fail to orient children well to hospitalization because they are too sweet (as if the child were going to a picnic rather than a hospital). Others may omit pertinent facts, such as surgery will involve some pain (stress the child will be given medicine so the pain will go away) or that when bedrest is required, the child will have to use a bedpan. Using a bedpan is difficult for toddlers and preschoolers to accept because they have just been toilet trained and have been told repeatedly they must use the bathroom.

Rogers, F. (1997). *Going to the hospital.* New York: PaperStar Publishers. (Grades K–3)

Because the imagination of preschoolers is at a peak, role playing is an effective means of preparing a child of this age for a new experience. To do this, a parent could encourage a child to act out a hospitalization experience with puppets or dolls. Or the child could change into pajamas and get into bed. The parent could then act out a physical examination, a meal in bed, a bedpan (a round cake pan simulates this), or anesthesia administration (a strainer can be used for an induction mask). At the end of the session, the parent should stress that when the child's tummy or throat is better, the child will be able to change back to street clothes and come home. Remind parents it is always better to use the word "fix" rather than "cut" when talking about surgery with young children, because "cut" automatically suggests pain and mutilation.

Preparing a School-Age Child or Adolescent. School-age children enjoy reading, so books about surgery and hospitalization can be helpful. Be sure both school-age children and adolescents receive factual explanations of what will happen during such an experience. This should include also what will not happen: for example, surgery will require a small abdominal incision, but it will not create a scar that will show when wearing a bathing suit.

Be certain that parents have the necessary factual information themselves so that they can provide accurate and appropriate explanations to school-age children. If they do not know the answer to a question, caution them that the best response is simply, "I don't know" rather than a guess. This prevents a child from feeling betrayed when the real answer is different.

Many community hospitals sponsor hospital orientation programs for children's groups or school groups during which hospitalization is discussed. These programs are beneficial because they lay a foundation for all children about what to expect in a hospitalization; then, if they must be admitted on an emergency basis, they may not be so frightened. Programs are offered by nurses at the hospital or on visits to children's groups or schools (Fig. 36.2). Box 36.4 provides guidelines for setting up hospital tours or discussions for early school-age children.

At approximately 9 years of age, when children first begin to understand the full meaning of death, parents need to be especially careful to explain that an anesthetic causes a "special sleep," not that a child is "put to sleep." Animals that are "put to sleep" are not seen again. Talking to another child who has undergone the same experience and come through it intact is yet another helpful way to introduce children and adolescents to hospitalization. Although parents cannot usually supply such a person in advance, on admission to the hospital, a visit to a recovering patient is often possible and is a constructive way to give reassurance.

If hospitalization is to be more than 1 week long, a parent must think about the means to continue the child's schooling. Advise parents to ask their physician at what point their child will be able to do homework. Many school systems provide tutors; children's hospitals often have their own teachers from the local school system to carry out this service.

What if... Becky's mother brought pots and pans to the hospital as Becky's favorite play items? Would you suggest she bring an actual toy?

FIGURE 36.2 Children learn what to expect from hospitalization during a prehospital program.

Box 36.4 ✻ Guidelines for Conducting Hospital Tours With Early School-Age Children

1. Keep groups small (about 10 children per group) so individual reactions to the presentations can be assessed.
2. Allow or encourage parents to join the tour so their anxiety about the hospital can also be relieved.
3. Conduct the tour for only 20 to 30 minutes to meet the short attention span of children.
4. Use an indirect method to present various aspects of a hospital, such as puppets, films, or a slide show, to decrease anxiety.
5. Present the features of a hospital in a nonthreatening environment, such as the hospital playroom. Avoid the emergency department, ICUs, or operating rooms while touring, because these are anxiety-producing areas for children. Talk about these areas by using slides or photographs instead.
6. Present explanations about hospitalization in concrete terms and at the child's level of understanding. Include only what the child will see, hear, and feel.
7. Avoid dwelling on unpleasant and threatening events or intrusive procedures, such as blood drawing or anesthesia, that may create anxiety.
8. Allow children opportunities to ask questions.
9. Allow children opportunities to play with dolls and hospital equipment, to both decrease anxiety and satisfy curiosity.

Preparing a Child With a Different Cultural Background. Perhaps the most important aspect to consider when preparing a child from a different culture for hospitalization is to identify what traditions or practices will be in opposition to health care facility practices. Ask enough questions and practice good listening skills to gain information about the particular needs of a child and family. When cultural differences do exist, be prepared to act as a liaison between the family and the health care team. If a different language is interfering with communication, a translator may be necessary in this preparation phase. Provide the opportunity for parents to voice their fears and ask questions at the time of hospitalization or treatment. When families speak a different language or are unfamiliar with hospital routine, allow more time and more opportunities for discussion and communication so these are not slighted.

Preparing a Physically Challenged or Chronically Ill Child. Physically challenged or chronically ill children frequently come to ambulatory health care settings for care; they often are admitted to the hospital for care, possibly remaining in the hospital for an extended time with continuing care at home. Think through ways in

which a new hospitalization or visit will be like past ones and other ways in which it will be different to determine how best to prepare the child. Help children to maintain contact with their families and school friends during a long hospitalization by encouraging telephone calls, e-mails, text messaging, letters, and visits.

Admitting an Ill Child and Family

Whether an ambulatory or inpatient hospital unit admission, children and parents need to be admitted as a single entity to encourage parents to feel they are true partners in care. A child coming to a hospital for an elective admission generally arrives at a reception area, where significant facts are obtained, such as name, age, address, and hospital insurance coverage. The child and parents are then brought to the hospital unit. Remember that first impressions count. If parents are left standing at a counter while nurses chat, they can easily feel that no one appreciates their concern and that possibly their child will not receive optimal care. Some days are busier than others and it is true that at certain times on a children's unit all nurses are busy finishing treatments for other children before they can take the time to admit a new child (Box 36.5). Even so, one nurse should take the time to meet and greet the parents and child and find a comfortable place for the family to wait until someone is available. When introducing yourself to children, stoop down so that your face is level with the child's face (Fig. 36.3). Call the child by name or ask for a nickname. Calling all children "honey" or "pumpkin" can cause children to worry they have been confused with another child.

FIGURE 36.3 A child is admitted to a hospital unit. Notice how the nurse greets the child at the child's own level.

On admission to a health care facility, all children should have an armband attached giving their name and hospital chart number. Because their hands are not much larger than their wrists and their feet are not much larger than their ankles, neonates (infants younger than 1 month of age) often need two bands in place as an extra safeguard. If a band falls off, secure it back onto the child: never tape it to the crib or bedside stand, as this is not adequate protection: if an infant is placed in the wrong crib by mistake, the infant could be given a medicine that is lethal before the mistake is realized.

Assessment on Admission

Assess each child's level of preparation for a hospitalization on admission to the facility (Box 36.6). Be aware of not only what the child describes orally but also what facial expressions or nervous manifestations may be indicating.

Interview parents on hospital admission for a nursing history to obtain the information needed to plan nursing care (Chapter 34 describes a full child database interview history). Many hospitals have information checklists for parents to bring with them. Obtaining information in this way is highly efficient, but it may not be as satisfying to worried parents as hearing a nurse taking a few minutes to ask questions personally or specifically review the completed form. Typical information that is necessary to obtain about a child is shown in Table 36.2. This is then included in the child's plan of care as a vital step of assessment (see Focus on Nursing Care Planning Box 36.7).

Make a note of any medication or food allergy on the child's plan of care and, if pertinent, post this information by the child's bed because unlike an adult, a child cannot call these things to the attention of health care personnel when food or medication is offered.

Take and record the child's temperature, pulse, and respirations. Measure height and weight to determine overall

BOX 36.5 ✻ Focus on Evidence-Based Practice

Is the length of children's hospital stay influenced by how full or empty the hospital is on the day of admission?
If a hospital is crowded, it is assumed that children who are newly admitted may be discharged earlier than usual in order to reduce the hospital's patient census. To discover if this is true, researchers analyzed the length of hospital stays for children aged 1 to 17 years. Results of the study showed that for children who were admitted with nonrespiratory disease, patient census had no effect. For children admitted with respiratory diseases, when admission-day occupancy rate was 60% to 100% children had an increase in their average length of stay over children admitted when occupancy rate was below this. Also, increased admission-day occupancy was associated with longer lengths of stay for less complicated respiratory admissions but not for children who were admitted with the most serious conditions. The researchers concluded that medical professionals, during times of increased workload, first focus their attention on more acutely ill children with a complicated course and thus delay treatment of children who have less complicated courses. This extends those children's hospitalization.

Based on the above, for which child would it be more important to advocate for to be certain a hospital stay is not longer than average? A child with pneumonia who is seriously ill or one admitted for diagnostic tests for a possible allergy?

Source: Lorch, S. A., et al. (2008). Impact of admission-day crowding on the length of stay of pediatric hospitalizations. *Pediatrics, 121*(4), e718–e730.

Box 36.6 Assessment
Assessing a Child for Effects of Illness

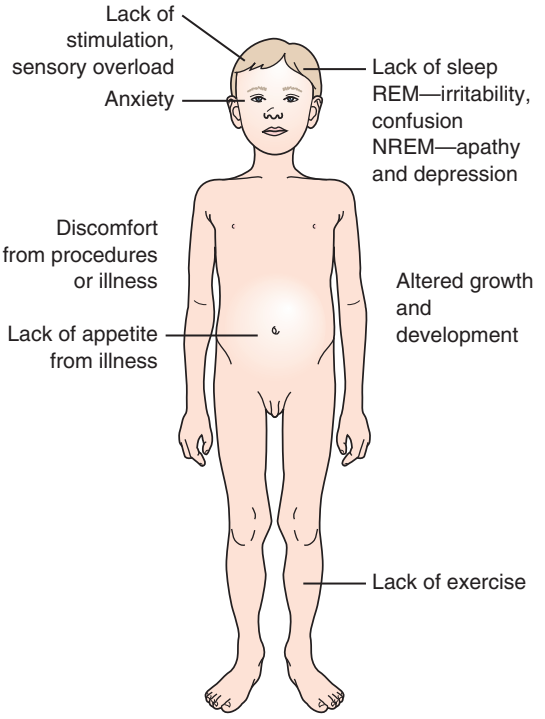

TABLE 36.2 ✻ Information Necessary for the Child's Plan of Care on Admission

Area of Information	Specific Knowledge
Chief concern	Determine what the parents' understanding is of why the child is being admitted. (This view may differ widely from the physician's view regarding the reason the child is being admitted.) What has the child been told about the reason for hospitalization?
Family profile	Obtain child's name and birthday. Who lives at home (include pets)? Ask about parents' occupation and education levels. Who is the child's primary caregiver? Have there been any disruptive happenings lately in the child's life, such as a move or a divorce, that would make the child particularly insecure at this time? Will a parent be staying with the child? If parents are separated or divorced, what will arrangements be? Who has legal authority to sign medical permission?
Past experience with illness or separation	Ask about previous hospital experiences and how the child feels about them. Has there been a recent hospitalization for anyone in the family that resulted in a bad outcome? Has the child been away from the parents before? Overnight at a grandparent's? Summer camp? What is the child's past experience with taking medicine? Has the child swallowed pills before? Does the child have any known allergies to food or medications? (Document these by asking for exact symptoms and happenings.)
Daily routines	Ask about the child's regular bedtime and sleep times. Does the child nap? Does the child have a bedtime ritual? What type of bed does the child sleep in? Does the child sleep with a favorite toy or blanket? What is bath time routine? Does the child need help brushing teeth or combing hair or is this done independently? What words does the child use for voiding and defecating? Is the child completely toilet trained? If a preschooler, is the child accustomed to using a potty chair or toilet? Does the child have enuresis (bedwetting)? What is the child's usual meal plan? Are there foods the child does not eat? What is the child's favorite toy? Did the child pack it for the hospital? What are the child's favorite games and hobbies or interests? Are there television programs the parents especially like the child to see or not see?
Developmental survey	Ascertain the child's developmental level. Does child feed self? Use a spoon, cup, bottle? Dress self? If school age, what grade in school?
Special information	Obtain any special information about the child that would make him or her more comfortable in the hospital.

BOX 36.7 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Child Having 1-Day Surgery

Becky is a 7-year-old who burned her foot in a campfire accident. She is going to be admitted to the hospital for 1-day surgery to have the wound debrided.

Family Assessment ✻ Child lives with parents and two older brothers (10 and 14 years) in a three-bedroom suburban home. Father works as sound technician at a recording studio; mother was a grade-school teacher, now is stay-at-home mom; home schools all three children. Father rates finances as, "All right. We have everything we need."

Client Assessment ✻ Client burned left foot on a campfire while on a family weekend camping trip. Was playing hide and seek with brothers and ran into fire. Treated at local hospital for third-degree burn; transferred to burn center for follow-up care. Becky's parents tell you that Becky "hasn't been herself" since the injury. She has reverted to temper tantrums and sulking, more like a 3-year-old than one of early school age. Even though she has been told eating meat is important because it provides protein for healing, she refuses to eat anything but Jell-O or soup. In the admission suite of the hospital, she picked up a doll and twisted its leg off. "What can I do with her?" her mother asks you. "How can we get our old daughter back again?"

Nursing Diagnosis ✻ Anxiety related to hospital admission and burn debridement

Outcome Criteria ✻ Child accurately describes what debridement will entail; cooperates with procedures with age-appropriate responses. Describes measures she will need to take after returning home to aid burn healing.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Assess the degree of self-care child usually carries out.	Allow child maximum inclusion in procedures.	Ability to carry out self-care helps "normalize" hospital procedures.	Child participates in self-care to extent possible with post-procedure bandage.
		Consultations		
Nurse	Consult with Child Life service on what type of therapeutic play would be most beneficial.	Conduct therapeutic play with child before and after debridement procedure.	Therapeutic play can be helpful to children to relieve their anxiety about a hurtful procedure.	Child participates in therapeutic play; demonstrates less anxious behaviors following debridement.
		Procedures/Medications		
Nurse	Assess what is child's greatest concern about debridement procedure.	Prepare child for surgery, stressing anesthesia will be used to relieve pain during procedure; analgesia will be available after procedure.	A clear understanding of what is to happen helps to relieve anxiety; knowing pain relief is available is invaluable to well-being.	Child and parent state they understand what procedure will entail; child cooperates in age-appropriate ways.
		Nutrition		
Nurse/ nutritionist	Assess what are child's favorite foods.	Suggest ways mother could incorporate protein into soup (meat soups) to increase protein in child's diet.	Jell-O is a protein source; adding meat to what child eats will provide protein yet respect child's choice of food.	Mother details ways she can increase child's protein intake without opposing child's food preferences.

(continued)

BOX 36.7 ✻ Focus on Nursing Care Planning (continued)

		Patient/Family Education		
Nurse/nurse practitioner	Assess what child and parent understand about debridement procedure.	Educate family about procedure and pre- and postoperative care.	Well-prepared child and family can better cooperate with care to make experience a positive one for child.	Child and parents ask questions about procedure; state they understand what it will entail.
		Psychosocial/Spiritual/Emotional Needs		
Nurse/nurse practitioner	Take history about burn accident.	Review with mother what she believes has caused the change in child's attitude. Does she think child or parent feels guilt about accident?	Children can believe they are being punished by procedures if they believe an accident was their fault; guilt can also influence parent's relationship with child.	Child and parent state they both should have been more diligent to avoid accident, but accidents happen even in the best circumstances.
		Discharge Planning		
Nurse	Assess what will be a typical day for child after return home.	Plan with parent what measures child will need to carry out to keep bandage clean, exercise foot, return to home schooling.	Prospective planning can help avoid problems in home care.	Child and parent review a typical day and decide on actions that will promote healing.
Nurse/ physician	Assess when follow-up visit will be necessary.	Schedule follow-up visit as determined by surgeon.	A follow-up visit will help ensure burn is healing without further complications.	Child and parent state they understand importance of follow-up visit and will keep appointment.

growth and to allow for determination of surface area, the measurement on which medication dosage is calculated. Whether blood pressure needs to be taken depends on the age (usually in children over 3 years of age) and condition of the child. Obtain a specimen for urinalysis as another routine procedure. Be sure to explain all equipment used and allow the child to touch and handle it as much as possible to help reduce anxiety.

Inspect for gross motor ability when weighing a child and measuring height. Listen for language ability (although children in strange situations may say nothing). Perform a physical examination (see Chapter 34) to gain the information necessary for nursing diagnosis and planning.

The way children deal with hospitalization is based on the same factors that determine how they deal with any crisis: perception of the event, whether support people are available, and effectiveness of past coping experiences or skills. After assessment, analyze whether a child's coping ability seems to be enough to balance the hazards of inpatient or ambulatory care hospitalization.

Nursing Diagnoses and Related Interventions

✻

Nursing Diagnosis: Parental and child anxiety related to the need for child's hospitalization

Outcome Evaluation: Parents and child state accurately the reason for child's hospital admission and therapy child will receive; state that although worried, they feel confident they can manage their anxiety.

To help reduce family anxiety regarding hospitalization, be certain a family is oriented to a hospital stay by discussing the need for hospitalization and what they can expect when the hospitalization is first suggested to them in an ambulatory care setting. When children are admitted for emergency care, this type of orientation must be completed immediately, as soon as their physical needs are met. Whether children are admitted for an ambulatory care admission or are being hospitalized for a potentially longer stay, be certain that the parents and the child are oriented to the unit, the personnel who will be caring for them, and any pertinent routines they will need to follow.

On admission, both parents and child need at least basic information. If the child's diagnosis is uncertain, what steps are being taken to confirm it? It helps if these steps are named specifically: for instance, blood work, x-ray studies, observation, recording of vital signs, or calling in a consultant. What is the tentative plan for the child? Complete bedrest or infection control procedures until the results of blood work or cultures are back? Special diet? Special procedures? If the primary care provider has written no orders as

yet, be honest: "The specific plan of care isn't written yet. I'll let you know as soon as I'm sure what it will be." Although this answer does not provide a family with information, it does tell them you appreciate how difficult and bewildering it can be when a child is admitted to a health care facility.

For an emergency admission, parents may have little understanding of their child's condition or the treatment plan. Conversely, someone might have taken a great deal of time to explain what was happening while the child was being cared for in the emergency department or brought to the unit. To determine the parents' knowledge level, ask them if they have any questions about their child's condition or the course of treatment they want to discuss with the inpatient facility's health care team.

If parents must leave rather than remain with a child, be certain they see the child's room before they go. This is important to convince children that parents will know where they can find them when they return. If there are other children in the room, introduce a new child to them. Let children wear their own clothes if possible rather than change into hospital gowns.

Promoting a Positive Hospital Stay

Promoting a positive hospital stay is important to the health of both children and their families. Several nursing actions are important to make the difference between a successful and an unsuccessful hospital experience.

Minimizing Length of Hospital Stay

Hospitalization should be limited to the shortest time possible. Be certain that diagnostic procedures are scheduled for a child's, not the hospital's, convenience so that no child stays in a hospital longer than is necessary. Pressure from concerned nurses who insist on having a voice in policies can make a big difference in a department's willingness to cooperate with scheduling.

FIGURE 36.4 Hospitalized children should have one nurse who is "theirs" to minimize the effect of separation from parents (primary care nursing). (From Susan Leavines/Photo Researchers, Inc.)

Providing Continuity of Care

To ensure that children are exposed to as few substitute care people as possible and to maintain the consistency and quality of care, nursing assignments are best if one nurse gives as much care to the same child as possible (either **primary nursing** or **case management nursing;** Fig. 36.4). These staffing patterns allow the same nurse to admit the child, take the nursing history, establish nursing diagnoses, set goals for care in cooperation with the parents and the child, and evaluate progress toward achieving goals. It allows children to have one main nurse to call their own. It allows parents to establish meaningful contact with hospital staff and maintains continuity of care, planning, and implementation.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Anxiety of child related to separation during hospitalization

Outcome Evaluation: Child actively relates to hospital personnel and hospital routine in ways appropriate to child's age and stage of development; manifests a minimum of nervous symptoms.

Promoting Open Parent Visiting. When possible, children younger than 5 years should have their primary caregiver room-in with them when they are in a hospital (Fig. 36.5). Children younger than 10 to 12 years continue to enjoy the feeling of security this provides. This policy is expensive for a hospital because a bed or cot must be provided for this person as well as for the child, and despite the presence of this person, no reduction in nursing staff is possible. In many instances, because so much parental education is

FIGURE 36.5 Rooming-in helps alleviate separation anxiety for both the child and the caregiver.

needed, requirements for health care personnel actually increase. However, such policies greatly reduce symptoms of separation anxiety.

Not all parents can stay in the hospital continuously. Mothers and fathers who cannot stay may need help in smoothing the transition of their coming or going. For example, when a toddler first sees his parents after being separated, his reaction might be to ignore them (a sign of despair). This is a defense mechanism: "I won't show them I love them until they show me they love me; that way I won't be hurt again." The parents' reaction to being treated this way may be anger. If this makes the parents go and play with a child in the next bed—a "well, be that way then" reaction—the toddler's worst fears are fulfilled: his parents do not love him anymore. However, if you urge the parents to speak to the child for a few minutes or try to interest the child in a toy, a child will generally reach out to be comforted and act relieved the parents are there.

Parents often need help in saying goodbye when it is time to leave a child to go eat a meal or go home for the night (if the parent is not sleeping in). Assure parents that although someone will not be in their child's room every minute while they are gone, the child will be well cared for. When the parents of an infant are leaving, go into the room a few minutes before they leave and hold or play with the infant. Help a parent to say once, "I have to go now," and then go. Prolonged departures only delay the process and do not reduce the amount of crying that may occur. After parents leave, infants may cry until they fall asleep from exhaustion. Hold and rock them, letting them know that they are safe.

If the parents of a toddler or preschooler have to leave, urge them first to give a warning they will soon have to go: "I have to leave now to fix dinner." When the time to go has come, parents should say firmly that it is time to go and then explain the time they will return. Time for a preschooler is best measured in terms of events rather than clock hours. "I'll be back after you've eaten supper," "after you wake up tomorrow," or "after nap time" gives the child a concrete event by which to measure time. Like infants, toddlers need someone with them when their parents leave; they like to be held or played with so they know they are not alone.

When parents leave a school-age child or adolescent, urge them to provide definite times when they will return and to leave suggestions for activities a child could do to occupy the time ("Why don't you finish your book? Start your homework and I'll check it when I come back"). Remind them it is more comforting to say specifically, "I will be back around 9 tomorrow morning" rather than, "I will be back sometime tomorrow."

Providing Opportunities for Parents to Participate in Child's Care. Participating in their child's care can make parents feel more in control, thereby reducing anxiety. Therefore, encourage parents to give as much care as possible during a hospital stay, such as bathing or feeding their child, giving oral medicine, helping with procedures such as warm soaks, or checking their child is awake from anesthesia. Most parents are eager to help and do these things spontaneously. Be certain they receive proper instruction on the tasks they will be able to do. Be sure parents who change diapers or feed children know whether the number of diaper changes or the amount of food intake should be recorded; ask them to report when they do these things or write them down on a flow sheet attached to the child's door or crib. Do not have them restrain childen for a procedure that will be painful.

Occasionally parents may be reluctant to give care for fear of being judged inadequate. You can assure them they are the persons from whom their child would most like to receive care. Parents may point out that they are paying for nursing care and so want a nurse to give care. This type of parent will usually soften if approached professionally and assured that nurses are willing to help but for the best interests of the child, the parent is the better caregiver.

Children may be apprehensive about undergoing a procedure without a parent present. There is rarely any reason a parent cannot accompany a child into a treatment room to help with undressing, measuring weight and height, and taking a temperature or accompanying a child to another department for a procedure such as an ultrasound or blood work. Most importantly, the mother or father can comfort the child in these strange surroundings.

Although helping with procedures can strengthen the parent–child relationship, remind parents their most important role is being parents. Sitting and rocking or reading to their child and just being there will be their best role to minimize the adverse effects of hospitalization. When a child is to have surgery, it may be especially difficult for parents to separate from their child so the child can leave for the operating room. Helping them do this is an important part of preoperative nursing care.

Supporting Sibling Visitations. Children in a family are under considerable stress while a sibling is hospitalized because their world changes so much (Gursky, 2007). Sibling visitation refers to allowing the brothers and sisters of hospitalized children to visit the ill child in the hospital. Allowing this alleviates loneliness on both sides and helps prevent other children at home from imagining the ill child is sicker than is true. It helps the ill child continue to feel part of the family. Siblings who visit need to be free of communicable disease. Nurses may need to help parents divide their time between the ill child and siblings during a visit (short, frequent visits may be better for young children than long ones). Before a visit, ensure that the ill child's room is safe for younger children's visits by such things as receiving poisonous substances or electric wires within reach.

Minimizing Negative Effects of Procedures. Ill children often undergo numerous diagnostic and therapeutic procedures that have the potential to cause pain, fear, and anxiety. Details related to specific procedures are discussed in Chapter 37. General guidelines to make any procedure less painful or frightening are discussed in the following sections.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Fear or anxiety related to diagnostic or therapeutic procedures

Outcome Evaluation: Child voices satisfaction with comfort measures; describes self-participation in a procedure.

Reducing or Eliminating Pain. Some pain and discomfort are unavoidable in association with health care. Limit this whenever possible, however, by such measures as advocating for the use of intermittent infusion devices such as heparin locks (see Chapter 37) to eliminate multiple punctures for intravenous medication or blood sampling, administering ample analgesia, including alternative therapy techniques such as distraction or imagery, providing traditional comforts such as a change of clothing or position, reading to a child, and planning a special project. Children do not always express discomfort as freely as adults; therefore, closer assessment may be necessary to reveal how they feel. Because pain increases with anxiety, reducing a child's anxiety with good preparation and encouraging a sense of control can also help to eliminate discomfort (see Chapter 39). Distraction by such a method as music may also be effective (Caprilli et al., 2007).

Maintaining the Child's Bed as a Safe Area. To assure children that their bed is an area that is safe, all painful procedures should be done in a treatment room, away from the child's bed. Be sure this rule is not broken, because only one painful experience at the bedside can be enough to significantly increase a child's anxiety. This rule should include finger punctures for blood work; although done quickly, these can cause as much pain and stress as venipunctures. In addition, dressing changes, although not necessarily painful, can cause worry and so should be done in a treatment room, not at a child's bedside as well.

Helping Children to Maintain Control. Events are always more frightening if they appear to be beyond our control. Explaining to children what will happen such as what they will feel or what they will see and helping them to make choices whenever possible limits this type of fear because these actions offer a sense of control (Fig. 36.6). In almost any procedure, there is some choice a child can make (use a straw to drink or not, decide what size of tape to use on a bandage, or walk one way in the hall or the other). Letting a child participate in signing a consent form can be an additional way to help the child feel a sense of control.

FIGURE 36.6 Include children in procedures whenever possible to offer them a feeling of control. Here a nurse gives a child a choice of fluids to drink with her medication.

Providing Adequate Play Facilities

Play is the medium through which children learn. To continue development during hospitalization, children need to be able to play as normally as possible, no matter how long their stay. Children's hospital units should be equipped with a playroom or play space in which children can feel secure and in which they know they will not be hurt. No medical procedures, not even painless ones, should be performed in this area. Children who are on bedrest need toys or crafts supplied for them in addition.

Because hospitalization is a traumatic experience, children need the opportunity to express their feelings through therapeutic play before painful procedures (Li, Lopez, & Lee, 2007). The uses of play and guidelines for providing therapeutic play are discussed later in this chapter.

Setting Limits on Behavior

Setting limits on behavior can help promote a positive hospital stay because it can help to provide a sense of security and safety for a child. Average children are motivated to follow instructions and demonstrate good behavior during a hospital stay because they want to get well again and return home as soon as possible. Occasional children who misbehave in a hospital setting usually do so because they lack a clear understanding of what is expected of them or are making a strong statement that their personal needs have not been recognized and met.

A child who needs frequent reminders to stop running in the hallway, for example, is probably bored with staying in a room. Providing more activities (playing a game with the child) or allowing more structured exercise (letting the child accompany a nursing aide to take a blood specimen to a laboratory) can prevent further unsafe activity.

Children who refuse to cooperate for procedures generally do so out of fear of the unknown rather than deliberate misbehavior. The better prepared a child is for such a procedure, therefore, the better a child is apt to accept it. For potentially painful procedures such as a bone marrow aspiration, lumbar puncture, blood sampling, or cast removal, any behavior short of hysterical screaming can be considered "good" behavior. If limit setting is necessary, such as with a child who hits or bites other children, confer with the child's parents about the need for limit setting and what measures they would suggest. Gain their cooperation and approval so that what you do is consistent with their care (Pao, Ballard, & Rosenstein, 2007). Using "time out" periods or removing the child to a nonstimulating

area for a short time is an effective measure. Be certain a child understands the rules (if the child bites or hits, sitting alone for a designated period will be necessary). The next time the child misbehaves, give one warning that the behavior is against the rules; if the behavior does not improve, take the child to the "time out" spot. If the child is disruptive, begin timing the period from when the child quiets down. When the child has been quiet for the specified duration (usually 1 minute per year of age), the child can leave the "time out" place and rejoin activities.

Discharge Planning

Discharge planning is an important link between hospital and home.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Parental health-seeking behaviors related to care for child at home after hospital discharge

Outcome Evaluation: Parents state accurately the care their child will need at home; describe and demonstrate any procedures they will need to perform with child.

Many children, particularly those having surgery, are hospitalized for only a few hours; as soon as they are able to take and retain fluid and have voided once, they are discharged. This represents such a short time that preparation for discharge must start even before they are admitted to the hospital (Melnyk et al., 2007).

If a child has been admitted on an inpatient basis, preparation for discharge should begin on the day of admission. If some procedures will need to be continued at home, allow parents to perform them in the hospital at least once so that they can become comfortable with the necessary technique and discover any problems while help is still available. Urge parents to think through problems they might have with a procedure at home. Suppose a parent will be doing warm sterile soaks for an open lesion at home. How will the parent sterilize water? Where can the parent buy dressings? Can the parent afford them? What can be used to keep the soaks warm for 20 minutes? What suggestions would be helpful to give the parent for keeping the child quiet and content for 20 minutes, so that the child does not move a great deal and knock off the dressing? These are real problems that must be worked out before a parent can perform the procedure at home. Do not leave this kind of instruction until the last day, because then there will not be time left to solve such problems (Wolf et al., 2009).

Discharge planners can be indispensable in helping ready parents for home care. In a general hospital setting, however, if a discharge planner is unfamiliar with specific procedures (or children), such a person may not be as helpful on a practical level as anticipated. Some parents require follow-up help in their homes that will be provided by a community or home health care nurse. Do not leave the full responsibility for teaching to these home care nurses either. Teach the parents what they must do on the first day they are at home before further help arrives. Be certain they know the person to contact if plans do not work out as anticipated and that they have a definite return appointment for follow-up care.

Many preschool children manifest behavior problems such as thumb-sucking, bed wetting, temper tantrums, and nightmares after returning home from a hospital stay; school-age children may manifest these behaviors to a lesser extent. You can assure parents these behaviors are part of a child's normal response to hospitalization. These behaviors do not happen because the child has been "spoiled" by the hospital staff or by the parents during the illness but because the experience was too intense for the child to handle easily, even with all the precautions taken to prevent stress. As children realize they are safely back home and the experience is over, these behavior reactions become less frequent and eventually disappear.

NURSING RESPONSIBILITIES FOR CARE OF AN ILL CHILD AND FAMILY

Nursing responsibilities will vary, naturally, with the type, extent, and seriousness of a child's illness, age, care setting, and individual circumstances. Several responsibilities, however, such as promotion of normal growth and development, sleep, stimulation, and play, cross all ages and phases of care. Chapter 37 discusses specific responsibilities related to diagnostic tests or interventions. Chapter 39 discusses the important role of promoting comfort in an ill child.

Promoting Growth and Development of an Ill Child

It is easy for children to fall behind in growth and development because of an illness unless health care providers monitor for this.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for delayed growth and development related to effects of illness

Outcome Evaluation: Child demonstrates only limited signs of regression to previous stage; is able to continue doing the activities most recently accomplished.

Illness represents a crisis event. In a crisis state, children, like adults, are susceptible to change or growth with only the slightest intervention. Without intervention, they are likely to be overwhelmed.

Promoting Growth and Development of an Ill Infant. To promote optimal growth and development, try to change an infant's normal routine as little as possible. Sameness provides security to a child and encourages

the development of trust. When admitting an infant to a hospital, ask parents what type of bed the child usually sleeps in. A child who is used to sleeping in a bassinet may feel loose and insecure in a large crib. You would need to swaddle such a child in a receiving blanket in a large crib to offer the same close, bound feeling of a smaller sleeping area.

Also, attempt to change the infant's diet as little as possible. Unless a child is diagnosed with failure to thrive or is obviously underweight, illness is not an ideal period in which to introduce new foods or formula. Unless their physical condition warrants a change, infants who breastfeed should continue to do so for as many feedings as possible. Expressed breast milk can be given by bottle to the child when the mother is not available. Overall, because infants cannot begin to understand the strange feelings accompanying illness, they need increased swaddling and comforting. As their condition improves, they need to be provided with stimulation and play opportunities.

Promoting Growth and Development of an Ill Toddler or Preschooler. Because illness can limit autonomy and prevent children from learning how to do new things, try to find opportunities to promote both autonomy in toddlers and initiative in preschoolers. Urge parents to encourage children to make choices about their care whenever possible. For example, coloring in a medication schedule is the kind of task that helps to encourage initiative in a preschooler.

If admitted to the hospital, toddlers and preschoolers who are not used to sleeping in cribs may resent being put in a crib unless the reason is explained to them ("All our beds here have side rails"). Watch toddlers closely to be certain they do not climb over crib rails to get out of bed. A child who does try may be safer in a bed than a crib.

As with infants, illness is a poor time to change the eating habits of toddlers and preschoolers. Because children of this age insist on self-feeding, they generally do poorly eating in bed and often do better sitting at low tables. Many child-care units in hospitals organize tables for toddlers and preschoolers to eat together. Some children do well at these tables, but others are too distracted by the activity and the noise and may need a separate low table by their bed to eat well. All children may eat better when their parents are present.

Illness is also a poor time to begin toilet training, even if it is appropriate to the child's age. If the parents have already begun toilet training, continue it with as normal a routine as possible.

Promoting Growth and Development of an Ill School-Age Child. School-age children need to continue to work on a sense of industry while ill. This means learning more about how and why things are done. Explain about specific procedures and involve them as much as possible in planning their care to help foster a sense of industry.

Remember that children who are ill are not at their best and so may not act as mature as usual. This means a 7-year-old whose parents describe him as very mature may seem to function at the level of a 5-year-old. Children of any age should not be held to their chronologic age when they are ill. In a hospital, school-age children enjoy sharing a room with another child close in age so they can play games together. School-age children do well with competition when they are healthy but often do poorly with competition when they are ill. They may revert to playing types of games they would normally dismiss as too young for them.

School-age children and adolescents should continue schooling if they are ill for a long time, provided their condition will allow it. Because it is age appropriate, ill children do well with school activities or working with a tutor. It is such a normal, everyday activity that it provides security in an otherwise insecure situation. It also reassures them that they are expected to get better and to return to school when this is over.

During the times a child will not be attending school, working on projects such as needlecraft, helping plan family menus, writing for brochures about the place the family plans to visit on vacation next year, or viewing videotapes on science or nature are activities that not only help pass the time but also encourage learning. School-age children also are developing moral responsibility and may find comfort in spiritual practices. Ways to assist with spiritual needs are shown in Table 36.3.

Encourage school-age children to carry out self-care and, if cared for at home, to contribute to household routines, such as helping with dishes or picking up after themselves, as much as they are able. This not only takes some burden off caregivers but also makes a child feel like an intrinsic part of the family.

Promoting Growth and Development of an Ill Adolescent. An adolescent who is struggling to develop a sense of identity may find it very difficult to be ill because the limitations imposed by an illness can make the development of a sense of identity difficult. Help adolescents to continue to participate in activities they did before becoming ill, if possible, to help them feel their world is not totally changing. Encourage them to maintain self-care activities and good hygiene practices to help preserve self-esteem.

Illness can be difficult for adolescents also because peer relationships are so important to them. They may miss acting in a school play, playing on a sports team, or competing for a scholarship. A girlfriend or boyfriend may fall in love with someone else while an adolescent is hospitalized. This makes them feel excluded and hurt. For these reasons, it is important for them to have visitors from their peer group, just as much as infants need visits from parents. Using a cell phone to text message is an easy way to contact friends and maintain relationships with individuals who are important to them.

Adolescents appreciate being hospitalized in a special adolescent unit or at least in a room free of childish decor. Adolescent hospital units should be organized with the same considerations for visiting parents as other children's units; anxiety and pain of separation are not limited to the under-13 set. Urge parents to stay overnight if they and the adolescent wish. Although adolescents enjoy having parents stay overnight because it is reassuring to know they

TABLE 36.3 ✻ Nursing Interventions to Meet Children's Spiritual Needs

Action	Implementation
Prayers	School-age children may be learning and saying prayers. Ask on hospital admission whether a child says grace with meals or a prayer at bedtime. Write it on the plan of care so that nurses can help with this. Remember that saying grace also applies to unconventional meals, such as a tube feeding. Bedtime prayers may be especially important by lending security in a strange environment.
Religious services	Many children of school age and older enjoy attending a religious service in a hospital chapel. Include time for this in the plan of care and be certain that transportation by wheelchair or cart is available.
Visits from clergy	Many school-age children and adolescents enjoy an active recreation or social program at a church facility when well. They enjoy a visit from clergy when they are ill, not so much for its religious importance as for support from a respected adult. Free the child's time as necessary for such visits.
Religious articles	A child's parent may wish to attach a religious article to the child's clothing or pillow or to post it over the bed. Be careful when changing linen that you do not throw away such articles. Mark their presence and importance on the plan of care.

are concerned, adolescents also enjoy being separated from their parents (assuming everything is going all right) so may not want their parent present all day and night.

Often adolescents convey a blasé attitude toward procedures: having radiographs taken is nothing; surgery is a cinch; a cast change is a snap. Listen carefully to make certain adolescents really feel this way and are not trying to convince themselves that a procedure is harmless. Remember adolescents are extremely worried about their body parts. Make sure they know what is going to happen in surgery and in other departments such as radiography. It is easy to assume from their attitude that they know more than they do.

PROMOTING NUTRITIONAL HEALTH OF AN ILL CHILD

Nursing responsibilities related to nutrition for ill children include maintaining optimal nutritional status in the face of illness or treatment that interferes with adequate intake; correcting nutritional deficiencies or otherwise aiding children and families to follow the nutritional care plan devised by the health care team; and educating a child and family regarding specific nutritional needs as well as overall sound nutritional health. Specific procedures for promoting nutrition such as measuring fluid intake and output and providing enteral feedings, gastrostomy tube feedings, and total parenteral nutrition are discussed in Chapter 37.

Nursing Diagnoses and Related Interventions

✻

Nursing Diagnosis: Risk for imbalanced nutrition, less than body requirements, related to lack of appetite

Outcome Evaluation: Child maintains skin turgor and age- and size-determined weight pattern; ingests 80% of prescribed diet daily.

An acute illness in a child, such as pneumonia, is often accompanied by a loss of appetite; gastrointestinal illnesses often cause nausea and vomiting. Because most acute illnesses last only a few days, there is no need for children to eat more than a small amount during this time as long as they can drink fluid. Trying to force them to eat only increases nausea and vomiting, which increases the possibility of creating an electrolyte imbalance. When an illness lasts for more than a few days, however, providing adequate nutrition becomes increasingly important because children need nutrients not only to repair ill or diseased tissue but also to maintain normal childhood growth.

Important points to address when planning nutrition for ill children are summarized in Table 36.4. Children who are hospitalized often tolerate hospital-prepared food, which can be repetitious and bland, better than do adults. Provided that it is the kind of food they like, such as hot dogs and hamburgers, these appeal to children more than elaborate dishes with spices and sauces preferred by adults. Children who are receiving care at home need as much nursing supervision of their nutrition as those in health care agencies (possibly more) because they may not have a dietitian planning meals to ensure adequate nutrition. Assess not only the quantity but also the quality of food to ensure that intake is optimal. If prescribed, ask whether nutrition supplements are being offered to increase intake (Evans et al., 2007).

Encouraging Fluid Intake. Increasing oral fluid intake has traditionally been termed "forcing fluid." It is better to avoid this term with children, however, because they can interpret the instruction to mean that someone is going to physically force them to

TABLE 36.4 ✻ Areas to Consider When Planning Nutrition for Ill Children

Area	Importance
Meaning of food	Early in life, infants learn to associate eating with being held and loved; if they cannot eat for some reason such as respecting nothing by mouth for surgery, they may view the restriction as punishment or restriction of love.
Opportunity for socialization	Mealtime is often a time of the day when children socialize with other family members; they may feel lonely eating alone and consequently may have a poor appetite.
Level of stress	Children under stress may either feel a loss of appetite or experience a need to snack frequently; planning is necessary to see that children maintain adequate intake if not hungry and that their snacks are nutritious.
Custom	Custom is important: for example, many children like foods served separately and resist eating them if they are mixed into a casserole.
Culture	Most children eat best those foods with which they are familiar; in many instances, parents can bring in favorite foods from home to provide culturally preferred items.
Environment	Hunger is associated with the sight and smell of food; many children are normally in the kitchen while meals are being prepared; they may not be hungry when food is served to them without their having seen and smelled it being prepared.

swallow fluid. A physician's order should state in detail the amount of fluid a child is to receive during 24 hours, because the amount differs so much for different ages. The following are some practical guidelines for encouraging fluid intake at any age:

- Offer small, full glasses frequently rather than half-full larger glasses; children are mid–school age before they evaluate the amount of fluid in a container rather than the size of the container.
- Determine the child's favorite fluid, and then offer it.
- Try changes of temperature in fluid offered (hot cocoa, then cold juice, then hot soup) for variety. Broth can be a nice change of liquid (many commercial types are quick to prepare, but be aware of their high sodium content).
- Popsicles and Jell-O count as fluids (Fig. 36.7).
- Children can drink more of a clear fluid (ginger ale, water) than a thicker fluid (milk shakes or cream soups), because thicker fluids are absorbed from the stomach much more slowly.
- Suggest soothing beverages such as Kool-Aid, Snapple, or milk for children with mouth lesions. They may be unable to drink fruit juices because the acid content stings their mouths; carbonated beverages may also cause discomfort.
- Because ice melts to one half its volume, count a glass of ice chips as only a half-full glass of fluid.
- Unless contraindicated, let children drink fluids with a straw; this is a novelty to many who do not normally use these so encourages intake.
- Introduce a game, such as "Simon Says" (Simon says, "Drink") or a board game in which a child takes turns and with each turn has to take a drink.

Encouraging Food Intake. **Calorie counting,** as the name implies, involves counting the number of calories that children ingest each day. To do this, record all the foods that a child eats during each 24-hour period, being certain to include snacks, candy, or gum. A dietitian then will analyze the list and determine the caloric intake. Be certain when doing this that you describe the types of food and amounts (not "some toast," but "half a slice of whole wheat toast"). Be sure that everyone caring for the child is aware that calories are being counted so that they also record this information accurately.

FIGURE 36.7 A nurse offers this young child a popsicle, a good source of fluid when children do not feel thirsty or hungry.

✔ Checkpoint Question 36.3

You want to encourage Becky to drink a lot of water. Which action would do this best?

a. Scold her for not cooperating to make herself well again.
b. Offer her small glasses of fluid so she can drink these frequently.
c. Offer her large glasses of fluid so she does not have to drink so often.
d. Alert her if she does not drink fluid, she will have to receive an IV.

PROMOTING SAFETY FOR AN ILL CHILD

A prime consideration of nursing interventions is to keep children safe during illness care.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for injury related to procedures or therapy necessary for care

Outcome Evaluation: Child remains free of injuries and accidents, such as a fall from bed or injury from medical equipment.

Promoting safety for children is a responsibility for all health care providers. Care of an ill or physically challenged child at home includes assessing the safety of the house and providing family teaching. It also includes making provisions for emergencies. For example, a family may need to install a counter-level telephone or purchase a cell phone so a child in a wheelchair can call for emergency help. They might need to make a plan for how to evacuate an ill child from the home in an emergency such as a fire.

Safety on a children's unit or clinic is the responsibility of everyone, from the administrator of the institution to part-time health care personnel. Important steps to follow to make a child health care environment a safer place are:

- Always be sure of the location of all children in your care.
- Ensure that doors or gates are provided near stairways or elevators.
- Ensure that back doors of health care facilities have working alarms to prevent children from going out and strangers from coming in.
- Be sure windows are covered by screens or guards so children cannot climb up on sills and fall out.
- Check that the side rails of beds and cribs are in good repair and raised appropriately.
- Always raise bedside rails after a child has received preoperative or sedative medication.
- Test a crib rail after it is raised to ensure the lock has caught so the rail will remain raised.
- Push bedside tables or stands away from cribs so a child cannot climb over the railing and use the stand as a step down.
- Be certain crib caps are provided for small children to prevent them from climbing out of bed.
- Fasten the seat belt restraint for infants in highchairs. Never leave an infant in a highchair (at home or in a hospital) without someone close enough to reach the child as infants can easily squirm out of a highchair restraint.
- Ensure that electrical cords or appliances such as hair dryers are not used in bathrooms, where they could come in contact with water.
- Be careful of the placement of television/call cords or Venetian blind cords so they cannot lead to strangulation.
- Never leave children younger than 5 years alone in a bathtub; they could turn on the hot water and scald themselves or slip under the water and drown.
- Never leave equipment or items that would be harmful to eat within the reach of children.
- Adhere to all fire precaution measures.
- Closely follow standard infection precautions to prevent the spread of infections.

Promoting Fire Safety. Fire precautions both in the home and in the hospital are essential in preserving the safety of ill or disabled children. Adults can usually take responsibility for removing themselves from a burning structure, but children depend on care providers. Ensure that there is a plan of action in case of a fire and that everyone in the home, in the clinic, or on a hospital unit knows it. To be certain a home is safe, having a smoke detector on each floor is a wise precaution. A downstairs bedroom is not only safest in case of a fire but also allows a child more self-care ability. Fire departments supply free decals for the bedroom windows of children or those who are physically challenged so they can be easily located in a fire. Encourage parents to contact their local fire department for this safety measure.

Electrical equipment such as respiratory and cardiac monitors, radiant heat warmers, special-care equipment, and electrical heating pads are often used in the care of children. Do not use equipment with frayed cords or equipment that is not properly grounded. Plugs should be three-pronged for extra safety; do not overload circuits with additional plugs. Electrical outlets should have safety caps to cover them when they are not in use so toddlers cannot poke objects into them and electrocute themselves.

Adhering to Standard Infection Precautions. In every health care setting, closely follow standard infection precautions to protect ill children, family, and staff from infections. Because of a compromised immune system, ill children may be more susceptible to repeat or secondary infections than usual, especially drug resistant strains of bacteria such as methicillin-resistant *Staphylococcus aureus* (MRSA), that can spread easily if not everyone is conscientious about precautions (Raymond et al., 2007). Proper handwashing technique, disposal of tissues and waste materials, and efforts to minimize exposure of other ill children or adults are all effective methods to decrease the risk of infection. For more details on infection control, see Chapter 43.

PROMOTING ADEQUATE SLEEP FOR AN ILL CHILD

Ill children need adequate rest and sleep so their body tissues can effectively use nutrients for repair and normal growth can continue (Meltzer et al., 2007). Children may not sleep well when they are ill because of discomfort, pain, administration of medications, or intensified symptoms of chronic sleep problems. They may not sleep well in a hospital because it is a strange setting; they may have to undergo so many procedures that they also do not nap or rest as much during the day as usual. Children who are recovering from trauma such as injuries from a car accident or burns may be unable to sleep because of nightmares about the accident. These nightmares can cause them to suffer sleep deprivation in the same way as a child who is frequently awakened for procedures during the night. Encourage parents to stay with these children for support and comfort. Remember, though, that parents who sleep in hospital rooms do not obtain adequate sleep either (Lee et al., 2007). Although their presence is healthy for children, it can lower the parent's ability to handle stress or interpret happenings.

Sleep Patterns

Sleep is influenced by anxiety level, state of health, habit, medication, and environment at the time of sleep. Stages of sleep are summarized in Table 36.5. Figure 36.8A shows a pattern of normal sleep. As a sleep cycle begins, children first enter **non–rapid eye movement (NREM) sleep.** This type of sleep occurs in up to 80% of total sleep time. As children fall deeper and deeper asleep, they pass from stage I to stages II, III, and IV of NREM sleep over a period of 20 to 30 minutes. **Rapid eye movement (REM) sleep** follows. In infants, most of sleep time is REM sleep, whereas young adults have the least amount of this type of sleep. The sleep pattern of a child who is awakened frequently during the night for procedures would resemble that shown in Figure 36.8B.

The purpose of NREM sleep, the first phase of sleep, is rest and restoration of the body; this stage keeps body cells functioning and healthy. During the periods of stage III and IV NREM sleep, the secretion of growth hormone (somatotropic hormone) from the pituitary is at its highest level. Growth hormone is necessary for protein synthesis and growth of new cells and for repair and maintenance of all cells. Corticosteroids and adrenaline from the adrenal gland, which are instrumental in the catabolism or breakdown of cells, are at their lowest levels. This balance of hormones produces the ideal combination for protein synthesis and cell growth and repair.

The purpose of REM sleep is less clear. The rapid eye movements may serve to coordinate binocular vision. Dreams that occur during this time apparently serve as a release of tension or help to integrate new knowledge and experience with old in the brain's memory system. Vital signs may fall during NREM sleep. During REM sleep, vital signs rise to near-normal levels. These periods of REM sleep interspersed with NREM sleep, therefore, may be a fail-safe measure to prevent vital signs from falling too low during sleep.

TABLE 36.5 ✻ Stages of Sleep in Children

Stage	Description	Nursing Implications
NREM		
I	A feeling of drifting or falling. Often described as twilight sleep. Temperature and heart rate decrease slightly; EEG waves show peaked, frequent waves (alpha waves).	A child can be roused easily from this early sleep by the slightest noise or even the silent presence of another person in the room. Reduce noise level in room to promote sleep.
II	Sleep deepens. Temperature and heart rate decrease slightly more.	It is more difficult to wake a child from sleep when this point has been reached.
III	Sleep deepens still further. An EEG tracing reveals mixed spindle and delta (slow) waves. Temperature and heart rate decrease further. This period lasts about 10 min.	It is very difficult to wake a child from stage III sleep. Use patience to wake a child fully to offer medicine.
IV	Approximately 20 to 30 min after beginning to fall asleep, a child enters stage IV sleep. Respirations are slow and deep, temperature and heart rate slow even more, and blood pressure decreases; EEG shows delta (slow, steady) waves. Children remain at a stage IV sleep level for approximately 30 min, then progress back through stages III and II until they then pass into a phase of REM sleep.	Children may be confused and unable to orient themselves readily if awakened from stage IV sleep. Use patience until a child is fully awake, particularly if asking a question.
REM	Eyes move in rapid, involuntary motions. Respirations are irregular; body turnings, movements, and penile erections may occur. Lasts 10 to 30 min and then a new sleep cycle with NREM sleep begins.	Dreaming occurs during REM sleep. Although children appear to be close to waking because of the active eye movements, they are really very soundly asleep. Children may wake afraid and crying, disturbed by a frightening dream.

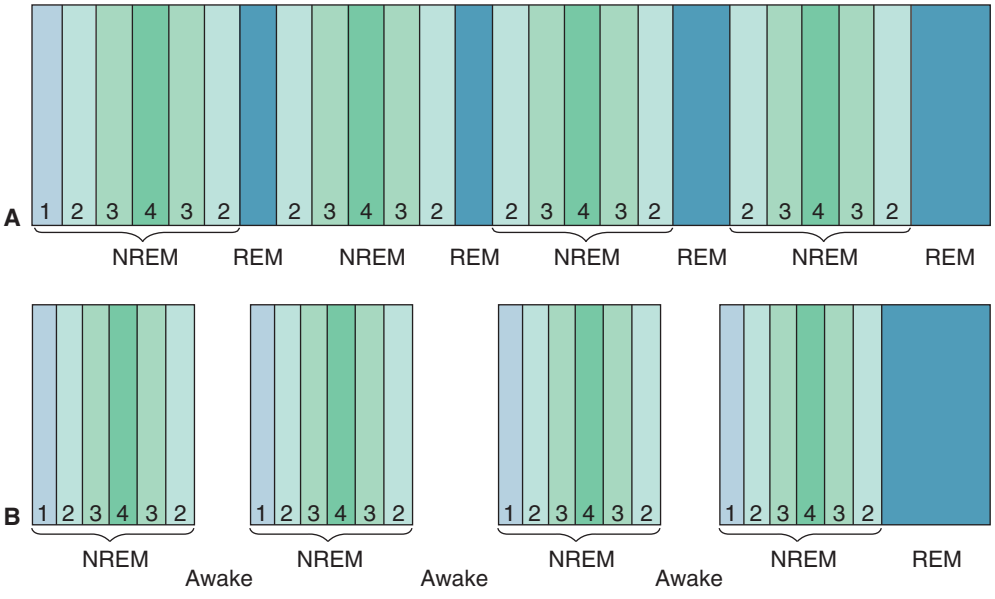

FIGURE 36.8 Sleep patterns. (**A**) Normal sleep pattern. Notice how the periods of REM sleep increase in length during the last half of the night. (**B**) The sleep pattern of a child who has been awakened frequently during the night. Notice how little REM sleep is present.

Sleep Deprivation

Children who do not receive enough sleep can suffer **sleep deprivation** just as adults. After approximately 4 days of poor sleep, this can cause them to experience difficulty in concentrating and experience episodes of disorientation and misperception. If a child states lack of sleep is a problem, an effective way to document how much sleep the child actually obtains is to ask the child to keep a diary listing start and wake times (Werner et al., 2008).

If the sleep loss is mainly REM deprivation, children show symptoms of irritability and difficulty concentrating. Lack of stage IV NREM sleep, in contrast, tends to cause apathy, physical fatigue, and depression and can slow recovery. This is the same phenomenon that can happen in adolescents if they are studying for exams. It easily occurs in younger children during illness if they are awakened frequently for treatments.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Disturbed sleep pattern related to timing of medication, discomfort, or sleep disorder

Outcome Evaluation: Child sleeps through the night without interruption (when therapeutic regimen allows); is alert and active during the day; is able to take nap during the day if that is part of usual sleep schedule.

Because sleep is so important for ill children, you need to take special steps to ensure that children are able to sleep during an illness. Be certain children are as free of pain and worry as possible. Try to let them maintain as normal a bedtime routine as possible (bath, change to nightclothes, nighttime story, prayers). Provide an atmosphere conducive to sleep (lights out, quiet surroundings, reassuring support people). Children who are bored with bedrest may catnap constantly during the day and then be wide awake at night. Providing more interesting activities for them during the day can help reduce their naps and increase nighttime sleep.

Managing Chronic Sleep Problems. Some children may have chronic sleep problems such as night terrors, nocturnal enuresis, somnambulism (sleepwalking), sleep talking, and sleep apnea. These sleep problems can intensify with illness and increase sleep deprivation in ill children.

Somnambulism is a common sleep problem in children. It apparently occurs during NREM sleep, probably during the deepest part of stage IV. It is frightening for children to wake and realize they have been sleepwalking. Sleepwalking can be potentially dangerous when children are ill because, while getting out of bed, they could dislodge intravenous tubing or oxygen equipment. It is untrue that sleepwalkers should not be wakened; instead, wake them gently, help them get reoriented, and then return them to bed after reassuring them they are safe. Be certain that the side rails are raised on the bed of a child who tends to sleepwalk. In a hospital, it may be necessary to move a child's bed out into the hallway at night near the nurses' desk if a parent will not be sleeping over, so the child can be observed for sleepwalking.

Sleeptalking seems to occur during REM sleep. Dreaming of some frightening or puzzling situation, a child calls out a name or instruction such as, "Stop!" Because illness is a stressful situation that increases anxiety, sleeptalking may also occur at an increased rate during this time. It is unnecessary to wake a child who is sleeptalking unless the child is thrashing about and would dislodge equipment such as intravenous tubing. Because sleeptalking usually results from a frightening dream, waking the child gently, however, is comforting. Parents may need to be assured that sleeptalking is harmless and will probably subside when their child is well again.

Some children are prone to night terrors, or wake screaming approximately 20 minutes after they fall asleep. The condition tends to be familial. Waking children and comforting them helps everyone in the house or hospital unit return to sleep. In the morning, children rarely remember the incident.

Sleep apnea is the cessation of respirations during sleep for 20 seconds or more. It tends to occur more frequently in obese children, possibly because of the increased weight of their chest. It may contribute to sudden infant death syndrome or failure to thrive (Barkin & James, 2007) (see Chapter 26). Infants who are diagnosed with sleep apnea may be prescribed respiratory monitors to evaluate their breathing pattern and warn against any cessation of respirations.

PROMOTING ADEQUATE STIMULATION FOR AN ILL CHILD

Children are in constant interaction with both their internal environment (body) and their external environment (surroundings) by means of their five senses and the central nervous system. This makes them capable of responding to changes in environment and by so doing meet basic needs. Any illness that changes their ability to respond can cause either sensory deprivation or sensory overstimulation.

Sensory Deprivation

Sensory deprivation is the condition of being deprived of, or lacking of, adequate sensory, social, physical, or cognitive stimulation. When this happens, children tend to lose the ability to make decisions and become easily confused and depressed. Some children are more prone to sensory deprivation than others.

Ill children may have sensory deprivation because they are confined to their homes or hospital rooms and their varied activities such as school, sports, and clubs are replaced with hours of watching television or playing video games. Hospital regulations for ICUs may limit parental visiting. When parental interaction is limited this way, children generally receive less-than-normal cognitive stimulation. Such children need cognitive stimulation from warm, reassuring health care personnel.

Children with hearing or visual deficits are more prone than others to sensory deprivation. Children with forms of sensory nerve loss or those receiving chemotherapy may lose their sense of touch, taste, or proprioception (sense of where they are in space). After losing these forms of perception, children may draw back from interacting with other people because they are self-conscious about the loss, so they may be further deprived of social and cognitive stimulation. Techniques for interacting with sensory-deprived children are discussed in Chapter 50.

Some children receive medication to lessen awareness of the stimulating factors in their environment. To ensure they do not suffer sensory deprivation, give them definite orientation measures, such as always mentioning the time of day and the day of the week in conversations with them. At the same time, they often must have overly stimulating factors reduced, such as the number of visitors, so that perceptions can be interpreted clearly.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Deficient diversional activity related to lack of appropriate toys and peers

Outcome Evaluation: Child demonstrates alert and interested attitude toward self-care and play activities.

Providing Stimulation for Children on Bedrest. Children on bedrest cannot secure materials for cognitive stimulation by themselves or participate in physical activities, except to a limited degree. A room where walls and windows offer no visual appeal and therapeutic equipment provides the only sound offers them little sensory stimulation. If no one comes into the room, they may suffer from social deprivation. When possible, encourage a child with restricted mobility to move out of bed into a wheelchair; this can provide some mobility and transportation to a place of interest, such as near a window or, in a hospital, near the nurses' desk. Watching television, a common activity for children on bedrest, provides little cognitive stimulation after the first 24 hours. Children can also be exposed to inappropriate programming if this is not carefully monitored (Powell, Szczypka, & Chaloupka, 2007).

Occasionally, a child must remain in bed to reduce stimulation for reasons such as to rest the heart or to increase kidney function, but generally bedrest is prescribed mainly to inactivate one part of the body, such as a fractured bone. When possible, other stimulation, such as a favorite toy, games, books, or simply talking with someone, must be provided for children to help them maintain physical bedrest; otherwise, they become bored and irritable and thrash and turn instead of lying still (Fig. 36.9).

If a child is home on bedrest and the bedroom is away from the main home activities, encourage family members to include the ill child in as many family activities as possible—bring the television set into the child's bedroom so the entire family gathers there, or set up a card table in the room so everyone can eat

FIGURE 36.9 Children on bedrest need stimulation. Here, a young child enjoys putting together a puzzle.

there—or encourage the child to join the rest of the family for activities by resting on the couch in the living room, a lounge chair in the backyard, or sitting in the kitchen. This principle applies to hospitalized children as well. To interact more easily, a toddler may rest in a parent's lap rather than in a bed.

Providing Stimulation for Children on Transmission-Based Precautions. Children who are placed on transmission-based precautions because of the possibility of contagious illness may experience severe sensory deprivation if everyone who enters the room must wear a gown and mask or if the number of visitors must be kept to a minimum. If gloves are part of precautions, a child can experience a significant loss of skin-to-skin contact as well. Transmission-based precautions are discussed in Chapter 43. Careful planning must be done to ensure that a child who is isolated this way is not psychologically isolated and that every possible measure is carried out to maintain sensory, social, physical, and cognitive stimulation. For example, try to visit with a child at a time in addition to those times in which you must perform procedures so you can simply talk; place the bed so the child can see out of the room; encourage the child to telephone or text message friends; make posters for the walls so they're no longer bare; or encourage interactive play such as electronic games. For ideas on providing stimulation to children in specific age groups, refer to Chapters 29 to 33.

Sensory Overload

Sensory overload, in contrast to deprivation, occurs when children receive more stimulation than they can tolerate or process. Children with sensory overload react similarly to those with sensory deprivation or feel confused, unable to make decisions, and feel severely fatigued. Sometimes it is difficult to determine the cause of these symptoms (whether they are caused by sensory deprivation or overload) unless assessed carefully.

The lights in ICUs, for example, are never turned out. Although children may find this comforting, it can also result in excessive stimulation. In addition to constant light, there is excessive sound such as the whir of machines, buzzing of ventilators, ringing of alarms, or mix of voices in consultation. Most ICUs have no windows because the wall space is used for monitoring equipment; therefore, night and day are not easily distinguished. It is easy for a child to become confused about time and place in such a setting. For children who are cared for at home in a family room where people talk constantly, the television is always on, and activity never ceases, sensory overload may also occur. An important nursing role is reducing sensory stimulation attributed to overload. Orient children to the time of day by making frequent references to it or by providing calendars and clocks. If necessary, provide eye covers or ear plugs to reduce stimulation.

PROMOTING PLAY FOR AN ILL CHILD

Play, often described as "the work of children," is an invaluable component of child health care. Providing a space and opportunity for play can help children feel more comfortable and allow for an important release of energy for children who are confined to a room or bed. Play also may be used to help assess children's level of knowledge and feelings about their condition so that more individualized nursing care can be planned. Depending on a child's age, play can also be a useful tool in health teaching (see Chapter 35).

Defining play is not a simple task because play activities vary greatly from child to child and among different age, cultural, and socioeconomic groups. A common definition is that play is any voluntary activity engaged in for the purpose of enjoyment. If a child views an activity as enjoyment, therefore, no matter what it is and whether it would be fun or not for an adult, it is play.

Play is clearly the means by which children develop increasing cognitive, psychomotor, and social capabilities. Touching a soft rabbit, passing colored blocks from one hand to the other, pounding with a plastic hammer, feeding a doll, and playing board games are all ways in which children are exposed to and learn about different textures and colors, experience the feeling of possessing and owning, and learn about competition, winning, and losing. A soft toy tells a child more clearly than can be described that this is what the word "soft" means. Colored blocks reveal how parts can join to make a whole, how things stacked too high will fall (there are limits one cannot go beyond), and practice makes perfect. As children talk with playmates during play, they develop both language and social skills. The repetitive acts involved in most games encourage the development of musculoskeletal skills. Play is not something children do when they have nothing else to do then; it is something children *have* to do. During illness, it provides a feeling of security because it is an activity that has continuity with everyday life.

The manner in which children play differs as they mature. Types of play and the age groups in which these types are seen most frequently are shown in Box 36.8.

Assessing Child Health Through Play

Children who are acutely ill do not play or play very little because they do not have the strength, the attention span, or the interest in activities required for play. They continue, however, to enjoy being read to, and they find comfort in holding a favorite toy even if they do not actively manipulate it. Once children are over the acute phase of an illness, interest in play returns. Whether a child is spontaneously playing, then, is a good index of health. The toys children use at play are a good indication of their growth and development level and emotional state.

The average parent knows a child's play preferences and current favorite game or toy. Asking for this information at a health interview helps to assess a child's developmental level and whether it is age-appropriate. It also helps to assess the quality of parenting (if parents view play as important or are familiar with the child's activities).

Providing Play in Ambulatory Settings

Children in ambulatory departments are under a great deal of stress. They sit in a waiting room and glance fearfully at the door that leads to the examining room. They hear children crying beyond the door and wait in terror for what lies in store for them when it is their turn.

BOX 36.8 ✻ Focus on Family Teaching

Understanding Different Play Types

Q. Becky's mother tells you, "When Becky was younger, she didn't like toys as much as the boxes they came in. What's normal for children and play?"

A. Children play differently at different ages. Examples of typical play patterns include:

Type of Play/Age	Description	Example
Observation/Infant	Child watches particular play intently, although not actively engaged in it.	Watching a mobile
Parallel/Toddler	Two children play side by side but seldom attempt to interact with each other.	Playing separately with similar push toy
Associative/Preschooler	Children play together in a similar activity; there is little organization of responsibilities	Engaging in typical backyard play
Cooperative/School-age	Children play with an organized structure or compete for desired goal or outcome.	Playing organized games with rules

Most parents know that when their child is coming to a hospital to be admitted, they should pack the child's favorite toy. Often they do not think of an ambulatory visit as a sufficiently threatening circumstance to warrant bringing a favorite toy, however, so the child has nothing to play with. Having a parent sit beside them is so comforting they may ignore or hesitate moving 4 feet away to get the toys furnished by the health care facility unless they are urged to do so.

It is best if ambulatory departments are stocked with toys that can be played with quickly and by single children. There should be a low table and chairs so a parent can come to a table and play with a child. Examining rooms should have toys also—they may be used to distract a child while a procedure such as an ear examination is performed, and because the wait in an examining room may be as long as the wait in a waiting room. Well siblings who accompany a parent and sick child to the facility can play with toys to distract them as well so that a parent can concentrate on the ailing child. Some hospitals furnish computer games for older children for this reason. Examples of ways that play can be used in an ambulatory care setting are shown in Table 36.6.

TABLE 36.6 ✻ Ways to Incorporate Play Into Ambulatory Nursing Care

Nursing Care	Play Activity
Aid with physical assessment	Distract child's attention with puppet during respiratory and cardiac assessment. Play "Simon Says" to encourage child to take deep breaths for respiratory assessment. Allow child to listen to own heart with stethoscope. Play "Follow the Leader" to assess gait. Draw a face on the tongue blade used to assess throat. Show child how to "blow out" the otoscope light. Draw child's outline on the table examining paper and give it to the child to take home to color.
Health teaching	Use puppets as teacher. Create word scrambles or crossword puzzles.

Providing Play in the Hospital

Ideally, all hospital units in which children are cared for should have a play space big enough for most of the children on the unit to come to. There should be enough space to accommodate children who are not fully ambulatory, such as those with casts or in wheelchairs (Fig. 36.10). Tables for board games and play materials such as crayons and paints should be available. Children can release a great deal of anger or tension by splashing water, squeezing or pouring sand, or smearing finger paint.

FIGURE 36.10 Children enjoying themselves in a hospital playroom, which is spacious and well equipped with age-appropriate toys and activities.

School-age children can play games such as shuffleboard or tossing sand bags for tension relief and competition. Adolescents enjoy table tennis and pool tables. A great deal of "play" in older school-age children and adolescents centers on conversation with peers.

Children who are hospitalized for 1 week or more may enjoy putting on a puppet show or playing school, store, or house. It is good if a corner of a playroom is devoted to this kind of imaginative play: a structure that will serve as a store front, puppet stage, house, or school, and dolls, cribs, empty food boxes and cans, and puppets are provided. Large blocks (6 × 12 inches) are available for playrooms so that such structures can be built and rebuilt each day. For ill children, the blocks are best if made of cardboard, not wood, because ill children tire easily when lifting heavier wood blocks. Table 36.7 lists games that require no equipment other than that readily available on a nursing unit for children who have brought nothing of their own to play with or who have grown bored with existing games.

Providing play equipment and supervision for a recreational play program in most instances is economically feasible through donations and volunteers. Generally, toys for a playroom can be secured through donations from clubs in the community. For safety reasons, children need to be supervised while they play. Because they do not feel well in a hospital or are shy in these different surroundings, they usually enjoy having a concerned adult to watch over them and suggest new activities. Such adults may be volunteers. Supervision is an excellent afterschool activity for members of a future nurses' club. Ideally, child support or play specialists supervise such play.

If play supervisors are unavailable through other sources, the nursing staff must free such personnel as necessary to lead play activities. This shows that play is important—for example, that supervising finger painting is as important a duty for assistive personnel as straightening beds, or that organizing a puppet show for long-term clients is as important as giving a bed bath. A clear sign that the nurses on a particular children's unit understand little about their young patients' needs is a locked playroom door and the explanation, "We have no one to staff it."

Providing Play for Children on Bedrest

Children who are on bedrest, at home or in a hospital, need to have play periods built into their day. The length of time for play and the toys individual children can play with depend on their age and physical and emotional states. Suggestions for play activities for children on bedrest are shown in Table 36.8.

Infants need toys in their cribs, such as mobiles, blocks, soft toys, and rattles. They also need to be out of cribs, sitting on a

TABLE 36.7 ✻ Games and Activities Using Materials Available on a Nursing Unit

Age	Activity
Infant	Make a mobile from roller gauze and tongue blades to hang over a crib.
	Ask the pharmacy or central supply for different-size boxes to use for put-in, take-out toys. (Do not use round vials from pharmacy; if accidentally aspirated, these can completely occlude the airway.)
	Blow up a glove as a balloon; draw a smiling face on it with a marker. Hang it out of infant's reach.
	Play "patty cake," "so big," "peek-a-boo."
Toddler	Ask central supply for boxes to use as blocks for stacking.
	Tie roller gauze to a glove box for a pull toy.
	Sing or recite familiar nursery rhymes such as "Peter, Peter, Pumpkin Eater."
Preschool	Play "Simon says" or "Mother, may I?"
	Draw a picture of a dog; ask child to close eyes; add an additional feature to the dog; ask child to guess the added part, repeat until a full picture is drawn.
	Make a puppet from a lunch bag or draw a face on your hand with a marker.
	Cut out a picture from a newspaper or a magazine (or draw a picture); cut it into large puzzle pieces.
	Pour breakfast cereal into a basin; furnish boxes to pour and spoons to dig.
	Furnish chart paper and a magic marker for coloring.
	Make modeling clay from 1 cup salt, 1/2 cup flour, 1/2 cup water from diet kitchen.
	Play "Ring-Around-the-Rosey" or "London Bridge."
School-age	Play "I Spy" or charades.
	Make a deck of cards to play "Go Fish" or "Old Maid"; invent cards such as Nicholas Nurse, Doctor Dolittle, Irene Intern, Polly Patient.
	Play "Hangman."
	Furnish scale or table paper and a marker for a huge drawing or sign.
	Hide an object in the child's room and have the child look for it (have the child name places for you to look if the child cannot be out of bed).
Adolescent	Color squares on a chart form to make a checker board.
	Have adolescent make a deck of cards to use for "Hearts" or "Rummy."
	Compete to see how many words an adolescent can make from the letters in his or her name.
	Compete to guess whether the next person to enter the room will be a man or woman, next car to go by window will be red or black, and so forth.
	Compete to see who can name the most episodes of "Star Trek" or "The Brady Bunch."

TABLE 36.8 ✻ Play Activities for Children on Bedrest

Care Measure	Play Activities
Bathing	Allow children to play in bath water with water toys. Play a game such as "I Spy" while giving a bed bath.
Encouraging fluid	Hold a "tea party" for a preschooler and drink "tea" with important but imaginary guests. Play a board game with a school-age child in which each turn starts with taking a drink. Draw a circle and let child color in a section each time a drink is taken. Play "Simon Says," in which Simon says, "Drink."
Deep breathing exercises	Have child blow soap bubbles in a glass of soapy water with a straw. Have child blow a cotton ball across the surface of a bedside table. Play "Simon Says," in which Simon says, "Take a deep breath." Allow the child to score points for reaching a high number on an incentive spirometer.
Muscle-strengthening exercises	Have children throw bean bags or large wads of paper (computer waste) at a wastebasket. Play "Simon Says," in which Simon says, "Raise your arms," and so forth. Have children throw and catch a ball. Have children squeeze and mold modeling clay. Encourage children to kick balloons suspended near foot of bed. Help preschoolers pretend they are butterflies, airplanes, and so forth.
Procedure such as blood transfusion	Save a favorite game or activity only for these times.
Health teaching	Use puppets as teacher. Make up board games, word scrambles, and crossword puzzles.

parent's or a nurse's lap, or sitting in strollers or swings. As soon as they are able, they need some time on the floor (with a sheet under them) to practice crawling or walking. At about 3 months, when infants discover their hands, those become that month's "toys." For a child learning to crawl or "cruise" or walk, that activity is the toy or interest for the month.

Toddlers need put-in and take-out types of toys such as blocks that can be repeatedly dropped into a bottle or that can be stacked to play with in bed. They enjoy listening to tapes of songs and nursery rhymes. Toddlers are in constant motion. They need to be out of bed as much as their physical condition allows, playing with take-apart, put-together, or pull-and-push toys. Preschoolers need creative materials such as modeling clay or sand. School-age children need quiet games such as books or crayons or markers by their bedside. While in bed, they enjoy radios, compact disk players, or tapes. Most activities for hospitalized children must be short-term projects because children are called away for treatments or procedures, and because when they are ill their attention span is shorter than usual. Short-term projects always appeal to the school-age child because they help this age child achieve a sense of industry.

Watching television is a nonparticipant activity, so it is not the best activity for children. There is some value in watching nature programs or "afterschool specials" on television that depict school-age children in real-life situations coping with problems common to the child's age group. Encouraging parents or friends to watch a game show with a school-age child and help the child guess the solution to a puzzle or watch "Sesame Street" with a preschooler can make the activity a participatory one. Watching a soap opera with an adolescent and then discussing the people and their problems can also turn television watching into active participation.

Safety With Play

Be certain to screen all toys for safety. They should be washable to prevent spreading disease, with no sharp edges and no small parts that could be swallowed or aspirated. A cylinder 1 inch in diameter, such as a rubber hot dog, is the most dangerous size for a toy because it totally occludes the trachea if it is aspirated. A toy smaller than this would cause only partial obstruction; something larger could not be inhaled into the trachea. As a rule, if a toy can fit through the center of a toilet tissue tube, it is too small for safe play.

Be certain toys offered will not lead children into danger. Tossing a ball to a toddler on bedrest is generally a safe activity. One who has a large cast in place, however, might lean over to retrieve a dropped ball and fall out of bed. Chasing a ball could lead to collisions with door frames or oxygen equipment.

If children become bored with a toy because it is not stimulating enough or they have had it for too long a time, they may begin to use the toy in an unsafe way. After toddlers grow tired of stacking blocks, for example, they may begin to throw them. Children who normally play safely with modeling clay but who are on a restricted diet may eat it because they are hungry. Knowing where children are and what activity they are engaged in at all times is the best prevention against unsafe play.

For the child cared for at home, parents may need to purchase new toys. This is especially true if the bulk of the toys they furnished previously were for outside play such as balls or rollerblades or skateboards. Because of an illness, they may now need to provide more "sit-down" toys such as markers, puzzles, or board games.

Child Support Programs

Child support programs are incorporated into all major children's hospitals and are an integral feature of child health care (Wilmot, 2007). As part of a child support program, a specialist offers children the opportunity to re-enact and thereby master the anxiety associated with illness. Through therapeutic play, child specialists provide programs that prepare children for hospitalization and, once hospitalized, prepare children for surgery or for procedures that could be painful. They consult with parents about good toys to choose for home care. These specialists help children air their frustration about painful or intrusive procedures, prevent social isolation of children by means of an active recreation program, and ensure that the total health care environment is conducive to children's well-being.

Such a program not only aids in promoting children's mental health but also leads to more cooperative responses of children to treatments or procedures. It is complementary to play programs initiated by nurses.

✔ Checkpoint Question 36.4

You worry about Becky aspirating a toy you give her. Which of the following items is most apt to be aspirated?

a. Pages in a coloring book.
b. Clothing from a baby doll.
c. Pieces of colored chalk.
d. Blocks 2 inches square.

Therapeutic Play

Anything almost automatically becomes less threatening when a person can talk about it. Many children cannot talk about what is happening to them during illness, however, because of fear or because their vocabulary is so limited they cannot describe their feelings.

Because play is the language of children, children who have difficulty voicing their thoughts in words can often speak clearly through play. **Play therapy** is a psychoanalytic technique used by psychiatrists to help children understand their feelings and thoughts and motivations better. In play therapy, the therapist attempts to interpret the child's verbal and nonverbal cues. Interpreting nonverbal cues and helping the child understand them this way requires the skill of a psychiatric nurse-clinician or others with specialized training. **Therapeutic play** is a play technique that can be used by nurses to better understand children's feelings and thoughts (William, Lopez, & Lee, 2007). For therapeutic play, only the child's verbal cues are used as responses.

Therapeutic play can be divided into three types:

1. Energy release
2. Dramatic play
3. Creative play

Energy Release

Children release energy by pounding, hitting, running, punching, or shouting. Furnishing children with materials that allow them to do these things helps them release anxiety as well. Toddlers pound pegs with a plastic hammer or pretend to cut wood with a toy saw. Other examples include giving modeling clay to a preschooler (an anxious child often pounds it flat; a relaxed child, however, will build it into shapes) or tying a balloon to an overbed trapeze for a school-age child or adolescent to punch.

Dramatic Play

Dramatic play is acting out an anxiety-producing situation. It is most effective with preschool children because they are at the peak of imagination. During illness, the situations about which children need to express feelings are illness related, and therefore the equipment needed for therapeutic play is common health care equipment: dolls, doll beds, play stethoscopes, intravenous equipment, syringes, masks, and gowns. Puppets of doctors, nurses, mothers, fathers, and children help young children express their feelings. Anatomically correct dolls are used to help children describe their feelings about sexual abuse.

It is good to have a play session with a child near the beginning of an illness to see whether the child communicates any fears about this experience through play. This initial session also serves as a way of preparing the child for events that will occur during the illness (Fig. 36.11). Repeat a play session after any painful or traumatic procedure such as surgery so that the child can express new feelings. A list of procedures that fall into this category is shown in Table 36.9. If such play sessions reveal fears, a child should be scheduled for other play sessions, perhaps once daily.

Furnish children with a wide range of equipment and then let them choose those items with which they wish to play. Children invariably choose a piece of equipment that has been used with them. They poke at a doll with a syringe or enjoy giving it a "shot." They wrap the doll in bandages or put tubes into its mouth or stomach, acting out things that were done to them or that they saw done to other children on a nursing unit or at a clinic visit they fear will be done to them. Allow play to be nondirective (let children proceed at their own pace, choosing freely what equipment to play with and what they want to do with equipment). As a child works through an experience this way, the experience becomes less fearful and the child gains increased control over it.

Observe for children who may be using equipment in an unusual way, such as hitting dolls with stethoscopes or poking them in the eye with a thermometer (suggesting they are

FIGURE 36.11 Therapeutic play allows children the opportunity to voice their fears of illness and procedures. (From Daemmrich/Stock Boston.)

TABLE 36.9 ✻ Therapeutic Play Techniques for Children After Procedures

Procedure	Play Activity (Provide a doll and. . .)
Radiograph	Table and box labeled "x-ray machine"; children sometimes worry that x-rays have injured them, just as laser rays in science fiction shows do.
Blood drawing	Syringe, alcohol wipes, tourniquet, or finger lancets; remember that finger sticks are as frightening for children as are needles.
Clean-catch urine	Alcohol wipes and a collection cup; children are often more embarrassed by urine collection than adults realize.
Intravenous therapy	Intravenous tubing, as well as restraints and armboard; some children are as angry about being restrained as having the needle inserted.
Endoscopy such as bronchoscopy, cystoscopy	Catheters or a penlight to simulate a scope
Scans	Intravenous fluid and tubing, because scans usually require the intravenous injection of isotopes
Bone marrow	Alcohol wipes, syringe
EEG, EKG	Electrode leads that attach to a box; children might be afraid of these procedures because of their fear of electricity.
Surgery	An anesthesia mask and a blunt kitchen knife; watch and listen for where the child cuts and how the experience is described.
Dental examination	Suction catheter, a penlight to simulate a drill, and a 4 × 4 piece of plastic to simulate a dental dam; some children are angered by the use of plastic in their mouth.
Dressing changes	Gauze and adhesive tape
Cast application or removal	Provide plaster to soak and apply; simulate a cast cutter with an electric razor or hair dryer.
Nasogastric tube insertion, enema, catheterization	Appropriate tubes
Temperature assessment	Thermometer

confused about the purpose of such equipment). Such behavior can alert you to the importance of explaining the purpose of equipment to children. Listen to what children say as they play. A comment such as, "I'm giving shots to all the bad dolls" suggests the child thinks injections are punishment. It would be important to stress the next time the child needs an injection that medicine is to make the child feel well again. A comment such as, "This doll is going to surgery, so you won't have her anymore" could suggest the child thinks she will not return from surgery (she may have heard a family member describe someone who died after surgery and is asking for reassurance that such a thing is not going to happen to her). Do not be surprised about the force with which children insert nasogastric tubes into dolls. In part, this reflects how they perceive these procedures, but it also represents energy or anxiety release, in the way that pounding or hitting releases anger.

To better understand how a child feels, repeat what the child says verbally: "You're giving the bad dolls shots?" or ask the child to tell you more about the activity: "Do you think that's the only kind of children who get shots—bad children?" Do not rush to reassure ("Don't worry, that isn't going to happen to you"). Quick reassurance tells children they should not ask any more questions or that the topic is not open for discussion.

Sometimes even children who seem well prepared may be taken by surprise during a procedure. For example, 7-year-old Tanya, seen in an ambulatory setting for a diagnostic workup after a urinary tract infection, showed little interest in dolls and syringes and tubing in the playroom. She had been prepared by her mother for the experience and seemed to understand what would happen during her x-ray procedure. After returning from the x-ray room, where she had a voiding cystourethrogram, however, she was obviously upset. Her nurse brought her a rag doll, a doctor and a nurse figure, a play x-ray machine, and some tubing that could simulate a urinary catheter and encouraged Tanya to play with them. Tanya picked up the girl doll and put her under the x-ray machine. She imitated the doctor doll shouting, "Pee in front of everybody!" Tanya's mother had not realized that she would have to void during a cystourethrogram and so had not prepared her for that. Tanya felt betrayed by not being really prepared for this embarrassing situation. Her play brought her emotion out in the open, where it could be talked about and handled. When Tanya was scheduled the next day for ureteral reflux surgery, her nurse was alerted to make the preparation absolutely thorough.

Children older than 9 or 10 years find playing with dolls too childish to be of benefit. They enjoy handling syringes, however, and being able to see and handle such equipment as nasogastric tubes in advance of their being placed. Active handling helps to eliminate fear because it identifies exactly what the child has to face; it meets their concrete-level learning needs.

Creative Play

Some children are too angry to be able to act out their feelings through dramatic play. However, they may be able to draw a picture that expresses their emotions or conveys the extent of their knowledge. To encourage this, give a child a

FIGURE 36.12 (**A**) Children who are concerned about body parts may draw pictures with that part missing or exaggerated. Note the missing left leg here. (**B**) After reassurance that her leg will be all right, the girl who did the drawing in *A* now draws a girl with two legs.

blank paper and crayons or markers. If a child seems reluctant to draw something spontaneously, suggest a topic: "Why don't you draw a picture of yourself?"

Some children are so concerned with particular parts of their bodies that when asked to draw pictures of themselves, they draw only the body part about which they are worried. Such children generally are saying they need to talk about that part of the body, to be given reassurance that it is going to be all right. Figure 36.12A shows a picture drawn by Becky when she was admitted to the hospital for 1-day surgery for debridement of a campfire burn on her left foot. She stated on admission she was being admitted to have the burn on her foot "cleaned out." This sounds like a child who understands what debridement involves. Note, however, that the figure she drew has no left leg. One has to wonder whether she was concerned she was going to surgery to have more than debridement. After the word "debridement" was explained to her, she drew the picture in Figure 36.12B. The child in the drawing now has a left and a right leg, the left leg covered by a bandage. Through a drawing, this child was able to say something she could not express without this help.

Many ill children draw pictures that reflect punitive images: a boy or girl tied to a bed or shut behind bars, or doctors and nurses frowning at them, obviously unhappy with them. Such children may need assurance that they are not being punished; they need to stay in bed or are being cared for by doctors and nurses to be made well (Fig. 36.13). Other children draw pictures that are symbolic of death: airplanes crashing, boats sinking, buildings on fire, children in graveyards. They need assurance that they will not die.

Other concerns such as fear of abandonment and loss of independence may also be manifested in drawings. For example, preschoolers may draw a child in one corner of a picture and an adult in a far corner. They may comment that the parent cannot find the child because she's gone to the hospital. They need to be reassured their parents know where

FIGURE 36.13 A picture drawn by a hospitalized child. Note the prison-like appearance of the crib. (Courtesy of Rita Crever.)

they are and although they're not there constantly, will visit them each day after work.

Older school-age children and adolescents may not be interested in drawing but can be interested in making a list of procedures or experiences they like and dislike. Examine the dislike list for procedures such as "shots" or "chemo." Mark the nursing care plan for nurses to take special time to explain these procedures and to offer special support when they must be done.

What if... While you're playing with her, Becky draws a purple person with only three body parts? Would this worry you? Why or why not?

Guidelines for Conducting Therapeutic Play

Use common sense when conducting therapeutic play. Be certain not to interpret a child's black and gloomy drawing as meaning the child is depressed; a black marker may have been the only one available. Many children 4 to 5 years of age draw a person lacking many body parts because that is the best human form they can draw.

Remember, too, that all children occasionally treat dolls badly. A 2-year-old pounding and banging a rag doll may not be expressing anger toward the doll image at all, but may be intent on discovering the feel of a new texture and is unaware for the moment that the object is a doll.

A conference with health care team members, including a psychologist or a psychiatric nurse specialist, may be called for if a child continues to express mutilating behavior after normal reassurance. Guidelines for conducting therapeutic play are summarized in Box 36.9.

Box 36.9 ✻ Guidelines for Therapeutic Play

1. Allow children to choose the articles with which they want to play (something may be too frightening for a child to play with immediately; more time may be needed to work up to the activity).
2. Provide the materials specific to the child's experiences of which you, the nurse, are aware such as a nasogastric tube, syringe, or bandages, but do not supply only those things; a child may have misunderstandings and fears of situations you cannot know about.
3. Allow play to be unstructured; let children use the materials however they wish. If a child seems uninterested in materials, initiate play such as giving a doll an injection to see if this reduces the child's anxiety enough to be able to handle items.
4. If a child cannot manipulate materials for some reason such as a large cast or traction, ask the child what would be good for you to do with an item.
5. Reflect only what the child expresses (verbal expression).
6. Do not criticize play; this inhibits further expression.
7. Use a therapeutic response—not "Don't worry, that won't happen," but "Are you worried that could happen?"
8. Ask children to describe paintings, not "That's a good picture of yourself," but "Tell me about your picture."
9. Do not be reluctant to use real equipment such as real catheters and blood lancets. Handling real equipment best helps to reduce stress.
10. Supervise therapeutic play, because some equipment could cause an accident (and therapeutically responding to the child's comments is necessary).

✔ Checkpoint Question 36.5

Becky will have a large bandage on her foot after surgery. Which type of therapeutic play would be best for her?

a. Letting her hold and handle a medicine syringe.
b. Giving her a doll and a bandage to change.
c. Helping her insert a nasogastric tube into a puppet.
d. Teaching her a rhyme about good girls.

Key Points for Review

- Illness may be more traumatic for children than for adults because of children's inability to communicate and monitor their own care and because they have different nutrition, fluid, and electrolyte needs. The stress of hospitalization can be so acute that it can result in posttraumatic stress syndrome.
- Separation from parents because of hospitalization can have permanent psychological effects on children. Methods to reduce this include keeping hospital stays as brief as possible, promoting open parent and sibling visiting, and providing primary or case management nursing.
- Currently, many medical procedures can be done on an ambulatory basis. Advocating for care to be done in such settings is a nursing responsibility.
- The presence of parents during health care can help reduce trauma to children. Making parents as welcome as possible in health care facilities makes it possible for them to room-in. Include parents in both the planning and the implementation of care. Parents reinfect children with fear if their own fear is not reduced.
- Preschoolers may have the most difficult time during hospitalization because they have so many fears. Preparation and promotion of therapeutic play may be essential to reduce trauma to a tolerable level.
- Because hospitalizations currently are so brief, parents need good discharge instructions to continue to care for children safely at home. Providing clear instructions including suggestions for play or how to avoid sleep deprivation is important.

CRITICAL THINKING QUESTIONS

1. Becky is the 7-year-old you met at the beginning of the chapter. Her foot was burned in a campfire accident. Since then she has refused to eat anything but Jell-O or soup. In the hospital playroom, she picked up a doll and tore off its leg. Her mother asked you why her daughter is acting this way. What suggestions would you make to her? The burn occurred because Becky was left momentarily unsupervised by a campfire. Is there a possibility her mother may not be acting her usual self because of guilt over the injury?
2. Suppose Becky's parents are called out of town on a family emergency, so Becky has no family with her for 3 days. What measures would you take to help make hospitalization and separation less traumatic for her?
3. Becky will be cared for at home after her surgery. Her mother is concerned that because Becky's home stay will be lengthy, she will be cut off from her friends for a long time. What suggestions could you make to help Becky maintain contact with her friends? Her mother is concerned she will become exhausted because of the need for round-the-clock care. What suggestions could you offer to make care easier?
4. Examine the National Health Goals related to care of ill children. Most government-sponsored funds for nursing research are allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to Becky's family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to care of ill children. Confirm your answers are correct by reading the rationales.

Chapter 37

Nursing Care of a Family When a Child Needs Diagnostic or Therapeutic Modalities

KEY TERMS

- aspiration studies
- barium contrast studies
- bronchoscopy
- clean-catch urine specimen
- colonoscopy
- computed tomography (CT)
- electrical impulse studies
- endoscopy
- gavage feedings
- magnetic resonance imaging (MRI)
- positron emission tomography (PET)
- radiopharmaceuticals
- single-photon emission computed tomography (SPECT)
- total parenteral nutrition (TPN)
- ultrasound

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe common nursing interventions used in the health care of children to aid diagnosis and therapy.
2. Identify National Health Goals related to diagnostic and therapeutic procedures for children that nurses could help the nation achieve.
3. Use critical thinking to analyze ways diagnostic and therapeutic procedures can be modified to be more family centered.
4. Assess children regarding developmental stage and knowledge level before beginning diagnostic or therapeutic procedures.
5. Formulate nursing diagnoses related to common diagnostic or therapeutic procedures used with children.
6. Identify expected outcomes for a child who needs a diagnostic or therapeutic procedure.
7. Plan nursing interventions to aid in diagnosis or therapy for children.
8. Implement nursing interventions relevant to diagnostic or therapeutic procedures such as preparing a child for magnetic resonance imaging.
9. Evaluate expected outcomes for achievement and effectiveness of care.
10. Identify areas related to nursing procedures with children that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of common diagnostic and therapeutic procedures with nursing process to achieve quality maternal and child health nursing care.

T.J. Balliff is a preschooler who is scheduled to have a magnetic resonance imaging (MRI) study because of a head injury. "How can I agree to this?" his mother asks you. "He's afraid of the dark. How can I allow him to be wheeled into a long dark machine that way?"

Previous chapters described the growth and development of well children. This chapter adds information about how to care for children who are having diagnostic or therapeutic procedures. This is important information because it builds a base for both care and health teaching.

How would you explain MRI to T.J.to make the procedure more acceptable to him?

Illness can be particularly stressful if many diagnostic and therapeutic procedures are necessary for care. In today's health care climate, there is less time for teaching and preparation than once available, so good planning and follow-through become essential when these are scheduled. Chapter 36 described measures to make an illness experience a more positive one. Health teaching, discussed in Chapter 35, is also a cornerstone in this process. Everything that nurses do with and for ill children can have a major influence on children's progress toward health as well as on children's and families' perception of professional health care and the ability to carry out healthful practices in the future (Shah & Ohlsson, 2009).

Many nursing actions offer an opportunity to accomplish several goals. Supporting a child and family during a diagnostic procedure, for instance, not only can aid in efficient diagnosis but also may help establish a trusting relationship between the family and health care providers that will make all future interactions more successful. This chapter describes the most common diagnostic and therapeutic techniques used in the care of ill children, including modifications needed to make these procedures safe and reduce associated stress, depending on the child's age and condition. National Health Goals that address this area of child health practice are shown in Box 37.1.

BOX 37.1 ✻ Focus on National Health Goals

A key component of minimizing the stress of hospitalization and procedures for children, and thereby maximizing safety, is to limit the length of time children spend in the hospital. Several National Health Goals address reducing the length of time that children spend in hospitals. One example is:

- Reduce hospitalization rates for three ambulatory care–sensitive conditions—pediatric asthma, uncontrolled diabetes, and immunization-preventable pneumonia and influenza—from baseline levels of 23 per 10,000, 7.2 per 10,000, and 10.6 per 10,000 hospital admissions to target levels of 17.3 per 10,000, 5.4 per 10,000, and 8.0 per 10,000 hospital admissions.

A major role of health care providers is to keep children free from disease so that they undergo a minimal number of procedures. A National Health Goal also addresses this:

- Increase the proportion of persons appropriately counseled about health behaviors (http://www.nih.gov).

Nurses can help the nation achieve these goals by providing health counseling to aid in preventing children from becoming ill and subsequently requiring hospitalization.

Areas related to these goals that could benefit from additional nursing research and application of evidence-based practice include determining what teaching techniques are most effective in keeping children well; what methods are efficient at ensuring that children's hospitalizations are as short as possible; and what techniques or supplies are most satisfactory to children when procedures are performed.

Nursing Process Overview

For a Child Who Needs Diagnostic or Therapeutic Procedures

Assessment

Before performing procedures such as assisting with a diagnostic test or collecting laboratory specimens, first carefully evaluate a child's age and developmental stage, as well as any special needs a child may have. Even the most common and painless procedures create a certain amount of stress for children and parents. During complex diagnostic procedures, this stress level is almost certain to increase even further. Unfamiliar doctors and nurses, high-tech supplies and equipment, and strange surroundings all add up to a frightening experience for most adults; imagine how frightening they can seem to children.

Assess a child's level of anxiety associated with unfamiliar equipment, circumstances, and surroundings as well as the child's knowledge concerning a technique before initiating a therapeutic procedure or beginning health teaching. Respecting a child's past experience with similar procedures can lay a foundation for knowledge and cooperation.

Nursing Diagnosis

Common nursing diagnoses related to diagnostic and therapeutic procedures are as varied as the procedures themselves. Some examples are:

- Fear related to new and strange surroundings of the procedure room
- Pain related to lumbar puncture
- Deficient knowledge related to technique for 24-hour urine collection
- Deficient diversionary activity related to hospitalization and lengthy procedures
- Imbalanced nutrition, less than body requirements, related to need for food restriction preprocedure and postprocedure
- Risk for injury related to need for intrusive procedures

Outcome Identification and Planning

As every procedure can result in even more stress than that caused by the primary illness, an important nursing goal is to cause the least degree of anxiety possible while completing interventions. To achieve this goal, plan specific ways to prepare children in advance, such as the best way to explain a procedure to a particular child. Also ensure the child is not overwhelmed by the number of diagnostic or therapeutic procedures performed in any one day. With small children, it may make more sense to stagger ambulatory diagnostic tests over several days to preserve a child's coping ability. Conversely, some older children (and parents) do better if they can complete all necessary tests in 1 day, so they do not have to anticipate more testing over a long period. Use nursing judgment and data from periodic assessments to help primary care providers determine the type of schedule that is in the child's and family's best interest. A helpful Web site to recommend for parents to help them prepare children for procedures is http://www.kidshealth.org.

Implementation

Whether assisting with a procedure or performing a therapeutic intervention, it is necessary to function in several roles at the same time: performing (or assisting with) the procedure, providing active support to the child and parents, and observing and then documenting the child's reactions. Providing support is a major role, and there are many ways to do this, such as holding a child's hand or placing a hand on the parent's shoulder. Playing a distracting game with an older child can also be helpful. Important observations to be made include signs of discomfort, changes in vital signs, or other signals of distress such as pallor or dizziness. Maintain a flow sheet of observations during a procedure. After a procedure the child's reaction, and specimens obtained can then be documented accurately and efficiently in the child's record.

As a final follow-through step, think of therapeutic play techniques to introduce that would be helpful in relieving stress caused by the procedure.

Outcome Evaluation

Evaluating expected outcomes related to diagnostic and therapeutic procedures not only helps in determining the effect of the procedure on a child but also aids in future planning, should other procedures be required. Recording that a particular child who did not appear nervous during a procedure later admitted to being "more scared than I've ever been before," for example, can help another nurse provide reassurance to this child, even when the child is masking emotions the next time. Examples suggesting achievement of expected outcomes are:

- Child says she is able to cope with second bone marrow aspiration.
- Child lists steps to take to collect 24-hour urine at home.
- Child participates in 1 hour of active exercise daily.
- Child eats a minimum of 1000 calories per day.
- Child experiences minimal loss of blood (less than 10 mL) during diagnostic procedure.
- Parent outlines plan to use alternative therapies to reduce the child's anxiety.

NURSING RESPONSIBILITIES WITH DIAGNOSTIC AND THERAPEUTIC TECHNIQUES

The most efficient way to reduce children's stress from hospitalization is to reduce the number of hospitalizations necessary. When hospitalization does become necessary, reducing the stress of the experience through being certain that procedures are carried out in the least stressful way possible is necessary. Responsibilities when assisting with procedures performed on children include:

- Helping obtain informed consent as needed
- Explaining the procedure to the child and the parents to be certain both are well informed
- Scheduling the procedure
- Preparing the child physically and psychologically
- Obtaining necessary equipment for the procedure
- Accompanying a child to a treatment room or hospital department where the procedure will be performed
- Providing support during the procedure using the least amount of restraint possible
- Ensuring adherence to standard infection precautions
- Assessing a child's response to the procedure
- Providing care to a child and specimens obtained once the procedure is completed
- Overseeing or cooperating with other health care disciplines to ensure the safety and efficacy of all procedures

Obtaining Informed Consent

Consent to perform a procedure must be obtained if a procedure carries any risk that would not be present if it were not performed. For a parent to sign a consent form, the parent must be knowledgeable about the content of the procedure and the risks of having or not having it performed. Although obtaining consent is the physician's responsibility, assuring that it is obtained is a nursing responsibility. Acting as an advocate for a family if they do not understand the consent form, the procedure, or the risks of the procedure is an important nursing role. Be certain the rights of emancipated minors are respected and that, in single-parent families, the custodial parent is the one who is asked to give the permission.

Explaining Procedures

To be able to explain procedures clearly and answer questions about them appropriately, try to observe as many procedures as you can. Asking children after any procedure what sensations they experienced can help children work through possibly frightening situations (often called "debriefing") and also increase your knowledge of common procedures (Wennstrom, Hallberg, & Bergh, 2008) (Box 37.2).

As a general guide, a child needs a detailed description of the procedure, such as, "I'll clean your finger. You will feel a small pinprick," as well as an explanation of:

- Why the procedure is being performed—for example, "The doctor needs to look at your blood to see why you're so sick."
- Where the procedure will be done—for instance, the radiography department or a treatment room
- Any unusual sensations to be expected during the procedure, such as, "Alcohol for cleaning your skin will feel cold."
- Any pain involved: "The needle will sting, although I'll put some cream on first to dull the feeling."
- Any strange equipment used, such as an x-ray machine
- The approximate length of time the procedure will take
- Any special care after the procedure—for example, "You will need to lie quietly for 15 minutes afterward."

Be certain to use age-appropriate language when explaining procedures. Also be careful not to use words that might be confusing during an explanation, such as "transducer" or "electrode," without defining them. Try to associate the procedure with something with which a child is already familiar and comfortable such as describing an x-ray machine as "a big camera." Try not to use the word "test" in explanations because school-age children associate the word "test" with a pass/fail situation. This can make them unduly worried after a procedure about whether they have "passed" it.

BOX 37.2 ✻ Focus on Evidence-Based Practice

Does "debriefing" help children adjust to surgical procedures?

Fear of separation, unfamiliar routines, anesthetic/operation expectations/experiences, and pain and needles are all potential sources of fear or worry in children. To see if perioperative discussions would help relieve stress, researchers selected 15 boys and 5 girls (aged 6–9 years) scheduled for elective day surgery. They collected data on the children's response to surgery by a tape-recorded preoperative interview, participant observations, and asking children to make a preoperative and postoperative drawing. Results of the study showed that the main problem children revealed was feeling forced into an unpredictable and distressful situation. Preoperatively, they did not know what to expect and did not like "breaking away from their daily routine." A common reaction was "trying to gain control" over the situation. During the perioperative period, the categories "losing control" and "cooperating despite fear and pain" were reported. Postoperatively, the categories "breathing a sigh of relief" and "regaining normality in life" emerged.

Based on the above, would it be important to talk to children about a surgical experience afterward or would it be less stressful if the subject wasn't brought up again?

Source: Wennstrom, B., Hallberg, L. R., & Bergh, I. (2008). Use of perioperative dialogues with children undergoing day surgery. *Journal of Advanced Nursing*, *62*(1), 96–106.

If you are unfamiliar with what a procedure entails, do not guess as nothing is more confusing to children or parents than being told two different versions of something. Most technical personnel will take the time to describe important information a child should know about a study or procedure to you so you can relay this to the child. Having a well-informed patient makes the technician's job easier. Be certain parents receive an explanation of the procedure as well as the child. A child has difficulty relaxing if parents are still anxious because they do not understand what is going to happen. Encourage parents to stay with a child during most procedures, because they can be extremely helpful in reducing a procedure's threatening aspects (Pruitt et al., 2008).

Scheduling

Most diagnostic procedures are scheduled on an ambulatory basis. Try to arrange for a child to have time for meals and some free play time between procedures. If food or fluid must be restricted for procedures, monitor the child's degree of discomfort and physiologic needs related to this; advocate as necessary for a time lapse between examinations or improved coordination in scheduling to decrease the time spent without food or fluid. Most of the time, small sips of water or ice chips are acceptable, depending on the procedure.

Preparing a Child and Family Physically and Psychologically

Physical preparation varies depending on what procedure is to be performed. In many instances, preparing a child for an examination such as a barium enema involves another procedure such as a saline enema, so physical preparation becomes education for the actual examination. In all instances, explain both the preparative and actual procedures. Appropriate explanations aid in reducing anxiety and fear.

For many procedures, especially those that may be painful such as a bronchoscopy (see section on Direct Visualization Procedures), children may be administered nitrous oxide (Farrell et al., 2008). Conscious sedation may also be used (Hertzog & Havidich, 2007). Conscious sedation refers to a depressed level of consciousness induced by the intravenous administration of a sedative such as midazolam in combination with a narcotic such as morphine sulfate and perhaps a hypnotic such as propofol. About 60 minutes before the procedure, children may be given oral chloral hydrate to relieve both apprehension and make them feel sleepy.

While under conscious sedation, children are able to maintain their ability to breathe independently and also respond appropriately to verbal commands such as to lift their head. They feel minimal pain, however, because of the analgesic administered. Conscious sedation is used in both ambulatory and inpatient settings. Before conscious sedation is begun, emergency equipment, including respiratory and pharmacologic measures, must be readily available. The child's level of consciousness and ability to respond, heart rate, respiratory rate, blood pressure, and oxygen saturation are monitored during the procedure. Using conscious sedation is very effective to allow children to accept a potentially painful procedure emotionally and physically. If this is used, be certain a child is prepared both for the diagnostic procedure and for the use of conscious sedation.

Accompanying the Child

If a procedure will be done at a different site from the primary care clinic or hospital unit with which a child is comfortable, ideally a nurse whom the child knows should accompany the child as well as a parent to the other department and remain with the child for the procedure, or at least until the child has met a primary person who will be responsible for the procedure. Having a parent accompany a child is of additional invaluable help. Older children do well with being accompanied by only a nursing assistant as long as they have been introduced in advance to the new person who will give them care.

Before leaving the child's patient care unit or clinic, have the child void for comfort unless this is contraindicated. Check for any medication or specific assessment procedures such as a blood pressure recording that should be given or done before leaving the unit for another department, in case the child is away from the primary unit for an extended time. If a child is an inpatient, check also that the identification band is securely in place and readily visible despite any intravenous equipment. If there will be a considerable wait in another department, ask children if they would like to bring along an activity such as a game or book. Hallways can be cool. Provide adequate blankets for comfort, especially for infants. Always use cart straps and side rails for safety.

Providing Support

Children do well with diagnostic and evaluative procedures as long as they have adequate support from a concerned provider or parent. Try to provide this both verbally (explain what is going to happen; assure the child everything is going well) and nonverbally (a hand on the arm or a nearby presence).

Modifying Procedures According to a Child's Age and Developmental Stage

A child's age and potential understanding of procedures must be considered when planning the number and order of tests and the way they are performed.

The Infant

The number of painful or uncomfortable procedures done on infants should be kept to an absolute minimum to avoid interfering with an infant's developing sense of trust. Parents should be allowed to accompany their infant to hospital departments and remain during procedures to offer support. Some parents may ask to hold their child during a procedure that causes pain, but do not ask parents to restrain the child during such a procedure. Their role should be a supportive and comforting one, not a policing one.

Infants become dehydrated quickly so the time they can remain NPO for procedures must be limited. You may need to advocate for time for breastfeeding before and after procedures for both an infant's and mother's comfort. If a procedure continues longer than 3 to 4 hours, provide the mother a room in which to use a breast pump, if needed.

Infants need to be picked up and comforted after procedures (a child of any age likes a hug or honest compliment for cooperation). It is important that obtaining blood specimens (which can deplete an infant's small blood stores) and x-rays (which are possibly harmful to immature bone marrow) are also kept to a minimum in infants. Help parents understand why these procedures are being limited so they do not think their infant's care is being compromised by so few diagnostic procedures.

The Toddler and Preschooler

Toddlers and preschoolers resist any diagnostic testing that involves any degree of discomfort or pain or that is unfamiliar to them. Give children of this age short explanations of what to expect, close to the time of the procedure, so that little time can be spent worrying about it. Try to associate any new equipment with things which they are already familiar.

The School-Age Child and Adolescent

School-age children are interested in the theory and reason for procedures. Often they can be persuaded to cooperate for a procedure by being promised a look at their radiograph or a point-of-care meter readout afterward. Be careful to ensure that viewing the results is actually possible before promising this to children; otherwise, it can be difficult to obtain any further cooperation. Adolescents may project an air of maturity or sophistication beyond their years to remain in control of themselves in the face of frightening procedures. Do not be misled into thinking a child this age would not appreciate an explanation or a comforting hand on a shoulder during a procedure.

What if... A 14-year-old adolescent who is scheduled for a series of diagnostic tests, says, "I'm not a kid, you know," and refuses to listen when you start to explain a procedure? Later, he acts angry because he has been "tricked" into having the procedure. How could you give explanations to him without offending him? What do you think is the basis for his actions?

Promoting Safety During Procedures

Safety is an important component of all patient care. Children's immaturity, which makes them unable to form mature judgments, leaves them vulnerable to harm unless their caretakers give special consideration to promoting safety during procedures.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for injury related to diagnostic procedures

Outcome Evaluation: Child remains free of injury from diagnostic equipment.

As a basic safety measure, before giving any food or performing any procedure, read the name on a child's identification armband. If an armband must be removed because it interferes with an intravenous infusion site, cut it away but immediately anchor it to another extremity with adhesive tape. Ask the admissions department to provide a new armband as soon as possible. Do not leave the old one off while waiting for a replacement band; this leaves the child susceptible to the danger of mistaken identity during the waiting period.

Because of their natural curiosity, children tend to fuss with equipment to see what will happen if they turn a knob or spin a dial. This means they need close monitoring while procedures are performed to ensure they do not touch any buttons or in other ways accidentally harm themselves. After a procedure, be sure to remove all equipment from a room. Children may pick up scissors or forceps left at bedsides and injure an eye; syringes and needles can cause puncture injuries. They may drink antiseptics such as alcohol or povidone-iodine left at bedsides and poison themselves. Young children can choke on small objects such as needle covers.

Use of Restraints

The purpose of a restraint is to keep a child safe during a procedure. Always use the least amount of restraint necessary and apply with care, because if improperly applied, restraints can cause extreme stress and possibly more harm than help (Brenner, 2007). Children can have difficulty distinguishing between restraint and punishment, so restraint should never be used more often or for any longer a time than necessary. Be certain parents receive an explanation of why their child

has a restraint in place—for example, because of a particular danger of this procedure, it is safer for their child.

If restraints are in place, check them every 15 minutes to be certain they are not occluding circulation; remove them temporarily every hour so the body part can be exercised (provided the exercise does not dislodge a device or interfere with a treatment). No part of a child's body other than that which is necessary should be restrained. When infants have scalp vein infusions in place, such as for injection of a radioactive isotope for a nuclear medicine scan, for example, their arms may need to be immobilized so that they do not touch the infusion site. Their trunk may need to be immobilized so they do not turn. Their lower extremities may not have to be restrained, however, so they can still actively kick and exercise. When a nurse or a parent is with a child, in most instances, all restraints can be removed.

Various types of restraints are described in Table 37.1 and shown in Figure 37.1.

Providing Care After Procedures

After a procedure, assess how well a child reacted to the procedure by both observation and history. Allowing children to explain what happened helps them retrace the procedure in their mind so they can conquer their fear of it. Fill in gaps in information as necessary to improve a child's perception of

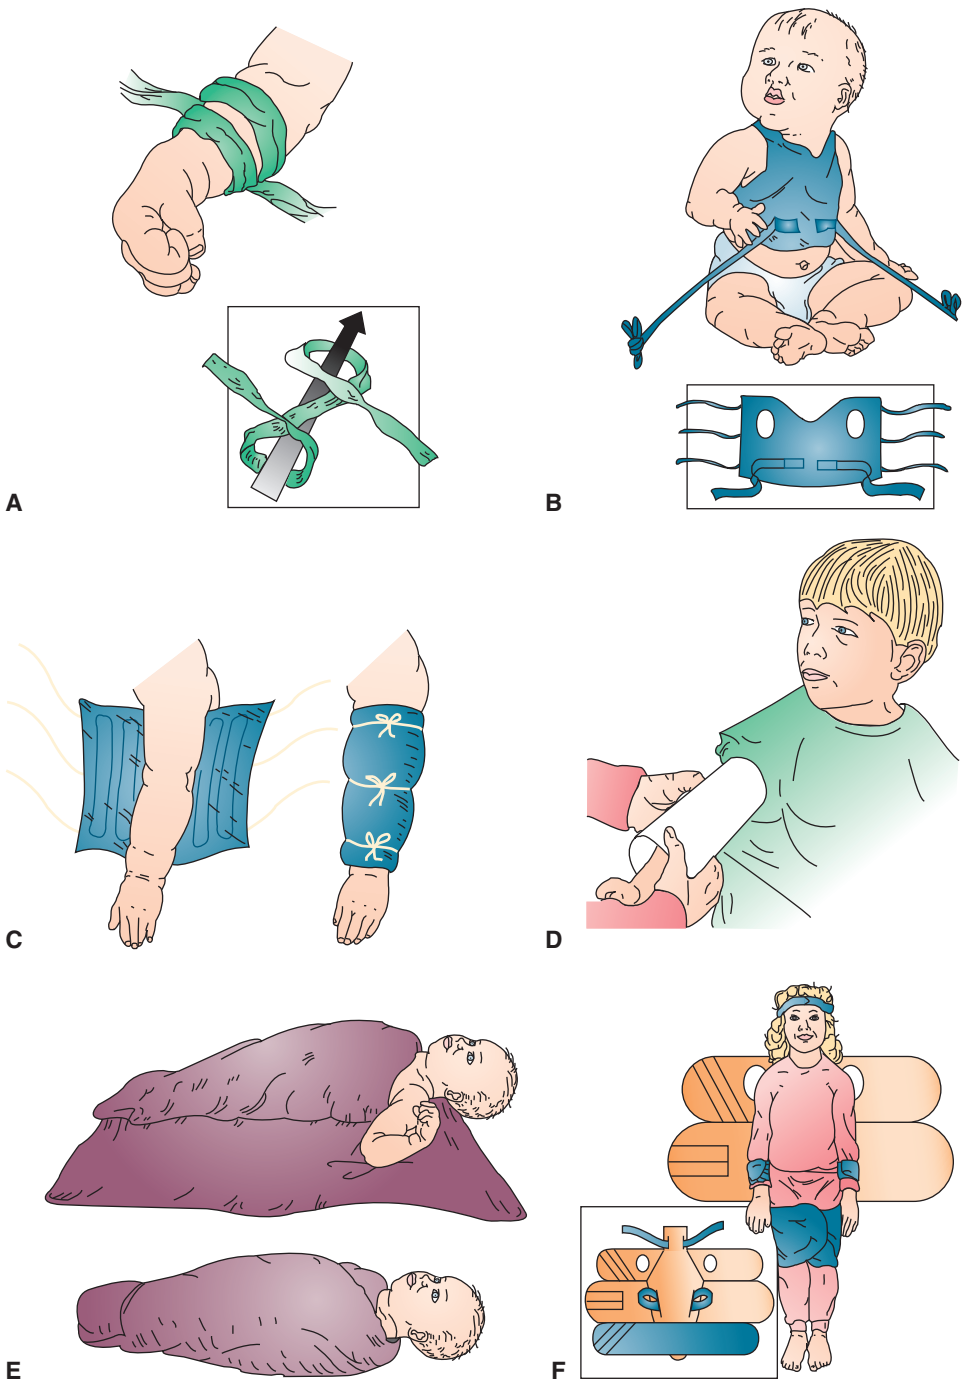

FIGURE 37.1 (**A**) Clove hitch restraint. (**B**) Jacket restraint. (**C**) Elbow restraint. (**D**) No-No sleeve or commercial elbow restraint. (**E**) Mummy restraint. (**F**) Papoose board.

TABLE 37.1 ✻ Safety Restraints

Type of Restraint	Purpose	Method
Wheelchairs and carts	Promote safety while transporting children to and from a procedure. Remind children to stay in a wheelchair while being transported. Prevent children from rolling off a cart while being transported.	For a wheelchair, use a vest restraint. Attach straps to the frame of the wheelchair with enough slack so the child has some mobility. For a cart, fasten a restraining belt and raise the side rails. Even with restraints in place, never leave a child unattended in hallways outside departments in a wheelchair or on a cart. Not only is this unsafe because the child may attempt to get down from the cart or wheelchair, but the anxiety of waiting in a strange department for a procedure is too acute for him or her to handle.
Clove-hitch restraints	Secure one arm or leg for a procedure, such as an intravenous infusion.	Use disposable restraints, gauze, or soft muslin tape. Soft muslin tape "gives" a little if the child exerts pressure against it so it will not pull too tight and reduce circulation or cause pain. Tie the restraint as shown in Figure 37-1A. If a child struggles against restraints, fold several layers of soft gauze around the wrist or ankle under the restraint. Secure the restraint to the underpart of the bed. Never tie restraints to side rails: when a side rail is lowered, it will jerk the child's arm or leg and possibly cause an injury. Release arm and leg restraints whenever someone can be with the child to keep the limb in the desired position.
Jacket restraints	Restrain children younger than 6 months in a supine position. (This method is not effective with older children because they are too active: they maneuver so much that they may squirm out of the jacket or put so much pressure on the trachea that they suffocate.)	Fasten the ties at the back of the jacket. Tie strips attached to the sides of the jacket under the mattress to keep the child in one position (see Fig. 37-1B).
Elbow restraints	Prevent children from touching the head or face—for example, during scalp vein infusion or after cleft lip or cleft palate repair.	Use a double-layered piece of soft muslin, which has pockets wide enough to fit tongue depressors. Place pockets vertically. Wrap the restraint around the child's arm. Secure the restraint with ties, tape, or pins (see Fig. 37-1C). It may be necessary to pin the restraint to the child's undershirt to prevent slippage. If No-No sleeves, a commercial elbow restraint, are used, slip the No-No sleeve up over the infant's arm and secure it by the Velcro strips (see Fig. 37-1D). The baby should wear a long-sleeved infant shirt under the sleeve to prevent irritation. Observe the child to be certain the sleeve is not too tight that it interferes with circulation.
Mummy restraints	Temporarily immobilize young children for a procedure involving the head, neck, or throat—for example, during insertion of a nasogastric tube or drawing blood.	Use this only for the duration of the procedure because it is a total body restraint. Follow the steps shown in Figure 37-1E. If the child is exceptionally strong, a few safety pins can be used to hold the restraint even more firmly. For the infant who needs continuous observation for respiratory function, fold the mummy restraint so the chest is exposed. For newborns or infants, use a "Papoose Board," a commercial restraint used in the same way as a full or mummy restraint (see Fig. 37-1F).

Activity:	Description:	Score:
Activity	Able to move four extremities	2
	Able to move two extremities	1
	Able to move no extremities	0
Respiration	Regular, able to deep breathe/cough	2
	Dyspnea, limited and obstructed breathing	1
	Apneic	0
Circulation	BP within 20 mm Hg of preprocedure	2
	BP within 20–25 mm Hg of preprocedure	1
	BP 25 mm Hg above preprocedure level	0
Level of consciousness	Awake, alert	5
	Drowsy, but easily aroused	4
	Stupor, aroused by vigorous stimuli	2
	Responds to pain only	1
	No response to pain	0
Skin color	Pink, warm, dry	2
	Pale, dusky, blotchy, clammy	1
	Cyanotic, diaphoretic, cold	0
Ambulation	Ambulates with minimum help	5
	Ambulates with minimum support	4
	Unable to ambulate	2

FIGURE 37.2 Post-Anesthesia Recovery Score. A passing score is at least 10 with a level of consciousness score no lower than 4. (From Tolia, V., et al. [2000]. Sedation for pediatric endoscopic procedures. *Journal of Pediatric Gastroenterology and Nutrition, 30*[5], 477–485.)

the procedure. Providing therapeutic play is another measure to reduce anxiety (see Chapter 36).

Be certain tissue samples obtained after a procedure such as bone marrow aspiration are sent to the proper department for analysis as soon as possible. Guard against specimens being dropped or improperly labeled; children do not have extra body fluids such as blood to sacrifice for additional specimen collection.

If conscious sedation was used, be sure children are awake before they are discharged home or return to an inpatient hospital unit. Using a postanesthesia score sheet (Fig. 37.2) is an effective method to rate recovery from anesthesia.

Children can be discharged as soon as 30 minutes after conscious sedation if they are awake and oriented, the airway is patent and respiratory status is stable (no retraction, stridor, or wheezing), oxygen saturation is 95% or greater in room air, and blood pressure, heart rate, and respiratory rates are appropriate for age, and the child is reasonably free of pain.

Parents often have questions about what care their child will need after they return home. Tips for parents following conscious sedation are highlighted in Box 37.3.

BOX 37.3 ✻ Focus on Family Teaching

Care After Conscious Sedation

Q. T.J.'s mother asks you, "My son received conscious sedation for his MRI. What special care will he need when he comes home?"

A. Here are some tips to help you when you get your son home:

- Keep in mind that most children sleep after leaving the ambulatory care facility or hospital. Some are sleepy for the remainder of the day.
- Do not allow the child to walk alone for at least 4 hours. The child may suddenly feel dizzy and fall without warning.
- Wait until getting home to give the child something to eat or drink, to avoid car sickness. Conscious sedation may cause children to feel nauseated more easily than usual.
- For the first 12 hours after the child wakes, do not ask him to do any activity that requires alertness, coordination, or balance, such as riding a bicycle, swimming, or doing homework. The sedative can affect the child's coordination and balance.
- Remember that the child may forget things readily for the rest of the day. This forgetfulness should go away after a night's sleep.
- Keep in mind that a sedative may cause children to behave in unexpected ways, such as losing self-control or becoming very emotional. By the next day, the child's behavior should return to normal.
- Give infants clear liquids (water, apple juice, tea) after getting home. Wait approximately 30 minutes to make sure the child does not choke or vomit. Then milk, formula, or other foods may be given.
- Do not allow children to drink until they can hold a cup without help, to make sure they are awake enough to keep from choking. Wait approximately 30 minutes. If there is no vomiting or choking, the child can be given food.
- Call your primary care provider if the child has pain or recurrent vomiting, or if any of the effects above last for more than 12 hours.

✔ Checkpoint Question 37.1

You are going to restrain T.J. to obtain a blood sample from his hand. What type of restraint would be best?

a. Ask his mother to hold him tightly on her lap.
b. Apply a jacket restraint to confine his body.
c. Ask a fellow nurse to hold his hand firmly.
d. Use a mummy restraint so he can't be hurt.

MEASURING VITAL SIGNS

Vital signs for children consist of temperature, pulse, respiratory rate, blood pressure, and pain assessment. All of these need to be recorded both conscientiously and with knowledge of the child's underlying condition so they can be analyzed meaningfully. Be especially alert that assessing any of these measures is not enough; if they are abnormal or if a child has pain, a measure to relieve the problem needs to be initiated (Schiavenato, 2008). Appendix G shows the average pulse rates, respiration rates, and blood pressures for children of different ages, as these differ according to the size and age of the child. Pain assessment is discussed in Chapter 39.

Temperature

Normal temperature values in children are the same as in adults: axillary, 97.6° F (36.5° C); oral or tympanic, 98.6° F (37.0° C); and rectal, 99.6° F (37.6° C). Thermometers that assess tympanic membrane temperature are ideal for assessment in children because they register within 2 seconds and therefore cause less fear in a child because a child has to be restrained for only a few seconds (Fig. 37.3A). Tympanic membrane temperatures may not be effective in newborns because of the vernix still present in their ears.

Newborns should not have their temperature taken rectally because of the danger of damaging their rectal mucosa with a thermometer; it should be taken by the axillary route instead (see Fig. 37.3B). Because preschoolers generally fear intrusive procedures, consider taking axillary or tympanic temperatures in children until 4 or 5 years of age.

For a tympanic temperature recording, insert the tip of the tympanic thermometer gently into the child's ear canal. Straighten the ear canal by pulling down on the earlobe in a child younger than age 2 and pulling up on the pinna of the child older than age 2. This directs the sensor beam toward the center of the tympanic membrane and not the sides of the canal. Tympanic membrane temperature is not affected by the presence of earwax, so it gives consistently accurate results. By 4 years of age, children are usually old enough to close their mouth sufficiently for oral temperature recording by an electronic thermometer.

For an axillary recording, place the tip of an electronic thermometer in the axilla and hold the child's arm down to the side to keep the thermometer firmly in place until it registers. For the rare occasions when a rectal temperature must be taken, insert a thermometer only to the length of the bulb (½ inch) in infants and not over 1 inch in older children, and hold it in place for 5 minutes.

Pulse Rate

As children grow older, the heart rate slows and the range of normal values narrows. If possible, measure a child's pulse rate at rest. An apical pulse (listening at the heart apex through a stethoscope) is taken in children younger than 1 year because their radial (wrist) pulse is too faint to be palpated accurately. In an infant, the point of maximum intensity, or the point on the chest wall where the heartbeat can be heard most distinctly, is just above and outside the left nipple (just lateral to the midclavicular line at the third or fourth intercostal space). This point gradually becomes more medial and slightly lower up to 7 years of age. By 7 years, it is at the fourth or fifth interspace at the midclavicular line. For greatest accuracy, count the pulse rate for 1 full minute.

Respiratory Rate

Respirations also should be measured before an infant is disturbed because the respiratory rate increases with crying. Take this while a child is sitting in a parent's lap or lying quietly in a crib before lowering the side rail if possible. Infants tend to breathe with their abdominal muscles; therefore, it is as accurate to take respirations by counting movements of the abdomen as it is to count chest movements. Again, for greatest accuracy, count respirations for 1 full minute.

Blood Pressure

Blood pressure is included in the routine physical assessment of all children older than 3 years of age. Offer a good expla-

FIGURE 37.3 Temperature taking. (**A**) Tympanic membrane temperature. (**B**) Axillary temperature.

nation of the procedure, especially to young children, because wrapping their arm and applying pressure can be frightening if they are not prepared for it.

Systolic pressure in children is read as the manometer pressure is dropping, at the moment that sound first appears. The point at which the sound disappears is considered the diastolic pressure. Blood pressure is difficult to measure in infants because of mechanical problems. The cuff used should be no more than two-thirds and not less than one-half the length of their upper arm; a wider cuff (larger bladder size) gives a lower reading and a narrower cuff gives a higher reading (Fig. 37.4). Doppler ultrasound blood pressure recording is especially effective with infants. This technique bounces high-frequency sound waves off body parts; the rate and pitch at which they return depends on the density of the body part that is struck. If a Doppler lead is placed over an artery, either the movement of the blood (pulse wave) or its tension (blood pressure) can be registered on a digital readout or monitor print. Doppler examinations can be adapted to broadcast the sound of the pulse waves for auscultatory assessment.

Electronic blood pressure recording is most helpful when a continuous assessment is necessary, but it can be used for a single recording. Watching the digital readout numbers is interesting for preschoolers. Electronic pressure readings are typically 5 mm Hg higher for diastolic and 10 mm Hg higher for systolic blood pressure compared with auscultatory techniques (Brayden, Daley, & Brown, 2008). Direct measurement (intra-arterial monitoring by an indwelling catheter into the radial or femoral artery) is used with children who are critically ill. This technique is reviewed in Chapter 41.

Lower extremity blood pressure can be obtained by wrapping the cuff over the thigh and palpating or auscultating the popliteal pulse (posterior knee). In infants younger than 1 year, the thigh and arm blood pressure should be equal. In children older than 1 year, the systolic pressure in the thigh tends to be 10 to 40 mm Hg higher, while diastolic pressure remains the same. If the thigh blood pressure reading is lower than that in the arm, suspect that coarctation of the aorta or an interference with circulation to the lower extremities may be causing this.

FIGURE 37.4 Measurement of blood pressure is essential during routine health assessments and before diagnostic or therapeutic procedures. Here a nurse assesses a child's blood pressure in preparation for a procedure.

When assessing blood pressure, be certain to pay attention to the pulse pressure—the difference between systolic and diastolic readings. Both unusually wide (more than 50 mm Hg) or narrow (less than 10 mm Hg) ranges may suggest congenital heart disease. An abnormally narrow pulse pressure, for instance, is a sign of aortic stenosis. An abnormally low diastolic pressure (causing a wide pulse pressure) occurs with patent ductus arteriosus.

REDUCING ELEVATED TEMPERATURE IN CHILDREN

Fever is such a common symptom in children that reducing temperature or giving a parent instructions on how to reduce a child's temperature at home is a common intervention with children.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for hyperthermia related to illness affecting temperature regulation, medications, or surgery

Outcome Evaluation: Child's temperature returns to 98.6° F (37° C) orally within 2 hours.

Because the temperature-regulating mechanism in children is immature, fever tends to be more marked in children than in adults and may even be out of proportion to the seriousness or extent of their disease. An increased temperature occurs because a child's temperature-regulating point (set point) has been elevated. The child's temperature cannot be reduced until the set point returns (or is returned) to normal.

Tylenol and Motrin are excellent antipyretics, so they are the drugs most often prescribed to reduce fever in children (Boxes 37.4 and 37.5).

BOX 37.4 Focus on Pharmacology

Acetaminophen (Tylenol)

Action: Used for moderate temperature elevation or pain; does not have anti-inflammatory properties (Karch, 2009)

Pregnancy risk category: B

Dosage: Oral: 10–15 mg/kg every 4–6 hours as needed; may repeat 4 or 5 times per day; do not exceed 5 doses in 24 hours

Possible adverse effects: Elevated liver enzymes, jaundice, rash

Nursing Implications

- Caution parents that drug can cause severe liver toxicity with overdose.
- Educate parents not to administer a larger dose or more frequently than prescribed.
- Encourage parents to increase the child's fluid intake to aid in reducing fever.

BOX 37.5 * Focus on Pharmacology

Ibuprofen (Advil, Pediaprofen)

Action: Used to reduce inflammation, fever, and mild to moderate pain

Pregnancy risk category: B; D if used in last trimester

Dosage: (for fever or pain) 5–10 mg/kg every 6–8 hours; do not exceed 40 mg in 24 hours

Possible adverse effects: Gastric upset, headache, dizziness, nausea, occult blood loss, prolonged bleeding, peptic ulceration

Nursing Implications

- Use with caution in children with gastrointestinal irritation.
- Drug can cause renal failure if child becomes dehydrated; encourage fluid intake.
- Administer with food or drink to minimize gastrointestinal irritation.

Parents often do not give an adequate dose of an antipyretic such as acetaminophen because they are afraid their child will have a bad reaction to it. This results in the high fever continuing. Encourage them to give a full dose of the antipyretic every 4 hours, up to five doses a day, until their child's temperature is reduced. Teach parents that fever is actually a body protection measure, and unless it is exceptionally high (more than 106° F [41.1° C]), it does no specific harm. In fact, there is some evidence that fever may be of value in helping to combat infection, because it aids in destroying microorganisms (Edwards et al., 2007). For this reason, caution parents that fever itself is not harmful so they don't give too high a dose of an antipyretic or a severe overdose where liver or kidney toxicity can occur (Karch, 2009). An antipyretic is generally ordered for any child whose oral or tympanic temperature is more than 101° F (38.4° C) or whose rectal temperature is more than 102° F (39.0° C). Caution parents not to give acetylsalicylic acid (aspirin) to children with fever because aspirin is associated with Reye's syndrome, a severe neurologic disorder (see Chapter 49).

In addition to antipyretic administration, parents should dress children with fever in lightweight clothing, such as summer pajamas. Remove all clothing but the diaper from an infant. Many parents dress febrile children warmly in flannel nightgowns to keep them from "getting a chill." This actually increases the child's temperature and does not prevent the shaking, trembling reaction that comes with high fever. Placing a cool cloth (not ice) on a child's forehead can feel comforting. Although sponging children to lower temperature may be effective in a small group of children, it is no longer recommended for children as a whole, because it can lead to extreme chilling and shock to an immature nervous system and has little advantage over the use of oral antipyretics (Meremikwu & Oyo-Ita, 2009).

Caution parents that common antipyretics for children's fever taste like candy. Be sure they know to lock antipyretics away or children can help themselves to more "candy" when a parent's back is turned.

COMMON DIAGNOSTIC PROCEDURES

Diagnostic and therapeutic procedures used with children vary depending on a child's condition and age but are similar to those used with adults. Blood, urine, and stool studies are commonly ordered. Respiratory illnesses require special procedures; these are discussed in Chapter 40 with respiratory disorders. Biopsies (surgical procedures to remove tissue for examination) are discussed in Chapter 53. Stress testing for cardiovascular pathology is discussed in Chapter 41.

Electrical Impulse Studies

Electrical impulse studies are those that include electrical conduction. Children need special preparation for studies such as electrocardiograms (ECGs; Fig. 37.5) or electroencephalograms (EEGs) because they have been warned not to play with electric wires and so may worry about being burned or electrocuted. They can be reassured that the electricity passes from their body to the machine, not the other way around; except for electromyelograms (study of the conduction paths of the spinal cord), children can be assured that these tests are painless. Electrodes are attached to the body by paste, which is easily removable. If possible, give the child a portion of the test strip afterward as a souvenir.

X-Ray Studies

A variety of x-ray studies are used to inspect internal body tissues. These range from simple x-rays to the more complicated computed tomography (CT) scan or dye contrast study.

FIGURE 37.5 Administering an ECG. Children can be assured this is a painless procedure. (From John Watney/Photo Researchers, Inc.)

FIGURE 37.6 Positioning of a child for an x-ray. (© Bachmann/Stock Boston.)

Flat-Plate Radiographs

Radiographs are used both to diagnose illness and check the placement of apparatus such as gastrointestinal feeding tubes. As a rule, children accept radiographs well because an x-ray machine can be compared with a camera, an instrument with which they are familiar (Fig. 37.6). Caution children that although you or a parent may be able to accompany them to the x-ray department, you will not be allowed to stay in the room while the picture is actually taken. If it is necessary for you to remain in the room to restrain a child, do not do this without lead apron and lead glove protection. Such protection is also necessary for portable radiographs taken at a child's or infant's bedside.

Dye Contrast Studies

To visualize a body cavity, some type of radiopaque dye may be swallowed or injected into the cavity and then examined on radiography. **Barium contrast studies,** for example, are used to observe the outline of the gastrointestinal tract. Barium may be swallowed to outline the upper gastrointestinal tract or instilled by enema to outline the lower portion. Caution a child that barium, even if flavored, does not taste terribly good. In studies such as an intravenous pyelogram (IVP), dye is injected intravenously; as it circulates to the kidneys, a radiograph is taken. Because iodine is incorporated in most radiopaque material, be sure to check whether a child is allergic to iodine before the procedure. When the dye is injected, the child may feel a hot flush, a sensation that can be frightening if the child is unprepared for this. Try not to use the word "dye" while describing the procedure to prevent young children from worrying they will be dyed like an Easter egg or will "die." Say "medicine" instead.

Children easily grow bored during this type of procedure because of the time involved waiting for the dye to reach the specific organ to be studied. Have the child take along an activity to make the time pass faster. If children are not allowed to eat for the duration of a long procedure, be certain that they receive supervision or else, not realizing the importance of this, they may decide to snack. Ensure that parents understand that children do not "radiate" x-rays or radioactivity after the procedure, so they will not be afraid to hold a child closely for comfort.

Computed Tomography

Computed tomography (CT) is an x-ray procedure in which many views of an organ or body part are obtained to represent what the organ would look like if it were cut into thin slices. As with any radiograph, dense structures appear white and less dense structures appear gray to black on the films.

The procedure may require injection of an iodine-based contrast medium. If a radioisotope is added, the study is referred to as **positron emission tomography (PET)** or **single-photon emission computed tomography (SPECT).**

Because a CT scan involves so many films, it is a lengthy procedure. The machinery is complex, large, and potentially frightening (Fig. 37.7A). Children must lie still during the long procedure to avoid creating shadows on the film. To help them lie still for an extended period, they may be given a sedative such as chloral hydrate before the procedure to make them sleepy. Conscious sedation also may be used. You

FIGURE 37.7 Some procedures are potentially frightening because of the size of the machinery used. (**A**) A CT scanner. (From Alexander Tsiara/Photo Researchers, Inc.) (**B**) An MRI scanner. (From Richard Nowitz/Photo Researchers, Inc.)

can assure parents that although the radiation exposure from CT scans occurs over a long period, such low doses are used that the actual exposure is comparable to a regular x-ray. Repeated CT scans, however, can carry a threat of excessive radiation exposure (Rice et al., 2007).

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) combines a magnetic field, radiofrequency, and computer technology to produce diagnostic images to aid in the diagnosis of disorders such as the cause of renal or brain pathology (Akpinar, Koroglu, & Ptak, 2007). The child lies on a moving pallet that is pushed into the core of the machine—the magnet (see Fig. 37.7B). When the magnetic field surrounding the child is turned on, it causes tissue atoms to line up in a parallel fashion. As radio waves are turned on and off, the atoms change position. This change is sensed and converted into a visual display on a computer screen.

The procedure has an advantage over radiography in that it has no apparent ill effects, it can reveal astonishingly clear structural defects in soft tissue, and if a contrast medium is required, it is not iodine based, so the danger of a reaction is minimal. Because metal may deflect the magnetic waves, children with a metal prosthesis or metal dental braces may be poor candidates for the procedure. Hairpins and eye makeup (which often has a metallic base), watches, or other jewelry or medals should be removed. Be certain a child's hospital gown does not have a metal snap at the neckline.

When the radio waves are turned on and off during the procedure, a booming noise occurs. Prepare children for this sound (often compared with the sound of drums) as well as the feeling of claustrophobia they may experience (see Focus on Nursing Care Planning Box 37.6). Because the procedure may take up to 45 minutes, some children need a sedative or conscious sedation so they can lie quietly for the duration of the procedure. Newer, more open MRI machines are able to alleviate the feeling of claustrophobia associated with the procedure.

Ultrasound

Ultrasound is a painless procedure in which images of internal tissue and organs, such as the appendix, are produced by the use of sound waves (Gracey & McClure, 2007). Because it is noninvasive, children accept ultrasound easily and may even enjoy watching the oscilloscope screen during the procedure. The transducer that is used on the body surface to pick up internal images can be compared to a television camera (Fig. 37.8). Be certain that parents understand that ultrasound is not an x-ray and appears to have no long-term effects, so it can be repeated over and over for serial determinations. Alert a child that a clear gel will be applied to the skin over the body part to be studied to aid sound conduction. The gel can feel cold and sticky.

Nuclear Medicine Studies

Radiopharmaceuticals are radioactive-combined substances that, when given orally or by injection, flow to designated body organs. When a scintillation machine (a form of Geiger counter) is passed over the organ where the radiopharmaceutical has collected, the pattern of the collected material outlines the organ; the pattern can be produced as a screen image or a photograph.

Parents may worry that a child will be harmed by such exposure to a radioactive substance. You can assure them the dose of radiation in these studies is no greater than that used for a diagnostic radiograph, so this is not a danger. Tagged iodine (iodine-131) is frequently the medium used for such studies. A danger of iodine is that it will go immediately to the thyroid gland rather than the organ to be studied when injected intravenously, with the result that enough concentrated radioactivity could accumulate to destroy the thyroid gland. For this reason, a blocking agent such as potassium perchlorate that prevents thyroid gland accumulation may be given prior to the test. This prevents the radioactive substance from concentrating in the thyroid, thereby protecting the gland. Always check whether a blocking agent is required before transporting a child to the nuclear medicine department.

Direct Visualization Procedures

Direct visualization procedures involve the observation of an internal body cavity by way of a thin tube inserted through a body surface opening. Types of direct visualization include endoscopy, bronchoscopy, and colonoscopy.

Endoscopy

Endoscopy involves an endoscope passed through the mouth to examine the gastrointestinal tract. It has become a common method of diagnosis for gastrointestinal disorders in children. When first developed, endoscopes were straight, stiff, metal instruments, so their use was limited. Currently, endoscopes are fiberoptic (using a flexible, easily maneuvered, brightly lit tube), so these examinations have become more common and certainly not as uncomfortable as before.

The procedure is often frightening, however, as manipulation is necessary. A child can easily understand an explanation of the procedure (the physician will extend the child's head and pass a tube down into the child's stomach for direct observation), but the child is uncomfortable at the thought of someone doing it. Children are placed on nothing by mouth (NPO) status for about 4 hours before the procedure. They may need a sedative or conscious sedation so they can lie quietly for the time needed. Good support during the procedure is also important. Ask whether a child can have a digital photograph taken during the procedure to keep as a souvenir. Endoscopy is also used as an emergency measure to remove objects such as quarters or safety pins swallowed by children.

After an endoscopy study, edema may occur from the pressure of the scope on the esophagus and pharynx. This means that the child requires close observation afterward to be certain edema is not interfering with a vital function such as respiration or causing discomfort. After the procedure, it is important to check that the child's gag reflex has returned before offering any fluid to drink. Observe closely the first time the child drinks after the procedure to ensure that the gag reflex is intact despite throat edema from the procedure or the effect of a local pharyngeal anesthetic that may have been sprayed into the throat before the procedure.

Bronchoscopy

Bronchoscopy is the direct visualization of the larynx, trachea, and bronchi through a lit, flexible, fiberoptic tube (a

BOX 37.6 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Child in Need of Diagnostic Tests

T.J. Balliff is a preschooler who is scheduled to have a magnetic resonance imaging (MRI) study for a possible head injury.

Family Assessment ✻ Child lives with single-parent mother in two-bedroom loft in refurbished inner-city warehouse. Mother is a commercial artist. Rates finances as "healthy."

Client Assessment ✻ Child was playing at community playground with nanny. Was pushed off top of slide by another child. Fell approximately 6 feet onto head. Brought to ER by mother. Neck brace applied. T = 100.6 tympanic; P = 90; BP = 100/65. Crying from pain in neck and upper back. "How can I agree to an MRI?" his mother asks you. "He's afraid of the dark. How can I allow him to be wheeled into a long dark machine?"

Nursing Diagnosis ✻ Anxiety (child and parent) related to necessary diagnostic procedure

Outcome Criteria ✻ Mother listens to explanation of advantages of MRI for diagnosis of head, neck, or spine injury. Voices agreement to allow procedure. Helps prepare child for anxiety-filled experience.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Assess by history if child has change of behavior from usual.	Review with parent that traumatic events can affect all body systems.	Head injury, if severe, can affect vital signs and thinking.	Parents states she feels child is reacting normally except for neck pain.
		Consultations		
Physician	Complete physical and neurologic exam. Assess if further neurologic consultation will be necessary.	Consult as necessary with neurologist about child's condition and continued care based on MRI findings.	A 6-foot fall could cause considerable intracranial swelling depending on whether child broke fall or not.	Neurologist on call completes necessary consult and any needed additional procedures.
		Procedures/Medications		
Nurse	Assess what medicine child is usually given for pain.	Administer acetaminophen per physician order to child.	Relieving pain is a prime responsibility with injured children.	Child swallows oral analgesic without complications.
Pain management nurse	Assess if child has past allergies or reactions to any medication.	Prepare child and administer conscious sedation.	Conscious sedation will allow child to sleep during an otherwise frightening procedure.	Child and mother consent to conscious sedation. Sedation is used during procedure without complication.
Nurse	Assess which MRI technician is available for procedure.	Meet with MRI technician to review child's fear of the dark.	Reducing children's fears often requires a multidisciplinary approach.	MRI technician takes active measures to try to reduce fear during procedure.
		Nutrition		
Nurse	Assess last time child ate or drank.	Keep child NPO prior to procedure.	Conscious sedation can cause aspiration in children with full stomachs.	Child remains NPO until postprocedure.

(continued)

BOX 37.6 ✻ Focus on Nursing Care Planning (continued)

		Patient/Family Education		
Nurse/nurse practitioner	Assess parent's understanding of the need and technique of MRI.	Fill in gaps of knowledge for parent about procedure.	A well-informed parent is able to make well-informed decisions about care.	Mother states she understands why procedure is needed. Signs procedure consent.
		Psychosocial/Spiritual/Emotional Needs		
Nurse/pain management nurse	Assess if child is mature enough to understand increasing increments.	Ask child to rate his pain by a FACES pain scale.	As pain is a subjective symptom, self-rating best reveals its nature.	Child uses pain scale to establish a baseline preprocedure and again postprocedure.
Nurse	Assess if child is still frightened from bullying episode at playground.	Review with child that bad things happen to good people.	Discussion of an accident can help to relieve guilt and increase self-esteem.	Child discusses what happened; states accident was not his fault.
		Discharge Planning		
Nurse/physician	Assess if parent understands importance of assessing child's temperature and pulse every 4 hours after return home.	Review with parent technique for temperature and pulse assessment.	An increasing temperature and decreasing pulse rate can indicate increased intracranial pressure.	Parent confirms she will be able to take vital signs accurately; will notify ER if vital signs vary from norms given her.

bronchofiberscope). The procedure is used with children who have aspirated a foreign object such as a peanut or to take culture and biopsy specimens (Righini et al., 2007). Before the procedure, the child may be given atropine by injection to reduce bronchial secretions and to encourage bronchial relaxation. Typically, the throat is sprayed with a local pharyngeal anesthetic to numb the area. Because the procedure can be frightening and this makes it difficult for a child to cooperate, a sedative or conscious sedation usually is administered. Any manipulation of the airway has the potential to cause increased bronchial secretions and edema, leading to narrowing of the airway. Therefore, closely observe the child's respiratory function and airway for at least 4 hours after the procedure. An ice bag applied to the neck often helps reduce the possibility of edema and relieve throat discomfort. Assess for the presence of a gag reflex before offering any oral fluids to the child after the procedure. Observe children carefully the first time they drink after the procedure to be certain their gag reflex is intact and they do not choke.

FIGURE 37.8 Ultrasound can be potentially frightening for children. Seeing the image on the television screen helps to relieve their fright. (From Simon Fraser/SPL/Photo Researchers, Inc.)

Colonoscopy

Colonoscopy is endoscopic examination of the large intestine with a flexible fiberscope inserted through the anus and advanced as far as the ileocecal valve. Air is then infused to expand the bowel walls. The technique allows the colon walls to be visualized; if abnormalities are found, photographs can be taken for analysis. It is used to diagnose inflammatory bowel disease or obtain biopsies if a malignancy is suspected (de Ridder et al., 2007).

Before the procedure, children are given a clear liquid diet for about 24 hours. Then they are given an isotonic saline laxative that causes fluid diarrhea so their bowel is clean for the procedure. It can be difficult for younger children to drink as much of the laxative solution as is needed to clear their bowel completely of stool. Playing games such as "Simon Says" can be helpful to gain their cooperation. If the laxative cannot be taken, a saline enema may be necessary. Conscious sedation is used during the procedure to reduce discomfort.

If done on an ambulatory basis, children are discharged about 2 hours after the procedure (keep them NPO during that time to allow the bowel to have a brief rest). Children may pass a great deal of flatus in the first 12 hours because of the air introduced during the procedure. Be certain parents have instructions on what to observe for after they return home: abdominal pain, blood in stool, weakness, or paleness (signs of bowel bleeding) especially if a polyp was removed or a biopsy specimen was obtained. Even with conscious sedation, colonoscopies are difficult procedures for children to accept. Give generous praise afterward for their cooperation with both the preparation for the procedure and the actual procedure.

Aspiration Studies

Aspiration studies (removal of body fluids by such techniques as lumbar puncture or bone marrow aspiration) are always anxiety-causing procedures; just looking at the size of the needle that will be used is frightening. Children may need a sedative or conscious sedation so that they can lie quietly. Support and restrain them by talking and using touch as appropriate. Assess for bleeding at the puncture site after the procedure and apply pressure as needed to halt bleeding completely (see Chapters 49 and 44 for specific procedural details).

COLLECTING SPECIMENS FOR ANALYSIS

The collection of body fluids, secretions, and excretions is a collaborative nursing function essential to the complete assessment of a child. Elements of these fluids can be measured by a variety of means and compared with baseline standards of health. Findings may be used to help diagnose an illness, evaluate the progress of a condition, or evaluate a child's response to therapy. As with all procedures, use of standard infection precautions is essential when obtaining, transporting, discarding, or storing specimens.

Obtaining Blood Specimens

Never underestimate how frightening obtaining a blood specimen can be to a child. For many children, their experience with losing blood has involved a nosebleed or a cut knee, which they remember as causing discomfort or pain. They have had injections for immunizations also, so they know that injections sting. Putting the two experiences together makes having blood withdrawn an extremely frightening procedure. For this reason, always obtain blood specimens away from a child's bedside if possible to try to keep the bed a "safe" area. A child also needs good preparation and support during the procedure.

Venipuncture

Even for very small infants, the usual sites for venipuncture (entrance into a vein) are the same as for adults: the superficial veins of the dorsal surface of the hand or the antecubital fossa. In a few instances, the jugular or femoral vein can be used (Fig. 37.9). Apply EMLA cream before venipuncture if possible to reduce pain (see Chapter 39), and use distraction techniques such as "I spy" or blowing bubbles generously (Windich-Biermeier et al., 2007). Children need a simple explanation of what will be done: "I need to take some blood from your hand. First, I'll put some cream on your skin. Then in a little while, when I come back to get the blood you won't even feel a pinprick because of the cream." Let the child know you understand how difficult it is to agree to the procedure. A statement such as, "No one likes to have blood taken; I'm going to do this as quickly as possible" is always a better approach than, "Be a big girl" or "Come on, show me how much of a big boy you can be." The second approach shames a child who is unable to hold still. Try not to use the phrase "drawing blood." This sounds as if an activity with crayons is being proposed, not a procedure with some discomfort (Box 37.7).

FIGURE 37.9 Positioning for jugular venipuncture. An infant's head is held sideways over the edge of the table by one nurse, while his body is restrained by a second nurse.

BOX 37.7 * Focus on Communication

T.J. is a 4-year-old who is going to have several diagnostic studies. He's coloring a picture when you approach him to obtain a blood specimen for electrolyte levels.

Less Effective Communication

Nurse: Hi, T.J. Is it all right if I draw some blood?
T.J.: Okay.
Nurse: Hold out your arm for me.
T.J.: Are you drawing on me?
Nurse: I'm going to wipe off your arm, then prick your skin. (T.J. begins crying.)
T.J.'s mother: He thought you meant you were going to play with him.

More Effective Communication

Nurse: Hi, T.J. Because you're not feeling well, I need to take some blood from your arm.

The nurse in the first scenario makes two mistakes in introducing a procedure: making the activity seem like a game and also asking for permission to carry it out. In the second scenario, the nurse takes a little more time to both explain what she needs to do and why it is important. It is easy to forget that what a word means to you may not be interpreted the same way by a young child.

Preschoolers may have to be restrained for blood sampling, because no matter how cooperative or brave they might be initially, the minute they see the needle, they can be too overwhelmed with fear to hold still.

Capillary Puncture

Capillary blood heel or fingertip punctures are often obtained for glucose and hematocrit determinations. The technique is described in Box 37.8. For fingertip punctures, be certain to use the side of the finger, not the center, to reduce discomfort afterward; for heel punctures, use the lateral aspect of the heel to avoid striking the medial plantar artery or the periosteum of the bone. Apply EMLA cream before the procedure to reduce discomfort if possible. Comfort the child afterward, as puncture techniques can be as painful as venipuncture (Shah & Ohlsson, 2009). In many settings, laboratory assessments such as glucose can then be completed immediately using a commercial meter (a point-of-care or POST test). Be certain when completing POST tests that you document completely and accurately, as your documentation, rather than a technician's, will serve as the only basis for continuation of or a change in care.

Obtaining Urine Specimens

Depending on the type of test required, urine may be collected with a usual voiding, after the external meatus has been cleaned (a clean-catch specimen), by catheterization, or by suprapubic aspiration. A specimen may require a single specimen or collection of all voidings in a 24-hour period.

Routine Urinalysis

Routine urinalysis requires only a single voiding specimen. The specimen will then be analyzed for appearance, glucose, specific gravity, and microscopic analysis. Specimens must be collected in clean containers to prevent contamination.

The Infant or Toddler. A child who has not been toilet-trained cannot be expected to urinate on command, so it is necessary to attach a collecting device to a girl's perineum or a boy's penis and scrotum to collect the next voiding. Be certain to wash and dry the site where the collecting device will be attached to ensure good adherence (Fig. 37.10A). If an infant attempts to loosen the collector, cover the device with a diaper to keep it out of reach. Otherwise, leave it visible so that it can be observed for voiding. Offer the child something to drink. Most infants void shortly after a feeding, so if the collector is applied just before a regular feeding, voiding will probably result soon afterward. Remove the collector as soon as the infant voids and transfer the specimen to a specimen cup by cutting a bottom corner of the bag.

Urine may be aspirated from diapers for tests such as specific gravity, dipstick protein, pH, or glucose. Even with disposable diapers, this does not pull enough lint into the specimen to change its specific gravity (see Fig. 37.10B). With disposable diapers, urine tends to be pulled into the diaper, so it is best available for testing if the diaper is torn apart. Placing cotton balls inside the diaper can be a help because they can be squeezed for additional urine. Although not an ideal method for urine collection, urine extracted from a disposable diaper can also be analyzed for bacteria for urinary tract infections. Note on the laboratory form how the urine specimen was obtained.

The Preschooler or School-Age Child. It may be difficult to obtain routine urine specimens from preschoolers or toilet-trained toddlers because they can void only when they feel a definite urge to do so, not on command. Another problem is language. It is not unprofessional to use words such as "pee-pee" if this is what the child will understand. Provide a potty chair if one is available; if not, put a urine collection cap device on a toilet. A generally successful approach with a child this age is to act as if voiding is not a difficult procedure. Offer the child a glass of water or other fluid, and ask a parent to reinforce the request to void so that the child knows a parent approves. Do not encourage children to drink more than one glass of fluid to induce voiding, however, or else their urine production may be so diluted that the specific gravity, protein, and glucose levels can be inaccurate. A school-age child is usually able to void when asked, although the child may find it more difficult than the adult.

The Adolescent. Adolescents are usually knowledgeable and cooperative about providing urine specimens. As with adults, give them a clean specimen container and tell them what is needed. Unless they have voided recently, they usually are able to void on command. Remember, however, that adolescents are concerned and self-conscious about body functions and therefore are often reluctant to carry a urine specimen through a crowded waiting room to the desk area. They may be too self-conscious to void if they know someone is nearby—just outside a curtain, for example. Send them to a nearby bathroom with a closed door, or leave the area to give them privacy.

Some adolescents are suspicious that a urine specimen is being requested for drug testing. Providing a good explanation of its actual purpose relieves this fear. If you are in doubt regarding whether the fluid returned to you is urine, not water, assess its specific gravity. Water has a specific gravity of 1.000; urine will have a specific gravity more than this (1.003 to 1.030).

Adolescent girls may be embarrassed to mention they are menstruating. Be sure to question an adolescent girl about this so the presence of any red blood cells in a urine specimen can be explained. To avoid having a urine specimen contaminated by menstrual blood (which changes the specific gravity, protein, and red blood cell analysis), ask the girl who is menstruating to wash her perineum well with soap and water and rinse and dry it to remove menstrual blood. Next, supply a sterile cotton ball for her to insert gently into her vagina just before voiding (and remove again following voiding). Mark the specimen "possibly contaminated by menstrual blood" even though it does not appear discolored, because red blood cells may be present microscopically.

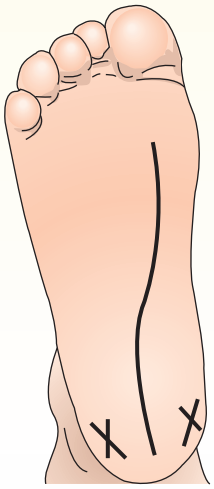
Twenty-Four–Hour Urine Specimens

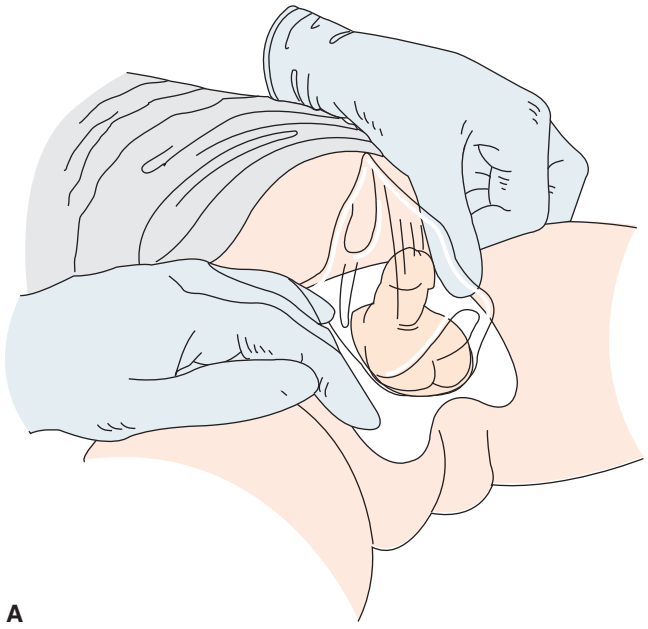
Although urinalysis of a single urine specimen will indicate the presence of substances such as protein or glucose, a 24-hour urine specimen may be necessary to determine how much of a substance is excreted during a day (quantitative analysis). To begin a 24-hour urine collection, ask a child to void (with an infant, attach a collecting bag and wait for the child to void). This specimen (the discard specimen) is then thrown away so that a specific time for the ensuing collection

Box 37.8 Nursing Procedure ✻ Technique for fingertip or heel capillary puncture

Purpose: To obtain a blood sample from a peripheral capillary.

Procedure	Principle
1. Wash your hands; identify child; explain procedure to child.	**1.** Prevents spread of microorganisms from you to child. Confirms you are performing procedure on the right child. Promotes safety and well-being.
2. Assess status of puncture site.	**2.** Site must be warm and free of lesions.
3. Analyze appropriateness of procedure; adjust plan to individual circumstances.	**3.** Nursing care is always individualized based on professional judgment of client need.
4. Plan and give health teaching and preparation information as necessary.	**4.** Health teaching and preparation is an independent nursing action always included in care.
5. Assemble necessary equipment: gloves, alcohol swab, lancet, collecting capillary blood tube, dry compress or cotton ball, adhesive bandage.	**5.** Organization and preparation help conserve energy and maximize efficiency.
6. Assess the temperature of the selected site. Fingertips and heels must be warm. Warm by holding finger or heel in your hand for a moment or two. Warming heels or fingers by immersing them in warm water or covering with a warm compress is not advised.	**6.** Although warmth helps to dilate vessels and allows blood to flow more freely, warm water methods increase the flow of blood so much that values become comparable with arterial, not venous, values.
7. Select the exact puncture site: sides of tip of finger; right or left of medial artery of heel (see figure below). Allow child to choose finger if appropriate.	**7.** Using the child's nondominant hand avoids the child from having to use the tender finger on dominant hand afterward. Allowing choices adds to child's feelings of control and self-esteem.
8. Apply gloves. Swab site with alcohol and allow to dry. Puncture with a quick thrusting movement; wipe away first drop of blood with dry cotton ball.	**8.** Allowing the alcohol to dry prevents burning from the puncture. Wiping away first drop prevents contamination or dilution of the specimen.
9. Hold heel or finger lower than proximal extremity; touch capillary tube to blood drop and tip to encourage flow. Do not squeeze tissue around site.	**9.** Capillary action will quickly fill the collecting tube; squeezing causes tissue injury.
10. After filling required number of blood tubes, apply dry compress to site; apply adhesive bandage.	**10.** Applying dry compress to site halts bleeding.
11. Label specimen appropriately and send to proper laboratory for analysis.	**11.** Labeling and prompt transport ensure continuity of care.
12. Evaluate effectiveness, efficiency, cost, safety, and comfort aspects of procedure; record procedure and child's reaction.	**12.** Evaluation determines effectiveness of care. Documentation provides evidence of nursing care and the child's status.





A

B

FIGURE 37.10 (**A**) Urine collector for infants. The trick to making the collector adhere is to be certain the child's skin is dry. (**B**) Testing specific gravity of urine with a refractometer. The advantage of this is that only one drop of urine is required.

is known. If the urine collection was started early in the morning and this first specimen was counted as part of the collection, the urine collected during the next 24 hours would include urine that had been forming all night, resulting in an approximately 32-hour collection period that would distort the analysis.

Record the start of the collection period as the time of the discarded urine. Save all urine voided for the next 24 hours and place it in one collection bottle. Have the child void (or watch for an infant to void) at the end of the 24-hour period and add the final specimen to the collection bottle. Record the time of the collection as being from the time of the discarded urine to the final specimen added to the collection.

For an infant, use a 24-hour rather than a single specimen urine collector. These types of collectors will adhere for this length of time only if a child's perineum is thoroughly dry at the time of application. Apply tincture of benzoin or a commercial product to toughen the perineal skin and make the skin somewhat tacky. Doing so helps to ensure the collector firmly adheres to the skin and also eases removal of the collector. After the collector is applied, place an infant in a semi-Fowler's position, if possible, to encourage urine to flow freely into the collector. Make certain the tubing from the collector is pinned out of the infant's reach or the infant may pull the collector free. It may be necessary to place a diaper on the infant to keep the apparatus out of sight. Provide activities; make sure the parents understand that they can pick up infants and hold them during this time, as long as they take care not to kink or pull the tubing.

To keep the bacterial count to a minimum, 24-hour collections are generally kept on ice or poured into a container that is then refrigerated during the 24-hour period until they can be transported to the laboratory for analysis.

With active infants, fitting them with a colostomy bag applied to cover the urinary meatus may be more effective than using a collector with tubing (Fig. 37.11). Puncture a small hole in the corner of the top of the bag. Insert a small feeding tube through this into the bottom of the bag and then apply the bag to the child's perineum. When the child voids, attach a syringe to the feeding tube and aspirate the urine. Transfer the specimen to the collection bottle. The advantage of this type of urine collector is that it allows a child to be ambulatory. For the active toddler, this collector may be the only type that is acceptable to obtain a day-long specimen.

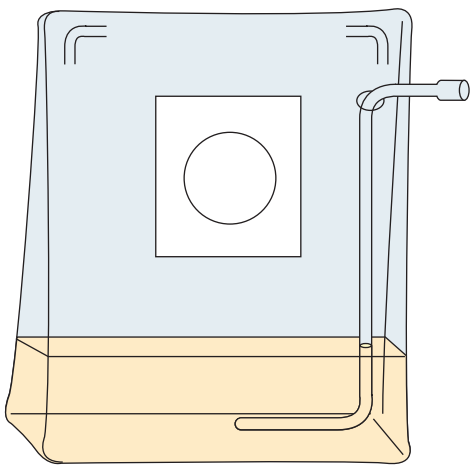


FIGURE 37.11 A 24-hour urine collector made from a colostomy bag. When the infant voids the bag fills with urine, which can be aspirated from the bag by the inserted feeding tube.

Clean-Catch Specimens

A **clean-catch urine specimen** is ordered when a urine culture for bacteria is desired. The objective of the specimen is to obtain urine that is uncontaminated by external organisms that would increase the organism count of the urine. Specimens used for protein or blood analysis may be ordered as clean-catch specimens also because this careful cleaning also reduces the possibility that vaginal or foreskin secretions, which contain protein or blood, would be added to the specimen. This type of specimen requires that the urinary meatus and the surrounding structures be cleaned before voiding.

The technique for obtaining a clean-catch urine specimen from an older child is the same as that for an adult (see Nursing Procedure 11.6). Some modifications are necessary for the young child or infant, as it is not always possible to obtain a midstream urine specimen from young children. To collect a specimen from a young child, ask the child to void into a sterile emesis basin or sterile container attached to a toilet or potty seat after you have washed the perineum or penis. Then dip a sterile container into the urine stream to obtain the specimen. If the child voids only a small amount, send that in the sterile container, marked "not midstream." To collect a specimen from an infant, wash the genitalia and apply a sterile urine collector. If the infant does not void within 2 hours, remove the collecting bag and recleanse the perineum or penis because some microorganisms will have collected after this period of time. After the area is recleansed, then reapply a new sterile bag. Again, mark specimens as "not midstream" or "obtained by a collector" for laboratory purposes.

Clean-catch urine specimens have a major advantage over bladder catheterized specimens: they are not intrusive, so they carry no risk of introducing a bladder infection. If clean-catch specimens are obtained with care, they practically eliminate the need for catheterization. A clean-catch specimen with a bacterial colony count of more than 100,000 per milliliter is considered a positive specimen, or evidence that a urinary tract infection exists.

It is almost impossible for young girls to wash their perineum thoroughly because they cannot see it well, so they usually need assistance. Young boys also must be assisted to wash until they have enough coordination to do it themselves. Be aware that this is embarrassing for children. Ask a parent to confirm for a child that the procedure is all right, because they have been told not to let adults touch this part of their body.

To be certain that school-age children and adolescents understand the procedure, have them repeat the instructions given to them; then send them to a nearby bathroom to carry out the procedure by themselves.

Suprapubic Aspiration

Suprapubic aspiration is the withdrawal of urine by insertion of a sterile needle into the bladder through the anterior wall of the abdomen. The technique is used to obtain urine for culture in infants who cannot void on command (Thilo & Rosenberg, 2008). It is usually done by physicians, although nurse practitioners or nurses in specialty units may perform it. The steps for suprapubic aspiration are:

1. The anterior abdominal wall is cleaned with an antiseptic.
2. The urinary meatus is blocked by gloved finger pressure, confining urine in the bladder.

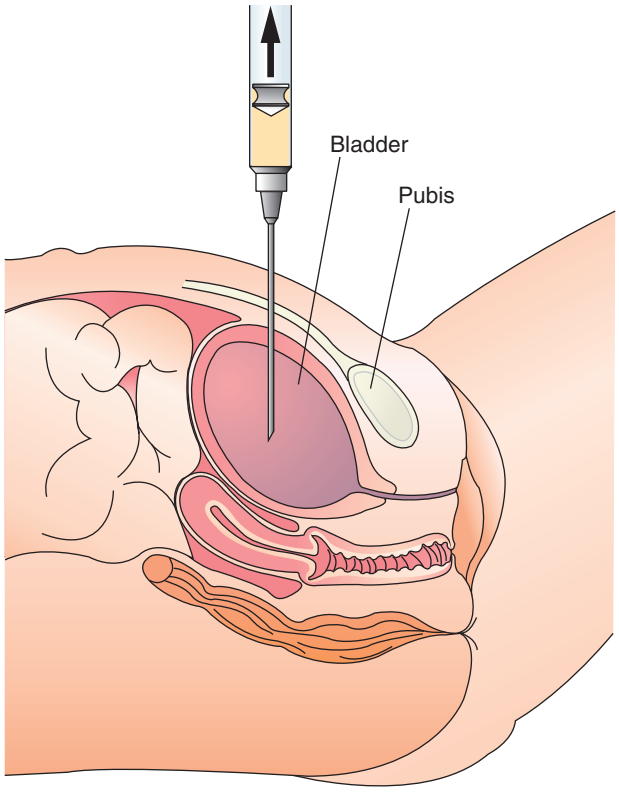

FIGURE 37.12 A suprapubic bladder aspiration. The full bladder is easily accessible by an abdominal puncture.

3. A needle is inserted just above the pubis into the bladder.
4. Urine is aspirated through the needle into a sterile syringe and the syringe and needle are withdrawn.

Although suprapubic aspiration for urine appears complicated, it is not. The bladder is the most anterior of abdominal organs and, when distended with urine, is easily accessible just under the abdominal wall (Fig. 37.12). Because the needle can cause a bladder spasm, however, it can produce sharp discomfort. Parents may not have heard of this procedure and may wonder why their child had urine drawn by needle and syringe instead of by catheter. The method is used because theoretically the risk of bladder infection from needle insertion is less than that from catheter insertion.

Catheterization

Bladder catheterization is accomplished most easily in children up to school age if a small (No. 5 or No. 8) feeding tube is used instead of a urinary catheter. This thin tube passes readily through the meatus of even an infant. Before beginning catheterization, be certain to observe the perineum of girls to locate the urinary meatus; it is not as readily observable in infants and young children as it is in adult women. Cleanse the perineum or penis well before inserting the tube to reduce the risk of infection.

Catheterization is an invasive procedure, so children must be prepared in advance. Caution children that the catheter will sting for an instant as it is inserted and they will have to lie still until the urine specimen is obtained. They need both support to submit to the procedure and praise afterward for

their cooperation. Preschool boys may need assurance that the procedure has no long-term consequences to reduce their fear of castration.

Obtaining Stool Specimens

Stool specimens are frequently obtained to be analyzed for blood or ova and parasites. Obtain stool specimens from children who are toilet-trained by asking them to use a potty seat or by placing a collector cap device on a toilet. For effective communication, be certain you know the word the child uses for stool. Transfer the specimen to a collection cup with tongue blades. To obtain a specimen from a child who is not toilet-trained, scrape stool from a diaper using tongue blades and place it in a stool collection cup. Some stool specimens need a preservative added to the container. If it is important to keep urine from contaminating the stool specimen, place a separate urine collector bag on an infant.

Be certain stool specimens are sent to the laboratory promptly so they do not dry and have to be collected a second time, because they can be difficult to obtain until at least 24 more hours. If the stool specimen is for ova and parasites, see that it arrives in the laboratory in less than 1 hour. Do not refrigerate ova and parasite specimens because refrigeration destroys the organisms to be analyzed.

✔ Checkpoint Question 37.2

T.J. will have a 24-hour urine specimen collected. You would time this from:

a. The time of the discard specimen.
b. The first urine voided in the morning.
c. A set time, such as 8 AM.
d. The first voiding after the discard urine.

HOT AND COLD THERAPY

Children who sustain muscle sprains or undergo procedures such as bronchoscopy or tonsillectomy may have cold applications prescribed to prevent inflammation and edema (Fig. 37.13). If inflammation or edema is already present, application of heat may be prescribed to help it resolve. It is important to implement measures to prevent both burns and boredom in the child during treatments. Guidelines for hot and cold applications are shown in Box 37.9.

BOX 37.9 ✻ Focus on Family Teaching

Guidelines for Hot and Cold Applications With Children

Q. T.J.'s mother tells you, "I need to apply cold compresses to my child's head to reduce swelling. How do I do this?"

A. When applying any type of hot or cold therapy such as cold or warm compresses, use the following guidelines:

- Apply neither heat nor cold for longer than 20 minutes unless prescribed otherwise, because after this time, the vasoconstriction caused by cold and the vasodilatation caused by heat is reversed.
- When using electrical sources of heat with toddlers and preschoolers, never make a game of plugging in and pulling out the apparatus that makes the light come on or a dial glow. Otherwise, the child may play with it after you leave.
- Supply a special activity for a child to enjoy while a hot or cold application is in place (playing a board game or reading a story to the child), so that the procedure is not viewed as a chore but as a pleasant time to look forward to.
- Put tape on the gauge of an electric appliance at the point where you want it, so that you will be able to tell if the child changes the setting.
- To be certain that solutions or heat sources are not too hot, always test them with your inner wrist or the dorsal surface of your hand before applying them to the child.
- Do not apply ice packs or ice directly to the skin. Cover the pack or ice with a towel or other cover to prevent frostbite and cell damage from cold.
- Be cautious using heat or cold applications with a child who is receiving an analgesic, because the child's perception of heat or cold may be reduced, and the site could easily be burned.

NUTRITIONAL CARE

Because almost all illnesses affect children's nutritional and fluid balance, assessment of these areas sheds a great deal of light on a child's general health. Nutritional assessment begins by asking a child or parent for a 24-hour recall of all the foods eaten during that time, followed by more specific measures such as intake and output measurements. Common therapies for nutritional deficiencies include enteral feeding, gastrostomy, and total parenteral nutrition (TPN).

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for imbalanced nutrition, less than body requirements, related to chronic illness

Outcome Evaluation: Skin turgor is good; no signs of dehydration are present; child gains a minimum of 1 pound weekly as evidence that nutritional needs are being met.

Measuring Fluid Intake and Output

Fluid is an essential element of nutrition because of the water supplied and because it can also be a source of calories and vitamins. To document fluid balance, some children may have fluid intake and output measured and recorded. This is especially true for children with vomiting, diarrhea, burns, hemorrhage, dehydration, cardiac and kidney disease, draining wounds, gastrointestinal suction, edema, and diuretic or intravenous therapy.

Fluid Intake

Estimating the intake of infants who are formula fed is simply a matter of estimating the kind and amount of fluids that were swallowed. Intake in breastfed infants is merely recorded as "breastfed." If it is necessary to estimate the amount more closely than this, an infant can be weighed before and after a feeding. The difference in weight (in grams) is the number of milliliters of breast milk ingested. This measurement is not very accurate, however, because if the child voided or had a bowel movement, weight is affected by these losses.

With preschool children, be certain to record fluids ingested during snacks as well as meals, because children this age usually have many during the day. At approximately 10 years of age, children can be depended on to record their own intake as long as they have a list of how many milliliters are contained in each glass or cup they use (an average cup is 150 mL; a glass, 180 mL). Remind them that soup, flavored frozen ice such as Popsicles, and sherbet are liquids and should be counted.

Fluid Output

Diapers can be readily used as a method of measuring urine output. Weigh a diaper before it is placed on an infant and record this weight conspicuously (mark it on the front of the plastic covering with a ballpoint pen). Reweigh the diaper after it is wet and subtract the difference to determine the amount of urine present. This difference will be in grams. Because 1 g = 1 mL, the amount can be recorded in milliliters. In infants who have liquid stools, it is difficult to separate stool from urine because these blend together in a diaper. Separate urine from stool by applying a urine collector; check it frequently for filling.

Girls often void along with bowel movements when they use a toilet, which means that a urine specimen is easily lost. To separate urine from bowel movements, teach older children to void first before trying to move their bowels.

Enteral Feedings

Enteral feedings, also called nasogastric tube feedings, are a common means of supplying adequate nutrition to an infant who is unable to suck or tires too easily when sucking, or to an older child who cannot eat. Enteral feedings have the advantage over parenteral nutrition because they preserve the stomach mucosa and also decrease the risk of intravenous infection. In infants, such feedings are traditionally called **gavage feedings** (Box 37.10 and Table 37.2).

Whether enteral catheters should be passed through the nares or the mouth is controversial. Orogastric insertion allows for easier breathing because the nose is not blocked. Because newborns are nose breathers, it seems reasonable that passing a catheter through the mouth in this size infant will lead to less distress than passing it through the nose. Orogastric insertion can also decrease the possibility of striking the vagal nerve and causing bradycardia. If the tube is to be left in place, however, it may be passed through a nostril. For the older child, insertion through a nostril is more comfortable.

Tube placement can be confirmed by x-ray; then at each feeding, measuring the length of the tubing is a method to make certain it has not moved. Children are generally offered bolus or intermittent feedings rather than continuous infusions to more closely mimic a normal feeding pattern. The formula used should be at room temperature to prevent chilling. Before a feeding, elevate the child's upper trunk 30 to 40 degrees so the fluid will remain in the stomach and not flow upward into the esophagus, possibly causing aspiration. Do this by holding an infant in the lap or placing the infant in an infant seat. For an older child, use pillows or elevate the head of the bed. If ordered, use a syringe to aspirate the tube for any stomach residual (this is important if there is a question regarding whether an infant is absorbing the quantity of fluid being given and also confirms tube placement is in the stomach). After noting the amount, replace this fluid so the child does not lose the electrolytes it contains. To administer the feeding, attach a syringe to the tube and allow the specified amount to flow by gravity only (to prevent reflux and possible aspiration).

After the feeding, flush the tube with a specified amount of clear water to clear it of the feeding solution. Keep the child's head elevated for at least 1 hour after a feeding to help prevent esophageal reflux.

Children with long-term neurologic disabilities may have enteral tubes left in place for continuous feedings administered by an enteric feeding pump. Give mouth care at least twice a day to children who are receiving nasogastric tube feedings; otherwise, their mouths become dry and ulcers can form.

Gastrostomy Tube Feedings

Children may have gastrostomy tubes inserted for feeding. Such feedings may be necessary for children who cannot swallow or have an esophageal stricture (Ramelli et al., 2007). With the use of regional anesthesia, the tube is inserted through a puncture wound in the abdominal wall into the stomach (Fig. 37.14). The tube used in children is usually actually an indwelling urinary catheter (Foley catheter) rather than a true gastrostomy tube. This is because a Foley catheter can be removed easily and changed should it become plugged. In addition, the balloon used to secure the tube is small enough so it does not obscure and fill the small stomach space.

Box 37.10 Nursing Procedure ✻ Initiating an Enteral Feeding for an Infant

Purpose: To supply nutrition by an enteral tube..

Procedure	Principle
1. Loosely swaddle the infant using a mummy restraint.	**1.** Mummy restraints effectively contain arms and legs without causing any unwarranted pressure on the infant.
2. Measure the space from the bridge of the infant's nose to the earlobe to a point halfway between the xiphoid process and the umbilicus using a no. 8 or no. 10 feeding tube. If the infant is older than 1 year of age, measure from the bridge of the nose to the earlobe to the xiphoid process.	**2.** Measuring the tube ensures that it will be long enough to enter the stomach. If a tube is passed too far, it will curl and end up in the esophagus; if not passed far enough, it will also be in the esophagus. Both situations could lead to aspiration of the feeding.
	
3. Mark the tube at the measured point with a small clamp or piece of tape. Lubricate the tip of the catheter with water.	**3.** Lubrication helps the tube pass through the esophagus without trauma. An oil lubricant is never used because although the tube is going to be passed into the stomach, occasionally it can accidentally pass into the trachea. Oil left in the trachea could lead to lipoid pneumonia, a complication an infant already burdened with a disease may not be able to tolerate.
4. Pass the catheter with gentle pressure to the point of the clamp or tape. If the catheter is inadvertently passed into the trachea rather than the esophagus, the infant usually will cough and become dyspneic. If this happens, withdraw and replace the catheter.	**4.** Using gentle pressure helps to ensure comfort and safety.
5. Assess the catheter for position (confirm that it is not in the trachea) before administering a feeding (see Table 37.2).	**5.** Assessing for proper placement helps to ensure that the feeding will enter the stomach, not the infant's respiratory tract.
6. Aspirate stomach contents to assess amount. If the amount aspirated is small (a few milliliters), merely replace it at the beginning of the feeding. If large (large is determined by comparing it to the physician's order), replace it through the tubing, and reduce the amount of the feeding by that amount.	**6.** Assessing stomach content amount aids in determining if the previous feeding was absorbed. Replacing stomach secretions rather than discarding them helps prevent electrolyte loss.

Box 37.10 Nursing Procedure ❇ Initiating an Enteral Feeding for an Infant

Procedure	Principle
7. After being certain that the catheter is in the stomach, attach a syringe or special feeding funnel to the tube. Elevate the infant's head and chest slightly to encourage fluid to flow downward into the stomach.	**7.** Elevating the infant's upper body allows the feeding to flow by gravity.
8. Add the specific kind and amount of feeding prescribed to the syringe or funnel and allow it to flow by gravity into the infant's stomach. Don't elevate the syringe end of the tube more than 12 inches above the infant's abdomen (see figure below).	**8.** Excessive elevation can cause the feeding to flow too quickly, filling the esophagus and increasing the risk for aspiration. Hurrying feedings by using the plunger of the syringe or a bulb attachment for more pressure also can lead to aspiration.
9. Offer a pacifier (nonnutrient sucking) during the feeding if the infant appears to enjoy this.	**9.** Nonnutrient sucking can help satisfy the infant's normal need to suck, which would otherwise go unsatisfied with gavage feedings.
10. When the feeding has passed through the tube, reclamp the tube securely and gently and rapidly withdraw it.	**10.** Clamping the tube before it is withdrawn is important to prevent any milk remaining in the tube from flowing out as the tube is removed and thereby reduce the risk of aspiration.

© Barbara Proud.

11. If the tube is to remain in place, flush it with 1 to 5 mL of clear water and cap it.	**11.** Flushing a tube helps prevent clogging and plugging of the tube with the feeding solution. Capping a tube helps to prevent air and bacteria from entering.
12. If the tube is to be left in place, tape it below the nose and to the cheek. Do not tape it to the forehead.	**12.** Taping a tube to the forehead can put pressure on the anterior naris, leading to ulceration.
13. Bubble the baby after an enteral feeding as you would after a bottle or breast feeding. If a parent is present, encourage him or her to do this.	**13.** Bubbling helps in preventing air accumulation and regurgitation of feeding. Encouraging parental participation aids in promoting close contact, which is essential to the baby's development.
14. Unswaddle and place the infant on the right side with the head slightly elevated or hold and rock the infant in this position.	**14.** Placing on the right side helps the feeding solution enter the pyloric valve, promoting stomach emptying.
15. Assess that the infant appears comfortable. If a parent observed the procedure, answer any questions or concerns.	**15.** Assessing the infant after the feeding aids in outcome evaluation. Helping parents feel comfortable with alternative feeding methods can help increase their self-esteem and promote bonding with the infant.

TABLE 37.2 ✻ Methods to Determine Proper Gavage Tube Placement

Method	Considerations
If an x-ray is obtained to document correct tube placement, measure the length of the tube evident at that time. Remeasure the length of tube before a feeding to document that the tube has not pulled out or advanced further.	This system has inherent problems as it requires an x-ray and does not verify that the tube is actually in the stomach but can be used if it is health care policy.
Attach syringe to the tube and aspirate stomach contents. Test for pH (below 7 is acid).	In most instances, stomach contents aspirated this way are returned to the stomach before the feeding; in small infants, the amount of stomach contents is subtracted from the prescribed amount of feeding; because stomach contents are highly acid, discarding them at each feeding can lead to alkalosis.
Inject 5 mL air into the gavage tube and listen over the stomach with a stethoscope to the sound of injected air.	The injected air is heard as a whistling or growling sound; do not use an adult-size stethoscope on small infants to listen for it; the diaphragm of the stethoscope will be partially over lung, and where one is hearing the air injection is unknown.

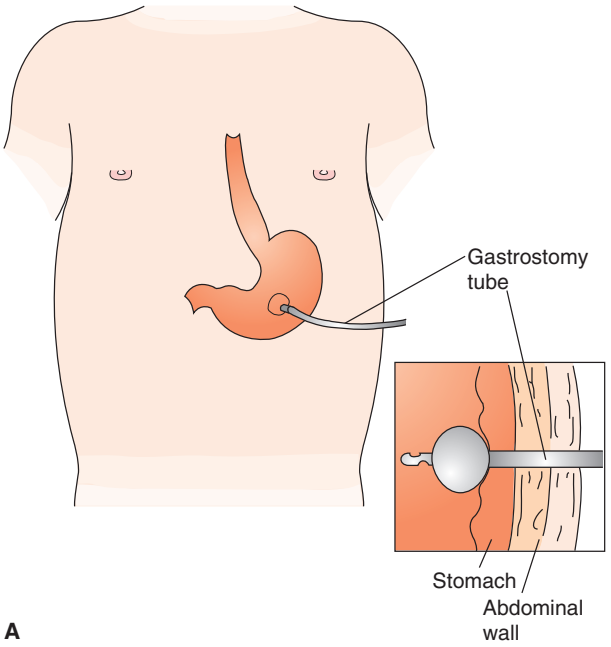

FIGURE 37.14 Children who are ill often need supplemental feeding by nasogastric or gastrostomy tube feedings. (**A**) Internal placement of a gastrostomy tube. (**B**) An infant with a gastrostomy tube in place. (From W. McIntyre/Photo Researchers, Inc.)

As with nasogastric feedings, gastrostomy feedings should be at room temperature to prevent chilling. Be certain to aspirate for stomach secretions before the feeding and allow the formula to flow by gravity, not be forced. If a child has had esophageal surgery, suspend the unclamped tube in an elevated position after the feeding. Leaving the tube unclamped and elevated this way ensures that if the child should vomit, vomitus will be evacuated from the stomach by the tube rather than past new sutures in the esophagus. If a tube is left elevated and unclamped, cover it with a clean piece of porous gauze to prevent bacteria from entering it.

Infants who are fed by gastrostomy tube miss the pleasure of sucking. Offer a pacifier to suck on during the procedure unless contraindicated. Talk or sing to the child as if the feeding were being given orally.

The biggest problem with gastrostomy tubes is that they may not fit snugly, so formula or gastric secretions can leak around the tube onto the abdominal skin. Gastric secretions are irritating because of their high hydrochloric acid content. To protect infant skin, consult a wound, ostomy, continence nurse specialist (WOCN) for wound care. Often commercially available skin protectants can be placed around the tube to protect the skin. One method of helping to provide a snug fit for the tube is to place a soft nipple used with premature infants (enlarge the nipple opening slightly) over the catheter (nipple tip up) so the base of the nipple fits against the skin protectant. Tape the tube to the nipple at the tip, which brings the balloon of the tube up against the stomach wall and prevents leakage. Tape the nipple to the skin and skin protectant securely using nonadhesive tape. Clean the skin around the nipple daily with a product such as half-strength hydrogen peroxide; change the skin protectant as directed by the manufacturer's instructions. At the time of the change, expose the skin to air for approximately 1 hour.

A major complication associated with the use of a gastrostomy tube is that it can move into the duodenum through the pyloric sphincter and cause obstruction. Observe and report any vomiting, abdominal distention, or brown or green tube drainage (duodenal secretions that would suggest the tube has moved). Testing residual aspiration fluid to see that it is acid is a guarantee that the tube is in the stomach (stom-

ach secretions are acid; duodenal secretions are alkaline). Putting a mark on the tube with an indelible pen just above the nipple lets you check that the tube has not migrated into the stomach but is remaining securely in place.

Tubes are replaced approximately every 6 weeks. To replace a tube, deflate the catheter balloon by withdrawing the water in it and then gently pull the tube free. Insert a clean catheter into the stomach opening approximately 1 inch beyond the balloon; inflate the balloon with 2 to 4 mL water. Attach a nipple and tape in place.

Most children receiving gastrostomy feedings will have the tube in place for an extended time. Teach the child's parents how to feed the child by this method, how to remove and to replace a tube, and the danger signs to watch for such as vomiting, abdominal discomfort, or skin excoriation. Help parents to view this as an alternative way of feeding rather than a totally different one. Be certain they are comfortable with the procedure before the child is discharged from the hospital, so they can effectively feed the child by this method. Reinforce with them the understanding that it does not hurt their child to have the tube replaced or to have pressure put against the tube, so that they need not worry about holding their child snugly. Many children on long-term gastrostomy feedings have gastrostomy buttons implanted for easier stomach access (Fig. 37.15). For feeding, a catheter is inserted through the device; the catheter is removed following the feeding. With a gastrostomy button in place, only a small access device is visible, not a large bulky tube.

Percutaneous endoscopic gastrostomy (PEG) tubes are feeding tubes that are passed using endoscopy through the esophagus into the stomach and then pulled through a stab wound to the outside of the abdominal wall. The tube is then held in place by an external restraining disc. Although tubes may be passed so formula is introduced into the jejunum by this same method, such tubes bypass normal stomach digestion rather than support it so they may not be appropriate for all children (McDermott, Tomkins, & Lazonby, 2007). The overall use of such tubes is limited because a small child's esophagus may not be wide enough to insert the tube by this route.

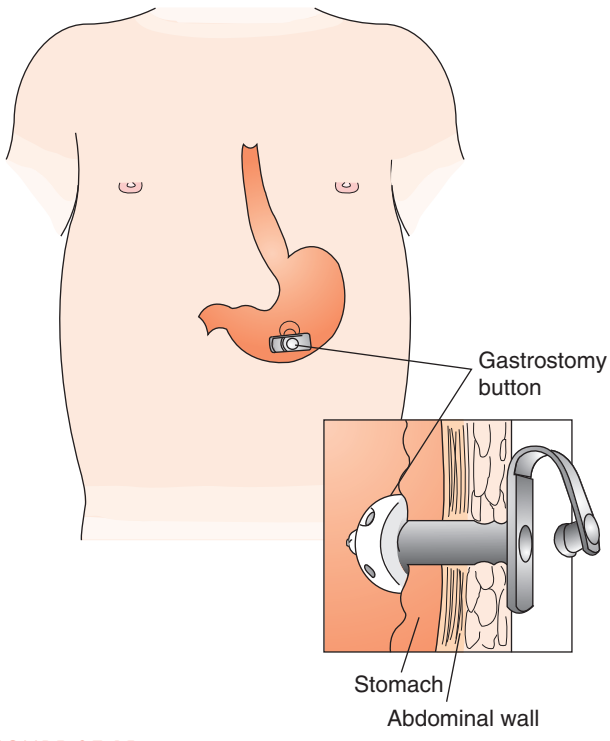

FIGURE 37.15 Placement of a gastrostomy button.

What if... A parent whose child has a gastrostomy tube in place tells you she's going to take the child to a restaurant so the child learns about "eating out." Would you agree with her that this is a good idea?

Total Parenteral Nutrition

Total parenteral nutrition (TPN) has become one of the most important therapies for children who have gastrointestinal illnesses that prevent proper absorption of basic caloric or fluid requirements or respiratory illnesses that make infants too exhausted to suck.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Imbalanced nutrition, less than body requirements, related to malabsorption of nutrients

Outcome Evaluation: Skin turgor is good; no signs of dehydration are present; child loses no weight during therapy; intestinal cramps and distention lessen.

Traditional intravenous therapy contains fluid, electrolytes, and sugars but not protein and fat, which are essential for the maintenance and growth of body tissues. With TPN, all of a child's nutritional needs can be met by a concentrated hypertonic solution of intravenous therapy containing glucose, vitamins, electrolytes, trace minerals, and protein. An intralipid solution (emulsified fat able to be administered intravenously) given once or twice per week supplies needed fatty acids. Children with chronic diarrhea or vomiting, inflammatory bowel disease, bowel obstruction, anorexia, or extreme immaturity are examples of children who benefit greatly from TPN.

TPN solutions may be administered via a central intravenous access site or via a peripherally inserted central venous catheter (PICC). If a central access site is chosen, a catheter is inserted through the right external jugular vein into the superior vena cava or directly into the subclavian vein under strict aseptic conditions (see Chapter 38). The catheter is secured at the site of insertion with sutures and covered with a sterile dressing to help reduce bacterial contamination. A major vein of this type is chosen to avoid inflammation reactions and resulting venous thrombosis from the high-caloric and high-osmotic fluid that will be infused (Ainsworth, Clerihew, & McGuire, 2009).

TPN solution is prepared in a pharmacy under sterile conditions according to prescription. A Millipore filter, which removes small particles in the solution that might cause an embolus to form, is inserted into the tubing. The solution should be administered by means

of a constant infusion pump so the rate can be governed. As a general rule, if the rate should fall behind, do not increase it the next hour to make up the amount of fluid, or serious cardiovascular overload could result because of the concentrated fluid being administered.

Infection is a major danger of TPN because the solution is a perfect medium for the growth of bacteria or *Candida* organisms. The dressing over the insertion site and the intravenous tubing are changed every 1 to 2 days to avoid infection; the tubing should not be used for obtaining blood or for adding medications (unless a double-barreled tube is used), because either process has the potential to introduce infection. Sterile technique is required in changing bottles of solution so that the tubing is not contaminated. Some health care facilities require nurses to wear both masks and gloves while doing this to avoid airborne and direct contamination. Fewer restrictions are necessary for home care. The insertion site should be inspected at the time of the dressing change for indications of local infection, such as redness, tenderness, or discharge as infection at the insertion site can lead to a serious sepsis or thrombosis (Marra et al., 2007).

A second major problem that can occur with TPN is dehydration. A TPN solution contains approximately twice the amount of glucose normally administered in an intravenous solution to ensure that the amino acids in the solution will be used for protein synthesis, not for energy. Dehydration may occur as the kidneys recognize the amount of glucose in the bloodstream as excessive and start to reduce it by excreting it (the same phenomenon that leads to high urine output in persons with diabetes mellitus). When TPN is begun, test urine for glucose and for specific gravity with each voiding. If two or more consecutive samples indicate a 3+ or 4+ glucose level, either the rate of the infusion or the amount of glucose in the solution may need to be decreased, or insulin my need to be added to the solution, to counteract the excess glucose. Generally, decreasing the concentration of glucose and then gradually increasing it again allows the child's body to adjust to the glucose overload.

After the first few days of TPN, a rebound effect (the child's body produces increased insulin) may cause hypoglycemia. A urine sample that suddenly is negative for glucose after several serial specimens have been highly positive is therefore not necessarily an encouraging sign; rather, it may be a warning that the child's glucose level has become dangerously low. TPN solution should never be discontinued abruptly but gradually tapered, or a glucose rebound effect could also occur. If a TPN catheter should be accidentally pulled out by a child, the child must be immediately assessed for hemorrhage from the insertion site and closely observed in the next few hours for signs of hypoglycemia such as lethargy, incoordination, fidgeting, or seizures. Parents need to be alerted to these concerns for safe home care.

Remember that to a child, eating is more than a means of receiving nourishment; it is also a means of receiving comfort and love. Even though children are able to voice the reason they must have TPN and appear to understand that they are receiving all the needed nutrients by infusion, they still may miss eating food and the natural social interaction that comes with it. While in a hospital, they may be upset by the smell of food from a hospital unit kitchen or by the fact that playmates have to leave to eat a meal. Finding an activity for a child receiving TPN while other children eat such as helping to check supplies on the emergency cart or stamping laboratory slips may be helpful to supply the interaction a child misses. Ask whether a child can be allowed chewing gum or occasional hard candy for chewing and taste sensations. Tooth brushing twice a day helps to keep oral mucous membranes healthy because the child is not chewing. An infant enjoys sucking pleasure from a pacifier.

Many children on long-term TPN are cared for by parents at home. Careful coordination with the home care agency is necessary to ensure that parents are familiar with the system and know how to obtain TPN fluid so the child's care continues safely. Make sure parents arrange for special time each day with the child to make up for the time normally spent interacting at meals.

ASSISTANCE WITH ELIMINATION

Two aspects of intestinal elimination that require special care are administration of enemas and ostomy care.

Administering Enemas

Enemas are rarely used with children unless they are therapy for Hirschsprung's disease or a part of preparation for surgery or an x-ray study. If an enema is necessary, offer a careful explanation of what the child can expect. As the sizes of children's bowels vary greatly, the usual amounts of enema solutions used are:

- Infant: Less than 250 mL (exact amount should be stipulated by physician's order)
- Preschooler: 250–350 mL
- School-age child: 300–500 mL
- Adolescent: 500 mL

For an infant, use a small, soft catheter (No. 10 to 12 French) in place of an enema tip to prevent rectal trauma. Infants and children up to ages 3 or 4 years cannot retain enema solutions, so they must rest on a bedpan during the procedure. Pad the edge of the pan so it is not cold or sharp. Place a pillow under the infant's or young child's upper body for positioning and comfort. Lubricate the catheter generously with a water-soluble lubricant and insert it only 2 to 3 inches (5 to 7 cm) in children and only 1 inch (2.5 cm) in infants. Be certain to hold the solution container no more than 1 foot above the level of the sigmoid colon (12 to 15 inches above the bed surface) so the solution flows at a controlled rate. If a child experiences intestinal cramping, clamp the tubing to halt the flow temporarily and wait until the cramping passes before instilling any more fluid. An older child can be asked to take a deep breath to help the cramping sensation pass. The amount of solution used in infants is so small that this is not usually a problem. If the enema solution

is to be retained, such as an oil solution, hold the child's buttocks together for about a count of 10 after administration.

Until late school age, children cannot retain an enema as adults can (rarely more than 5 to 10 minutes). For this reason, be certain the bathroom the child will use is available before administering the enema.

Commercial enemas, such as Fleet enemas, are not routinely administered to children younger than 2 years because of the harsh action of the sodium biphosphate and sodium phosphate they contain. Tap water is not used because, as it is not isotonic, it causes rapid fluid shifts of water in body compartments, leading to possible water intoxication. Normal saline (0.9% sodium chloride) is, therefore, the usual solution used. It can be made by parents at home by adding 1 teaspoonful of salt to 1 pint (500 mL) of water.

After enema administration, praise a child for cooperating. Allow a preschooler an opportunity for therapeutic play, because this is a frightening procedure for a child of this age.

Providing Ostomy Care

An ostomy is an opening of the bowel on the surface of the abdomen. Ostomies in newborns are created to relieve bowel obstruction caused by conditions such as ileal atresia, necrotizing enterocolitis, and imperforate anus. In older children they are constructed for conditions such as inflammatory bowel syndrome and Hirschsprung's disorder (Ekenze, Agugua-Obianyo, & Amah, 2007). If an ostomy is created in the ileum (an ileostomy), the stoma is located on the right side of the abdomen and drains liquid stool, which is extremely irritating to the skin because of the digestive enzymes it contains. If an ostomy is created in the sigmoid portion of the bowel (colostomy), the stoma is on the left lower abdomen and passes normally formed stool (Fig. 37.16).

An ileostomy requires the use of a collecting ostomy appliance to contain acid stool and prevent excoriation of the abdominal skin. Older children also may use an appliance with a colostomy. For an infant colostomy, parents may choose (with support and advice) whether to use an appliance.

Two basic problems commonly arise when using an ostomy appliance with an infant: it may be difficult to locate one small enough to contain liquid drainage without leaking, and the skin under the appliance may become extremely irritated. Consulting with a WOCN can be helpful. Clear plastic colostomy bags without a ring can often be cut more easily to fit the size of the stoma and the contour and size of an infant's abdomen than a ring type. A commercial skin sealant is helpful to harden the skin surrounding the stoma. Apply it according to the brand directions and fan to dry. If a spray is used, protect the infant's face so that the child does not inhale the solution. Apply the chosen stoma collection appliance. Tuck it inside the diaper to help keep the infant from pulling it loose.

Check the appliance or bag for collecting stool at least every 4 hours. To protect the underlying skin, do not remove a self-adhering bag if it is full, but drain collected stool from the bottom of the appliance into a basin or paper cup for disposal. To reduce odor, flush the appliance bag with a warm water and soap solution, using a bulb-type syringe (an Asepto syringe), and rinse with clear water. Change the bag no more frequently than the point at which leakage occurs (perhaps as long as 1 week) to reduce skin irritation. To remove a bag that was placed with a sealant, be certain to use the designated solvent to prevent pulling or harming underlying skin. Then wash the solvent away with soap and water or it will become an irritant itself. Because most infants enjoy tub bathing, a long, soaking bath is an excellent way to loosen an appliance.

If an appliance or bag is not used, stool will be discharged onto the abdomen three or four times a day (no different than a usual newborn or infant stool pattern). Wash and dry the stoma and surrounding skin area well. Follow your agency's protocol for skin care, such as applying karaya powder, an ointment such as Desitin, or a skin protectant to protect the skin. Apply ample absorbent gauze (fluffed) and an absorbent pad. Secure in place with nonadhesive tape or a binder. Check the dressing approximately every 4 hours. Remove and replace it when soiled, washing the skin well and applying new powder or ointment as necessary. Without an appliance in place, stool is kept from touching the skin only by the protection of the ointment and frequent changing of the dressing. Turning an infant from side to side after every feeding may be helpful in keeping stool from flowing continuously to one side. Leaving the ab-

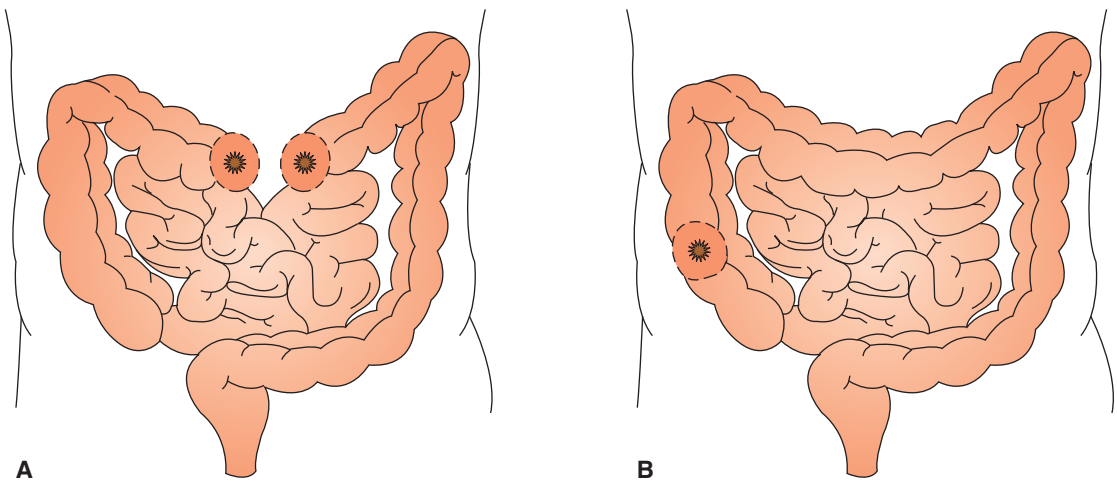

FIGURE 37.16 Different sites for ostomies. (**A**) A double-barrel colostomy. (**B**) A single-barrel colostomy.

dominal skin exposed to air for at least 1 hour per day also helps protect skin integrity.

Stress to parents that caring for an infant with an ostomy is little different from usual. All parents must change their infant's diapers frequently and clean the diaper area. Stress that the stoma has no nerves, so a parent can feel free to wash it without hurting the child and that compression against the stoma will not cause a child pain. These explanations can help the parents feel comfortable placing an infant on the abdomen or holding the infant closely against their body for comfort.

Colostomies are rarely irrigated in children. On occasion, to prepare a child for second-stage abdominal surgery, irrigation of the "blind-end" bowel (bowel between the rectum and colostomy) of a double-barreled colostomy may be ordered daily to keep it lubricated and to maintain bowel tone. The exact amount of fluid to be used should be specified by the surgeon. Typically, the amount is small, approximately 40 to 100 mL in infants. Normal saline (0.9% sodium chloride) should be used in place of tap water, which could lead to water intoxication because tap water is not isotonic.

Children who have had a colostomy since infancy adapt well to it because they have never known another method of defecation. Parents should begin toilet-training for urine control at the usual time. In contrast, school-age children often have a great deal of difficulty adjusting to a colostomy. Encourage children to perform self-care as fully and as soon as possible so they can be independent. Preschool children usually benefit from therapeutic play that helps them work through their feelings about a colostomy. Provide some time for older children to discuss concerns about being accepted by others and how to answer questions about a colostomy for other children. Adolescents with a colostomy may have questions regarding sexuality and need reassurance that this should not interfere with intimate relationships. They may appreciate open discussion of how they see this affecting their life.

WOUND CARE

Children frequently have a dressing or bandage in place to cover a surgical incision or sutured laceration. Such dressings differ from adult dressings in terms of material, size, and methods used to secure them. Keeping a dressing dry to avoid introducing infection to the wound in infants and toddlers who are not toilet-trained can be a major problem. In many instances after surgery, collodion (a clear substance similar to nail polish) or other commercially available "wound glues" are used to cover the incision. Wound glue not only takes the place of stitches but also serves as a dressing to keep the incision line from coming in contact with urine or feces. Since these materials are clear, they allow good visualization of the healing surface as well. Assure parents that such a covering is adequate and actually preferable if the incision is in the groin, such as a hernia repair. They are also preferable if an incision or laceration is on the face as they heal with less scarring than if sutures were used.

If a gauze dressing is used, it can be covered with plastic and securely held in place with nonadhesive, waterproof tape to protect it from becoming wet. Be certain when cutting plastic to cover a dressing not to leave an extra piece behind in the crib; children could pull this over their head and suffocate.

Occlusive dressings (hydrogel sheets, hydrocolloids, or polyurethane films) are dressings especially designed to provide a healing surface over a wound. These need to be applied and removed according to each product's directions.

The skin of infants and young children is usually too sensitive for adhesive tape to be used to secure dressings. Use nonadhesive tape (silk or paper) instead or secure a dressing with a nonadhering bandage (Kling) or roller gauze. Young children, as a rule, find bandages comforting and accept them as a "badge of courage," displaying them proudly. Apply adhesive bandages (Band-Aids) generously after venipuncture or finger punctures for this reason. Preschool children have little concept of how long healing takes; they are often surprised that their incision or wound has not yet healed the day after surgery. Preschoolers are often worried that a part of their body under a dressing is missing and find it reassuring to see that the body part is still there (so they may pull a dressing away to do this). It is better to know what something is like than to worry about the unknown. Therefore, do not discourage children from looking at their incision during dressing changes. Even if the area looks raw and unhealed, it may look better than what the child has envisioned was under the dressing. Teach parents and children how to continue wound dressings when they return home.

✔ Checkpoint Question 37.3

T.J.'s younger brother receives total parenteral nutrition. Why does dehydration tend to occur with this?

a. The glucose solution leads to diuresis.
b. Infection occurs easily and causes fever.
c. Only 100 mL of fluid can be infused daily.
d. Children tend to develop diarrhea.

Key Points for Review

- Preparing children for procedures reduces anxiety. Prepare a child and parents by trying to relate a procedure to something with which a child is already familiar, such as comparing an x-ray machine to a camera.
- Include parents in both the planning and implementation of care, as parents can reinfect children with fear if their own fear is uncontrolled. Try to give explanations on two levels: "I'm going to change the dressing on her suture line" for a parent; "I'm going to put a clean bandage on your tummy" for the child.
- Minimize the number of painful procedures; for instance, combine blood sampling procedures, if possible.
- Perform any procedures that will cause pain in a treatment room or away from the child's bedside so the bed remains a "safe" place.
- Perform treatments without chilling or exposure. Even small children expect modesty to be respected.
- Allow a child to voice anger or fear of a procedure. Provide therapeutic play after a procedure to help reduce these reactions.

- Children enjoy adults who are secure in their actions. Practice as necessary the steps of a procedure before you begin so you can demonstrate confidence and skill.
- Once you have announced that a procedure needs to be done, proceed to do it; waiting for something to happen is often as stressful as actually having it done.
- Involve children in procedures, as this gives them a sense of control. Allow a child to examine electrodes or apply gel for electrode contact before a procedure. Give children a portion of an ECG strip as a badge of courage after the procedure, or let children apply their own adhesive bandage.
- Praise children for cooperation even if none was visibly obvious. For painful procedures, any behavior short of hysterical screaming counts as cooperation.
- Following the use of conscious sedation, observe children carefully until they are fully awake. Check for the return of the child's gag reflex before offering any fluids to minimize the risk of aspiration.
- Help make feeding by a route such as a gastrostomy tube as close to normal as possible by talking to the child to simulate mealtime conversation and socialization.

CRITICAL THINKING EXERCISES

1. T.J. is the 4-year-old you met at the beginning of the chapter who is frightened of dark places. He is scheduled to have an MRI of his head, which means he will be wheeled into a huge, dark, noisy, hollow tube. How would you prepare him for this?
2. T.J. is also scheduled for a CT scan with dye injected. His mother asks you to assure her that her son will not have a reaction to the dye. How will you answer her?
3. T.J.'s new brother had bowel surgery at birth and now has a temporary colostomy. His grandmother cares for him two mornings a week while his mother attends school. The grandmother tells you that she cannot imagine how she can care for an infant with a colostomy. What could you do to try to make her feel more comfortable with the baby's care? Will his care really be much different from that for other newborns?
4. Examine the National Health Goals related to health care of children. Most government-sponsored funds for nursing research are allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to the Balliff family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to diagnostic procedures or therapy in children. Confirm your answers are correct by reading the rationales.

Chapter

38 Nursing Care of a Family When a Child Needs Medication Administration or Intravenous Therapy

KEY TERMS

- absorption
- distribution
- excretion
- intermittent infusion devices
- intracath
- metabolism
- pharmacokinetics
- vascular access port

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe common methods of medication and intravenous therapy used in the health care of children.
2. Identify National Health Goals related to medication or intravenous therapy that nurses could help the nation achieve.
3. Use critical thinking to analyze ways that medicine or intravenous therapy can be modified to be more family centered.
4. Assess the developmental stage and knowledge level of children and adolescents before beginning medication or intravenous therapy.
5. Formulate nursing diagnoses related to medication or intravenous therapy with children.
6. Identify expected outcomes for children receiving medication or intravenous therapy.
7. Plan nursing interventions to aid in making medicine and intravenous therapy maximally effective.
8. Implement nursing interventions concerned with medication and intravenous therapy and children, such as introducing patient-controlled analgesia.
9. Evaluate expected outcomes for achievement and effectiveness of care.
10. Identify areas related to medication or intravenous therapy with children that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of medication and intravenous therapy with nursing process to achieve quality maternal and child health nursing care.

Terry, an 8-year-old with Down syndrome, is brought to the emergency department by her parents because she has pain in her ankle. She is diagnosed with osteomyelitis, a bone infection. When you give her a tablet of acetaminophen (Tylenol) for pain, she spits it out. She does the same when you repeat with a second tablet. Her mother tells you Terry can't swallow pills. Her father tells you, "You'll have to give her medicine intravenously." Previous chapters described the difficulty children may have adjusting to illness and also diagnostic and therapeutic procedures that are frequently used with children. This chapter adds information about techniques for administering medication and intravenous (IV) therapy to children. As therapy for almost all illnesses today involves some form of medicine or IV administration, this information is pertinent to the care of almost all children.

What technique would you use to help Terry learn to swallow pills? How would you gain her cooperation?

Most adults have little difficulty understanding that taking medicine will be important to relieve whatever symptoms they are experiencing from an illness. Because children do not necessarily have this same level of understanding, they may resist taking medicine unless its importance is thoroughly explained to them and the medication is given to them by a method that best meets their preference. Many children do not have enough coordination to swallow tablets or pills until they are 6 or 7 years of age. This can make taking oral medication difficult unless it is furnished in a liquid or melt-away form. Almost all children fear intrusive procedures. This can make them resist accepting medication given by a rectal, nasal, intramuscular (IM), or intravenous (IV) route. Because children range in size from as small as 1 pound (0.5 kg) if premature to over 200 (90.9 kg) pounds by late adolescence, there is no "standard" dose of medicine. This can make it difficult to determine the correct dose (Hartling et al., 2009). In addition, children have difficulty reporting adverse effects of medicine as accurately as adults. This can make it difficult to determine if side effects or adverse effects are occurring. All these things make medicine administration for children one of the most challenging interventions in nursing. National Health Goals that address this area of child health practice are shown in Box 38.1.

BOX 38.1 ✻ Focus on National Health Goals

When administering medicine to children or teaching children and parents how to take medicine, remember that medicines can be as dangerous in overdoses as they are helpful in the correct doses. They can be ineffective if the doses are inadequate or missed. Poisoning and drug abuse are addressed by the following national health goals:

- Reduce the incidence of childhood poisonings, from a baseline of 348 per 100,000 population to a target of 292 per 100,000 population.
- Increase the proportion of adolescents not using alcohol or any illicit drug during the past month from a baseline of 79% to a target of 89%.
- Reduce the rate of steroid use among adolescents in the past year from a baseline of 1.5% to 0.4% (http://www.nih.gov).

Nurses can help the nation achieve these goals by educating parents about safe drug storage (locked in elevated cabinets) and teaching children and parents about effective nonpharmacologic ways to relieve stress or anxiety to help reduce drug dependence.

Areas related to these goals that could benefit from additional nursing research to strengthen evidence-based practice would include studies on the most effective ways to teach parents about safe drug storage, the phenomenon that drug poisoning increases when families are under stress, and effective ways to impart information to adolescents about the seriousness of drug abuse and its possible consequences.

Nursing Process Overview

For a Child Needing Medication/Intravenous Therapy

Assessment

Because children vary so greatly in size and individual need, medication administration to children begins by assessing the child's height and weight so a correct dose of medicine or amount of IV fluid can be calculated based on the child's surface area. Also crucial to assessment is the child's developmental age. This is important because it will reveal if a child can swallow oral medicine or can use such self-medication methods as patient-controlled analgesia; in addition, it will1 help you determine which site would be best for an IM or IV injection. Also assess the child's chronological age and cognitive level to aid in planning the level of explanation that will be needed. Include an assessment of the child's past experience with taking medicine to help predict what a present response to medicine administration might be. Last, inquire about the family's cultural beliefs and attitudes toward medications, including use of herbal or folk remedies.

People's attitude about the worth or wisdom of medicine is not consistent across cultures. Not all families, therefore, can be expected to accept medicine administration as enthusiastically as others; some families believe an herb or home remedy would be preferable. Because of this, a family may accept a prescription but then not fill it or administer the medicine. In addition to prescribed medicine, some families give herbal remedies that can duplicate or counteract a medicine's effect. Keep in mind, too, that medicine is expensive and difficult for many families without health insurance to afford.

As part of health histories, always ask if a child commonly takes any type of herbal or home remedy or if the child has been given anything specific for the present illness. When you give parents a prescription, ask them if they think they will have any difficulty with obtaining or giving it, assessing for the medicine's effect, or returning for a follow-up appointment to evaluate the medicine's effect. Such questions allow parents to say they have questions about the medicine or are uncertain whether they should give it because of a cultural belief.

Following medicine administration, careful observation must continue to determine if the medication is having its desired effect and if any unwanted or adverse effects are occurring.

Nursing Diagnosis

Common nursing diagnoses related to medicine administration vary widely. Some examples are:

- Disturbed sleep pattern related to q4h (every 4 hours) timing of medication administration
- Deficient knowledge related to action and side effects of medicine
- Fear related to IV administration of medicine
- Discomfort related to rash as side effect of medicine
- Health-seeking behaviors by parent related to desire to learn more about different types of medicine available for child's illness

Outcome Identification and Planning

Planning for medicine administration for children involves the same safe rules of administration as those for adults. Extra consideration is necessary at each step, however, because determining the right form and route of medicine such as liquid or capsule, oral or IM, varies so widely. Establishing that a dose is accurate for that size child can involve recalculating the dose using a nomogram that shows body surface area. The schedule for administration must be not only one that is effective for the drug's action but also one that will not interfere with school activities, eating, or sleep.

Explain to children the effects that can be expected from any medicine. Be certain to give this explanation at an age-appropriate level, and be sure it is consistent with any prior explanation that a parent or other health care provider has given. The American Academy of Pediatrics Web site (http://www.aap.org/) offers information on general medicine administration and tips on how to read medicine labels and is a useful site to recommend to parents. The RN Voice site (http://www.ManageIVpain.com) offers helpful tips on how to reduce insertion pain.

Implementation

Medicine and IV interventions with children include both administering medicine to ill children and teaching parents and children how to continue to take the medicine when at home or at school. As long as a child is uncomfortable or has definite disease symptoms, parents tend to give medicine conscientiously. However, when symptoms fade, a child returns to school, or the family returns to its busy everyday schedule, it is easy for parents to forget to give medicine. This can leave children open to a recurrence of the condition or symptoms, such as pain or recurrent infection, because the organisms causing the illness were only suppressed, not killed. Helping parents fill out administration schedules to post in a readily visible location, such as on the refrigerator or a bathroom mirror, can be as important an act as explaining the drug's action to help ensure all doses of medicine will be given.

Outcome Evaluation

Expected outcomes associated with medication administration should ensure that a child received the medicine as prescribed and that the medicine had the desired effect. Specific examples suggesting outcome achievement are:

- Child states she understands she must continue to take thyroid hormone for a lifetime.
- Parents list the adverse effects of the drug and state the telephone number they will call if adverse symptoms occur.
- Adolescent describes an administration program that includes four doses daily but allows time for sports activities after school.
- Child contracts to allow IV therapy if it is inserted into nondominant hand.

MEDICATION ADMINISTRATION

Medications in children are given by a variety of routes: orally, intranasally, transdermally, topically, rectally, and via injection (subcutaneous, IM, IV, intraosseous, or epidural) or by inhalation. Epidural administration is described in Chapter 16. Inhalation techniques are discussed in Chapter 40.

To administer drugs safely, it is important to have a good understanding of **pharmacokinetics** (the way drugs are absorbed, distributed throughout the body, metabolized, inactivated, and excreted).

Pharmacokinetics in Children

The four basic processes of absorption, distribution, metabolism, and excretion determine the intensity and duration of a drug's action. The immaturity of body systems in children (and especially in newborns) plays a major role in drug action throughout each of these processes (Stavroudis, Miller, & Lehmann, 2008).

Absorption

Drug **absorption** (transfer of the drug from its point of entry in the body into the bloodstream) is influenced by the route of administration as well as by the concentration and acidity of the drug. Some routes of administration in children are limited and so are rarely used. For example, children younger than school age usually cannot hold tablets under their tongue for sublingual administration; they tend to swallow them instead. The small muscle size of young children limits sites for IM injection. Infants pull off transdermal patches because they do not understand that this is a drug. Gastrointestinal absorption may be so immature at birth that oral absorption in newborns can be reduced. Vomiting and diarrhea, frequent symptoms of childhood illnesses, also interfere with absorption because a drug would not remain in the gastrointestinal tract long enough to be absorbed.

Distribution

Distribution refers to the movement of the drug through the bloodstream to a specific site of action. Many drugs are distributed bound to serum albumin (manufactured by the liver). This binding action limits the amount of free drug in the circulation, thereby providing protection against toxic levels of a drug. As free drug is used, the bound drug is released to maintain a therapeutic level. Newborns with immature liver function may not have enough serum albumin to transport drugs readily. This is particularly true if elevated bilirubin levels are present, because bilirubin is also carried by serum albumin. Bound to serum albumin this way, bilirubin is harmless. In free form, however, it can leave the bloodstream and enter other body tissues. If it enters the brain cells, it destroys their ability to function (kernicterus). If a newborn who has a high level of bilirubin from destruction of fetal hemoglobin receives a drug such as sulfonamide that competes for albumin binding sites, a large quantity of bilirubin may be left unbound and the infant may develop kernicterus or not receive benefit for the sulfonamide because it can not be carried to the infection site. In addition, newborns have sluggish peripheral circulation, so distribution in children this young may not be effective. Any child with cardiovascular disease also may have limited distribution of drugs because of poor circulation.

Metabolism

Metabolism involves the conversion of the drug into an active form (biotransformation) or an inactive form (inactivation). Because a child's basic metabolic rate is faster than that of an adult, certain drugs are metabolized more rapidly in children. This means the drug must be administered more frequently to a child to maintain effective drug levels than it would be in adults. Some drugs, such as the salicylates and chloramphenicol, are metabolized directly by liver enzymes. Because liver enzymes are not fully developed in newborns, these drugs cannot be metabolized and so will reach toxic levels rapidly. Older children with liver disease who have impaired liver enzymes also have a decreased ability to inactivate or transform drugs.

Excretion

The **excretion** (elimination of raw drug or drug metabolites, a process that largely prevents properly administered drugs from becoming toxic) of drugs is potentially limited until about 12 months of age, when kidney function becomes mature. If a child has kidney disease, excretion potential is limited at any age. A few drugs such as digitoxin are excreted in bile. In the newborn with sluggish bile formation, excretion of these drugs is questionable. Monitoring intake and output is important in children receiving drugs to be certain that urine excretion or an outlet for drug metabolites is adequate.

What if... Terry's mother tells you her child's school has a "no drug" policy, so the school nurse will not be able to give Terry even a prescription drug in school? How would you advise her?

Adverse Drug Effects in Children

Children respond to drugs in much the same way as adults, but they may experience unique or exaggerated side effects because of immature liver function or rapid metabolism during periods of rapid growth. The newborn may suffer adverse effects from drugs taken by the mother prenatally or from drugs taken by a breastfeeding mother.

Safe Storage of Drugs

Because young children do not appreciate that overdoses of medicine can be serious and even fatal, they may help themselves to additional medicine and poison themselves (Dart & Rumack, 2008).

Adolescents can deliberately take extra doses of drugs such as steroids or pain medicine, hoping for an added effect. Oxycodone (OxyContin), for example, is an analgesic that may be prescribed for adolescents (Baker & Jenkins, 2008); it is also frequently abused by them. Ritalin (methylphenidate), administered to children with attention-deficit/hyperactivity disorder, is a second prescription drug that is also frequently abused (Szobot & Bukstein, 2008).

As with adults, always be certain medicine is stored in a safe place. A toddler walking past a medicine cart, for example, could easily explore it and remove a handful of pills. For the same reason, never leave medicine on a bedside table for children to take later if they are playing a game or taking a shower; a nearby toddler could take the medicine first.

When teaching parents about administering medicine at home, stress that they also need to keep drugs in a safe place. In most homes, this is in a locked medicine cabinet or drawer above the height their child could reach. Remind parents that most childhood poisonings occur when a family is under stress because, during these times, the family may forget usual procedures. Reinforce the need to take special precautions to lock away medications at these times. Be certain to teach parents they should never take medicine in front of children (children can imitate this action with the parent's medication when the parents are out of sight). Another caution is not to pour or prepare medicine in the dark. Because almost all medicine bottles dispensed from local pharmacies look and feel the same, it is easy to pour the wrong liquid, extract the wrong pills, or read the bottle instructions incorrectly without adequate light.

Safe Administration of Drugs

Administering drugs safely to children requires that you first determine that you are giving the right drug to the right child, in the right dosage and by the right route, at the right time. You also need to ensure that the parents or child have the right information about the medicine.

Right Medicine

Most medication errors are made in situations where the number of medications being given is high and speed in administration is crucial. Intensive care units and emergency departments, therefore, are the highest areas at risk for medication errors (Root, 2007). A prescriber may write an order using a generic or a trade name. As the number of medicines available grows, so does the possibility that two drugs have similar names. That makes the step in medicine administration—identifying you have the correct drug—even more important than ever.

Right Child

Children cannot be depended on to give their correct names. Anxious to please, a preschooler will answer the question, "Are you Johnny Jones?" with "yes." He may also agree with any other name you propose. School-age children who want to avoid taking a medicine may deny they are the person whose name you called. To prevent these types of errors, never ask children their names for identification. Instead, read their identification arm bands and compare them with the medication sheet or medical record. In ambulatory care settings or homes, ask a parent to confirm the child's identity.

Right Dosage

The correct dosage of most drugs for children is based on body surface area using a nomogram (Fig. 38.1). To calculate surface area using such a chart, find the child's height in the left column (40 cm, for example); next, find the child's weight in the right column (20 kg). Hold a ruler or straightedge to connect the two points. The mark at which the ruler crosses the center column is the child's body surface area (0.38 m^2 in the example). Before administering any medication to a child, confirm that the dose ordered is correct for the child's weight or this body surface area. Take and record height and weight measurements at health visits or on hospi-

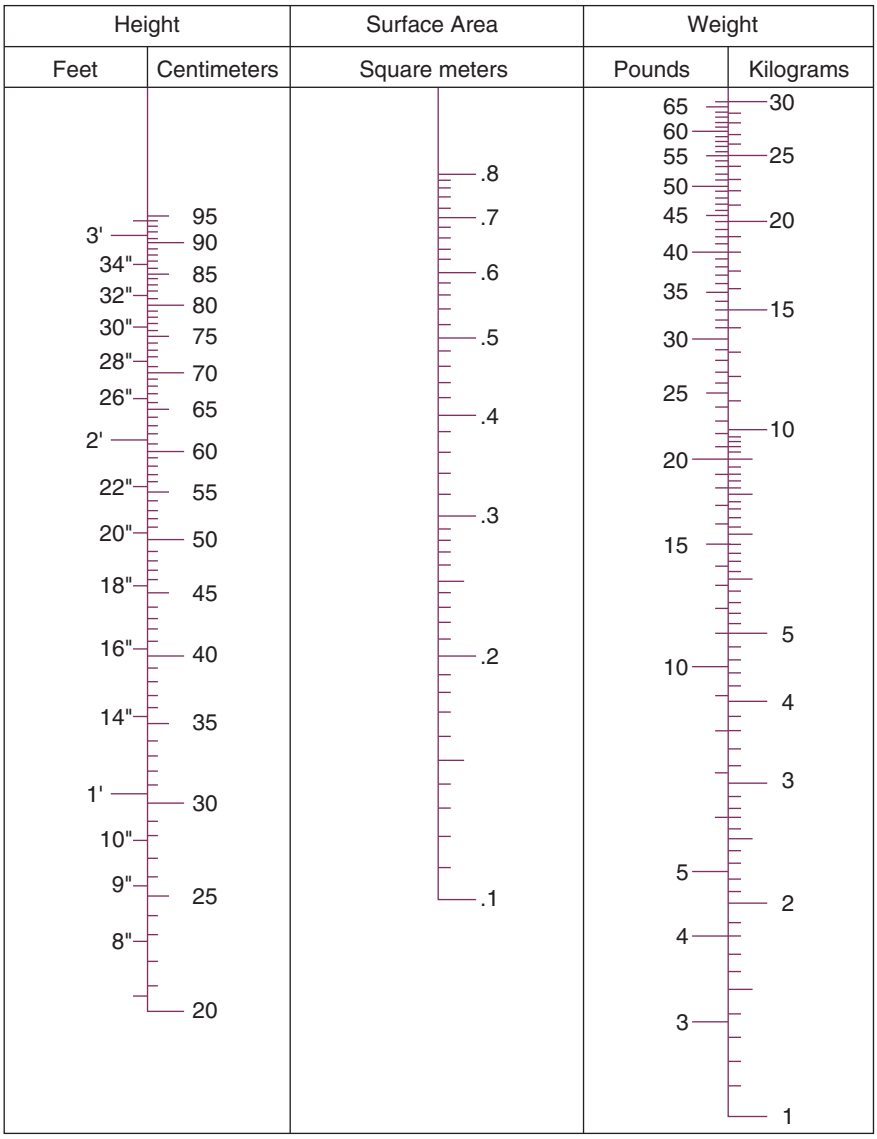

FIGURE 38.1 A nomogram to estimate body surface area. To use such a chart, draw a line from the child's height to the child's weight. The point at which it crosses the middle line is the child's surface area.

tal admission (or as frequently as daily during an admission) to obtain this information for dose calculation.

Many hospitals use color coding to help identify a correct drug dose. Every pediatric unit or clinic should have a drug reference, such as the *Physicians' Desk Reference*, to help determine safe drug doses. However, there are always exceptions to a rule. For example, a child with a gunshot wound may receive more than the usual dose of antibiotics because the risk of infection is so high. A 3-year-old weighing only as much as a 1-year-old would receive a dose of an antibiotic consistent with that given to a 1-year-old (not the child's actual age) because of small body size. Because of such exceptions, an ordered dose that does not conform to the standard dose may still be correct; however, recheck the dose for accuracy with the prescriber before it is administered. Preventing medication errors in children is everyone's responsibility.

Although most medication on hospital units is supplied in unit doses, nurses may still need to calculate fractional dosages (Box 38.2). By verifying drug dosages, nurses serve as a child's first line of defense against dosage error. When talking to parents about giving medicine, stress that if a medicine comes supplied with a dropper or dosing cap, they should use that to measure the amount of medicine (Sobhani et al., 2008).

Right Route and Time

Possible routes of administration for medicine in children are discussed below. Each of these methods requires special techniques, as most children do not enjoy taking medicine and need strong support during administration.

Right Information and Documentation

Because so many medications are advertised directly today on television or in magazines, many parents are already aware of drug names and the action of individual drugs. However, because they have been given only snatches of information (or listened to or read only that much), they also may have misconceptions about a particular drug. Be certain when giving medicine to a child or handing a prescription to a parent that you explain the drug's purpose and action, when and how it should be taken, and any side or adverse effects the parent should be aware of. People under stress do not "hear" well, so

BOX 38.2 ✻ Fractional Calculation of Medication Dosages

To calculate a fractional drug dose use the formula:

$$\frac{\text{Strength Desired (D)}}{\text{Strength You Have (H)}} \quad \frac{\text{Quantity Desired (QD)}}{\text{Quantity You Have (QH)}}$$

= Answer

For example, you have an order for 90 mg acetaminophen. It is supplied as 125 mg drug in 5 mL liquid. Using the formula:

$$\frac{\text{90 mg (D)}}{\text{125 mg (H)}} \times \frac{\text{QD (what you are asking)}}{\text{5 mL (QH)}} = ?$$

125 QD = 450(5 × 90)

450 divided by 125 = 3.6 mL

although the prescriber may have reviewed this same information with them when the prescription was written, this may be the first time they actually hear it. Correct documentation assures other health care providers that a drug was administered and allows for continuity of care.

✔ Checkpoint Question 38.1

You are going to give acetaminophen (Tylenol) to Terry in the emergency department. She has no ID band in place as yet. What would be the best way to identify her?

a. Ask her what is her name.
b. Tell her you need to know her name.
c. Ask a parent to identify her for you.
d. Ask to see her school bus pass I.D.

Oral Administration

Children younger than 9 years often have difficulty swallowing tablets. For children younger than 3 years of age, it is virtually impossible. Most oral medication for young children, therefore, is furnished in liquid form, chewables, or meltaways (Sammons & Conroy, 2008).

In infants, oral medication can be given with a medicine dropper or a unit dose syringe (without a needle). Gently restrain the child's arms and head by holding the child against your body with the head raised. Never give medicine with the child lying completely flat; otherwise, a child could choke and aspirate. A crying child is already opening the mouth for you; otherwise, gently open the mouth by pressing on the child's chin. Press the bulb of the medicine dropper or use the plunger of the syringe so that the fluid flows slowly into the side of the child's mouth. Be certain that the end of the syringe or dropper rests at the side of the infant's mouth to help prevent aspiration (Fig. 38.2). An infant also may be given fluid from a small glass or spoon. Allow the fluid to flow a little at a time so that the child has time to swallow between small sips. As oral solutions are pleasantly flavored, most infants resist the first drop but then suck the remainder of the medicine into their mouth.

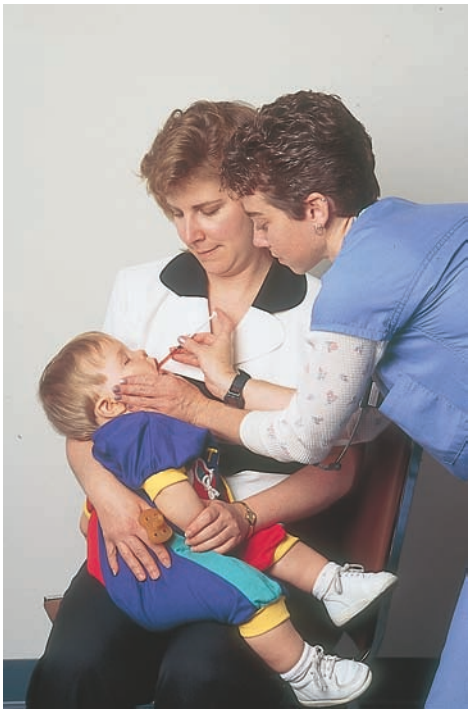

FIGURE 38.2 To administer oral medicine with a syringe, place the medicine at the side of the child's mouth.

Because firm pressure is used to give medicine to infants, they may be frightened afterward. Take time to sit and comfort or let a parent do this afterward. This action is as important as checking the correct dosage of the drug because protecting a child's mental health is as important as protecting physical health.

Preschoolers and early school-age children respond well to rewards such as stickers they can paste into a book each time they take their medicine. For older children, hand them the glass of medicine as if you expect them to take it. Offer a "chaser" if necessary and not contraindicated (Box 38.3). If a child has difficulty swallowing tablets, they can be crushed and added to a teaspoonful of applesauce or a flavored syrup. If pills are not to be chewed (capsules or enteric-coated tablets), be certain a child knows not to chew them. Some children are old enough to swallow tablets but have never done it before. You can use small bits of ice for practice; they melt rapidly and do not stick in the back of the throat or esophagus. Have the child put the ice on the back of the tongue, tip the head slightly to the side, take a sip of water, and swallow the water. Praise the child for learning this new skill. Do not use candy for practice; you do not want to suggest that medicine is the same as candy.

Another useful technique to help a child swallow pills is to push them into a teaspoonful of ice cream or pudding. Children tend not to chew this type of food; rather, they swallow it along with the pill. If using this technique, push the pill into the ice cream or pudding in front of the child. The intent is not to hide the pill, but to help the child learn to swallow medicine.

Box 38.4 gives additional guidelines for administering oral medication to children or teaching parents how to give medicine at home.

BOX 38.3 ✻ Focus on Communication

You want to give acetaminophen (Tylenol) to Terry, 8 years old, to help relieve her pain.

Less Effective Communication

Nurse: I have your medicine, Terry. Swallow these for me?
Terry: No. My ankle is too sore.
Nurse: If you don't swallow them, I'll put them into a shot and give it that way. And that will really hurt.
Terry: I'd rather get a shot, my ankle is so sore.
Nurse: Well, I can't do that. Tylenol doesn't come that way.
Terry: Then I'm not going to take it.

More Effective Communication

Nurse: I have your medicine, Terry. Swallow these for me.
Terry: No. My ankle is too sore.
Nurse: That's why I want you to swallow the pill. It'll take away the hurt.
Terry: I'd rather get a shot, my ankle is so sore.
Nurse: This type of medicine has to be swallowed. Do you want orange juice or soda pop to drink after it?
Terry: Soda pop.
Nurse: Okay. Take a big swallow and it'll be gone.

The nurse in the first scenario makes some important medication administration errors: first, he *asks* the child if she will swallow the tablets rather than *telling* her to swallow them; second, he threatens the child; even worse, he threatens with a measure he cannot enforce (acetaminophen does not come in an injectable form). When the child refuses the request and contradicts his threat, he is left powerless. A better approach is shown in the second scenario: here, the nurse explains the advantage of taking the medicine and conveys that he expects the child to be cooperative. Allowing a secondary choice, such as a choice of beverage, offers children a sense of control but does not allow them to say no to the primary request.

BOX 38.4 ✻ Focus on Family Teaching

Guidelines for Administering Oral Medication

Q. Terry's mother tells you, "All my children fight me anytime they need to be given medicine. How can I get them to take medicine without a battle?"

A. Use the following guidelines to help make this task a bit easier:

- Do not say, "*Can* you drink this for me?" If an adult seems unsure whether children can do a task, children can develop grave doubts themselves.
- Do not say, "*Will* you drink this for me?" This leaves a child the opportunity to say no and creates the awkward position of having to admit that the child really does not have a choice in the matter; the child *must* take the medicine.
- State firmly, "It's time for you to drink your medicine now." Give the child a secondary choice that allows a sense of control: "It is time to drink your medicine now; do you want milk or water to swallow after it?" is a suitable choice, assuming both milk and water are compatible with the medication.
- Never refer to medicine as candy. If they think it is candy, children may help themselves to fatal amounts of medicine when everyone's back is turned.
- Do not bribe children to take medicine. Bribing may work for one dose, but when a second dose is due, the child will ask for a bigger bribe; for a third dose, an even bigger one. At some point (generally reached quickly), it is impossible to supply such large bribes and therefore it is impossible to enforce the rules.
- Do not threaten. Statements such as, "Take this quickly or I'll ask the doctor to make it into a shot" cannot be followed through. The child calls the bluff (many medicines do not come in a form that can be injected intramuscularly), and once more the child is in control. A statement such as, "Take this or I'll call your doctor" is unfair (the physician has been made the villain) and ultimately undermines your authority (it is obvious that you must not have much power, or you would not need help).
- Do not lie about the taste of medicine. Children expect honesty from adults. If in doubt about the taste, taste it (with the obvious exception of drugs such as digitoxin). Most children's medicines are artificially flavored with raspberry, orange, or cherry syrup, so they do not taste bad.
- If a medicine tastes bitter, mix it with a spoonful of strained applesauce or a teaspoonful of flavored syrup. Do not mix medicine with a full jar of baby food, because the child will then have to eat the entire jar of food to get all of the medicine. As a rule, encourage children to take medicine straight, then follow it with a pleasant-tasting drink to take away any bitter taste.
- If a medicine is supplied in tablet form, crush or dissolve it in water and mix it with syrup or applesauce for a better taste if appropriate. Be certain before removing the particles from a capsule that the medicine will work properly when not in capsule form: some are encapsulated to keep them from dissolving in the stomach and to bring them into the intestine, where they have their therapeutic effect. The same precaution must be followed when giving enteric-coated tablets.
- Never leave medicine by a child's bed for the child to take "in a minute" or "after your shower." The child may become involved with another activity "in a minute" and will not take it, or a smaller child could find the medicine appealing and swallow it.

What if... Terry's father tells you Terry is such a "picky eater" that she rarely eats a full meal? When should he give a medicine that should be taken with a meal?

Intranasal Administration

More medications are supplied as nose drops or spray every year (Holsti et al., 2007). These are advantageous in that a nasal spray is easy for a parent to administer. Having someone drop medicine into the nose can be very uncomfortable, though. Tell the child you understand this, but that the medicine is important because it will help the child get better. Explain what you are going to do: "I'm going to place two drops of medicine into your nose. Then I want you to sniff for me [demonstrate]. Then I'll put two drops into the other side of your nose and I want you to sniff again."

Turn the child onto the back. A school-age child could extend the head over the side of the bed so that it is lower than the trunk. Preschoolers generally are too frightened by this strange position and do better with a pillow under their shoulders so that their head extends over the pillow and rests downward. An infant may need to be restrained in a mummy restraint for nose drop administration (see Chapter 37 for a discussion of appropriate restraints).

Instill the appropriate number of drops into one nostril. Turn the child's head to the side—to the left after the left nostril, to the right after the right nostril—so that the medicine stays in the nose longer. If the child is a preschooler or older, ask him or her to further "sniff" the medicine. Have the child remain in the head-flat position for at least 1 minute to let the medicine come in contact with the mucous membrane of the nose. If a child gets up immediately, the medicine will flow out and will be less effective.

Give children high praise even if they did not cooperate well. Praise tells children you understand how hard it was to stay still.

Children over about age 6 can use nasal sprays competently after they have been introduced to the technique. Acknowledge that spraying a liquid into the nose is uncomfortable because it tickles or causes a sneezing sensation. Have the child sit or stand upright, hold the spray bottle upright with the tip just inside one side of the nose, and gently squeeze the spray bottle. In most instances, a child should then tip the head to the side (the right side for the right nostril, the left side for the left nostril) or sniff, depending on the bottle instructions, for best absorption. The administration is then repeated for the second nostril. Stress that although this form of medication administration seems simple and "fun," drugs are well absorbed across the nasal mucosa so this route is an effective means of drug administration and can be a route for important and even life-sustaining drugs. Spray bottles should be individually prescribed for children and not used by any other child to prevent the spread of disease organisms. As influenza vaccine is now supplied in this form, in the near future, children will be more and more familiar with this route of medicine administration and, hopefully, less resistant to the method (Carpenter et al., 2007).

Ophthalmic Administration

Eye medications, in particular antibiotics to treat eye infections, are most often administered by being dropped into the conjunctival sac of the eye (Renouf, 2007). This type of administration, like nose drops, is frightening for children because they have been warned many times never to put anything into their eyes. Also, children know that getting something in the eye, such as dust, which has probably happened at some point, can be painful. As a result, infants and preschoolers generally must be restrained in a mummy restraint for eye drop administration. Always explain what you are going to do and that the medicine will not hurt (assuming that is true). Place the child on the back. Open the eyes of infants and preschoolers by gently but firmly pressing on the lower lid with the thumb and on the upper lid with the index finger. A school-age child or adolescent will open eyes cooperatively, but you may need to rest a hand on the eyelid to keep the eye open long enough for the drug to be administered (Fig. 38.3). Be sure that your fingernails are cut short to avoid scratching the child's cornea.

Instill the correct number of drops into the conjunctiva of the lower lid. Allow the eyelid to close. Avoid placing the drops directly on the cornea, because that can be painful. To prevent the conjunctiva from drying, do not hold the eyelids apart any longer than necessary. After the child has blinked two or three times, allow the child to get up. Praise the child for cooperation even if cooperation was not evident; the child accomplished a major feat by allowing you to touch and invade an eye this way.

To instill an ophthalmic ointment, apply a fine line of the ointment along the inside rim of the conjunctival sac, working from the inner to the outer eye canthus. If the eye is pus-filled, applying medication under pressure toward the midline can force pus across to the other eye or down the lacrimal duct, so applying the medicine from the medial aspect to the outer one may prevent transferring infected mucus from one eye to the other. Eye medicine should be individually prescribed and not used by other children, because if the tip of the dropper or tube touches the conjunctival sac it is contaminated with body fluid.

Otic Administration

Otic administration refers to administering medicine, primarily drops, into the ear canal. Like other forms of medicine, this is difficult for children to accept because they have been told many times not to put anything into their ears.

FIGURE 38.3 Administering eye drops.

Also, because ear drops are generally administered for earache, which is sharp, excruciating pain, a child may worry that having medicine put into the ear will make the pain even worse. In addition, a child cannot watch what is happening (always frightening), and the odd sensation of drops of fluid running into an ear can cause a tickling, uncomfortable sensation. Assuming that you have been honest with the child up to this point, remind the child, "Remember how I told you the injection would hurt a little? Well, if this would hurt, I'd tell you now, too. But this doesn't hurt." Remind the child that ear drops can feel funny, however, as if someone were tickling the ear. Ear drops must always be used at room temperature or warmed slightly. Cold fluid, such as medication taken from a refrigerator, does cause pain and may also cause severe vertigo as it touches the tympanic membrane.

Place the child on the back, in a mummy restraint if necessary. Turn the head to one side (Fig. 38.4). The slant of the ear canal in children is shown in Chapter 50. If the child is younger than 2 years, straighten the external ear canal by pulling the pinna down and back. If the child is older than 2 years, pull the pinna of the ear up and back. Instill the specified number of drops into the ear canal. Hold the child's head in the sideways position for at least 1 minute to ensure that the medication fills the entire ear canal. Praise the child for cooperation after the procedure.

Rectal Administration

A good route for administering medication to children who are unconscious is by rectal insertion, because this avoids the danger of aspiration and allows a drug to be absorbed across the mucous membrane of the intestine (Kleiber, 2008). Rectal administration may be used to give a drug such as Tylenol to uncooperative young children or those who are vomiting. Most children, however, rate this as the least desirable method for receiving medication so it is not a major route of administration.

Some medications are given by rectal suppository; a few are given by retention enema. Because the child cannot see what is happening with rectal administration, a child can be easily frightened by this procedure. Show the child the medication so that the child can be certain it is not an injection. Having been honest with the child up to this point will be helpful again: "If it were anything else, I would tell you so."

FIGURE 38.4 Administering ear drops. For the child over 2 years old, the pinna of the ear is pulled up and back.

Many suppositories are supplied already lubricated. If not, add a drop of water-based lubricant such as K-Y Jelly to the tip. Use a glove and insert the suppository gently but quickly beyond the rectal sphincters (approximately ½ inch or as far as the first knuckle of the little finger for infants, and approximately 1 inch or as far as the first knuckle of the index finger for older children). Withdraw your finger and press the child's buttocks together firmly for a count of approximately 10, or until the child's urge to evacuate the suppository passes.

If the medication is to be administered by a retention enema to a young child, use usual enema technique, but with as small an amount of fluid as possible so the child can retain it. Press the child's buttocks firmly together for approximately 15 seconds after administering the enema or a child will expel the solution almost immediately and the medicine will be lost. Using a distraction technique, such as asking the child to count backward or saying the alphabet backward, can also help a defecation reflex to pass. Remember that invasive procedures are particularly threatening to the preschooler. Give lavish praise for cooperation.

Transdermal/Topical Administration

Children who have skin irritation or need medicine to relieve itching or dryness may have topical creams or lotions prescribed. Most children accept this type of application well because the medicine brings almost immediate relief. Children as young as toddlers can help apply this type of medicine with your supervision. Be certain they wash their hands afterward so they do not lick any extra off their fingers and inadvertently take it orally.

Several children's medicines are available by transdermal patch, because absorption of drugs through the skin can be yet another effective and pain-free route for administration. Be certain that the child's skin is dry and intact at the site where the patch will be applied. Apply patches over the trunk or a major muscle, not on distal extremities, for best absorption. Assess the skin under the patch every time a patch is changed to be certain the site is not becoming irritated. Change the site every time a new patch is applied to decrease the possibility of irritation to the skin.

Young children tend to remove transdermal patches the same as they do Band-Aids because of normal curiosity about what is underneath. Putting clothes on the young child immediately so the patch is out of sight is helpful. Be certain patches applied to children wearing diapers are not placed where a leaking diaper could wet the patch and irritate the skin or dilute the medicine.

Intramuscular and Subcutaneous Administration

IM injections are rarely prescribed for children because many children do not have sufficient muscle mass for easy deposition of medication, and they are often painful. For IM injections in infants, the mandatory site for administration is the vastus lateralis muscle of the anterior thigh (Fig. 38.5). Use the lateral aspect rather than the medial portion, where an injection would cause more pain. Using the gluteal muscle in

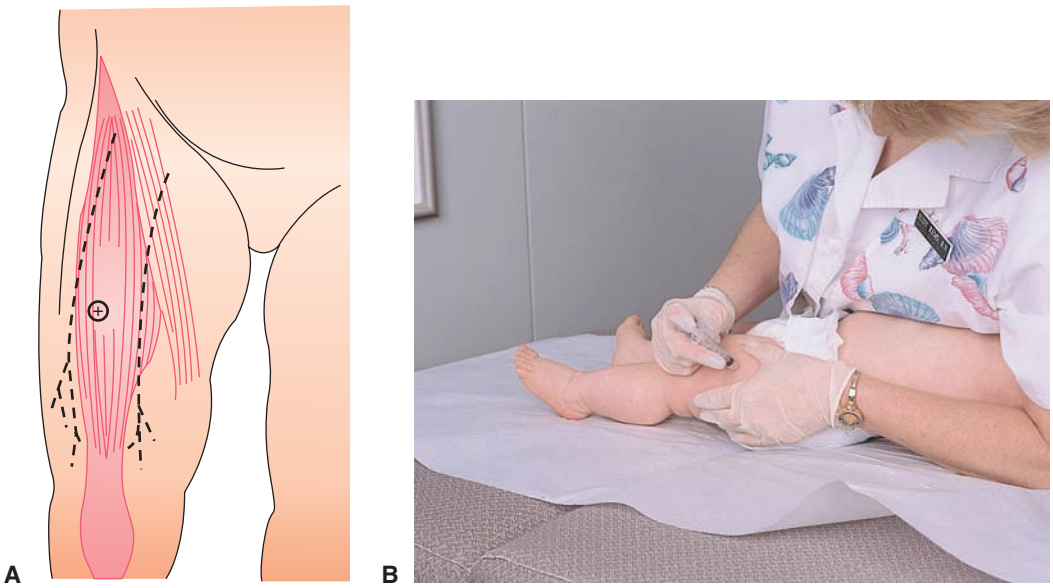

FIGURE 38.5 (**A**) For infants under walking age, use the vastus lateralis muscle for intramuscular injections. (**B**) Technique for administering an intramuscular injection to an infant. Note the way the nurse uses her body to restrain and stabilize the infant.

children younger than 1 year is extremely hazardous as this muscle does not develop until a child walks. This means that the sciatic nerve occupies a larger portion of the area than later on and could be permanently damaged by gluteal injections. Figure 38.5 shows an effective restraining technique for giving injections to infants. In older children, as in adults, the deltoid muscle (see Fig. 38.6A) or a ventrogluteal site (see Fig. 38.6B) should be used.

Never give injections to children who are sleeping in the hope they will not wake up and notice what is happening. They will wake up and will be terrified at being attacked. Instead, always give a short explanation of what you are about to do. Be honest about the pain involved; try to describe it accurately so that the child knows it has limits (a small amount of pain for a short time) with an explanation such as, "I have some medicine for you. I'm going to put it into your leg. It will sting for a second just like a pinprick. Then it will be over." To reduce pain further, ask for a prescription for an analgesic cream to be applied an hour before the injection (see Chapter 39). Most children react well to injections if you acknowledge that even with an anesthetic cream, injections can still hurt.

When giving injections, once you have described the drug's purpose and what you are going to do, do not delay giving the injection further by trying to distract the child or make a case it will not be bad. The suspense the child can feel while waiting can be worse than the actual injection. Give the injection quickly, but always use good technique. Remember to aspirate (if indicated). Quickness counts, but safety is your priority. Massage the area briefly after the injection to help ensure absorption of the medication, but remember that the rubbing may be painful and may be experienced as intrusive.

Statements such as "Don't cry" are not therapeutic. When children feel pain, they should be allowed to cry. As a way of giving children a better sense of control, you can tell them to say "ouch" or yell or scream when the needle is inserted. Most children appreciate being given approval to vent their feelings this way.

If necessary, ask for help in restraining a child when giving an injection to ensure safe administration. School-age children, however, may be proud they are able to lie still; being re-

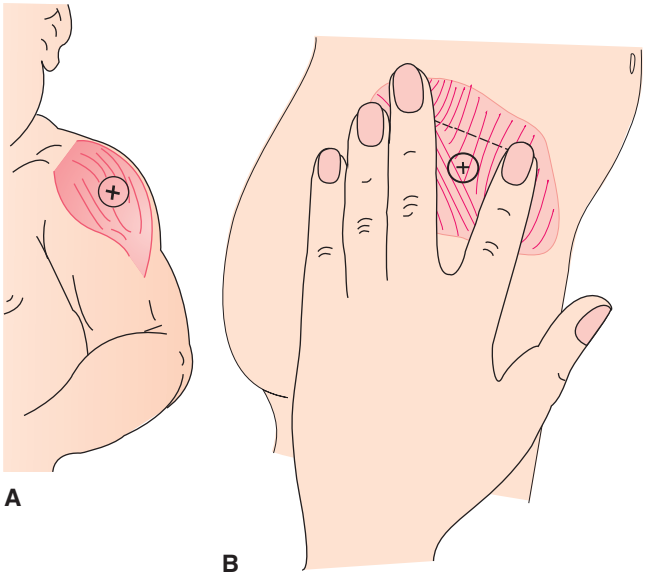

FIGURE 38.6 Sites for intramuscular injection. (**A**) In older children, the deltoid muscle is an acceptable site. (**B**) A ventrogluteal site may also be used in older children. Place the heel of the hand on the greater trochanter and the index finger angled toward the child's anterosuperior iliac crest, spreading the middle finger along the crest posteriorly. The triangle formed by the space between the index and middle fingers is the correct site.

strained would shame them. Hold and comfort a young child after all painful procedures, or let a parent do this.

Record the site of an IM injection as well as the medication injected, so that sites can be rotated for better absorption.

Continuous Subcutaneous Pump Infusion

Continuous subcutaneous pump infusion is administration of a medication by the constant infusion of a medication into the subcutaneous tissue using a medication pump (Khan & Younger, 2007). Continuous pump infusions supply a constant level of medicine to sustain consistent blood levels. The disadvantage is that a child must be careful to protect the pump from damage.

With an infusion pump, the drug is instilled into the subcutaneous tissue by the constant forward movement of a plunger of a medicine-filled syringe. The site chosen is usually the abdomen, as this both protects the pump and allows it to be out of sight. Insulin (see Chapter 48) and heparin are two drugs often prescribed for use with infusion pumps. Based on the success of this infusion technique for long-term drug administration, the system likely will be even more frequently used in the future.

The syringe is filled with medicine, and a small tube with the needle attached at the distal end is attached to the hub of the syringe. The syringe is then clamped to the pump, and the skin site is cleaned with alcohol and the needle inserted at a 45-degree angle (usual subcutaneous insertion technique). As soon as the needle is taped in place, the pump is turned on (see Fig. 20.5).

The insertion site should be changed every 1 to 2 days to reduce the possibility of infection. The pump should be removed to shower (the syringe, tubing, and needle can be left taped in place). For swimming or tub bathing, the entire pump, syringe, tubing, and needle should be removed. In children who are not toilet-trained, it is important to keep the pump and insertion site away from an area that could be soiled with urine or stool.

Older children, like adults, can be worried at first that the pump will fail to operate, so they check it often to be certain the syringe is emptying. With small children, cover the pump with clothing to prevent them from touching or trying to manipulate the syringe.

✔ Checkpoint Question 38.2

Suppose Terry needs to have ear drops. What is the best technique for giving these?

a. Have her place them herself to give a sense of control.
b. Refrigerate the drug first so it numbs the ear canal.
c. Pull the pinna of her ear down to straighten the canal.
d. Keep her head turned to the side to help retain the drops.

INTRAVENOUS THERAPY

In the past, IV therapy was used extensively as a rapid means of hydrating children who had become dehydrated because of diarrhea. Today, oral rehydration therapy is most often used in this way (Hartling et al., 2009). IV therapy is a fast and effective means of administering medicine to ill infants or children, however, so it still has a common place in care. It can be used to maintain fluid and electrolyte balance, to produce therapeutic levels of drugs in the body quickly, and to provide rehydration and nutritional support (Ford, 2008). Blood or blood product replacement is another common therapy (see Chapter 44). IV fluid may be infused into a peripheral vein, a central venous access device, or a peripherally inserted central venous catheter. The amount, type, and rate of IV fluids for children are prescribed carefully to prevent fluid overload.

Determining Fluid and Caloric Needs of the Child

IV fluid administered to children and infants must be isotonic (exerts the same osmotic pressure as their bloodstream) to prevent destruction of red blood cells or water intoxication. Using isotonic fluid prevents a pressure gradient that would lead to fluid shifting into the interstitial tissue (as would happen if the IV fluid were hypotonic) or fluid shifting from interstitial tissue into the bloodstream (as would happen if the IV fluid were hypertonic). Lactated Ringer's and 0.9% normal saline are two isotonic IV fluids commonly used in children. Normal saline 0.45% is a hypotonic solution that may be used with children who are dehydrated to restore blood volume quickly. Dextrose 10% in 0.9% sodium chloride is an example of a hypertonic solution that might be used to cause fluid to shift into the bloodstream to relieve cerebral edema for a child with a head injury. A typical fluid used for maintenance is 5% dextrose in 0.2% normal saline.

It is important to understand the principles of IV therapy, including the fluid and caloric needs of the child (which differ significantly from those of the adult) so you can act as a second level of protection against overhydration or underhydration.

Table 38.1 shows a method of calculating fluid requirements for children. Fluids administered using this table should contain 5% dextrose and 25 mEq sodium and 20 mEq potassium per liter so nutrients for energy and electrolytes are also replaced. Common IV solutions and oral rehydration formulas used with infants (rehydralyte and pedialyte) contain these proportions. According to Table 38.1, a child weighing 45 kg would need 2000 mL of a maintenance solution containing 5% dextrose, 25 mEq sodium, and 20 mEq potassium per liter. A flow rate would be calculated for this amount (2000 mL fluid in 24 hours = 83 mL/hr).

TABLE 38.1 ✻ A Method to Calculate Fluid Requirement

Body Weight	Fluid Requirement per 24 Hours
Up to 10 kg	100 mL/kg
11–20 kg	1000 mL + 50 mL/kg for each additional kg over 10 kg
More than 20 kg	1500 mL + 20 mL/kg for each additional kg over 20 kg

Box 38.5 Nursing Procedure ✻ Initiating a Scalp Vein Infusion

Purpose: To provide a route for intravenous therapy.

© Lesha Photography

Procedure	Principle
1. Adequately restrain the infant, using a mummy restraint.	**1.** Restraining the infant promotes safety. Mummy restraints are useful because it is physically exhausting to try to hold the infant's arms and legs still.
2. Press the child's head to the side and hold it firmly in that position, one hand on the occiput, the other securing the front of the head. Be certain that the hand resting over the child's face does not obstruct the child's breathing.	**2.** This positions the child without interfering with respirations.
3. Lather the site over the temporal bone with a cleaning solution.	**3.** The cleaning solution reduces the possibility of infection.
4. Carefully shave the hair. Assure parents that the hair will grow in quickly after the procedure. Ask parents if they want to save the clippings of hair if it is their child's first haircut.	**4.** Hair removal allows a clear view of the insertion site and possibly reduces the risk of infection.
5. Apply EMLA cream to the chosen site. After 60 minutes, place a rubber band around the infant's head at the level of the forehead.	**5.** A tourniquet is needed to dilate scalp veins. EMLA cream decreases discomfort but takes time to anesthetize the site.
6. Reswaddle the infant. Wash the shaved area with an antiseptic solution.	**6.** Washing the scalp further reduces the possibility of infection.
7. Insert a special small scalp vein needle or polytetrafluoroethylene (Teflon) catheter. Scalp vein needles have protruding plastic "wings" (often referred to as butterflies) on the sides to allow easy manipulation.	**7.** Use of an appropriate insertion device establishes a fluid route.
8. Continue to hold the infant firmly until the needle is securely taped in place, and until satisfied that the infusion is running well.	**8.** Securing the infant and device ensures an effective insertion site.
9. Cover the infusion needle with a piece of gauze (a plastic protector taped onto the site provides additional protection).	**9.** Covering the site keeps the infant from brushing the needle out of place when he or she turns the head.
10. If necessary, pin the shirt sleeves to the sides of the diaper or use a trunk or jacket restraint for an infant who is old enough to turn over.	**10.** Pinning the shirt keeps the infant from brushing at the site. Using restraints prevents the infant from turning over.
11. Spend some time comforting the child, talking and smiling at him or her, and lightly touching and stroking. Many infants enjoy sucking a pacifier after painful procedures; being held and rocked is the best comfort.	**11.** The infant may be frightened by the pinprick of the needle insertion, as well as by having been held so firmly for a length of time.

Obtaining Venous Access

The needle size for IV therapy varies depending on the solution and the rate at which it will be administered. Commonly used needle sizes include 22 gauge, 24 gauge, and 25 gauge (in newborns). "Butterfly" needles are metal needles with a flange of plastic added on both sides of the needle hub to give the person starting the infusion a wider surface to grasp, thereby making it easier to guide needle placement. Butterflies are also termed "scalp vein needles" because they were originally designed for use in infant scalp veins. A length of narrow tubing leads from the needle to the fluid administration tubing. This tubing must be flushed with IV solution before the needle is inserted to avoid an air embolus.

Sites frequently used for IV insertion in young children or infants include the veins on the dorsal surface of the hand or on the flexor surface of the wrist. Leg and foot veins also may be used. Another site is a scalp vein over the temporal area. An infusion placed in a scalp vein can be frightening to parents because it seems a much more serious procedure than an infusion administered into a hand. Explain to parents that scalp vein infusion is an effective method of administering fluid or medicine to infants and ultimately might cause the least discomfort for their child because needles there do not infiltrate readily (Box 38.5).

Preschoolers and older children often express a preference regarding where they want an infusion inserted. Offer a choice, if possible, or suggest the nondominant hand. Act as the child's advocate and see that wishes are respected.

Children who have IV infusions for long periods may require the placement of an **intracath** (a slim, pliable catheter threaded into a vein). The advantage of this type of device is that it cannot be dislodged as easily as a normally inserted IV needle, allowing a child to move about more freely.

For all children (including adolescents), IV infusions are usually secured in place with at least a small armboard. Although children may say they will be careful not to move their arms, without an armboard it is easy to move unintentionally to turn off the television set or reach for something that fell off the bed and accidentally dislodge the needle. Tape a board to the arm of an older child with the words, "This is just to remind you to keep your arm still"—an explanation more acceptable than if children think you doubt their ability to hold their hands still.

Determining Rate and Amount of Fluid Administration

Because children's hearts and circulatory systems are smaller than those of adults, IV fluid must be infused at a slower rate. If administered at an adult rate, the child's cardiovascular system could quickly become overloaded. Automatic rate-flow infusion pumps are useful when giving potent medications, and they should be mandatory for small children because they regulate the flow accurately to a few drops per minute (Fig. 38.7). Overloading of IV fluid in infants and children can also be prevented by use of fluid chambers, devices that allow only 50 to 100 mL of fluid into the drip chamber at a time. With these in place, even if the pump fails, only the amount of fluid in the drip chamber will be allowed to enter the child's circulation, not the entire contents of the bag suspended above the child's head.

FIGURE 38.7 An infusion pump and calibrated infusion chamber are safety features used with children's intravenous infusions.

A third fluid safety measure is the use of a minidropper, a device that reduces the size of the drop in the control chamber to 60 drops per mL (usually there are 10 to 15 drops per mL). With a normal dropper in place, an infusion regulated to administer 30 mL/hr drops at a rate of 7 or 8 drops per minute, so it is difficult to regulate. With a minidropper in place, the drops are smaller: the same infusion (still providing the same amount of fluid per hour) drops at 30 drops per minute. This flow is easier to regulate and provides more accurate IV administration.

Keep a careful record of both the rate and amount of IV fluid administered to guard against fluid overload. At least once an hour, record the type and amount of fluid; the rate of flow (including the number of drops per minute); and, for a cross-check, the amount of fluid remaining in the bag. Signs of fluid overload are those of congestive heart failure: increased pulse rate and blood pressure. As the heart becomes overwhelmed by excessive fluid, blood pressure falls and signs of edema develop. Watch for changes in vital signs such as these when children are receiving IV fluids. In addition, assess the specific gravity of urine at least every 4 hours to detect extremely dilute urine (specific gravity under 1.003) as this suggests the child is excreting a large quantity of fluid in an effort to reduce overloaded circulating volume.

It is difficult for children to lie still and wait for an IV infusion to finish (see Focus on Nursing Care Planning Box 38.6). Provide them with activities and allow them out of bed as much as possible. Infants and preschoolers may need to have their other arm restrained to keep them from playing with an infusion needle. Be sure parents understand the importance of the IV therapy and help guard the infusion site as well. Infants who receive total fluids by IV infusion generally enjoy sucking on a pacifier to fulfill their oral needs.

Parents and children often have numerous questions about IV therapy; Box 38.8 supplies appropriate answers.

BOX 38.6 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Child Receiving Medication

Terry is an 8-year-old with Down syndrome whom you see in the emergency room. She is diagnosed with osteomyelitis, a bone infection. When you give her a tablet of acetaminophen (Tylenol) for pain, she spits it out. She does the same when you repeat with a second tablet. Her mother tells you Terry cannot swallow pills. Her father tells you, "You'll have to give her medicine intravenously."

Family Assessment ✻ Child is youngest of four siblings. Lives with parents and other siblings in five-bedroom home on dairy farm. Parents rate finances as, "Fine, as long as people keep drinking milk."

Client Assessment ✻ Child diagnosed with Down syndrome at birth; IQ approximately 60. Lacerated right foot on farm equipment by fall from hay loft 2 weeks ago. Laceration cleaned and bandaged by mother; not seen by health care provider. Today, wound has not healed; is open and erythematous; foot swollen; pain radiates up leg from foot. X-ray reveals abscess in bone (osteomyelitis). Child is so frightened by injections that she screams at the sight of any kind of needle. Child placed on bedrest and prescribed intravenous antibiotic and Demerol.

Nursing Diagnosis ✻ Pain related to disease process (infection) in foot

Outcome Evaluation ✻ Child rates pain on pain scale as 2 or below. Cooperates with IV medication therapy to supply antibiotic and pain relief.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Assess what self-care measures child can complete by herself while on bedrest.	Explain resting foot and maintaining IV therapy are crucial measures.	Rest and antibiotic therapy will best cure condition and relieve pain.	Child, nurse, and parent agree on plan of care for activities of daily living.
		Consultations		
Nurse/ physician	Assess if pain management team advice will be necessary.	Meet with pain consultant to discuss problem: child is in pain but needs to remain still for IV therapy.	Sustained antibiotic therapy is necessary to treat bone infection; consultation can help avoid infiltration.	Pain management consultant meets with child and parent as appropriate; agrees on pain management plan.
		Procedures/Medications		
Nurse	Assess if child has a preference for IV therapy site.	Begin IV therapy in nondominant hand if possible per M.D. order.	Allowing a child as much freedom as possible helps to prevent a feeling of entrapment.	Child helps to identify insertion site; cooperates to the best of ability with IV insertion.
Nurse	Ask child to rate pain by FACES pain scale.	Explain to child and parents how IV will supply pain medication; begin IV infusion.	IV Demerol will effectively control child's pain.	Child agrees to use of IV for pain relief. Rates pain level hourly.
		Nutrition		
Nurse	Assess if child has had past experience with eating in bed.	Discuss with child and parent the importance of continuing nutrition while on bedrest. Suggest taking pain medication bolus before meals.	Hospitalization can be a major stress to children. Pain can interfere with nutrition.	Child discusses intent not to let hospitalization or pain interfere with nutrition.

		Patient/Family Education		
Nurse	Assess if child has had experience with IV therapy in the past.	Review importance and plan for IV therapy with child and parents.	Knowledgeable patients and parents can aid in the success of therapy.	Child and parents state they understand why antibiotic and analgesia is needed and why administration method is required.
		Psychosocial/Spiritual/Emotional Needs		
Nurse	Explore (if known) why child is so afraid of needles.	Discuss advantages of IV therapy, which will minimize injections yet supply antibiotic.	Fear of needles is common in children; advocating for IV therapy can help relieve this fear.	Child states she understands IV therapy will involve a needle but needle will be inserted only once.
		Discharge Planning		
Nurse	Assess if parents have questions about child's care at home.	Explain the importance of continuing oral antibiotic, adequate oral pain relief.	Continuing antibiotic administration will be necessary to combat deep-seated infection.	Parents state they understand importance of continuing medicine administration. Keep follow-up visit for evaluation.

BOX 38.7 ❊ Focus on Family Teaching

General Considerations for Intravenous Therapy

Q. Terry's mother asks you a lot of questions about intravenous therapy, such as "Why can't Terry just drink fluid?"

A. Parents and children often want to know more about IV therapy. Some of the typical questions parents ask are:

- Will the insertion hurt? (Yes, but only as the needle is inserted; after that the infusion will be pain-free.)
- How long will the infusion be necessary? (The duration differs depending on the medicine and fluid prescription and can vary depending on the effect of the medicine or fluid.)
- Isn't there another way to administer the same medicine? (Usually, no. IV administration allows medicine to reach the bloodstream immediately and so is the method of choice when immediate effect is important; also, some medications can only be given intravenously.)
- What can the child do during the infusion? (Any activity that will not interfere with the infusion. If a child will have medicine administration daily, help the child plan a special activity such as play a board game, listen to special music, or watch a favorite TV program, an activity reserved for only that time. This changes the IV infusion from a dreaded activity to a "can't wait for" activity.)
- Will it hurt when the needle is removed? (No, although taking off the tape that holds the needle in place may cause some discomfort.)

Intravenous Medication Administration

Medications may be added to an IV line as a small, one-time administration (bolus) or by piggyback for longer infusions. As with any medication administration, identify the child before adding medicine to an IV line. Also ensure that the drug to be injected is compatible with the IV fluid being infused.

To administer medicine by a bolus technique, clamp the IV tubing above the medicine port in the IV line; clean the port with alcohol; insert the needle of the syringe filled with the prescribed medicine into the port; and inject the medicine slowly and gently based on the manufacturer's instructions. Once the medication has been given, remove the syringe and needle and reopen the IV line immediately to allow the IV solution to flush the medicine into the child.

For a piggyback infusion of medicine, medication is provided by the pharmacy and prepared and diluted in small fluid-filled plastic bags. To begin a piggyback infusion, hang the piggyback bag, clean the medicine port on the IV line, and insert the piggyback system into the port. Lower the level of the main infusion bag and adjust the flow rate to that desired to allow the piggyback system to operate. As soon as the piggyback bag has emptied, elevate the maintenance bag of fluid again and make sure the IV line is flowing well and at the proper rate.

Children accept piggyback administrations of fluid well because it seems no different from receiving maintenance IV fluid. Older children can take an active role in alerting health care providers that the total medication amount has infused and it is time to return to maintenance fluid.

Analgesics are commonly administered to older children by patient-controlled analgesia machines (D'Arcy, 2008). Because these machines are set with lockout time intervals, they are safe to use with children as young as early school age (see Chapter 39). Although, when programmed, such pumps help protect against medication errors, they are not foolproof (Box 38.8).

BOX 38.8 ✻ Focus on Evidence-Based Practice

Does use of patient-controlled analgesia help reduce medication errors?

One of the advantages of patient-controlled analgesia is that the system can reduce medication errors, because if the pump is programmed correctly, no further thought toward medication administration seems necessary. To see if PCA administration does reduce errors, researchers analyzed medication errors from a national reporting service over a 5-year period. Of all the orders reported only 1% were related to PCA pumps. Of that 1% of errors, over one third (38%) involved an improper dosage or quantity, while 17.4% involved an omission and 17.3% an unauthorized or wrong drug. Overwhelmingly, human factors were the main cause of PCA errors. Equipment issues (19.5%) and similar drug names and product packaging (11.6%) were also implicated. Distractions (37.8%) and inexperienced staff (26.3%) were the leading contributing factors.

Based on the above study, do you need to check that a PCA pump that was programmed by another nurse is programmed correctly or should you just assume that the child is protected from a medication error because of the pump?

Using Intermittent Infusion Devices

Intermittent infusion devices, still sometimes called heparin locks, are devices that maintain open venous access for medicine administration while allowing children to be free of IV tubing so that they can be out of bed and more active (Fig. 38.8). The veins of the back of the hand are generally chosen as the IV site. Scalp vein tubing is used and capped at the end with a specially designed rubber stopper or a commercial trap. The tubing is filled with a dilute solution of heparin or normal saline through the rubber stopper and flushed again with solution every 2 to 8 hours (depending on hospital policy) to keep it patent. IV medication can be added to the site as needed. The tubing and stopper must be firmly secured to the wrist and an armboard taped in place to remind a child to protect the site from trauma.

FIGURE 38.8 An intermittent infusion device in place. Advocating for this type of apparatus minimizes pain.

Children who are hospitalized or receiving home care for a long time and who need only IV medication, not additional fluid, are good candidates for such devices. Intermittent infusion devices also can be used if frequent venous blood samples are required. If blood is drawn from the already inserted tubing, the child is pricked only once (when the device is originally placed) no matter how many samples are drawn. Similar devices may be inserted into arteries when arterial blood is required—for example, for the child who is having blood gases monitored frequently.

Using Central Venous Access Catheters and Devices

Venous access for long-term IV therapy can be obtained using a catheter inserted into the vena cava just outside the right atrium; the catheter exits the chest just under the clavicle (Fig. 38.9). Typical catheters used in this way include Broviac, Hickman, and Groshong catheters. Such catheters have a wrinkle-resistant fabric (Dacron) cuff that adheres to the subcutaneous tissue and helps to seal the catheter in place and keep out infection. These catheters are inserted by physicians or nurses who are specially prepared and are used to administer bolus or continuous infusions of medications and fluid (Jardine, Inglis, & Davies, 2009). Care of the catheters (depending on agency policy) consists of daily or weekly changes of dressings over the exit site and periodic irrigation with heparin or saline to ensure patency.

Such catheters are advantageous because discomfort from further skin punctures is avoided. One disadvantage is that the catheter could become snagged on something and accidentally be pulled out. If this happens, it is an emergency situation because the child could lose an appreciable amount of blood from the point of entrance into a vein as major as the vena cava. Unless there is a waterproof dressing covering the insertion site, children with central venous catheters in place are usually not allowed to swim or take showers, to avoid infection.

Vascular access ports (VAPs; infusion ports that can be implanted) are small plastic devices that are implanted under the skin, usually on the anterior chest just under the clavicle, for long-term fluid or medication administration via bolus or continuous administration (see Fig. 38.9D). A small catheter threads from the port internally into a central vein. Common brands include Port-A-Cath, Infus-A-Port, and Groshong Venous Port. After skin cleansing, blood samples can be removed or medication can be injected by a puncture through the chest skin into the port. Although this device requires a skin puncture (causes pain), it may be well accepted by children because it is not as visible as a central venous catheter, no dressing is required, and it allows a full range of activities, such as showering and swimming. Be certain when accessing these ports to use only the needle supplied by the manufacturer, because a regular needle tends to "core" or remove a small circle of the membrane over the port and destroy the integrity of the device. Use EMLA cream to decrease discomfort as necessary.

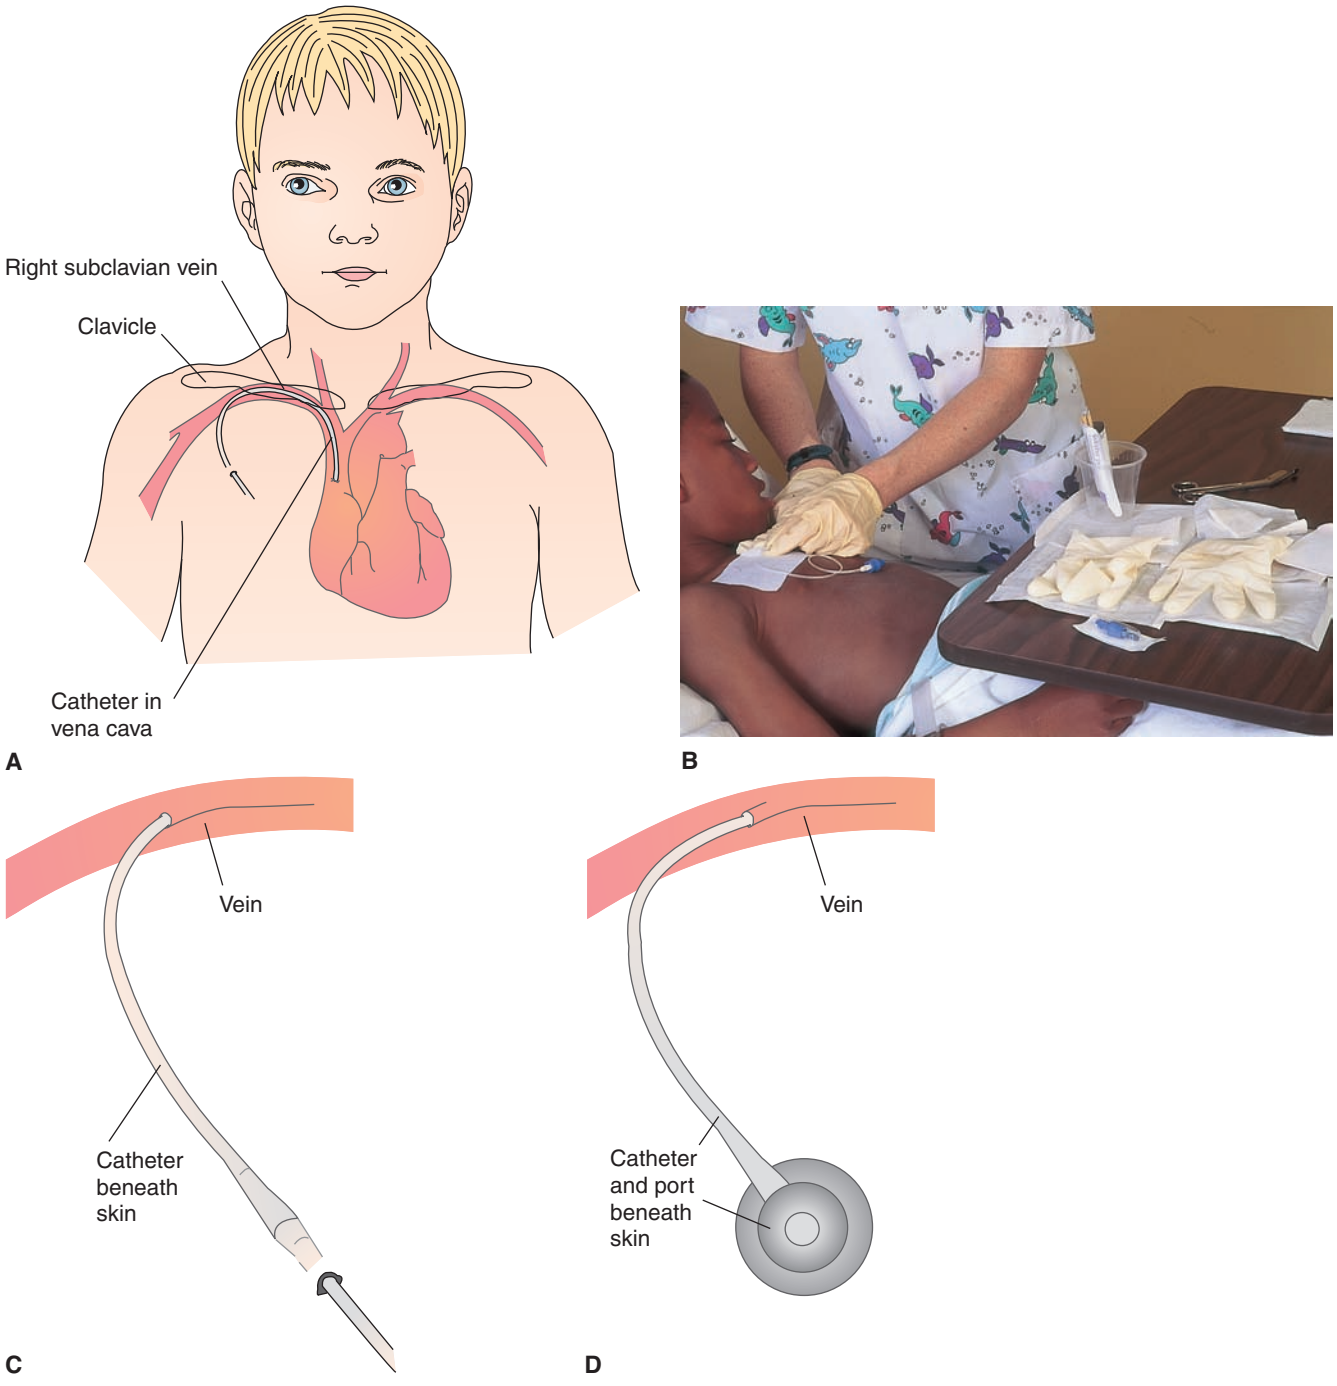

FIGURE 38.9 (**A**) Insertion site for placement of a central venous catheter for intravenous infusion. (**B**) Changing a dressing for a central venous catheter. (**C**) Central venous catheter beneath the skin. (**D**) A vascular access port (VAP) device beneath the skin.

Children also may have peripherally inserted central catheters (PICC lines) for therapy (Linck, Donze, & Hamvas, 2007). These are advantageous particularly for home care because they can remain in place for up to 4 months without being changed. These catheters are inserted into an arm vein (usually at the antecubital space into the median, cephalic, or basilic vein) and advanced until the tip rests in the superior vena cava. If a shorter catheter is used, the tip will rest closer to the head of the clavicle (a midline insertion).

Drugs commonly administered by PICC lines are antibiotics and analgesics. After medication is administered, the line is flushed with a solution such as normal saline. The dressing over the insertion site is changed according to agency policy.

Many parents seem more comfortable with this type of insertion than with a central venous catheter because it appears so much more like a routine IV. Newborns can have a catheter inserted into an umbilical vessel, with fluid and medications being administered by that route (see Chapter 26).

All central venous access systems have the potential to cause thromboses because they partially occlude a vein. In addition, the dressing must be changed using strict aseptic technique to prevent infection.

Administering an Intraosseous Infusion

Intraosseous infusion is the infusion of fluid into the bone marrow cavity of a long bone, usually the distal or proximal tibia, the distal femur, or the iliac crest (de Caen, 2007). Because the bone marrow communicates directly with the circulatory system, fluid reaches the bloodstream as quickly by this route than if it were administered IV. All fluids that can be administered IV, including whole blood or medication, can also be administered by this route.

Intraosseous infusion is used in an emergency when it is difficult to establish usual IV access or in a child with such extensive burns that the usual sites for IV infusion are not available. Intraosseous infusion is a temporary measure until a usual route of administration can be obtained because of the danger of osteomyelitis, a devastating infection with long-term effects to bone marrow. It must be initiated with sterile technique, and if continued for an extended time, the infusion point is rotated about every 2 to 3 days to minimize the risk of infection.

Intraosseous infusion is painful as the needle enters the bone marrow cavity. Prepare the child for this and offer support.

Steps to initiate an intraosseous infusion are:

1. The skin over the chosen site is cleaned with povidone–iodine and anesthetized with a local anesthetic.
2. A small incision is made into the skin with a scalpel blade.
3. A large hypodermic or bone marrow needle is inserted through the incision into the cavity of the bone.
4. To ensure that the needle tip has reached the bone marrow cavity, a syringe is attached to the needle and bone marrow is aspirated.
5. When bone marrow is obtained, the syringe is removed and IV tubing, including a filter and the fluid to be administered, is attached to the needle and opened to a gravity flow.
6. A dressing with additional iodine is then applied over the needle site.
7. A restraint is applied to the leg to help the child hold the leg still.

Tubing must be changed about every 48 hours and the dressing over the site changed about every 24 hours—again, to reduce the possibility of infection. Assess for a distal pulse and adequate temperature and color of the leg every hour throughout the infusion to ensure there is adequate circulation to the extremity. If the needle should become dislodged, symptoms of circulatory impairment or pain and taut skin over the site occur.

Occasionally during fluid administration, a bone chip or thick marrow will occlude an intraosseous needle and slow the infusion. If this occurs, a stylet passed through the needle clears it and allows for continued fluid administration.

Administering a Subcutaneous (Hypodermoclysis) Infusion

Before safe IV infusion was perfected for infants, fluid was given to them subcutaneously (perfusing fluid into subcutaneous skin layers by an IV infusion set). The technique is still used for children with blood disorders who receive a medication such as deferoxamine (Desferal) to remove stored iron from their body (see Chapter 44). Sites used for hypodermoclysis generally include the pectoral region, the back, and the anterolateral aspects of the thighs. The IV needle is inserted into the subcutaneous layer of the skin and the infusion apparatus is opened. The rate is governed by the rate of absorption by the subcutaneous layer of skin, not by a set rate.

✔ Checkpoint Question 38.3

Terry is going to have an antibiotic infused intravenously into her dominant hand. What would be the best activity for her while her medicine infuses?

a. Listening to a story you read.
b. Coloring a hospital brochure.
c. Completing a jigsaw puzzle.
d. Fingerpainting or drawing.

Key Points for Review

- The effectiveness of medicines varies depending on the pharmacokinetics (absorption, distribution, metabolism, and excretion) of the drug.
- The principles of safe medicine administration for adults also apply to children: right medicine, right child, right dose, right route, right time, and right patient instructions.
- The correct drug dose in children is usually calculated according to the child's body surface area, determined by using a nomogram.
- Use adequate restraints when giving medicine to be certain that children will not inadvertently harm themselves in the process.
- Teach parents safe actions for giving medicine at home so children continue to receive accurate doses after hospital discharge.
- In children, the majority of medications are given orally or intravenously to avoid the pain of IM injection. Subcutaneous pumps infuse medicine such as insulin.
- IV therapy may be administered peripherally or via a central venous access site. A scalp vein is a common IV site used for infants.
- An intraosseous infusion is used in an emergency when it is difficult to establish usual IV access or in a child with such extensive burns that the usual sites for IV infusion are not available.
- Hypodermoclysis is the instillation of fluid into subcutaneous tissue.

CRITICAL THINKING EXERCISES

1. Terry is the 8-year-old you met at the beginning of the chapter who has never learned how to swallow pills. What technique would you use to help Terry learn to swallow pills? How would you gain her cooperation?

2. Suppose Terry needs to have an intraosseous infusion. How would you explain what this is to her parents?
3. Suppose Terry's mother tells you that she does not believe in introducing any "foreign" substance into her child's body, so she does not intend to give her the antibiotic for her infected foot. Would there be a way to change her mind? How would you counsel her?
4. Examine the National Health Goals related to medicine administration in children. Most government-sponsored funds for nursing research are allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to Terry's family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to medication or intravenous therapy in children. Confirm your answers are correct by reading the rationales.

Chapter

39 Pain Management in Children

KEY TERMS

- acute pain
- conscious sedation
- chronic pain
- cutaneous pain
- distraction
- epidural analgesia
- gate control theory
- nociceptors
- pain
- pain threshold
- pain tolerance
- patient-controlled analgesia
- referred pain
- somatic pain
- substitution of meaning
- thought stopping
- transcutaneous electrical nerve stimulation
- visceral pain

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe the major methods and techniques of pain management for children.
2. Identify National Health Goals related to pain management in children that nurses can help the nation achieve.
3. Use critical thinking to analyze ways nursing care for a child in pain could be more family centered.
4. Assess a child regarding whether pain management is needed or adequate.
5. Formulate nursing diagnoses for a child in pain.
6. Identify expected outcomes for a child in pain.
7. Plan nursing care for a child in pain.
8. Implement nursing care related to a child in pain such as suggesting an alternative therapy.
9. Evaluate outcomes for achievement and effectiveness of care of a child in pain.
10. Identify areas related to care of children in pain that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of pain in children with nursing process to achieve quality maternal and child health nursing care.

Robin Harvey is a 3-year-old girl who was admitted to your hospital unit and has just returned from a bone marrow aspiration to rule out the possibility of leukemia. Robin received intravenous morphine sulfate during the procedure. Her mother asks you if Robin could have some more. "I know she's not having pain yet," her mother tells you, "but I want her to have something before the pain comes back." Previous chapters described the growth and development of children and general care of ill children. This chapter adds information about care of children when they need pain management. Such information builds a base for care and health teaching in a crucial area.

Is this mother's assessment or Robin's assessment of her pain apt to be most accurate? Would anticipating pain in this way be the best intervention for Robin?

Pain is a difficult concept to define because it is experienced uniquely. It is important to remember that it is subjective (experienced by the person), not objective (able to be determined by observation). McCaffery's classic description of pain (Pasero & McCaffery, 2004) is the one most useful with children: "The sensation of pain is whatever the person experiencing it says it is, and it exists whenever the person says it does."

For children, pain is not only a hurting sensation, but it can also be a confusing one because a child did not anticipate the pain, does not have words to explain how it feels, and cannot always understand its cause. In addition, preschoolers and younger children lack an understanding of time, which makes it difficult to explain when the pain will go away. Children may feel frustrated or angry because no one can prevent their hurt or give them relief. Because children may have difficulty describing pain in a manner adults can understand, it is difficult to assess the extent of their discomfort. Because pain is an individualized sensation, it may be experienced and expressed differently by different children. In some families, for example, pain may be expressed very openly and freely. In others, children are expected to be stoic about pain. Because the expression of pain is culturally determined this way, two children who have the same degree of pain may express it very differently (Eccleston et al., 2009).

Additionally, children's perception of the situation influences their response to the situation, independent of the intensity of the pain. This means that children experiencing procedures that are less intrusive but who are feeling maximum anxiety may describe the degree of pain felt as more intense than they otherwise might, because of the accompanying anxiety.

Both helping children describe the type and extent of pain they are feeling and performing active interventions to relieve pain are important nursing roles. Assessing for pain is so important that pain can be considered the "fifth vital sign."

National Health Goals do not address pain relief in children directly, but they do address the reduction of accidental injury, which is a major source of pain in children. These goals are shown in Box 39.1.

BOX 39.1 ✻ Focus on National Health Goals

Although National Health Goals do not speak directly to alleviating pain in children, many of the goals speak to reducing unintentional accidents, which are a major source of pain in children. Some of these objectives are:

- Increase the rate of use for automobile safety belts and infant safety seats to 100% for children under age 4 from a baseline of 92%.
- Increase the rate of helmet use to at least 79% of motorcyclists from a baseline of 67%.
- Increase the number of states with laws requiring bicycle helmets for riders under the age of 15 from a baseline of 10 states to all states.
- Increase the presence of functional smoke detectors to 100% of all inhabited residential dwellings from a baseline of 88%.
- Reduce the rate of hospital emergency department visits for nonfatal dog bite injuries to 114 per 100,000 of the population from a baseline of 151 per 100,000 (http://www.nih.gov).

Nurses can be help the nation to reduce pain among children by teaching about the importance of using safety belts and bicycle helmets. As primary care providers, they can lead the effort to be certain that children and parents receive counseling on safety precautions. Additional nursing research that is needed in the area of pain relief concerns identifying the best way for children to rate pain and the nonpharmacologic measures that work best with different age groups.

Nursing Process Overview

For a Child in Pain

Assessment

Children, like adults, experience pain differently depending on the type and cause of the pain, their temperament, their previous experience with pain, and their expectation of relief. Infants and young children cannot verbalize what they are feeling so have the most trouble communicating how they feel.

Beginning with preschool age, children can indicate where they feel pain and can learn to express the degree of pain through a system such as comparing it to a number of poker chips or drawings of faces. Older school-age children and adolescents can be asked to rate their pain on a scale of 1 to 10. Be aware that children may be reluctant to admit pain because they are trying to be brave. Some may be reluctant to say they have pain because they are afraid they will receive a "shot" to relieve it, and that will cause more pain. As a rule, including assessment of pain level along with vital sign measurement is an efficient way to ensure that pain is assessed. Be alert that this is only the first step in pain management, though. If children have pain, they need some intervention as a second step to relieve it. Let children know that admitting to having pain is necessary for them to obtain adequate relief.

Parents often are unclear what role they should assume in pain management. Frequently parents believe nurses and doctors are the experts and so will automatically treat their child's pain. Nurses, on the other hand, may assume that parents will speak up if their child is in pain. How pain will be assessed, the parents' role, and what is available for pain relief should be discussed clearly and openly so these misunderstandings do not occur. Be certain that you also reassess pain to be certain that interventions such as administration of an analgesic or distraction or improved positioning were effective.

Nursing Diagnosis

Nursing diagnoses for children with pain focus not only on the pain but also on the stress, fear, or anxiety that pain produces. Examples of nursing diagnoses are:

- Pain related to frequent invasive procedures
- Fear related to anticipation of painful procedures

- Disturbed sleep pattern related to chronic pain
- Anxiety related to planned dressing changes that cause pain

Outcome Identification and Planning

The mark of efficient pain control is to anticipate when pain will occur and plan interventions to prevent it rather than let it occur and then relieve it. Three common reasons why nurses may not provide adequate pain relief to children are a belief that infants and young children do not experience pain, a fear that children will become addicted to pain relief medications, and a fear of causing respiratory depression from analgesics. Infants and young children do experience pain, and there is no confirmation that children receiving narcotics during a short hospital stay will become addicted to pain medication or that opiates cause greater respiratory depression in children than in adults. Although the use of opiates can lead to dependency, this is very different from addiction and can be addressed with a weaning regimen if needed. The American Academy of Pediatrics' pain management suggestions are available at http://www.aap.org/.

Implementation

Implementation for pain relief includes choosing the specific method of pain relief best for each child. All persons involved in a child's care need to be aware of the signs and symptoms an individual child uses to express pain and specific ways that will help the child manage pain. If children are reluctant to admit they have pain because of the fear of receiving an injection, advocate for an oral form of analgesia or an intermittent intravenous (IV) infusion device or patient-controlled analgesia (PCA) as appropriate options. Many parents are unsure about the safety of using strong analgesics for pain relief so often give less than the prescribed dose. Therefore, educating parents about the need for pain relief, proper doses, and taking actions to involve them in the assessment and evaluation process are essential. Planning and assisting with complementary therapies is yet another area to consider.

Outcome Evaluation

Evaluation of expected outcomes is a key aspect of managing pain because no one pain relief measure is effective for everyone. After a child is given an analgesic, look for nonverbal clues, assess vital signs, and listen to the child's statements about pain to determine whether a drug was effective. Based on these findings, it may become clear that the technique of pain management being used may need to be modified or increased. A new technique may need to be added to the regimen so a child receives maximum pain relief.

Possible examples indicating achievement of expected outcomes are:

- Child states pain is now at a tolerable level.
- Adolescent says she has managed her fear through imagery.
- Child rates pain as no greater than 2 on a 1-to-10 scale.
- Child describes ways he will help reduce pain when it returns.
- Child resumes age-appropriate behaviors following analgesia administration.

PHYSIOLOGY OF PAIN

As in adults, pain in children occurs for one of four reasons: reduced oxygen in tissues from impaired circulation, pressure on tissue, external injury, or overstretching of body cavities with fluid or air. The stimuli causing pain are not always visible or measurable. In addition, anxiety can lead to increased pain regardless of the physical stimuli.

Pain conduction consists of four major steps: transduction (sensing the pain sensation), transmission (routing the pain sensation to the spinal cord), perception (the brain interprets the sensation as pain), and modulation (steps taken to relive pain).

Transduction begins in the peripheral nerves when a mechanical, thermal, or chemical stimulus activates **nociceptors,** a specialized group of sensory receptors. Several neurotransmitters (e.g., substance P) are also stimulated and involved in conducting pain. Sharp pain impulses are conducted by both A-alpha and A-beta fibers (large fibers that are myelinated and conduct the response at a rapid rate). Light pressure and vibration are conducted by A-delta fibers, fibers that are smaller and conduct at a slower rate. C fibers are smaller yet and conduct at an even slower rate.

Pain impulses join central nervous system (CNS) fibers in the dorsal horn of the spinal cord. Here the impulses are projected upward to the brain, where they will be perceived as pain.

- **Acute pain** is sharp pain. It generally occurs abruptly after an injury. Paper cuts are examples of lacerations that cause acute pain.
- **Chronic pain** is pain that lasts for a prolonged period (often defined as 6 months). Acute pain usually causes extreme distress and anxiety; chronic pain can lead to depression and less ability to achieve (Eccleston et al., 2009).
- **Cutaneous pain** is pain that arises from superficial structures such as the skin and mucous membrane. A paper cut is an example.
- **Somatic pain** is pain that originates from deep body structures such as muscles or blood vessels. The pain of a sprained ankle is somatic pain.
- **Visceral pain** involves sensations that arise from internal organs such as the intestines. The pain of appendicitis is visceral pain.
- **Referred pain** is pain that is perceived at a site distant from its point of origin. Right lower lobe pneumonia, for example, is often first thought to be abdominal pain because the pain of this is referred to the abdomen.

A child's **pain threshold** refers to the point at which the child first feels pain. This varies greatly from person to person and is probably most influenced by heredity. All people also have a point above which they are not willing to bear any additional pain. This is a person's **pain tolerance.** Pain tolerance levels are probably most affected by cultural influences.

When pain is felt the pituitary and hypothalamus glands attempt to modify pain by releasing *endorphins* or polypeptide compounds that simulate opiates in their ability to produce analgesia and a sense of well-being. Children also modify pain by physical actions such as shifting position or rubbing the body part.

Several theories have been proposed to explain the transmission of pain and how pain can best be managed. Of these, the gate control theory is the best known.

Gate Control Theory of Pain

The **gate control theory** of pain (Melzack & Wall, 1965) attempts to explain how pain impulses travel from a site of injury to the brain, where the impulse is actually registered as pain. This theory envisions gating mechanisms in the substantia gelatinosa of the dorsal horn of the spinal cord that, when activated, can halt an impulse at that level of the cord. This prevents the pain impulse from being received at the brain level and interpreted as pain. Gating mechanisms can be stimulated by three techniques: cutaneous stimulation, distraction, and anxiety reduction.

Cutaneous stimulation has an effect because when the peripheral nerves next to an injury site are stimulated, the ability of the A-delta or C-fiber nerves at the injury site to transmit pain impulses appears to decrease. Rubbing an injured part such as a stubbed toe and applying heat or cold to the site are effective maneuvers to suppress pain because they activate these nearby fibers. This technique is especially effective with children because the rubbing is not only comforting from a physical standpoint but also conveys psychological warmth.

Distraction allows the cells of the brainstem that register an impulse as pain to be preoccupied with other stimuli so a pain impulse cannot register. Having a child focus on an action or a thought is a common form of distraction. Telling a child to say "ouch" while an injection is administered is the simplest use of this technique.

Pain impulses are perceived more quickly by the brain if anxiety is also present. Therefore, attempts to reduce a child's anxiety as much as possible can help reduce the feeling of pain. Teaching a school-age child about what to expect with a procedure is the kind of technique that does this. As well as knowing when something is going to happen, children also should know when nothing is going to happen. Being told that a clinic visit will not involve painful procedures allows a child to relax and feel less anxiety.

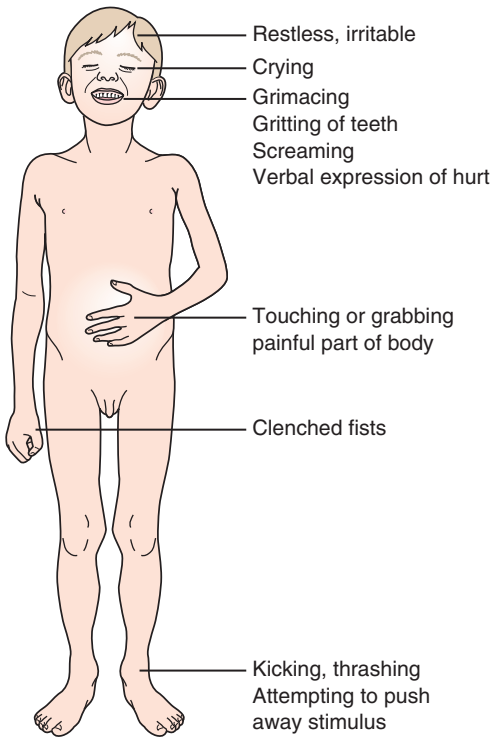
The effectiveness of gate control theory techniques varies with a child's age, ability to cooperate, degree of pain, and time allowed for learning and applying the techniques. Because memory may influence the sensation of pain (expecting to have pain produces anxiety, which increases pain), these techniques are best taught to children before they begin to have pain. In all instances, children should know to use them just before or at the moment they first feel the pain. If they wait until pain is intense, the pain may be so distracting they cannot concentrate on using a technique. Children who were able to use a distraction technique in the past but can no longer do so need to be evaluated for what is changing. Is it their ability to cope with the pain, or is the pain increasing in intensity? Contrary to common belief, familiarity with diagnostic or therapeutic procedures does not necessarily lessen either the fear or the pain experienced.

ASSESSING TYPE AND DEGREE OF PAIN

Pain assessment is difficult with children, not only because children have difficulty describing pain but also because some children will suffer with pain rather than report it, unaware that someone could make it go away. Other children may distract themselves by methods such as concentrating on play. Some children may sleep, not from comfort but from the exhaustion caused by pain. Cultural differences also influence how pain is expressed (Box 39.2). All of these things can make using only subjective measures, such as observation, to assess pain misleading.

Pain assessment in children is also difficult because techniques vary widely from assessment of a nonverbal infant to an older adolescent. Keep in mind a child's developmental level as well as chronological age when assessing for pain.

Box 39.2 Assessment
Assessing a Child With Pain



The Infant

In the past, it was believed that infants do not feel pain because of incomplete myelinization of peripheral nerves. This is no longer believed to be true, because myelinization is not necessary for pain perception.

A second argument against needing to provide pain relief to infants was that they have no memory. It can be shown, however, that physiologic changes occur with pain even in premature infants, so even with a lack of memory, it is clear pain is experienced. In all ages, pain has been shown to have the potential for serious physical harm. Because they are preverbal, observing for cues such as diffuse body movement; tears; a high-pitched, sharp, harsh cry; stiff posture; lack of play; and fisting are all cues to reveal discomfort (American Academy of Pediatrics [AAP], 2007). Even newborns instinctively guard a body part by holding an extremity still or tensing the abdomen. Perhaps the chief mark of pain in infants is that when pain is present, they cannot be comforted completely. Preterm neonates may have a particularly

difficult time organizing a distress response to cue a health care provider to the presence of pain. When working with infants of this age, be sensitive to situations that could cause pain and reduce them to the maximum extent possible. Be alert for subtle alterations in facial expression, such as eyes squeezed shut or a quivering chin, that might be a signal of pain.

The Toddler and Preschooler

Determining when and how much pain is present continues to be difficult with toddlers and preschoolers because they may not have a word in their limited vocabularies to describe the sensation they feel (Box 39.3). Parents may have encouraged children this age to refer to pain as "my boo-boo" or some other word instead of "pain." They may have difficulty comparing the pain they feel now to past pain (is it better or worse?) because they have had little experience with past pain. Words such as "sharp," "nagging," or "aching" have no meaning in relation to pain until a child has experienced each type. To assess such a child's pain accurately, use the child's term or teach the child that "pain" is the same as "boo-boo." For some toddlers, pain is such a strange sensation that, aside from crying in response to it, they may react aggressively (pounding and rocking) as if to fight it off. They also may avoid being touched or held.

BOX 39.3 ✻ Focus on Communication

Robin, 3 years old, has just returned from surgery. You want to assess her level of pain.

Less Effective Communication

Nurse: Robin? How are you feeling?
Mrs. Harvey: I don't think she hurts yet.
Nurse: I'm going to show you some faces, Robin. Just point to the one that looks the way you feel. If you point to a sad one, I'll get you a shot to take away your pain.
Robin: (Points to the first face—the "no pain" face.)
Nurse: No pain? Good. That's probably because your anesthetic is still working.

More Effective Communication

Nurse: Robin? How are you feeling?
Mrs. Harvey: I don't think she hurts yet.
Nurse: Robin? Remember the faces we looked at this morning before surgery? I want you to use them to tell me how you feel. This one means "no hurt." This one means "the most hurt you could have." Point to the one that shows how much hurt you have.
Robin: (Points to the middle face—the "hurts even more" face.)

It is important when using pain rating scales to introduce them to children before surgery or before they have pain from procedures, so that both the pain and the rating tool are not new to the child all at once. It is important also to give the correct instructions for standardized assessment tools, or the results will not be accurate. Mentioning a "shot for pain" can cause children not to report pain because they imagine the injection will cause even more pain, rather than relieve it.

Preschool children can describe they have pain but continue to have difficulty describing its intensity. They begin to use comforting mechanisms, such as gritting teeth, pressing a hand against a forehead, pulling on their ear, holding their throat, rubbing an arm, or grimacing, to control or express pain. Some preschoolers do not think to mention they have pain because they believe it is something to be expected or, because of their egocentric thinking, they assume adults are already aware of their pain. They may think pain is punishment for some act, so this is what they deserve. It is sometimes difficult to comfort children this age during painful procedures because they do not yet have a perception of time. Soothing statements such as, "It's only for a minute" are not comforting to the preschooler who does not know how long that is.

For all young children who cannot fully verbalize their pain state, carefully examine their behavior. In addition to behaviors already discussed, young children may regress or become very withdrawn when in pain. Ask yourself, "What would this child normally be doing (for example, playing, eating, sleeping)?" Deviations from usual behavior may, in the absence of any other verbal description, be signs a child is in pain. Input from parents on how their child usually behaves can be valuable in evaluation. Keep in mind that any procedure or condition that would normally cause pain in an adult will cause pain in a child. In a nonverbal child, a trial dose of analgesia may be used. You can then evaluate behavior changes after the dose is given. Children who resume their usual behavior after analgesia were probably in pain before the analgesia took effect.

The School-Age Child and Adolescent

Children who think concretely (preadolescents) can have difficulty envisioning that a word like "sharp" applies both to knives and to the feeling in their abdomen. Because of this, they continue to have difficulty describing pain. They may also assume that you, as an authority figure, already know they have pain (Schiavenato, 2008).

Some children of school age will regress with pain such as baby-talk or lying in a fetal position. Children this age can understand that if pain will last only an instant, such as with an injection, it can be controlled through nonpharmacologic activities such as distraction techniques.

Children may be in middle school before they can understand how to use a numerical pain rating scale or that the scale intensifies from left to right. Doing some preassessment work with them, such as giving them 10 different-sized triangles and asking them to arrange them from smallest to largest, is a good way to evaluate if they understand incremental measurements. The child who can arrange triangles this way understands the concept of least to most. Once children have grasped this concept, they can describe pain intensity in a very measurable way. A scale of 1 to 5 can be used in younger children if 1 to 10 seems overwhelming. Yet another technique is to turn the scale vertically so it measures bottom (little pain) to top (a lot of pain).

Adolescents commonly use adult mechanisms for controlling pain. Some are even more stoic in the face of pain than adults, trying to avoid stereotypes of "crybaby" or "chicken." This tendency makes assessment for body motions that could indicate pain, such as clenched hands, clenched teeth, rapid breathing, and guarding of body parts, not as helpful as it may be in adults.

PAIN ASSESSMENT

Common fallacies about pain in children are shown in Table 39.1. The techniques to assess pain must vary depending on the age of the child and the type and extent of pain. Although monitoring for physiologic findings such as a change in pulse or blood pressure may give some indication that a child is under stress, these are not the most dependable indicators of pain. Because pain is a subjective finding, once children can speak, asking them to tell you about their pain (self-reporting on a pain rating scale) is the most accurate method for assessment.

A variety of pain rating scales have been devised for use with children. None has been proven to be consistently better than the others, mainly because both children and the type of pain they can be experiencing vary so much. As a rule, pick a well-documented effective scale and use that consistently for a child rather than asking a child to adapt to different assessment techniques. Be sure to follow the specific instructions for that scale.

Pain Experience Inventory

The Pain Experience Inventory is a tool consisting of eight questions for children and eight questions for the child's parents. It is designed to elicit the terms a child uses to denote pain and what actions a child thinks will best alleviate the pain. Such a form can be used when a child is admitted to an acute care facility or on an initial home care visit (Box 39.4). If possible, it should be used before the child has pain.

BOX 39.4 ✻ Pain Experience Inventory

Questions for Child

Tell me what pain is.
Tell me about the hurt you have had before.
What do you do when you hurt?
Do you tell others when you hurt?
What do you want others to do for you when you hurt?
What do you not want others to do for you when you hurt?
What helps the most to take away your hurt?
Is there anything special that you would like me to know about you when you hurt? (If yes, have child describe.)

Questions for Parents

Describe any pain your child has had before.
How does your child usually react to pain?
Does your child tell you or others when pain is experienced?
How do you know when your child is in pain?
What do you do for your child when your child is hurting?
What does your child do to help relieve pain?
Which of these actions work best to decrease or take away your child's pain?
Is there anything special that you would like me to know about your child and pain? (If yes, have parents describe.) (Hester & Barcus, 1986.)

CRIES Neonatal Postoperative Pain Measurement Scale

The CRIES inventory is a 10-point scale on which five physiologic and behavioral variables frequently associated with neonatal pain can be assessed and rated (Krechel & Bildner, 1995):

- Amount and type of crying
- Need for oxygen administration
- Increased vital signs
- Facial expression
- Sleeplessness

Each area is scored from 0 to 2, and then a total score is obtained (Table 39.2). On the scale, infants with a score of 4 or more are most likely to be in pain and need interventions to reduce discomfort. The scale cannot be used with infants

TABLE 39.1 ✻ Common Fallacies About Pain in Children

Fallacy	Fact
Nurses can accurately estimate children's pain from physical appearance or activity.	Nurses commonly underestimate children's pain when they do not rely on children's self-reports.
Young children, particularly newborns, do not feel pain.	Newborns and children do feel pain.
A child who resumes usual activity or sleeps cannot be in pain.	Some children distract themselves with play or music while in pain. They may sleep from exhaustion from the pain.
Because of the possible adverse effects, narcotic analgesics are too dangerous for young children.	Narcotics can be used safely with children, including low-birth-weight infants.
Experiencing pain will not harm an infant or young child.	Newborns with pain can become cyanotic and bradycardic; no one knows the psychological stress of pain at this age.
If children deny they are feeling pain, you should believe them.	Children may deny pain to avoid a procedure, such as an injection, which they view as more painful. They may be afraid, fearing that they are being punished, or believe others know how they feel.

TABLE 39.2 ✻ CRIES Neonatal Postoperative Pain Measurement Scale

	Infant's Score		
Assessment	***0***	***1***	***2***
Crying	No	High-pitched	Inconsolable
Oxygen required for saturation above 95%	No	>30%	>30%
Increased vital signs	Heart rate and blood pressure within 10% of preoperative values	Heart rate or blood pressure 11–20% higher than preoperative value	Heart rate or blood pressure 21% or more above preoperative value
Expression	None	Grimace	Grimace/grunt
Sleepless	No	Waking at frequent intervals	Constantly awake
Total infant score

who are intubated or paralyzed for ventilatory assistance because they would have no score for cry, and because their faces are obscured, it is difficult to rate them for facial expression.

The COMFORT Behavior Scale

The COMFORT behavior scale is a pain rating scale devised by nurses to rate pain in very young infants (van Dijk et al., 2005). On the first part of the scale, six different categories (alertness, calmness/agitation, crying, physical movement, muscle tone, and facial expression) are rated from 1 to 5. Six is the lowest score (no pain), and 30 is the highest (a great deal of pain). In addition to rating physical parameters, the infant is then observed for 2 minutes and the evaluation of the baby's pain is documented on an analogue (1-to-10) visual scale.

FLACC Pain Assessment Tool

The FLACC Pain Assessment Tool (Merkel et al., 1997) is a scale by which health care providers can rate a child's pain when a child cannot give input, such as during circumcision (Brady-Fryer, Wiebe, & Lander, 2009). It incorporates five types of behaviors that can be used to rate pain: facial expression, leg movement, activity, cry, and consolability. Data indicate the scale is reliable and valid. Because a child does not provide active input, an older child may experience a loss of the self-control that can come from active participation by using this scale.

Poker Chip Tool

The Poker Chip Tool (Hester & Barcus, 1986) uses four red poker chips placed in a horizontal line in front of the child. The technique can be used with children as young as 4 years of age, provided the child can count or has some concept of numbers. To use the tool, tell the child, "These are pieces of hurt." Beginning at the chip nearest the child's left hand and ending at the one nearest the child's right hand, point to the chips and say, "This is a little bit of hurt, this is a little more hurt, this is more hurt, and this [the fourth chip] is the most hurt you could ever have." Then ask the child, "How many pieces of hurt do you have right now?" Children without pain will reply they don't hurt; others will point to one of the poker chips. To gain more understanding of how much pain the child is feeling, clarify the child's answer by a follow-up question such as, "Oh, you have a little hurt? Tell me about the hurt." This is an effective tool for young children because the poker chips are concrete items and children are concrete thinkers (Fig. 39.1).

FACES Pain Rating Scale

This scale consists of six cartoon-like faces ranging from smiling to tearful (Fig. 39.2). Explain to the child that each face from left to right corresponds to a person who has no hurt up to a lot of hurt (Wong & Baker, 1996). Use the words under each face to describe the amount of pain the face represents. Next, ask the child to choose the face that best describes the child's pain and record the number under the face the child chooses. Children as young as 3 years can effectively use this scale. The scale appeals to health care providers because it is cute; however, because it is not as concrete a measure as the

FIGURE 39.1 Use a pain rating tool to assess children's pain. Here, a child points to the poker chip indicating the degree of pain she is experiencing.

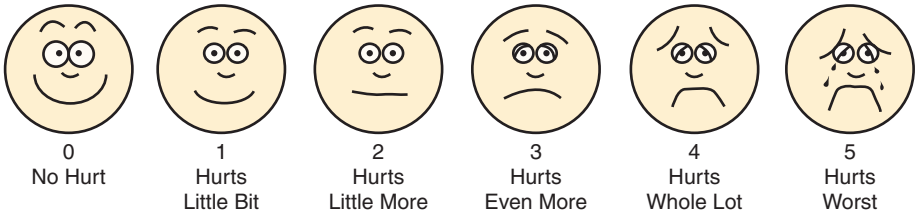

FIGURE 39.2 The FACES pain rating scale. (From *Whaley and Wong's essentials of pediatric nursing* [5th ed., p. 1216] [1997]. Copyright by Mosby–Year Book, Inc. Reprinted by permission.)

Poker Chip Tool, it, therefore, may not be as effective with all children.

Oucher Pain Rating Scale

The Oucher (Beyer, Denyes, & Villarruel, 1992) scale consists of six photographs of children's faces representing "no hurt" to "biggest hurt you could ever have." Also included is a vertical scale with numbers from 0 to 100. To use the photograph portion, point to each photograph and explain what each photo represents. Ask the child to point to the photo that best represents the child's degree of hurt.

To use the numbered scale portion, point to each section of the scale and explain 0 means "no hurt"; 1 to 29 means "a little hurt"; 30 to 69 means "middle hurt"; 70 to 99 means "big hurt"; and 100 means "the biggest hurt you could ever have." Ask the child to point to the section of the scale that represents the present level of hurt. Children as young as 3 can use the tool by pointing to the photograph that best describes their level of pain. If the child can count to 100 by ones and understands the concept of increasing value, the numbered scale can be used. The Oucher scale has white, African American, and Hispanic American photograph versions. Allow children to select the version they want to use or present the version that most closely matches the cultural characteristics of the child.

Numerical or Visual Analog Scale

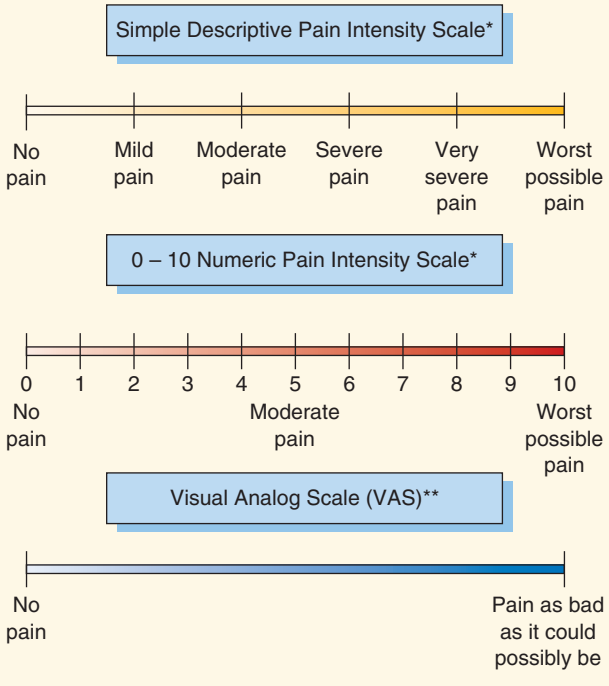
A numerical or visual analog scale (Fig. 39.3) uses a line with end points marked "0 = no pain" on the left and "10 = worst pain" on the right. Divisions along the line are marked in units from 1 to 9. Explain to children that the left end of the line (the 0) means a person feels no pain. At the other end is a 10, which means a person feels the worst pain possible. The numbers 1 to 9 in the middle are for "a little pain" to "a lot of pain." Ask children to choose a number that best describes their pain. As soon as they can count and have a concept of numbers, children can use a numerical scale. Be certain to show school-age children the scale; do not just say score your pain from 0 to 10. Until children reach late adolescence, they use concrete thought processes so need the help of seeing the line to rate their pain accurately.

Adolescent Pediatric Pain Tool

The Adolescent Pediatric Pain Tool (APPT) combines a visual activity and a numerical scale (Savedra et al., 1992). On one half of the form (Fig. 39.4) is an outline figure showing the anterior and posterior view of a child. To use the tool, tell a child to color in the figure drawing where pain is felt. In addition, on the right side of the form, tell the child to rate present pain in reference to "no pain," "little pain," "medium pain," "large pain," and "worst possible pain." For a third activity, tell children to point to or circle as many words as possible on the form that describe their pain (words such as horrible, pounding, cutting, and stinging). The scale is suggested for use in children 8 through 17 years. As many children below this level need so much help reading and interpreting the multitude of words that describe pain it makes the form impractical below this age. This is a useful tool for involving parents to talk with their child about pain. Reading the words together helps children examine the type, location, and level of pain they are experiencing. It also helps parents to better understand what their child is experiencing.

Logs and Diaries

Having children keep logs or diaries in which they note when pain occurs and then rate the pain each time it occurs is useful for assessing children with chronic but intermittent pain. Examining such a diary can not only reveal when pain occurs but also provide direction for pain management. For example, if the diary shows the child always awakens with pain in the morning, the child may need a longer-acting analgesic to take at bedtime; if pain is worse during weekends spent at a



* If used as a graphic rating scale, a 10-cm baseline is recommended.
** A 10-cm baseline is recommended for VAS scales.

grandparent's house, investigate whether something different is happening in that setting than at home that is causing increased pain.

What if... Robin completely colored in the figure on an Adolescent Pediatric Pain Tool to show where she has pain? Would you assess she has pain all over?

PAIN MANAGEMENT

Pain management techniques, like assessment techniques, vary greatly depending on the age of a child and the degree and type of pain a child is experiencing. Many health care agencies employ nurses specially prepared in pain management to serve on an interdisciplinary team of health care providers, including physicians, anesthesiologists, patient advocates, and wound therapy nurses, to plan individual pain management programs for children (Box 39.5).

Children with chronic pain or pain not relieved with standard approaches may benefit from a referral to a pain management specialist or team. Relief of frequent pain episodes or prolonged pain may require intense, consistent assessment and intervention, which is difficult to achieve in an acute care setting or during infrequent office visits. Whatever assessment tools or methods of pain relief are used, staff should become familiar and comfortable with their use. It is important that pain be assessed in an organized and consistent manner so relief and interventions do not vary based on the health care provider.

In the past, children frequently were not prescribed potent analgesics because of the fear that the drugs commonly used, such as morphine, would decrease their respiratory rate to an unsafe level. Children who had adequate analgesia prescribed may not have received it because a nurse was overly concerned about causing respiratory distress. Today, it is recognized that if the dosage of an opiate such as morphine is based on the child's size, there is no more danger of respiratory depression in children than in adults. Therefore, after checking that the correct dosage has been

BOX 39.5 ✻ Focus on Evidence-Based Practice

Can nurses be instrumental in teaching other health care providers about pain management?

Pain management programs work best if all health care providers are aware of both assessment and management aspects of the program. To see if pain management on a hospital unit could be improved, researchers asked five senior house officers to take a 1-hour education program on pain management provided by the hospital play specialist. Following care by the newly educated house officers, nurses reported on the clinicians' adherence to best practice, and 21 children who had undergone painful procedures were interviewed with their parents to assess their levels of pain, distress, satisfaction, and coping style. Results of the study showed that house officers had increased their knowledge of how to work with children undergoing painful procedures. The main changes in knowledge were involving nurses and the play specialist, preparing the equipment out of sight of the child, and using distraction techniques. Parents and children reported low levels of distress during painful procedures and high levels of satisfaction with procedures and listed several coping strategies such as distraction that helped the child, and the parent, to cope during the procedure.

Based on the above study, would you try to change the attitude of health care providers toward pain management or rate that as too difficult to attempt?

Source: Lawes, C., et al. (2008). Impact of an education programme for staff working with children undergoing painful procedures. *Paediatric Nursing, 20*(2), 33–37.

prescribed, opiates can be given with confidence to decrease pain without untoward effects. To give nurses more leeway in pain management, it is helpful if a range is given for a dose, rather than a set number so the dose can be adjusted based on the degree of pain (Pasero, Manworren, & McCaffery, 2007).

A good rule for determining whether children need pain relief for a procedure is to remember that if the procedure would cause pain in an adult, it will also cause pain in a child. Often a combination of nonpharmacologic and pharmacologic methods is most effective for pain relief (see Focus on Nursing Care Planning Box 39.6). Many health care professionals such as laboratory technicians, physicians, and x-ray or endoscopic assistants are called on to perform procedures with a child that could cause pain. Health care is a collaborative enterprise. Assist these individuals to schedule procedures at times when a child can be administered optimal pain relief. Help them institute nonpharmacologic measures of pain management such as distraction (Gatlin & Schulmeister, 2007).

General measures to alleviate pain that are helpful to parents as well as health care providers are summarized in Box 39.7. These guidelines are based primarily on the gate control theory.

NONPHARMACOLOGIC PAIN MANAGEMENT

Nonpharmacologic pain relief measures can be used independently or as complements to pharmacologic pain relief. They fit under the umbrella of alternative and complementary therapies.

Distraction

Distraction techniques aim at shifting a child's focus from pain to another activity or interest (Fig. 39.5). Blowing soap bubbles, for example, could be used during an injection to accomplish this. If oral glucose is offered to infants during painful procedures, the pain they experience appears to be significantly less (Hatfield et al., 2008). It is hypothesized that drinking glucose not only serves as a distraction technique but also activates endorphins and produces a central analgesic effect (Stevens, Yamada, & Ohlsson, 2009). Breastfeeding may also be used in this way but is not advised to avoid the infant making an association between breastfeeding and pain. When helping parents teach a distraction technique such as blowing soap bubbles to their child, be certain they do not interpret "distraction" as just talking to the child or suggesting a video game to divert attention. Although these are distractions, simple distraction like this can allow pain to break through.

Substitution of Meaning or Imagery

Substitution of meaning or guided imagery is a distraction technique to help a child place another meaning (a nonpainful one) on a painful procedure (Russell & Smart, 2007). Children are often more adept at imagery than adults because their imagination is less inhibited. Success with this technique requires practice, so it has limited application in an acute care setting. This technique works well with quick, simple procedures such as venipunctures or chronic pain. A venipuncture, for example, could be viewed as a silver rocket probing the moon to transport specimens back to earth or a submarine diving under the water to escape torpedoes just in time. Be certain a child thinks of a specific image. Help the child elaborate on the image to make it more concrete each time it is used so the child's mind stays on the image (what color is the rocket ship? Are there stripes on the sides? What does the pilot look like?).

Thought Stopping

Thought stopping is a technique in which children are taught to stop anxious thoughts by substituting a positive or relaxing thought. As with imagery, this technique requires a great deal of practice before it is used in a painful situation. Anticipatory anxiety is a negative force because it increases the pain experience during a procedure and makes the time before it full of anxiety as well. For this technique, help children to think of a set of positive things about the approaching feared procedure. For a bone marrow aspiration, for example, this might include, "It doesn't take long; the doctor and nurse who do it are helping me; it's important to help me get better." Whenever children start to think about the impending procedure, they should stop whatever they are doing and recite the list of positive thoughts to themselves if

BOX 39.6 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Child Requiring Pain Management

Robin Harvey, a 3-year-old girl admitted to your hospital unit, has just returned from a bone marrow aspiration to rule out the possibility of leukemia. Robin received IV morphine sulfate during the procedure. Unfortunately, the bone marrow obtained for analysis is not adequate, so a repeat procedure is scheduled for 3 hours from now.

Family Assessment ✻ Child is only daughter of two parents. Father works as a welder in a local steel mill; mother works part time at a local convenience store. Family rates finances, "Doing good."

Client Assessment ✻ A 3-year-old girl with a history of frequent nosebleeds, petechiae, and bruising admitted for diagnostic testing. First experience with hospitalization. Screams at the sight of a syringe and needle. Both parents at bedside talking with child. Child upset and crying, "Don't let them hurt me!"

Nursing Diagnoses ✻ Anxiety related to fear of the unknown and anticipation of painful procedure

Outcome Criteria ✻ Child identifies pain as no higher than 1 with Oucher Pain Rating Scale; exhibits few to no nonverbal indicators of pain; exhibits age-appropriate coping behaviors, including one nonpharmacologic pain relief technique.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Assess if IV morphine provided adequate pain relief for last procedure.	Review with parents the necessity for the repeat procedure and possible methods to help child with pain.	Being prepared for coming procedure can reduce anxiety in both parents and child.	Parents state they understand why repeat procedure must be done; are satisfied with pain relief measures to be used.
Nurse	Assess vital signs and child's present pain rating.	Engage the child in quiet activities for the first hour postprocedure.	The child is at risk for bleeding from the puncture site. Quiet activities reduce the risk for bleeding and also provide distraction.	Vital signs remain stable; pain rating is not over 1 on child rating scale. Child colors quietly.
		Consultations		
Nurse/ physician	Assess if pain management team member is available for consultation.	Consult with pain management team member for best pain relief for frightened preschool child.	Well-planned pain relief can best meet the needs of an anxious child.	Pain management team member meets with parents and child; determines best method of pain relief.
		Procedures/Medications		
Nurse	Assess if bone aspiration site is free of inflammation.	Apply anesthetic cream to aspiration site and cover with an occlusive dressing 1 hour before scheduled procedure per MD order.	An anesthetic cream anesthetizes skin. An occlusive dressing enhances absorption and tissue penetration.	Child cooperates with application procedure. Occlusive dressing remains in place preprocedure.
Nurse	Assess reddened or blanched skin at site of anesthetic cream just prior to procedure.	Just prior to the procedure, remove the occlusive dressing and wipe away the EMLA cream.	Removal prior to the procedure is necessary to cleanse skin. Reddened or blanched skin indicates that the drug has been effective.	Child cooperates with removal of occlusive dressing and anesthetic cream. Skin appears as if anesthetic effect has been achieved.

Nurse	Assess if child or parents have preference for where IV line should be inserted.	IV analgesia or conscious sedation is administered by IV route.	A bone marrow aspiration is painful, so a route for pain relief is necessary. Allowing choice of IV site offers a sense of control.	IV line is safely inserted; child chooses site that will best allow her to color quietly following the procedure.
		Nutrition		
Nurse	Assess when child last ate.	Keep NPO for 30 minutes preprocedure.	Heavy analgesia can lead to aspiration if stomach is full.	Parents state they understand temporary restriction for fluid.
		Patient/Family Education		
Nurse	Assess what child and parents believe was most traumatic aspect of previous bone marrow aspiration.	Review with child feeling of pressure with needle insertion.	Anticipatory knowledge of events and feelings helps to prepare the child and aids in coping.	Child and parents state they feel prepared for new procedure.
Nurse	Assess if pain assessment tool was used with child during prior procedure.	Introduce the child to Oucher Pain Rating Scale.	Introducing the child to the tool prior to the onset of pain minimizes anxiety associated with a new experience and increases the tool's usefulness and accuracy in determining the child's pain level.	Child rates her pain preprocedure as 0 to 10 to demonstrate she understands how to use scale. Sets a baseline for comparison.
Nurse	Assess the child's understanding about the reason for the bone marrow aspiration.	Review procedure with child and parents.	Assessment and review reveal information about the child, her knowledge base, and possible clues to her anxiety, providing a foundation on which to build future strategies and teaching.	Child and parents voice accurate understanding of the procedure of bone marrow aspiration and importance for diagnosis.
		Psychosocial/Spiritual/Emotional Needs		
Nurse	Assess if child has had experience with therapeutic play.	Provide opportunities for therapeutic play with a doll and syringe before and after procedure.	Therapeutic play helps the child express her feelings about painful procedures and possibly reduces anxiety.	Child plays with doll and syringe under nurse supervision. Does not demonstrate behavior suggestive of extreme anxiety or fright.
		Discharge Planning		
Nurse	Assess if child is free of pain postprocedure; if parents received adequate information on outcome of procedure.	Ask child to rate pain on Oucher scale; ask parents if they have received procedure report and understand results.	Postprocedure evaluation helps to meet further needs of child and parents and improve skills of health care providers.	Child rates pain as 1 or below on pain rating scale. Parents state they have results of procedure and understand the next step needed for diagnosis and treatment.

BOX 39.7 ✻ Focus on Family Teaching

Pain Management With Children

Q. Mrs. Harvey asks you, "How can I be sure I can keep my daughter free from pain after she returns home from the hospital?"

A. Here are some ways to offer pain relief in addition to just giving medicine:

- Let the child know it is important to you to try to take the pain away, and you will work with her to relieve it. Use a positive approach: "This medicine will take away your pain," not "Take this and let's hope it works."
- Administer pain medication before pain becomes intense to help prevent pain rather than just relieve it. If a child is in the hospital, inform the staff if a particular approach works or does not work.
- Never just give an analgesic. Make the child comfortable in ways such as straightening the sheets or offering a backrub.
- Ask your child about measures she thinks will be helpful, such as an additional pillow, the television turned on, a favorite toy nearby.
- Help your child talk about and describe the pain she is experiencing. This can help make it more concrete and not as psychologically frightening.
- Relieve anxiety about other phases of life, if possible. Relaxation reduces muscle strain and tension that add to pain.
- Offer emotional support to your child. Pain never seems as bad when a support person is present. Reassuring your child that she is loved and that you will be there for her can be very comforting.
- Try not to use such statements as, "Be a big girl" or "Stop crying" when a child is in pain from a procedure such as an injection. Say instead, "It's all right to cry. I know it hurts," to avoid shaming a child who cannot stop crying.

others are present or out loud if they are alone or only important support people are present. Children can then return to a usual activity. Every time the anxious thoughts appear, however, a child should stop and recite the list.

Thought stopping is an effective technique because it allows children to feel in control of their thoughts, which is different from merely saying, "Don't think about it." This technique does not suppress thoughts; rather, it changes them into positive ones. The secret for success is for the child to use the technique every time the disturbing, anxious thought appears even if, at first, such thoughts crowd in as frequently as every few minutes.

Hypnosis

Hypnosis is not a common pain management technique with children but can be very effective when a child is properly trained in the technique (Robertson, 2007). For best results, a child needs to train with a therapist before anticipated pain,

FIGURE 39.5 A child using distraction as a pain management technique.

so at the time of the pain, the child can produce a trance-like state to avoid sensing pain (Shakibaei et al., 2008).

Aromatherapy and Essential Oils

Aromatherapy is based on the principle that the sense of smell plays a significant role in overall health. When an essential oil is inhaled, its molecules are transported via the olfactory system to the limbic system in the brain. The brain responds to particular aromas with emotional responses. When applied externally, the oils are absorbed by the skin and then carried throughout the body. Essential oils may be able to penetrate cell walls and transport nutrients or oxygen to the inside of cells. Jasmine and lavender are oils thought to be responsible for relieving pain. When a drop of lavender oil is placed on the skin, a child should be able to taste it within 15 seconds.

Magnet Therapy

Magnet therapy is based on the belief that magnets can control or shift body energy lines to restore health or relieve pain. Magnets can be applied as jewelry or sewn into clothing or shoes. Although many people find relief from magnet therapy, the relief may be more of a placebo effect than an actual change in pain level (Pope & McNally, 2007). Copper also is believed to have pain-relieving ability and is often incorporated into rings and bracelets for this reason.

Music Therapy

Music therapy is the use of music for calming or improving well-being and can be effective even for premature infants. It can help to relieve pain both because it can be relaxing and is a distraction (Windich-Biermeir et al., 2007). Children may "blast" music not because they enjoy hearing it that loud but because they are feeling great pain and need that level of distraction to feel free of pain.

Yoga and Meditation

Yoga, a term derived from the Sanskrit word for union, involves a series of exercises that were originally designed to

bring people who practice it closer to God. It offers a significant variety of proven health benefits, such as increasing the efficiency of the heart, slowing the respiratory rate, improving fitness, lowering blood pressure, promoting relaxation, reducing stress, and allaying anxiety. Exercises consist of deep-breathing exercises, body postures to stretch and strengthen muscles, and meditation to focus the mind and relax the body. Yoga may be helpful in reducing pain through its ability to relax the body and possibly through the release of endorphins (Galantino, Galbavy, & Quinn, 2008).

Acupuncture

Acupuncture involves the insertion of needles into critical positions (meridian lines) in the body to achieve pain relief (Vas et al., 2007). Although acupuncture is almost painless, children can be very afraid of it at first because of the sight of the needles. This level of stress can make it an unattractive option for pain management for children. Children who consent to having it done, however, particularly those with chronic pain, report that the overall process is pleasant and the method offers good pain relief.

Crystal or Gemstone Therapy

Some people believe that gemstones or crystals have healing powers, which are magnified when they are positioned around the body. If these are being used, be careful when changing bedding or rearranging equipment in a child's room that you do not tip them over. A child may feel they may lose their pain-relieving powers if placed in a different position (Vantol, 2008).

Herbal Therapies

Parents may believe that specific herbs are helpful in relieving pain for their child and in general improving their child's health. Some examples include chamomile tea (inflammation reduction), garlic (anti-inflammatory, anticancer), ginger (nausea or vomiting reduction), goldenrod (urinary tract inflammation reduction), or peppermint (abdominal pain relief) (DerMarderosian & Beutler, 2007). Always ask when taking health histories if a child is being given any herbs, both to be informed about common herbs and to be certain that what the child is receiving will complement, not interfere with, the effects of a pain medication.

Biofeedback

Biofeedback is based on the belief that people can regulate internal events such as heart rate and pain response (Tsai et al., 2007). A biofeedback apparatus is used to measure muscle tone or the child's ability to relax. Biofeedback can be effective with adolescents but is less effective with school-age and younger children because they tend to resist the biofeedback information or cannot concentrate for long enough for training to be effective. Children who want to use biofeedback need to attend several sessions to condition themselves to regulate their pain response.

Therapeutic Touch and Massage

Therapeutic touch is the use of touch to provide comfort and relieve pain (Dowd et al., 2007). It is based on the concept that the body contains energy fields. When these are plentiful, they lead to health, but when they are in lesser supply, ill health results. Proponents believe it is possible to redirect energy fields to increase the release of endorphins. Therapeutic touch may also be effective as it serves as a form of distraction.

Transcutaneous Electrical Nerve Stimulation

Transcutaneous electrical nerve stimulation (TENS) involves applying small electrodes to the dermatomes that supply the body portion where pain is experienced (Poole, 2007). When children sense pain, they push a button on a control box, which then delivers a small electrical current to the skin. The principle underlying this technique is the same as rubbing an injured part: the current interferes with the transmission of the pain impulse across small nerve fibers.

TENS can be used to manage either acute or chronic pain. Some children (and parents) dislike TENS therapy because they are afraid or nervous about the electric current. Assure them the current is a very mild one and will not harm their child. TENS is not recommended if the child is incontinent or has a wound that is likely to cause the electrodes to get wet.

Heat or Cold Application

Cold reduces pain by constricting capillaries and therefore reducing vessel permeability and edema and pressure at an injured site. After the first 24 hours of an injury, applying heat may be more helpful because this dilates capillaries, increases blood flow to the area, and again helps reduce edema.

✔ Checkpoint Question 39.1

You teach Robin imaging to help reduce pain. Why does a technique such as imagery work well for children?

a. Children's pain is not as acute as is adults' pain.
b. Intravenous pain relief is not effective in children.
c. Children's imaginations are at their peak.
d. Children's muscles are less tense than adults' muscles.

PHARMACOLOGIC PAIN RELIEF

Pharmacologic pain relief refers to the administration of a wide variety of analgesic medications (D'Arcy, 2007). Many children need analgesic agents in addition to nonpharmacologic techniques for pain relief, especially for acute pain. Medications can be applied topically or given orally, intramuscularly, intravenously, or by epidural injection. As a rule, intramuscularly administered analgesia should be avoided in children because children dislike injections. Be certain children understand it is acceptable to ask for medication for pain; they may not know they can unless this is stressed by health care providers.

Topical Anesthetic Cream

To reduce the pain of procedures such as venipuncture, lumbar puncture, and bone marrow aspiration, a local anesthetic cream or a solution of lidocaine and epinephrine can be used (Subramanian et al., 2008).

BOX 39.8 ✻ Focus on Pharmacology

EMLA Cream

Classification: EMLA (an eutectic mixture of local anesthetics) is a topical analgesic cream containing lidocaine and prilocaine.

Action: Acts to anesthetize skin before potentially painful procedures (Karch, 2009).

Pregnancy risk category: B

Dosage: Dollop of cream to intended skin site for at least 1 hour before procedure (2–3 hours before deeper procedures such as lumbar puncture or bone marrow aspiration)

Possible adverse effects: Hypersensitivity

Nursing Implications

- Explain to the child that the cream will help prevent pain during a procedure.
- Apply a dollop of cream to the intended site and cover with a transparent occlusive dressing at least 1 hour before the procedure. Do not spread cream or rub it in.
- If the cream is to be applied at home, instruct the parents how to apply the cream and the occlusive dressing. Suggest that the parents use plastic wrap, such as Saran Wrap, for the occlusive dressing.
- Instruct the child not to touch the dressing while it is in place. If necessary, cover the occlusive dressing with an opaque material to prevent the child from touching or playing with the dressing.
- Just before the procedure, remove the dressing and then wipe the skin to remove cream.
- Observe the skin. Look for reddened or blanched skin, which indicates that the drug has penetrated the skin.
- Do not use the drug for a child with a known history of sensitivity or allergy to local anesthetics such as lidocaine.
- The drug is not approved for use in infants younger than 1 month.

The cream is applied to the skin, and the site is then covered with an occlusive dressing or plastic wrap. To be most effective, it must be applied at least 1 hour before an expected procedure (Box 39.8). Parents can apply anesthetic cream at home before bringing a child to a clinic visit for a procedure such as bone marrow aspiration (Fig. 39.6). Caution them not to allow their child to remove the dressing and eat the cream (it could anesthetize the gag reflex). It also is potentially dangerous if rubbed into the eyes. Anesthetic creams have changed procedures such as obtaining blood from painful ones to painless ones. They also can be used effectively for pain relief with circumcision (Taddio, Ohlsson, & Ohlsson, 2009). A disadvantage of EMLA cream is that it must be applied at least 1 hour before the procedure; however, it can be applied up to 3 hours before a procedure and still be effective. A newer compound, ELA-MAX (LMX), containing only lidocaine, takes effect in 30 minutes or less

FIGURE 39.6 A father applies an anesthetic cream at home prior to a painful procedure.

(Subramanian et al., 2008). It can be purchased without a prescription.

What if... Robin is scheduled to have blood drawn at 10 AM and, to prepare her for this, you apply an anesthetic cream that takes an hour to be effective at 9 AM, but then the technician who will take the blood arrives early? Would you ask the technician to wait, or explain to Robin the cream is not going to work?

Oral Analgesia

Oral analgesia is advantageous because it is cost-effective and relatively easy to administer. Many analgesics can be prepared as elixirs or suppositories for children unable to swallow pills. Analgesia can be adequately achieved if dosing is correct.

Over-the-counter analgesics, such as acetaminophen (Tylenol), are flavored to make them taste good. Caution parents that even though such drugs taste sweet, they should never refer to medicine as "candy." Reinforce with them the need for proper storage (locked or out of the child's reach). Otherwise, children may help themselves to more when the parent leaves the room. Toxicity from too-frequent or overly large doses of acetaminophen can lead to severe liver damage in children (Karch, 2009).

Nonsteroidal anti-inflammatory drugs (NSAIDs) are excellent for reducing the pain that accompanies inflammation in injuries such as sprained ankles or rheumatic conditions. Examples of NSAIDs include ibuprofen and naproxen. Long-term administration of any NSAID can lead to severe gastric irritation and may be associated with heart attacks, so it should not be used longer than prescribed. Help parents

giving any analgesia around the clock for several days to make out a medication sheet to hang on their refrigerator door. This reminds them when the next dose is due and alerts them not to give the drug doses too close together.

Children should not receive acetylsalicylic acid (aspirin) for routine pain relief, especially in the presence of flulike symptoms, because there is an association between aspirin administration and the development of Reye syndrome (see Chapter 49).

For managing severe or acute pain, such as postoperative pain or the pain of a sickle-cell crisis, opioids, such as morphine, codeine, and hydromorphone (Dilaudid), are the usual drugs of choice. Codeine may be given in combination with acetaminophen. Because this class of drugs is also referred to as narcotics, parents may be reluctant to give their children these medications, concerned their child will become addicted. Acknowledge their concern but reassure them the risk for addiction during short-term use is remote. Reinforce that the main concern is supplying adequate pain relief for their child.

Intramuscular Injection

Opiates are available as intramuscular injections. Analgesia for children is rarely given by this route, however, as injections are associated with pain on administration and also produce great fear in children. It is also associated with several risks, including uneven absorption, unpredictable onset of action, and nerve and tissue damage. Other routes should be used whenever possible.

Intravenous Administration

IV administration of analgesia, the most rapid-acting route, is the method of choice in emergency situations, in the child with acute pain, and in a child requiring frequent doses of analgesia but in whom the gastrointestinal tract cannot be used. Common opioids given by this route include morphine, fentanyl, and hydromorphone (Dilaudid). Hydromorphone is 8 to 10 times stronger than morphine but very similar to morphine in action. Fentanyl has a shorter duration of action than morphine. Side effects of pruritus and vasodilatation are less. These features make it an ideal drug to use for short, painful procedures, such as debriding a burn or inserting a chest tube to relieve a pneumothorax.

These analgesics can be given by bolus injection or by continuous infusion. If doses will be given periodically by an IV line, advocate for the use of an intermittent infusion device to avoid repeated venipunctures with each dose or the need for a confining IV line to be in place.

If a child's pain is frequent or constant, continuous IV administration may be necessary to reduce the level of pain. As the child becomes able to take medications by mouth, oral forms of analgesics are then administered. When switching from IV to oral medications, it is important to use equianalgesic doses. As-needed (PRN) dosing should be avoided because it leads to inconsistent administration.

All opioids have the potential to decrease respiratory rate, although this is not a worry with accurate dosing. Other side effects include nausea, pruritus, vasodilatation, cough suppression, and constipation. If toxicity with opioids should occur, naloxone (Narcan) can be administered to counteract the effects.

✔ Checkpoint Question 39.2

Robin was given analgesia intravenously. Why is the intramuscular route infrequently used to administer analgesia to children?

a. The average child has a tremendous fear of injections.
b. IM doses must be larger in children than in adults.
c. IM medications must be administered cold or chilled.
d. IM solutions are readily confused with IV solutions.

Patient-Controlled Analgesia

Patient-controlled analgesia (PCA) is a form of IV administration that allows a child to self-administer boluses of medication, usually opioids, with a medication pump (see also Chapter 16). Children as young as 5 or 6 years may be able to assess when they need a bolus of medicine and press the button on the pump to deliver the new dose through an established IV line. Parents or a nurse can administer a new dose to children younger than this. Morphine is a common analgesic used for PCA administration (Cho, Ha, & Rhee, 2007). The pump is set with a lock-out time so that after each dose the pump will not release further medication even if the button is pushed again; because of this, children cannot overmedicate themselves. If pain is constant, a continuous infusion should be used so that pain relief continues even while the child sleeps. The pump can still be programmed for bolus dosing to cover episodes of increased pain.

Conscious Sedation

Conscious sedation refers to a state of depressed consciousness usually obtained through IV analgesia therapy (Hertzog & Havidish, 2007). The technique allows a child to be both pain-free and sedated for a procedure. Unlike with the use of general anesthesia, protective reflexes are left intact and a child can respond to instructions during the procedure. The technique is used for procedures such as extensive wound care; bone marrow aspiration, which is potentially very painful; magnetic resonance imaging, which may require a child to lie still for a long period of time; and endoscopy, which is both potentially frightening and requires a child to lie still for a period of time. In many health care settings, conscious sedation is administered and monitored by nurses specially prepared in the technique (Fig. 39.7). Drugs used for conscious sedation can be something as common as chloral hydrate or as involved as a sedative-hypnotic-analgesic combination that relieves both anxiety and pain and depresses the child's memory of the event.

Intranasal Administration

Intranasal administration is becoming an attractive way to dispense medicine for children. Influenza vaccine, for example, is now available in an intranasal form (Carpenter et al., 2007). Midazolam (Versed) is a short-acting adjuvant sedative that can be administered intranasally by nasal drops or nasal spray before surgery or procedures such as nuclear medicine scanning (Karch, 2009). Because it has a very short duration of action, it may require repeat administration. Because midazolam has no analgesic action, analgesia, such as with morphine, should also be used if the procedure will be painful.

FIGURE 39.7 A nurse monitors the vital signs of a child who has received conscious sedation.

Local Anesthesia Injection

Local anesthetics stop pain transmission by blocking nerve conduction of the impulse at the site of pain. Children receive local anesthetic injections, such as lidocaine, before procedures such as bone marrow aspiration and peritoneal dialysis. For many children, the sight of the anesthetic needle is so frightening that they cannot listen to the assurance that the momentary needlestick will actually prevent further pain. The use of an anesthetic cream before the injection relieves the needlestick pain and allows the anesthetic to numb the deeper tissues.

Epidural Analgesia

Epidural analgesia, injection of an analgesic agent into the epidural space just outside the spinal canal, can be used to provide analgesia to the lower body for 12 to 24 hours. An opioid, often combined with a long-acting anesthetic, is instilled continuously or administered intermittently. Opiate receptors in the spinal cord are affected directly, providing analgesia. Epidural anesthesia is commonly used for childbirth (see Chapter 16). Children who have orthopedic or chest surgery, for example, may have an epidural catheter inserted in the operating room and continue to receive analgesia by this method to relieve postsurgical pain (Schoen, 2007). This is a very effective route of analgesia in the postoperative child in the first few days.

Some parents may be reluctant to allow this type of analgesia because they equate it with spinal anesthesia, which can be followed by severe headaches. You can assure them that an epidural needle does not enter the cerebrospinal fluid, so spinal headaches are rare.

ONGOING PAIN RELIEF

Be certain children who begin a pain management program in a health care setting are provided with support and follow-up pain management to the extent necessary when they return home. Early discharge and the increased use of outpatient surgery necessitate adequate pain management in the home setting. Otherwise, lack of pain relief at home can be overwhelming.

Either oral or IV analgesia may be needed in a home setting. Be certain parents have instructions on dosing, administration, frequency, expected outcomes, and expected level of relief. Provide them with the name and telephone number of a health care professional whom they can call if they have questions about pain management.

✔ Checkpoint Question 39.3

Suppose Robin is scheduled for conscious sedation to have her repeat bone marrow aspiration. Which would be the best explanation to prepare her for this?

a. "You'll be given a special medicine to put you to sleep for surgery."
b. "I'll give you some medicine, but you'll still be awake and feel pain."
c. "Conscious sedation is an analgesic, not anesthetic, method of pain relief."
d. "I'll give you medicine so you're very sleepy but can still talk to me."

Key Points for Review

- Many children and infants are undermedicated for pain relief because of common misperceptions by health care personnel, such as that infants do not feel or remember pain.
- Inviting parents and the child, if preschool age or older, to participate in assessment and pain management is an important aspect of pain therapy.
- Pain in children is best assessed by means of a standardized self-report tool such as the Poker Chip or FACES tool. Without self-report forms, both nurses and parents may underestimate children's pain.
- Many children benefit from a combination of nonpharmacologic and pharmacologic methods of pain management.
- Many nonpharmacologic pain relief measures such as imagery, distraction, and TENS are based on the gate control theory of pain management.
- Few analgesics are administered intramuscularly to children. Instead, IV administration is the method of choice for the child with acute pain. Patient-controlled analgesia, commonly used to administer morphine, can be used effectively with children.
- Conscious sedation is useful for potentially frightening procedures. Protective reflexes are left intact, and the child can respond to instructions during the procedure.

CRITICAL THINKING EXERCISES

1. Robin is the 3-year-old girl you met at the beginning of the chapter. She was given IV morphine in surgery 1 hour ago for a bone marrow aspiration. Her mother asks

you now if Robin can have some more, not because her pain has returned, but because the mother wants it given before any pain comes back. Is this mother's assessment or Robin's assessment of her pain apt to be most accurate? Would anticipating pain in this way be the best intervention for Robin?

2. Robin is prescribed an intravascular antibiotic twice daily. She always screams the second she sees the syringe even though the addition of the medicine to her IV line should cause minimal pain. What type of pain management should be used? How should the child's anxiety be addressed?
3. A fellow nurse tells you that she does not use self-report tools with children; she feels they take the place of her nursing judgment. You like to use rating scales. How would you justify your view? What are the pros and cons of pain assessment tools?
4. Examine the National Health Goals related to pain assessment and management in children. Most government-sponsored funds for nursing research are allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to Robin's family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to pain management in children. Confirm your answers are correct by reading the rationales.

Chapter 40

Nursing Care of a Family When a Child Has a Respiratory Disorder

KEY TERMS

- adventitious sounds
- anoxia
- arterial blood gases
- aspiration
- atelectasis
- clubbing
- cyanosis
- expiration
- hypoxemia
- hypoxia
- inspiration
- paroxysmal coughing
- percussion
- pneumothorax
- rales
- retraction
- steatorrhea
- stridor
- tachypnea
- tracheostomy
- tracheotomy
- vibration
- wheezing

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe common respiratory disorders in children.
2. Identify National Health Goals related to children with respiratory disorders that nurses could help the nation achieve.
3. Use critical thinking to analyze ways nursing care for a child with a respiratory disorder could be more family centered.
4. Assess a child with a respiratory disorder.
5. Formulate nursing diagnoses related to respiratory disorders in children.
6. Identify expected outcomes that address the priority needs of a child with a respiratory disorder.
7. Plan nursing care for a child with a respiratory disorder.
8. Implement nursing care for a child with a respiratory disorder such as administering oxygen to a child.
9. Evaluate expected outcomes for achievement and effectiveness of care.
10. Identify areas related to care of children with respiratory disorders that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of respiratory disorders in children with nursing process to achieve quality maternal and child health nursing care.

Michael is a 4-year-old who is brought to the emergency department by paramedics after responding to an emergency call by his grandmother at his home. He has a sharp, barking cough, is crying loudly, and is obviously short of breath. "He can't breathe!" his grandmother shouts at you. "I gave him some chocolate. Is he allergic to that?" his grandmother asks. Michael is diagnosed as having laryngotracheobronchitis (croup) and admitted to an ambulatory care unit.

Previous chapters described the growth and development of well children. This chapter adds information about the dramatic changes, both physical and psychosocial, that occur when children develop respiratory disorders.

What emergency care does Michael need? What about Michael's action would lead you to believe his airway is not yet completely obstructed?

Respiratory disorders are among the most common causes of illness and hospitalization in children. Overall, respiratory dysfunction in children tends to be more serious than in adults because the lumens of a child's respiratory tract are smaller and therefore more likely to become obstructed. Because respiratory disorders range from minor illnesses such as a simple upper respiratory tract infection to life-threatening lower respiratory tract diseases, such as pneumonia, and because the level of acuity can change quickly, respiratory disorders are often difficult for parents to evaluate. Both a child and parents need a great deal of nursing support when disease interferes with the function of breathing, because even very young children can panic when breathing becomes labored. Early diagnosis and treatment are essential in preventing a minor problem from turning into a more serious one (Merelle et al., 2009).

Because respiratory disorders are such a common cause of childhood illness and hospitalization, National Health Goals have been established for children with respiratory illnesses (Box 40.1).

BOX 40.1 ✻ Focus on National Health Goals

Several National Health Goals focus on respiratory illness in children:

- Reduce the rate of asthma deaths in children aged 5 to 14 years from a baseline of 3.3 per million to a target level of 0.9 per million.
- Reduce the rate of hospital emergency department visits for children with asthma younger than 5 years from a baseline of 150 per 10,000 to 80 per 10,000.
- Reduce the rate of cigarette use by adolescents from a baseline of 35% to a target of 16%; cigar use from 18% to 8%, oral tobacco use from 8% to 1%, and bidis use from 4% to 2%.
- Reduce the incidence of invasive pneumococcal infections in children younger than 5 years from a baseline of 76 per 100,000 to a target of 46 per 100,000.
- Reduce the incidence of tuberculosis from a baseline of 6.8 per 100,000 cases yearly to a target level of 1.0 per 100,000 (http://www.nih.gov).

Nurses can help the nation achieve these goals by teaching children to avoid beginning cigarette smoking, including the use of bidis (chocolate-flavored tobacco products), teaching children ways to help avoid respiratory infections such as good handwashing, and reminding parents to come for child health maintenance visits so that children can receive pneumococcal immunization or screening for tuberculosis, as appropriate.

Additional nursing research is needed about the accuracy of parents in self-reading and interpreting tuberculosis screening tests and information required by new parents to better manage respiratory illness in infants and young children.

Nursing Process Overview

For a Child With a Respiratory Disorder

Assessment

Respiratory illness can begin as early as moments after birth if a newborn has difficulty initiating a first breath or establishing regular respirations. Rating a newborn using an Apgar score can help to quickly identify a newborn who may be experiencing respiratory difficulty at this early stage.

As a nurse in an emergent care or health maintenance organization, you are often the first health care provider to talk to a parent about a child's respiratory illness. It is important to establish both the onset and duration of the problem so that its seriousness can be rapidly determined. An episode of sudden coughing is suggestive of an acute respiratory disorder. Infants who cannot finish a bottle feeding because of exhaustion or rapid breathing or children who cannot run with other children because they do not have enough breath should be suspected of having a chronic respiratory disorder.

A child admitted to the hospital with a respiratory disorder is usually in an acute stage of the illness. A child's condition may worsen rapidly in the first few hours until a prescribed medication, such as an antibiotic or bronchodilator, begins to take effect. Nursing assessment that a child is developing tachypnea or retractions may be the first indication of a child's worsening condition.

Nursing Diagnosis

Nursing diagnoses established for children with respiratory disorders focus both on the alteration in mechanisms of breathing and on the emotional distress such problems can create. "Ineffective airway clearance" is a common diagnostic category used in this area. The problem may be related to any one of a variety of factors, such as ineffective cough, fatigue, weakness, viscous secretions, pain, aspiration (inhalation of a foreign object into the airway), or lack of knowledge about the importance of coughing.

The diagnostic categories "Impaired gas exchange" and "Ineffective breathing pattern" also may be used, although because a nurse does not generally prescribe definitive treatment for these problems (except when caused by hyperventilation), it may be more appropriate for a nursing diagnosis to focus on the effects of impaired gas exchange or ineffective breathing on daily activities and psychosocial health. Examples of nursing diagnoses are:

- Activity intolerance related to insufficient oxygenation
- Fatigue related to impaired gas exchange
- Fear related to inability to breathe without effort
- Impaired social interaction related to difficulty in keeping up with physical activities of peers
- Deficient knowledge related to need for continued treatment

Outcome Identification and Planning

If a child is experiencing an acute respiratory problem, the expected outcomes and plan of care will focus on supporting the child and family through prescribed therapy and

keeping parents informed about their child's health status and response to treatment. Often the treatment period for respiratory illness is prolonged, so parents of children with chronic conditions need to learn how to continue therapy at home. Helping parents to plan programs of exercise and teaching chest physiotherapy and the actions of prescribed medications are important nursing activities. Parents also need to understand that their approach to these programs must change as their child grows older. With an infant, they simply need to perform the prescribed procedures. A game might be a good way to get a toddler or preschooler to breathe deeply ("Simon says, cough. Simon says, take five deep breaths"). Parents need to plan exercise programs for school-age children and adolescents around their school day. Otherwise, children may have difficulty carrying out the program or carry it out only sporadically. If parents include other family members, such as older siblings (within reason) or grandparents, in a respiratory therapy program, this can help to diffuse the burden of care and also to unite the family in working toward a common goal. Helpful Web sites for parents to consult about respiratory illnesses are http://www.kidshealth.org and http://www.everydayhealth.com. Some organizations to recommend as support to parents of the child with a respiratory disorder include American Lung Association (http://www.lungusa.org), National Asthma Education and Prevention Program (http://www.nhlbi.nih.gov), National Easter Seal Society (http://www.easterseals.com), and Cystic Fibrosis Foundation (http://www.cff.org).

Implementation

Collaborative nursing interventions in the care of a child with respiratory dysfunction include suctioning to remove respiratory secretions, administering oxygen, and providing humidification and expectorant therapy to help maintain clear airways. Some of the most important nursing interventions in this area are independent nursing functions: placing a child in an upright position to help the child cough more effectively; providing an interesting game to teach a child the importance of strengthening chest muscles; supporting a child and family through the anxiety created when a child is not breathing normally; and teaching parents of a child with chronic respiratory dysfunction the basics of percussion or chest physiotherapy techniques. All of these interventions require sound nursing judgment and skill to carry out or teach effectively.

Outcome Evaluation

An acute respiratory illness such as pneumonia is extremely frightening for parents as well as the child. After the child has recovered, talk with the parents to determine whether they have come to terms with their fear and can treat the child as a well child again. Otherwise, overprotection of a child by the parents may result in a well but dependent child. This pattern is one that nursing evaluation can help to prevent.

Expected outcomes for a child with chronic respiratory disease will change as a child grows and develops. No matter what the specific concerns are, however, evaluation should always include examination of how well a child individually and the family as a whole have adapted to managing the limitations imposed by the disorder while maintaining a lifestyle that fosters growth and development for all family members.

Examples of expected outcomes that would indicate achievement of goals are:

- Infant, at 3 months, maintains respiratory rate of at least 30 breaths per minute.
- Child describes a reduced program of school activities he will maintain to reduce fatigue.
- Child's P_{O_2} is maintained at 80 to 100 mm Hg in room air.
- Child lists steps she will take if breathing becomes impaired while at school.
- Parents demonstrate correct techniques for performing respiratory therapy at home.

ANATOMY AND PHYSIOLOGY OF THE RESPIRATORY SYSTEM

The respiratory system can be separated into two divisions: the upper respiratory tract, composed of the nose, paranasal sinuses, pharynx, larynx, and epiglottis; and the lower tract, composed of the bronchi, bronchioles, and alveoli. Through **inspiration** (breathing in), the respiratory system delivers warmed and moistened air to the alveoli, transports oxygen across the alveolar membrane to hemoglobin-laden red blood cells, and allows carbon dioxide to diffuse from red blood cells back into the alveoli. Through **expiration** (breathing out), carbon dioxide–filled air is discharged to the outside. Levels of oxygen and carbon dioxide in the lungs, blood, and body cells are shown in Figure 40.1.

The respiratory center is located in the medulla of the brain. Peripheral receptors located in the aortic arch and carotid arteries sense diminished P_{O_2} levels and respond by increasing the respiratory rate. Central respiratory receptors in the medulla sense increased P_{CO_2} levels along with body acidity, temperature, and blood pressure as another stimulus to respiration. Depth of respiration is influenced by proprioceptors located in the lung periphery that register lung fullness. An inhibitory center in the pons halts inspiratory impulses before the lungs become overextended. Often children with chronic lung disease such as cystic fibrosis have adapted so well to a chronically high P_{CO_2} level that central receptor sites no longer register this as abnormal. In these instances, the main stimulus for respiration is a low oxygen level. In such children, administering high levels of oxygen can be dangerous because it alleviates oxygen want or their main respiratory stimulus.

Respiratory Tract Differences in Children

Embryologic development of the respiratory tract is discussed in Chapter 9. Because the respiratory tract continues to mature during childhood, children have several important differences in respiratory anatomy and physiology than adults. The ethmoidal and maxillary sinuses are present at birth; the frontal sinuses (the sinuses most frequently involved in sinus infection) and the sphenoidal sinuses do not develop until 6 to 8 years of age. Due to rapid growth of lymphoid tissue, tonsillar tissue is normally enlarged in early school-age children.

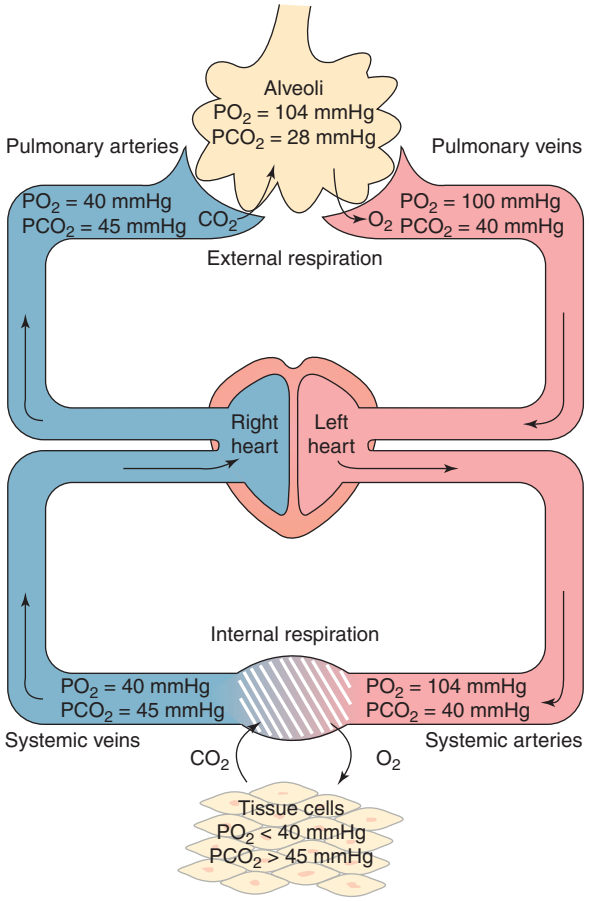

FIGURE 40.1 Partial pressure of gas (mm Hg) as measured in peripheral and systemic circulation. Because of the differences in partial pressure of the gases in the different areas, O_2 moves from alveoli to pulmonary capillaries (i.e., the gas moves from the area of greater concentration to one of a lesser concentration). When it reaches the tissue capillaries, O_2 partial pressure in cells is less, so O_2 goes into the tissues and CO_2 moves out.

Respiratory mucus functions as a cleaning agent by moving invading organisms or other particles out of the lungs. However, newborns produce little respiratory mucus, which makes them more susceptible to respiratory infection than older children. Excessive production of mucus in children up to 2 years of age can actually lead to obstruction because the bronchial lumens are so small in children of this age.

After 2 years of age, the right bronchus is noticeably shorter, wider, and more vertical than the left. This is the reason that inhaled foreign bodies most often lodge in the right bronchus. Infants' chest muscles are not fully developed, so they use their abdominal muscles to assist in inhalation. The change to thoracic breathing begins at 2 to 3 years of age and is complete at 7 years. Because accessory muscles are used more in children than in adults, weakness of these muscles from disease may more easily result in respiratory failure in children than in adults.

In infants, the walls of the airways have less cartilage than in older children and adults and so are not as strong and more likely to collapse after expiration. An advantage of immature development is that a lessened amount of smooth muscle in the airway means an infant does not develop bronchospasm as readily as an older child or adult. Therefore, **wheezing** (the sound of air being pushed through constricted bronchioles) may not be a prominent finding in infants even when the lumen of the airway is severely compromised.

ASSESSING RESPIRATORY ILLNESS IN CHILDREN

Assessment of respiratory illness in children includes an interview, physical examination, and laboratory testing. If the child is in acute distress, the interview and health history may cover only the most important details: when the child first became ill and what symptoms are present. It is important, however, to get as accurate a picture as possible, because the problem could be the result of a variety of circumstances (Box 40.2).

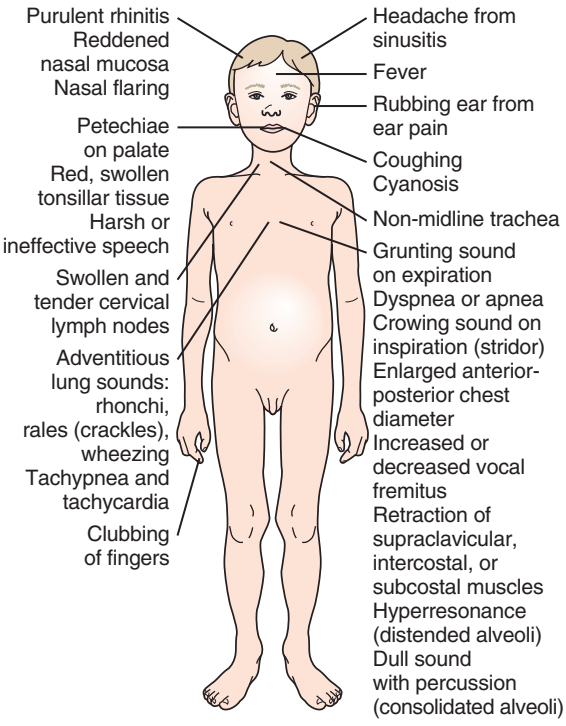
Symptoms of **hypoxemia** (deficient oxygenation of the blood), for example, are often insidious. Peripheral vasoconstriction (a mechanism to save the available oxygen for central life-sustaining body organs) leads to a pale appearance. Tachypnea and tachycardia (efforts to oxygenate cells better) can lead to anxiety and confusion (caused by limited cerebral

Box 40.2 Assessment
Assessing a Child for Signs and Symptoms of Respiratory Dysfunction

History

Chief concern: Cough, rapid respirations, noisy breathing, rhinitis, reddened sore throat, lethargy, cyanosis, difficulty sucking, fever.
Past medical history: Poor weight gain, difficulty with respirations at birth, prematurity.
Family history: History of family member with asthma; other family members with respiratory infection.

Physical examination



perfusion). A poor feeding pattern may be one of the first signs noted in the infant because an infant cannot suck and breathe rapidly at the same time. Cardiac arrhythmia may occur because of inadequate cardiac tissue perfusion. Always ask about home remedies that may have been used in an attempt to increase breathing space or effort.

Physical Assessment

Physical assessment of a child with a respiratory disorder includes observation of symptoms such as cough, cyanosis, or pallor, as well as evaluation of respirations and breath sounds (Hueston, 2008). Breath sounds are best heard if an infant or child is not crying. Spending time comforting a child to prevent crying is time well spent.

Cough

A cough reflex is initiated by stimulation of the nerves of the respiratory tract mucosa by the presence of dust, chemicals, mucus, or inflammation. The sound of coughing is caused by rapid expiratory air movement past the glottis. Coughing is a useful procedure to clear excess mucus or foreign bodies from the respiratory tract. It only becomes harmful and needs suppression when there is no mucus or debris to be expelled and the amount of coughing becomes exhausting. This might occur with respiratory tract inflammation. **Paroxysmal coughing** refers to a series of expiratory coughs after a deep inspiration. Commonly, this occurs in children with pertussis (whooping cough) or those who have aspirated a foreign body or a liquid they attempted to drink.

Although helpful in removing mucus, coughing increases chest pressure and so may decrease venous return to the heart. This lowers cardiac output and can lead to fainting (syncope). Paroxysmal coughing may increase the pressure in the central venous circulation to such an extent that bleeding into the central nervous system (CNS) can result. Because young children often vomit after a series of coughs, they may be suspected initially of having a gastric disturbance even though their main illness is respiratory.

Rate and Depth of Respirations

Tachypnea (an increased respiratory rate) often is the first indicator of airway obstruction in young children. When assessing respiratory rate, particularly in infants, try to count respiratory rate before waking them, because crying distorts respiratory rate. Assess also the depth and quality of respiration, as these also reveal **anoxia** or lack of oxygen in body cells.

Retractions

When children must inspire more forcefully than normally to inflate their lungs because of an airway obstruction or stiff, noncompliant lungs (as in newborns with pulmonary dysplasia), intrapleural pressure is decreased to the point that the nonrigid parts of the chest (the intercostal spaces) draw inward, creating **retractions** (Fig. 40.2). Retractions occur more commonly in newborns and infants than in older children because the intercostal tissues are weaker and less developed in younger children. Retraction of upper chest muscles (supraclavicular or suprasternal) suggests upper airway obstruction; retraction of intercostal or subcostal muscles suggests lower airway obstruction.

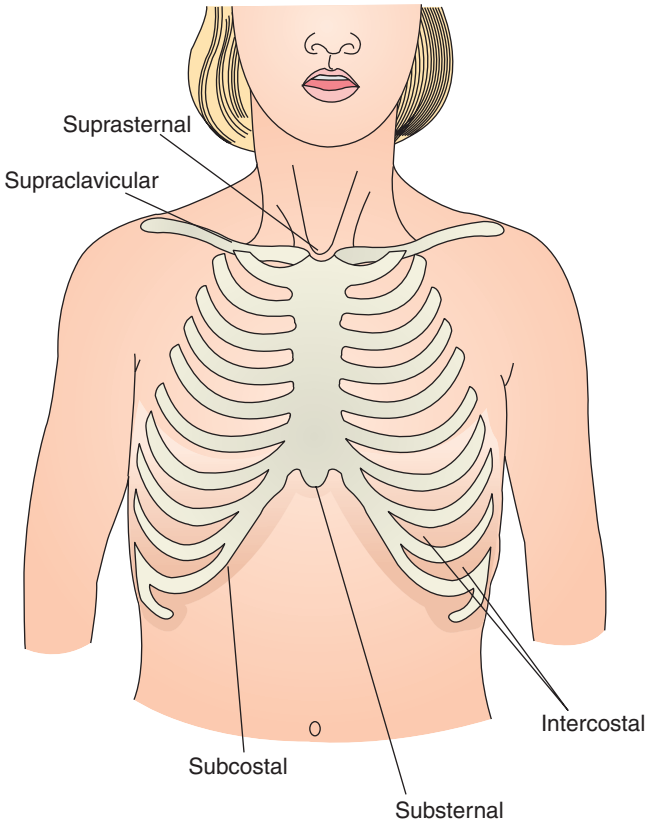


FIGURE 40.2 Sites of respiratory retraction.

Restlessness

When children or infants have decreased oxygen in body cells **(hypoxia),** they become anxious and restless. Be careful not to interpret the excessive movements of infants with respiratory distress as a sign that they are improving; anxious, restless stirring may be their only way of signaling that their respiratory obstruction is becoming acute; it may be one of the first signs of airway obstruction.

Cyanosis

Cyanosis (a blue tinge to the skin) indicates hypoxia. It becomes apparent when the P_{O_2} is under 40 mm Hg or the level of unoxygenated hemoglobin increases to over 3 g/100 mL (because incompletely oxygenated red blood cells in the circulation are what give blood a dark color). If children have a low red blood cell count, cyanosis may not be apparent because there are not enough red blood cells to give the arterial blood its blue tinge. This occurs at hemoglobin levels below 5 g/100 mL. The degree of cyanosis present, therefore, is not always an accurate indication of the degree of airway difficulty. When children have accompanying peripheral vasoconstriction caused by shock, cyanosis of the extremities also may or may not be apparent.

As the P_{O_2} drops and cyanosis results, children increase their respiratory effort in an attempt to supply more oxygen to their tissues. When they do this, the difference in pressure between the intralumen of a not yet fully developed trachea and the surrounding tissue becomes so great that the trachea may collapse, compounding the obstruction problem.

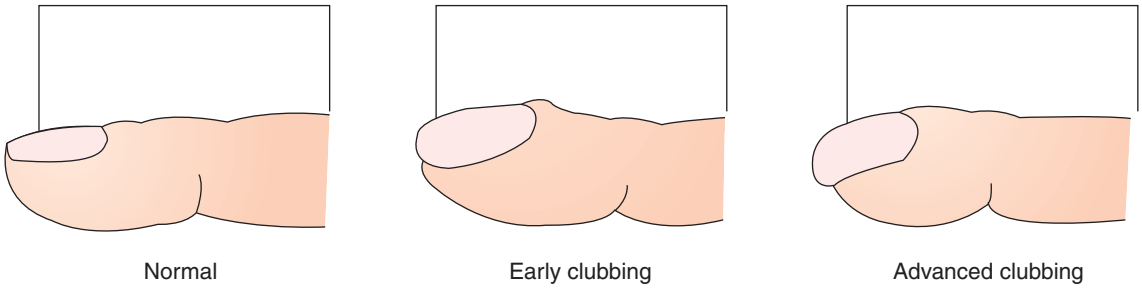

FIGURE 40.3 Clubbing of the fingers. (*Left*) The angle between the nail and digit is normally about 20 degrees in a child. (*Center*) Flattened angle represents early stage of clubbing. (*Right*) In advanced clubbing, the nail is rounded over the end of the finger. Note also that the distal phalanx is bulbous and of greater depth than the proximal portion of the finger (interphalangeal depth).

Clubbing of Fingers

Children with chronic respiratory illnesses often develop **clubbing** of the fingers, a change in the angle between the fingernail and nailbed because of increased capillary growth in the fingertips (Fig. 40.3). The increased capillary growth occurs as the body attempts to supply more oxygen routes (more capillaries) to distal body cells.

Adventitious Sounds

Normal breath sounds are reviewed in Chapter 34. **Adventitious sounds** (extra or abnormal breathing sounds) are caused by pathologic conditions and can be heard on lung assessment in children with respiratory disorders. Normally, on chest auscultation, the inspiratory sound is softer and longer than the expiratory sound. This is referred to as *vesicular breathing*. If you listen over the trachea, this pattern in terms of the length of inspiration and expiration is reversed. This is *bronchial or tubular breathing*. If you hear bronchial breath sounds in the periphery of the lungs, where normally you would expect to hear a vesicular pattern, it indicates that gas exchange in peripheral alveoli is so compromised (as in pneumonia) that you are listening to transmitted tracheal sounds.

Accessory sounds of respiration result from the vibrations produced as air is forced past obstructions such as mucus. If the obstruction is in the nose or pharynx, the noise produced is a snoring sound (*rhonchi*). If the obstruction is at the base of the tongue or in the larynx, you will hear a harsh, strident sound on inspiration. This is laryngeal *stridor*. It is often most marked when a child is in a supine position and less marked when a child sits upright. If an obstruction is in the lower trachea or bronchioles, it is most noticeable on expiration. An expiratory whistle sound (*wheezing*) occurs. If alveoli become fluid-filled, fine crackling sounds **(rales)** are heard. Diminished or absent breath sounds occur when the alveoli are so fluid-filled that little or no air can enter them.

Chest Diameters

With chronic obstructive lung disease, children may be unable to exhale completely, allowing air to be chronically trapped in lung alveoli (hyperinflation). This produces an elongated anteroposterior diameter of the chest, sometimes termed a "pigeon breast." There is an accompanying tympanic or hyperresonant (loud and hollow) sound heard on percussion (see later discussion on chest physiotherapy) over lung spaces.

Laboratory Tests

Several laboratory tests can be used to confirm or rule out the presence of a respiratory disorder and to help identify the cause and severity of the problem. These include analysis of arterial blood gases, nasopharyngeal culture, and sputum analysis.

Blood Gas Analysis

Blood gas analysis is an invasive method for determining the effectiveness of ventilation and acid–base status. The normal values of **arterial blood gases (ABGs)**—the amount of oxygen and carbon dioxide in the blood—are shown in Table 40.1.

Blood gas analysis provides important information about oxygenation of the blood, as values may indicate not only whether the arterial partial pressure of oxygen (P_{O_2}) is adequate but also whether the oxygen saturation of hemoglobin is adequate. The oxygen saturation level will fall if adequate oxygen cannot reach the bloodstream because of respiratory distress or if the hemoglobin is defective and cannot carry a full complement of oxygen (as with sickle cell anemia or thalassemia major). If a child has a severe anemia, the saturation level may be adequate (95% to 100%), but body cells may still not be receiving enough oxygen because of the limited number of red blood cells carrying oxygen. With increased P_{CO_2} or decreased P_{O_2}, a low pH, or decreased temperature, the ability of hemoglobin to accept oxygen diminishes so, again, cells may become hypoxic.

P_{CO_2} measures the efficiency of ventilation. In children who are hypoventilating (breathing very shallowly), P_{CO_2} will be increased because they cannot blow off CO_2; in children who are hyperventilating (breathing deeply), P_{CO_2} will be decreased because children are blowing off too much. When children cannot evacuate accumulated CO_2 because of an obstruction or hypoventilation, the partial pressure of CO_2 in the arterial blood rises and the concentration of carbonic acid (formed when carbon dioxide dissolves in H_2O in plasma) also rises. This leads to acidosis (a decrease in serum pH or an increase in acidity).

The body can compensate for developing acidity for a long time by gradually increasing the amount of bicarbonate in the bloodstream by decreasing the amount of bicarbonate excreted by the kidneys. When respiratory distress is relieved (by removal of an obstruction or by assisted ventilation), the amount of bicarbonate present in the bloodstream may ex-

TABLE 40.1 ✻ Arterial Blood Gas Values

Measure	Definition	Normal Value	Clinical Significance
P_{O_2}	Partial pressure of oxygen in arterial blood	80–100 mm Hg	Decreased if child cannot inspire adequately
P_{CO_2}	Partial pressure of carbon dioxide in arterial blood	35–45 mm Hg	Increased if child cannot expire adequately
O_2 saturation	The percentage of hemoglobin carrying oxygen	95%–100%	Decreased if O_2 cannot reach red blood cells, if unoxygenated cells are being mixed with oxygenated ones, or if hemoglobin is defective
pH	The hydrogen ion concentration of blood	7.35–7.45	Decreased if CO_2 is being retained as carbonic acid in blood
HCO_3	The bicarbonate concentration in blood	22–26 mEq/L	Increased in respiratory alkalosis; decreased in respiratory acidosis
Base excess	Bicarbonate available for buffering	−2.5 or +2.5 mEq/L	(+) = alkaline excess (−) = alkaline deficit

ceed the amount of acid produced at that point, and the child's condition may change from acidosis to alkalosis. With alkalosis, the respiratory rate decreases as the child tries to conserve CO_2. As a result, periods of apnea may occur. Children require close observation during this time, including frequent blood gas and electrolyte determinations to ensure prompt treatment to detect and reverse these changes. Respiratory alkalosis and respiratory acidosis are compared in Table 40.2. Box 40.3 shows steps for evaluating ABGs.

To analyze blood gases, arterial blood rather than venous blood must be used (arterial blood will reflect how well the lungs are oxygenating the blood, whereas venous blood will reflect only the oxygenation of the particular extremity from which the blood was drawn). In the young infant, the temporal artery may be used as a site for blood gasses; in newborns, an umbilical artery catheter can be used. In older children, the radial artery is the site of choice because of the collateral circulation present at the wrist. (If clotting should occur in the radial artery, the hand would still be well nourished by collateral circulation; see the Allen test in Box 40.4.)

For an ABG assessment, a specimen is withdrawn into a heparinized syringe (to prevent clotting). After any arterial puncture, always firmly compress the site. Otherwise, blood from the punctured vessel can seep into subcutaneous tissue, possibly causing a large hematoma and obscuring the site for further assessment. If frequent specimen collections are required, an arterial catheter, inserted either peripherally or centrally, may be used. Doing so allows frequent specimen collections without the trauma of additional punctures. Be sure to apply dressings over the area where an arterial catheter exits the skin to help prevent a young child from fussing or playing with the site. Soft restraints, such as an elbow or hand restraint, may be needed to keep a child from dislodging the catheter.

TABLE 40.2 ✻ Comparison of Respiratory Alkalosis and Respiratory Acidosis

Acid–Base Condition	Cause	Findings
Respiratory alkalosis	Hyperventilation	Rapid, deep breathing Confusion, unconsciousness Elevated plasma pH (above 7.45) Elevated urine pH (above 7) Decreased P_{CO_2} (below 40 mm Hg) Plasma bicarbonate –Initially normal –Compensated: below 20 mEq/L Base excess: 0 or a negative reading such as −4
Respiratory acidosis	Hypoventilation trapping carbon dioxide in alveoli	Shallow breathing; inability to expire freely Confusion, disorientation Decreased plasma pH (below 7.35) Decreased urine pH (below 6) Elevated P_{CO_2} (over 40 mm Hg) Plasma bicarbonate –Initially normal or elevated –Compensated: above 25 mEq/L Base excess: 0 or a positive reading such as +4

BOX 40.3 ✻ Quick Assessment of Arterial Blood Gases

Use a systematic format to assess ABGs quickly:

1. Evaluate the pH: Normally, pH falls between 7.35 and 7.45. A pH below 7.35 denotes acidemia; one above 7.45 reflects alkalemia. If the patient has more than one acid–base imbalance at work, the pH identifies the process in control.
2. Evaluate P_{CO_2}: The partial pressure of arterial CO_2 (P_{CO_2}) normally ranges between 35 and 45 mm Hg. A P_{CO_2} greater than 45 mm Hg indicates ventilatory failure and respiratory acidosis from CO_2 accumulation. A P_{CO_2} less than 35 mm Hg indicates alveolar hyperventilation and respiratory alkalosis.
3. Evaluate HCO_3: A bicarbonate (HCO_3^-) less than 22 mEq/L or a base excess (BE) less than –2 mEq/L denotes metabolic acidosis. A bicarbonate level greater than 26 mEq/L or a BE greater than 2 mEq/L reflects metabolic alkalosis. If the two measurements conflict, the BE is the better indicator of metabolic status.
4. Determine which is the primary and which is the compensating disorder: Often, two acid–base imbalances coincide; one is primary, the other is the body's attempt to return the pH to normal. When both the P_{CO_2} and the HCO_3^- are abnormal, one denotes the primary acid–base disorder and the other denotes the compensating disorder.
   a. To decide which is which, check the pH. *Only a process of acidosis can make the pH acidic; only a process of alkalosis can make the pH alkaline.* For example, if steps 2 and 3 indicate that the patient has respiratory acidosis and metabolic alkalosis and the pH is 7.25, the primary disorder must be respiratory acidosis. The remaining disorder is compensating for the primary problem.
   b. When pH rises (becomes alkalotic), P_{CO_2} decreases in amount (will be below 35 mm Hg). When pH decreases (becomes acidotic), P_{CO_2} increases (will be above 45 mm Hg). When an opposite problem exists this way (pH increased; P_{CO_2} decreased), the problem is respiratory in origin.
   c. pH and HCO_3 normally move in the same direction (when pH is elevated, HCO_3 is elevated). When these two measurements correspond this way (pH decreased, HCO_3 decreased), then the cause of the problem is metabolic in origin.
   d. Three states of compensation are possible: *noncompensation,* reflected in an alteration of only P_{CO_2} or HCO_3^-; *partial compensation,* in which both P_{CO_2} and HCO_3^- are abnormal and, because compensation is incomplete, the pH is also abnormal; and *complete compensation,* in which both P_{CO_2} and HCO_3^- are abnormal but, because compensation is complete, the pH is normal. To identify the primary disorder when compensation is complete, consider a pH between 7.35 and 7.40 indicative of primary acidosis and a pH between 7.40 and 7.45 indicative of primary alkalosis.
5. Evaluate oxygenation: Normally P_{O_2} remains between 80 and 100 mm Hg. A P_{O_2} between 60 and 80 mm Hg reflects mild hypoxemia; between 40 and 60 mm Hg, moderate hypoxemia; and below 40 mm Hg, severe hypoxemia.
6. Interpret the findings: Your final analysis should include the degree of compensation, the primary disorder, and the oxygenation status; for example, "partially compensated respiratory acidosis with moderate hypoxemia."

BOX 40.4 ✻ Allen Test

Before obtaining an ABG from the radial artery, it is important to establish that a child has collateral circulation to the hand. Otherwise, the needle puncture may block the artery and block blood flow to the hand.

To prove that there is collateral circulation, compress both the radial and ulnar arteries on the inner side of the wrist and elevate the hand until color disappears. Release the pressure over the ulnar artery and observe for a color change in the hand. If the hand does not pinken (proof the blood has flowed into the hand), the radial artery on that wrist should not be used for catheter insertion.

In small infants, when it is impossible to obtain arterial blood directly, heel or finger punctures may be used. If the heel or finger is warmed for about 20 minutes with a warm compress before the procedure, local blood flow increases so much that the blood gas levels of the capillaries approach those of arteries.

Be certain to note the use of oxygen, if any, and its liter flow on laboratory slips for ABG assessments. Also note the site where the specimen was obtained. While being transported to the laboratory, ABG specimens should be kept on ice to ensure accurate results (CO_2 levels decline in room air).

The oxygen saturation of hemoglobin can also be obtained noninvasively using pulse oximetry and transcutaneous oxygen monitoring.

Pulse Oximetry. Pulse oximetry is a noninvasive technique for measuring oxygen saturation. For the measurement, a sensor and a photodetector are placed around a vascular bed, most often a finger in a child or a foot in an infant (Fig. 40.4). Infrared light is directed through the finger from the sensor to

A B C

FIGURE 40.4 Types of pulse oximetry probes include (**A**) infant continuous; (**B**) finger continuous; and (**C**) finger intermittent. (From *Maternity and Pediatric Nursing*. Philadelphia: Lippincott Williams & Wilkins.)

the photodetector. Because hemoglobin absorbs light waves differently when it is bound to oxygen than when it is not, the oximeter can detect the degree of oxygen saturation (SaO_2) in the hemoglobin.

Oxygen saturation is closely aligned with PO_2 (Fig. 40.5). When SaO_2 is 95%, the PO_2 is within the normal range of 80 to 100 mm Hg. When SaO_2 has fallen to 90%, the PO_2 is 60 mm Hg. An easy rule to remember concerning the relationship between SaO_2 and PO_2 is the 60 to 30, 90 to 60 rule: when SaO_2 is 60, PO_2 is 30; when SaO_2 is 90, PO_2 is 60. Any SaO_2 reading under 90, therefore, is a cause for concern.

One advantage of pulse oximetry is that it is noninvasive. A second advantage is that the continuous monitoring provided by a pulse oximeter allows you to modify your care appropriately. If an oxygen level should begin to fall while you are handling an infant, for example, you could immediately stop care until the infant's PO_2 again returns to normal. A disadvantage is that the sensor is small and must be checked frequently to see that it remains in place. Excess light in a room can distort the reading. Therefore, the sensor may need to be covered with a blanket in a neonatal intensive care unit or brightly lit nursery for readings to be accurate. Young children also tend to remove the sensors just as they frequently remove adhesive bandages from their fingers.

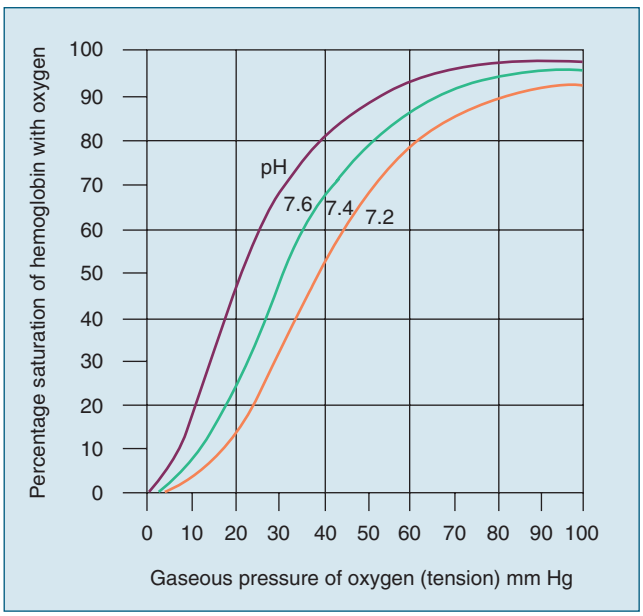

FIGURE 40.5 Oxyhemoglobin dissociation curve.

Transcutaneous Oxygen Monitoring. Transcutaneous monitoring is another means of continuous, noninvasive measurement of oxygen saturation. For this determination, electrodes heated to 44° C are attached to an infant's chest. The heat causes vasodilation underneath the skin and brings the peripheral arterial blood to the surface to be read for oxygen content. This is converted to mm Hg for a monitor readout. The oxygen saturation level read by this method correlates with intra-arterial PO_2, the same as with pulse oximetry. Transcutaneous monitoring has a disadvantage compared with pulse oximetry because the probe position needs to be changed about every 3 to 4 hours to prevent a burn to the skin, and sensor recalibration is necessary with each position change.

Nasopharyngeal Culture

When done efficiently, nasopharyngeal cultures cause little discomfort and reveal a great deal of information about the microorganisms causing a disease. However, most children are terribly frightened by having something placed in their noses or throats and so may resist accordingly. Firm, calm support during the procedure while you touch a moistened swab to the mucus membrane of the nose or throat is essential. Nose and throat cultures can reveal only the organisms present in the upper respiratory tract. As a result, they may not show organisms causing a lower respiratory tract infection. A throat culture will miss pathogenic organisms if the culture tip is not touched to the infected aspect of the pharynx.

Respiratory Syncytial Virus Nasal Washings

Nasal washings are obtained to diagnose an infection by the respiratory syncytial virus (RSV). For this, a child is placed

in the supine position, and 1 to 2 mL sterile normal saline is dropped with a sterile needleless syringe into one nostril. The nose is then aspirated using a small, sterile bulb syringe. The secretions removed are placed in a sterile container to be sent to the laboratory for analysis. Nasal washings are even more uncomfortable for children than nasal swabbing because of the saline that is instilled. Provide comfort to a child afterward and assure the child the specimen collection is over.

Sputum Analysis

Because they cannot raise sputum with a cough, sputum collection is rarely feasible in children younger than school age. Older children, however, are able to cough and raise sputum. Teach them exactly what you want (a specimen of what they are coughing up, not just clearing from the back of their throat). Then ask them to breathe in and out several times, cough deeply and spit mucus they have raised into a sterile specimen jar.

Diagnostic Procedures

In addition to cultures, several other diagnostic procedures are used to identify respiratory disorders in children. Many of these procedures are also used with adults, with modifications to account for the physical and developmental differences of children. Bronchoscopy (visualization of the bronchi through a bronchoscope) is discussed in Chapter 37.

Chest Radiography

Chest x-ray films will show areas of infiltration or consolidation in the lungs; if a foreign body is opaque, an x-ray study will show its location. Chest x-ray films are more difficult to obtain in infants than in older children, because infants cannot take a breath and hold it when instructed. It is therefore difficult to picture the lungs at their most expanded position. Computed tomography (CT) scans may be ordered for children with chronic lung disease because this technique can best mark disease progress.

Bronchography

On a chest radiography, the air-filled larynx, trachea, and major bronchi are revealed as dark spaces. Any obstruction or distortion in the organs is apparent. For further definition of structures, a radiopaque solution may be introduced into the respiratory tract by an ultrasonic nebulizer or by a catheter inserted into the trachea before the x-ray study is performed. Children may require conscious sedation for this because nebulization or having a catheter passed into the airway can be frightening. Afterward, children may have increased mucus production from bronchial irritation by the procedure. Observe them carefully after such a procedure for possible respiratory obstruction from accumulating mucus.

Pulmonary Function Studies

The process of ventilation, or the work of breathing, involves three main forces: (a) an inertial force that must be overcome to change the speed and direction of air when the lungs change from exhalation to inhalation; (b) an elastic force to help the lungs expand with inhalation; and (c) the flow resistance force or resistance to the movement of air through the bronchial tree that must be overcome. Flow resistance must be at a minimum for best ventilation. It becomes increased when the bronchioles are narrowed or plugged with mucus. Pulmonary function tests measure the forces of inertia, elasticity, and flow resistance. Peak flow, a commonly used measure, is the amount of air that can be moved out of the lungs with a forceful breath.

The alveoli of the lungs are never completely empty at the end of expiration because the bronchioles collapse, trapping air in the alveoli before alveoli are completely empty. In contrast, alveoli are never completely filled on inspiration because their potential for expansion exceeds that necessary for good respiratory function. Children with obstructive lung diseases such as asthma or bronchiolitis have some difficulty moving air into the lungs, but they have even more difficulty moving air out of the lungs. Even if they do expire the same amount of air as the average child, they expire it over a longer period. Children with restrictive ventilatory disorders, such as neuromuscular disorders, have equal difficulty with inspiration and expiration.

Several lung capacity studies can be done to determine the degree of obstruction or restricted ventilation ability. For these studies, the child breathes into a spirometer, a device that records the force of air exchange.

Children younger than 4 years of age are usually unable to participate in pulmonary function tests because these tests require their cooperation. All children need good preparation and teaching for these tests because they must breathe forcefully through the mouth into a mouthpiece on cue. Some tests require the nose be closed by a clamp or clip or an assistant's hand while the child blows out. This can be a frightening feeling for children with respiratory disease. They may need some trial runs to assure themselves that they can breathe with the clamp in place. Without good orientation to the equipment, they may become so anxious about their performance that they develop tachypnea or fail to inhale or exhale at their full capacity, so the test results are skewed.

Common pulmonary function tests are outlined in Table 40.3. The results of pulmonary function studies help determine the nature and extent of a child's respiratory problem and the best methods for achieving more effective ventilation.

HEALTH PROMOTION AND RISK MANAGEMENT

Several ways to promote respiratory health are available for parents and children. The common cold is the most common respiratory disorder seen in children. Children as young as toddlers can be taught to help avoid spreading colds through their family by washing their hands, properly disposing of tissues, and covering their mouth while coughing. These measures need to be stressed again with school-age children to help prevent them from contracting or spreading germs through their schoolroom. The incidence of *Haemophilus influenzae* type B (HIB), the cause of bronchiolitis, as well as influenza can be reduced by ensuring that children receive their routine immunizations against these (HIB and influenza vaccine). Children with chronic respiratory illnesses also should receive the pneumococcal vaccine. Reducing respiratory irritation by reducing secondary smoke can help prevent upper

TABLE 40.3 ✻ Pulmonary Function Tests

Test	Measurement	Clinical Implications
Vital capacity (VC)	The maximum amount of air expelled after a maximum inspiration	Decreased if bronchial lumens are narrowed or obstructed
Tidal volume (TV)	The amount of air inhaled and exhaled in a normal respiratory movement	Decreased if bronchial lumens are constricted
Residual volume	The amount of air remaining in the lungs after a maximum expiration	Increased if there is air trapping in alveoli, as in obstructive lung disease
Functional residual capacity (FRC)	The volume of air remaining in the lungs after a normal expiration	Increased if ability to breathe out is impaired
Forced expiratory volume (FEV)	The amount of air expired in 1 second	Decreased in obstructive disease that prevents free expiration
Peak flow	The strength of air expired in a forceful expiration	Decreased in obstructive disease that prevents free expiration

respiratory infections, reduce the incidence of asthma attacks, as well as otitis media (middle ear infection).

THERAPEUTIC TECHNIQUES USED IN THE TREATMENT OF RESPIRATORY ILLNESS IN CHILDREN

The primary goal of nursing interventions in the care of children with respiratory disorders is to maintain or re-establish the airway to help ensure that adequate oxygen reaches the blood. Often this includes interventions aimed at liquefying and removing mucus secretions so they do not clog the bronchial pathways. Such clogging prevents adequate oxygenation and contributes to the development of bronchial and alveolar infections.

Expectorant Therapy

Any irritation of the respiratory tract causes the production of large amounts of mucus. The amount produced can become so great that the natural mechanisms for clearing it (coughing and upward cilia action) are no longer adequate. If a child is breathing rapidly because of respiratory distress, the frequent passage of air over the mucus tends to dry it and make it more viscid, compounding the removal problem. Several measures may be used to liquefy dried mucus and help raise it.

Liquefying Agents

Pharmacologic agents (expectorants) such as guaifenesin (Robitussin), given orally, are designed to liquefy mucus in the trachea and bronchi. Instilling saline nose drops or using saline nasal sprays can be effective in moistening and loosening dried mucus in the nose (Karch, 2009).

Humidification

Humidification is the provision of moisture to the airway. Common methods of delivering moisture include vaporizers and nebulizers.

Vaporizers. Vaporizers emit a stream of air moistened by fine droplets of water into a room, providing either a cool or a warm mist to the entire room. Caution parents when using warm mist that a serious scald burn can result if children accidentally pull a vaporizer over on themselves. To avoid this type of accident, they should be certain the vaporizer is placed up, out of reach of the child. Although cool mist can create a clammy atmosphere in a room, this can be advantageous for a child who also has a fever, helping to cool and moisten the whole environment. Caution parents to clean vaporizers thoroughly after use to prevent the growth of *Pseudomonas* or other pathogenic organisms.

Nebulizers. Nebulizers are mechanical devices that provide a stream of moistened air directly into the respiratory tract. Most are hand-held masks that fit over the nose and mouth and are attached to an electrical pump as a power source (Fig. 40.6). Ultrasonic nebulization delivers such minuscule droplets into the respiratory tract that even the smallest bronchioles can be moistened. Nebulizers also serve as an important means for the delivery of respiratory tract medications (Subramanian, 2008). Drugs such as antibiotics or bronchodilators can be combined with the nebulized mist and sprayed into the lungs.

Many children find nebulizer treatments uncomfortable because the feeling of the mist in their upper respiratory tract can be frightening or irritating. Assure them that aerosol administration is the most effective route for moisture and medication to reach and cause an effect in the respiratory tract.

FIGURE 40.6 Child using a nebulizer.

During aerosol medication administration, watch carefully for signs of both local tracheal or bronchial effect (spasm or edema) that might result from airway irritation as well as systemic symptoms that might result from absorption of a medication by the membrane.

Coughing

As a rule, encourage coughing rather than suppress it in children because it is an effective method of raising mucus. Changing a child's position and suggesting mild exercise or deep breathing are helpful techniques to initiate coughing. If a cough is caused by mucus dripping from the nose because of nasal congestion, a decongestant such as pseudoephedrine (Sudafed) will best halt the draining mucus and therefore the cough. Caution parents not to give cough syrup routinely to children. Several of these contain codeine in doses that may be too high for a child's weight. Others produce little effect and the risk of overdose, incorrect dosing, and adverse events is greater than the benefit of the syrup (Ryan, Brewer, & Small, 2008). Because of this, cough and cold remedies are no longer recommended for children under 2 years of age (DHHS, 2008).

Mucus-Clearing Devices

A mucus-clearing device (a Flutter device) can be used to aid in the removal of mucus. This device looks like a small plastic pipe. A stainless-steel ball inside the device moves when the child breathes out, causing vibrations in the lungs (Fig. 40.7). This vibration helps loosen mucus so that it can be moved up the airway and expectorated. This device is used most frequently with children who have cystic fibrosis or pneumonia to help remove mucus from the lungs.

Chest Physiotherapy

Simply changing a child's position helps mucus to move, initiate a cough reflex, and be expelled. When a child is positioned so the chest is lower than the abdomen, gravity aids in the removal of mucus from the lower lobes and bronchi. When a child sits upright, gravity aids drainage from the upper lobes into the bronchi. When lying supine, anterior alveoli drain; when prone, posterior alveoli drain. Frequent changes of position are important, therefore, to prevent mucus from pooling in certain lung areas. If a child has a localized mucus problem, lying predominantly in one position can encourage drainage of that lung segment. When the child is repositioned and the mucus drains into new bronchi, this will often cause a cough from irritation caused by this new drainage.

Three techniques are involved with chest physiotherapy (CPT) to further loosen mucus for expectoration: postural drainage, percussion, and vibration. Each technique can be used alone, but they are usually more effective at moving mucus toward the mainstem bronchus when performed together.

CPT is best scheduled before meals or at least an hour after a meal so the subsequent coughing does not cause vomiting. Techniques are described in Box 40.5 and summarized below. Limit CPT to approximately 30 minutes each time, because these techniques are tiring. Modifications in the techniques or shortening of the time periods may be necessary, depending on a child's ability to tolerate the position changes and the techniques. For example, before breakfast, the upper right and the left upper and lower lobes might be done; before lunch, the right lower lobe and right middle lobe might be done; before supper or at bedtime, the upper and lower lobe on both sides might be done.

Common postural drainage positions for the infant are shown in Figure 40.8. An infant may be positioned on your lap, whereas a slant board or other surface is needed for postural drainage with an older child. Not all positions are tolerated well. Be ready to modify the positions used depending on the child's condition and tolerance.

Percussion involves striking a cupped or curved palm against the chest to determine the consistency of tissue beneath the surface area. This technique causes a loud, thumping noise that sounds as if it hurts, but you can assure parents it does not. In infants and some small children, a specialized device, a nipple, or a small oxygen mask may be used as the palm of the hand is too big (Fig. 40.9). These devices concentrate the motion and may increase the amount of mucus removed.

Vibration is done by pressing a vibrating hand against a child's chest during exhalation. Like percussion, it mechanically loosens and helps move tenacious secretions upward. Vibration also may be accomplished by a mechanical vibrator or a vibrating vest.

Position a child so the lobe of the lung to be drained is in a superior position. Apply vibration or percussion. After each position, ask the child to cough. Children cough best if you

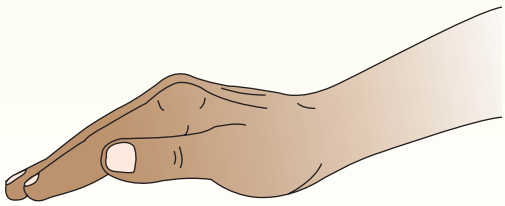
Box 40.5 Nursing Procedure ✻ Chest Physiotherapy

Purpose: To encourage the loosening and raising of mucus from the respiratory tract through the use of postural gravity drainage and percussion (clapping) and vibrating techniques.

Procedure	Principle
1. Wash your hands; identify child; explain procedure to child.	**1.** Handwashing prevents spread of microorganisms. Identifying the child ensures that you are performing the procedure on the right child. Explaining the procedure beforehand promotes child's understanding and adherence and helps to minimize anxiety.
2. Assess child as to status; analyze appropriateness of procedure; modify plan as necessary.	**2.** Chest physiotherapy is physically exhausting; can increase intracranial pressure when head is lowered in dependent position. Wait 1 h after meals to avoid inducing vomiting with coughing.
3. Assemble supplies: pillow or slant board, disposable tissues (sputum cup if specimen for culture is desired); percussion device (if infant); nebulizer with correct fluid and medicine if prescribed.	**3.** Organizing care increases efficiency and helps prevent tiring child. Nebulization before postural drainage may be prescribed to promote bronchodilation, dilute mucus, and aid mobility of secretions.
4. Select a drainage position (see Fig. 40.8). Position child appropriately but comfortably. Auscultate and percuss lung area for baseline determinations.	**4.** Positions aid in the gravity drainage of secretions.
5. Use percussion and clapping technique (see figure) for 1–2 min and vibrate during 4 or 5 exhalations the section of chest indicated for the position. Observe child closely for respiratory distress.	**5.** Percussion and vibration loosen bronchial mucus and allow it to be coughed from the respiratory tract. As mucus moves, it may plug a bronchus; observe for cyanosis, tachypnea, dyspnea, and violent coughing as signs of this.
	


6. Ask child to deep breathe and cough to raise secretions. Auscultate lung section to ascertain clearing of secretions.	**6.** Coughing also helps move secretions.
7. Reposition; percuss and vibrate the chest areas in additional drainage positions as prescribed. Continue to observe for signs of respiratory distress. Provide rest as necessary between positions.	**7**. Position changes allow for loosening and drainage in other lung segments. Child may grow tired after repeated percussion/vibration.
8. At finish of prescribed positions, return child to bed. Provide mouthwash if desired (and age-appropriate); discard used tissues.	**8.** Coughed sputum may taste unpleasant. Use standard infection precautions to avoid touching soiled tissues.
9. Evaluate effectiveness, cost, comfort, and safety of procedure. Plan health teaching as necessary, such as benefits of procedure.	**9.** Evaluation allows for determining effectiveness of the procedure and need for modifications for future treatments. Health teaching is an independent nursing action always included in nursing care.
10. Record procedure, description of sputum raised, and child's reaction to procedure. If sputum specimen is obtained, send to laboratory for analysis.	**10.** Documentation provides evidence of nursing care, child's status, and effectiveness of interventions.

demonstrate the proper technique by taking a deep breath, blowing it out, taking a second deep breath, blowing that out, taking a third deep breath, and then coughing. The irritation of mucus in the major airway by the third breath makes a cough happen almost spontaneously.

Formerly, CPT was done in hospital settings by respiratory therapists. However, in today's health care climate of managed care, nurses are now often the health care provider who perform CPT and teach it to parents. One or both parents may need to learn the technique before their child is discharged so that it can be continued conscientiously at home. The technique is used most frequently with children with bronchiolitis or cystic fibrosis (van der Schans, Prasad, & Main, 2009).

FIGURE 40.8 Positions for bronchial drainage for major segments of all lobes in infants. This procedure is most readily performed with the infant in your lap, with your hand on the chest over the area to be cupped or vibrated. (**A**) Apical segment of left upper lobe. (**B**) Posterior segment of left upper lobe. (**C**) Anterior segment of left upper lobe. (**D**) Superior segment of right lower lobe. (**E**) Posterior basal segment of right lower lobe. (**F**) Lateral basal segment of right lower lobe. (**G**) Anterior basal segment of right lower lobe. (**H**) Medial and lateral segments of right middle lobe. (**I**) Lingular segments (superior and inferior) of left upper lobe.

What if... Michael needs to cough to raise bronchial mucus. What if he refuses to? How can you get him to cough?

Therapy to Improve Oxygenation

Improving oxygenation almost automatically relieves breathing distress.

Oxygen Administration

Oxygen administration elevates the arterial oxygen saturation level by supplying more oxygen to red blood cells through the respiratory tract. Oxygen may be delivered to infants by flooding an incubator or by using a plastic hood, mask, or cannula. Plastic oxygen hoods are tight-fitting enclosures that can keep oxygen concentration at nearly 100% (Fig. 40.10). Always check that a hood fits snugly over the infant's head, making sure it does not rub against the infant's neck, chin, or shoulders. Be sure the gas does not blow directly into the infant's face.

Although a nasal catheter or nasal prongs can be used for infants, they are usually reserved for older children. These provide a concentration of approximately 50% with an oxygen flow of 4 L/min. Most children do not like nasal prongs or catheters because they are intrusive. Assess their nostrils carefully when using these as the pressure of prongs can cause areas of necrosis, particularly on the nasal septum.

A snug-fitting oxygen mask is a method for supplying nearly 100% oxygen and is the method frequently used in

FIGURE 40.9 Alternative percussion device. To assist with percussing an infant or small child, a nipple or mask such as that from a manual resuscitation bag may be used.

FIGURE 40.10 Oxygen hood for an infant.

emergencies (Fig. 40.11). Masks, like prongs or catheters, are often not well tolerated by children because they tend to slip and obstruct their view. If necessary, let them hold a mask rather than strapping it in place to allow them more control.

Regardless of the delivery method used, oxygen must be administered warmed and moistened. Without proper humidification, oxygen dries mucous membranes and thickens secretions, compounding breathing difficulty. Oxygen, like any other drug, requires careful administration and follow-up assessment. If concentrations are too low, oxygen is not therapeutic; in concentrations greater than those desired, it can be toxic. If newborns are subjected to oxygen concentrations over 100 mm Hg for an extended time, retinopathy of prematurity can occur (see Chapter 26). In any child, administering oxygen concentrations of 70% to 80% for an extended period may lead to a thickening of the lung alveoli and a loss of lung pliancy (oxygen toxicity or bronchopulmonary dysplasia). For these reasons, oxygen should not be given in high concentrations for long periods unless adequate facilities for blood gas analysis are available (Marino, 2007).

When caring for a child with any form of oxygen equipment, follow good safety rules. Because oxygen supports combustion, keep open flames away from oxygen and minimize the risks of sparks. Since oxygen is humidified, oxygen equipment is a good source of microbial contaminants. Change equipment according to your agency's policy, but at least once a week to keep bacterial counts within safe limits. Monitor and record a child's oxygen saturation level via pulse oximetry or transcutaneous pulse oximetry as indicated. Obtain ABG measurements with any change in condition or oxygen flow or as otherwise ordered.

Pharmacologic Therapy

Children notice difficulty with exchange of air when their airways become obstructed because of unusual mucus production, bronchoconstriction, or inflammation. Several drugs may be used in children to reverse these processes. Nasal sprays such as normal saline can be administered to

FIGURE 40.11 Types of oxygen administration include (**A**) simple oxygen mask, (**B**) nasal cannula, and (**C**) a nonrebreather mask. (From *Maternity and Pediatric Nursing*. Philadelphia: Lippincott Williams & Wilkins.)

moisten and loosen nasal secretions. Antihistamines given by this route can reduce mucus production and thereby enlarge the airway. Decongestants cause vasoconstriction, leading to shrinkage of the mucous membranes, which expands breathing space. Expectorants such as guaifenesin (Robitussin) help to raise mucus. Most of these agents also cause drowsiness, so their doses must be regulated, especially in adolescents who will be driving. Bronchodilators such as albuterol (Ventolin), terbutaline (Brethine), and levalbuterol (Xopenex) are examples of drugs used to open the lower airway (Box 40.6). Antibiotics may be given intravenously, intramuscularly, orally, or inhaled through nebulization to reduce infection and limit purulent mucus and inflammation. Corticosteroids taken either orally or by inhalation enlarge the airway by reducing further inflammation (Deglin & Vallerand, 2008). Caution parents not to give cough and cold medications to children under 2 years of age unless specifically prescribed by their health care provider (DHHS, 2008).

BOX 40.6 ✻ Focus on Pharmacology

Albuterol Sulfate (Proventil, Ventolin)

Classification: Albuterol is a beta-2–adrenergic agonist.

Action: Acts selectively to cause bronchodilation and vasodilation for relief of bronchospasm (Karch, 2009).

Pregnancy risk category: C

Oral Dosage:

- Children older than 14 years—2 or 4 mg, 3 or 4 times daily; not to exceed 32 mg/day
- Children ages 6 to 14 years—2 mg, 3 or 4 times daily, not to exceed 24 mg/day
- Children ages 2 to 6 years—0.1 mg/kg, 3 times daily, not to exceed 2 mg/day; gradually increasing to 0.2 mg/kg, 3 times daily, not to exceed 4 mg/day

Inhaled Dosage: Children 12 years of age and older—2 puffs every 4 to 6 hours: 2.5 mg (0.5 mL of 0.5% solution diluted with 2.5 mL of 0.9% sodium chloride) OR 3 mL of 0.083% solution, 3 or 4 times daily

Possible adverse effects: Restlessness, apprehension, anxiety, fear, nausea, cardiac arrhythmias, paradoxical airway resistance with repeated, excessive use of inhalation preparations, sweating, pallor, and flushing

Nursing Implications

- Instruct parents and child in method to administer drug. Teach child and parents about use and care of nebulized solution or metered-dose inhaler and spacer devices, if ordered.
- Caution child and parents not to exceed the number of ordered puffs, to prevent possible tolerance to drug.
- If more than one inhalation is ordered, advise child to wait 1 to 2 minutes before taking the second puff.
- If the child is also receiving an inhaled corticosteroid, advise the child and parents to have the child use the albuterol first to open the airways and then wait approximately 5 minutes before using the corticosteroid, to maximize its effectiveness.

Metered-Dose Inhalers. A metered-dose inhaler (MDI) is a hand-held device that provides a route for medication administration directly to the respiratory tract. The child inhales while pressing a trigger on the apparatus. Some devices include a spacer device attached to the apparatus, a plastic extension tube or chamber that helps better coordinate inhalation with the medication delivery. For successful use, children need to follow five general rules: shake the canister, exhale deeply, activate the inhaler as they begin to inhale, take a long slow inhalation, and then hold their breath for 5 to 10 seconds. They should take only one puff at a time, with a 1-minute wait between puffs (Karch, 2009). Metered-dose inhalers require that children trigger the inhaler at the same time they breathe in (Fig. 40.12A). Because it is difficult for children younger than approximately 12 years to do this, placing a spacer tube between the inhaler and the mouthpiece better coordinates inhaling and trigger release (Fig. 40.12B).

Incentive Spirometry

Incentive spirometers are devices that encourage children to inhale deeply to aerate the lungs fully or move mucus. Although manufactured in different configurations, a common type consists of a hollow plastic tube containing a brightly colored ball or dome-shaped disk that will rise in the tube when a child inhales through the attached mouthpiece and tubing. The deeper the inhalation, the higher the ball rises in the tube.

Children need instruction on how to use this type of device, because their first impression is that they should blow out against the mouthpiece rather than inhale (Fig. 40.13A). Incentive spirometry is effective with children because the device and procedure resemble a game more than an actual treatment.

Breathing Techniques

Some children need exercises prescribed to help them better inflate alveoli or more fully empty alveoli. Blowing a piece of cotton or a plastic ball across a table, blowing through a straw, or blowing out with the lips pursed are effective techniques for better emptying alveoli (see Fig. 40.13B). Yet another method for increasing aeration is to ask a child to blow up a balloon, as this requires the child to take a deep inhalation. For best results, make these activities a game or contest rather than an exercise.

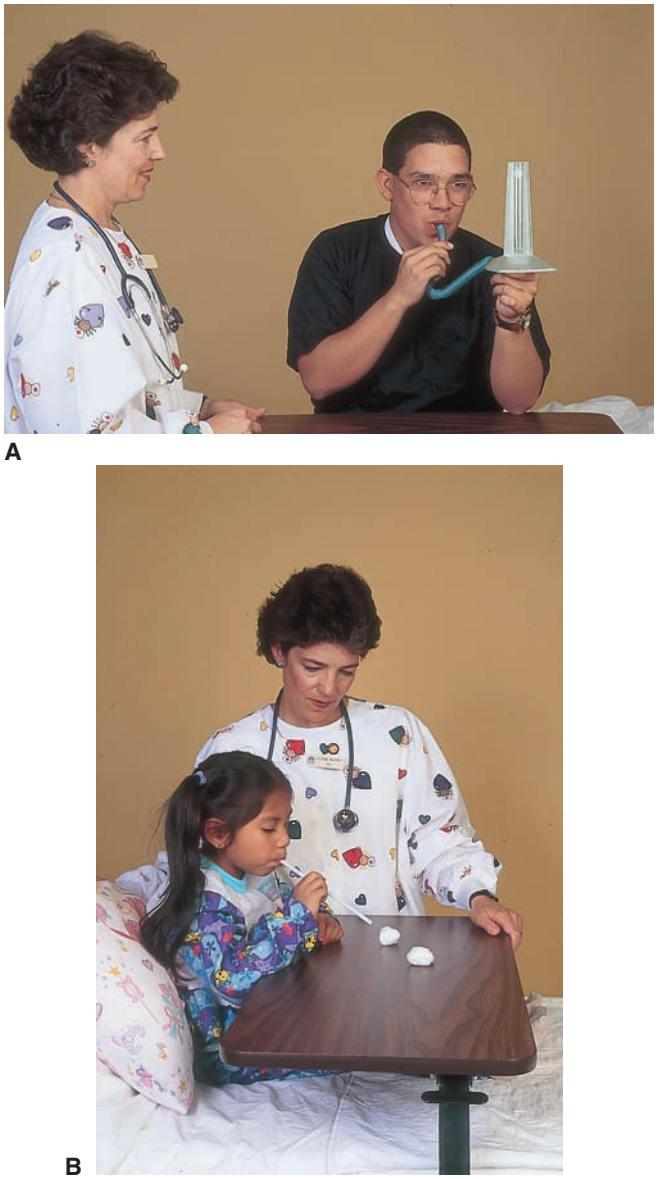
Tracheostomy

A **tracheostomy** is an opening into the trachea to create an artificial airway to relieve respiratory obstruction that has occurred above that point (Yu, 2008). The procedure to create the airway is called a **tracheotomy;** the resultant airway is the tracheostomy. Tracheostomies also may be used as a route for suctioning mucus when accumulating mucus causes lower airway obstruction. A danger of tracheostomies is that they eliminate the warming and filtering action of the nose and pharynx, making children more susceptible to infection. For these reasons, endotracheal intubation, not tracheostomy, has become the method of choice to relieve airway obstruction and for short-term oxygenation. The exception to this is obstruction in the pharynx, because it is often impossible to pass an endotracheal tube beyond obstruction at this point. Tracheostomies are also still used for long-term home care.

Emergency Intubation. Few medical emergencies are as frightening to a child or parents as an acute obstruction of a child's upper airway requiring a tracheotomy or endotracheal intubation. The child suddenly becomes limp and breathless, with color changing quickly to systemic cyanosis. Tracheotomies are done more easily on a treatment room table than on a bed or crib, so it is generally best to carry a child immediately to a treatment room for the procedure. If a child cannot be moved quickly, however, because of accessory equipment, do not lose time in transport. For tracheotomy, the cricoid cartilage of the trachea is swabbed with an antiseptic; if readily available, a local anesthetic may be injected into the cartilage ring. (This is not necessary in the unconscious child.) An incision is made just under the ring of cartilage and a tracheostomy tube with its obturator in place is inserted into the opening (Fig. 40.14A). When the obturator is removed, the child can breathe through the hollow tracheostomy tube (see Fig. 40.14B). Have suction equipment available for immediate use to clear any blood caused by the incision (this is minimal) and any obstructing mucus from the trachea.

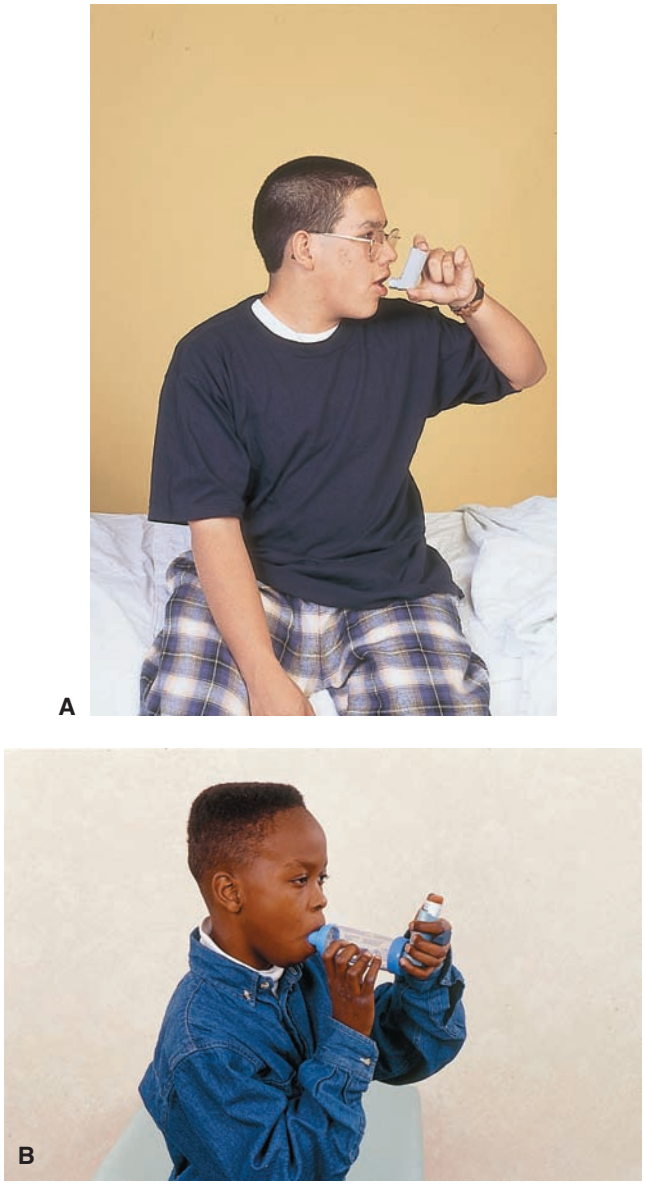
The color change in children after tracheostomy is usually dramatic. They inhale deeply several times through the tube, and color returns to normal. A few sutures may be necessary at the tube insertion site to halt bleeding or to reduce the size of the incision so the tube fits snugly.

As children begin to breathe normally and, if unconscious, regain consciousness, they often thrash and push at people around them, both from oxygen deficit and from fright. They call for a parent but can make no sound, adding



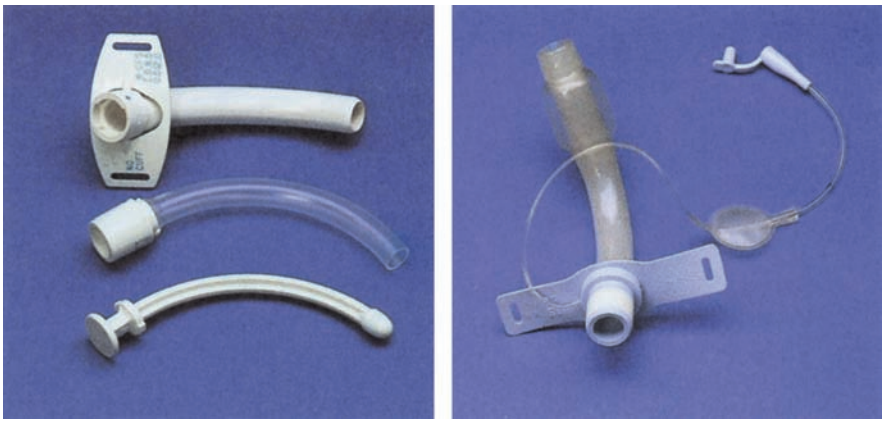
A B

FIGURE 40.13 (**A**) Incentive spirometry is an appealing method to encourage children to aerate their lungs. (**B**) Encouraging children to take a deep breath and try to blow a cotton ball across the table is also an entertaining way to help them fully expand their lungs.



A B

FIGURE 40.12 (**A**) Many children use a metered-dose inhaler to administer a bronchodilator to themselves. Be certain children respect such medicine as medicine so they use sensible precautions. (**B**) Younger children need a "spacer" with inhalers so they do not need to correlate administration with inhalation.



A

B

FIGURE 40.14 (**A**) Tracheostomy tubes: (*left*) a plastic tube, inner cannula, and obturator; (*right*) a plastic, cuffed tube. (**B**) The tracheostomy collar allows for humidification of inspired air or supplemental oxygen. (From *Maternity and Pediatric Nursing*. Philadelphia: Lippincott Williams & Wilkins.)

to their fright. Assure children that everything is all right, even though they cannot speak. A school-age child can understand a simple explanation such as, "You can't speak right now because of the tube in your throat." As soon as children's respirations are even and they are no longer experiencing acute respiratory distress, show them how, by placing a finger over the tracheostomy tube opening, air will again flow past the larynx and they can speak. If this causes a child to become short of breath, supply a paper and pencil or chalkboard for communication.

Be certain parents understand why the tube is in place and how important it is that it remain patent. Assure them that it is a temporary measure to provide oxygen (provided this is true). If they were not present in the room for the procedure, encourage them to visit the child as soon as possible to assure themselves their child is again all right. Children have difficulty relaxing enough to accept this strange new way of breathing until their parents can relax and accept it also. Some children hyperventilate, not because of respiratory difficulty, but because of this fear.

Suctioning Technique. Most tracheostomy tubes used with children today are plastic. They do not include an inner cannula that would require removal and regular cleaning. Most children, however, do require frequent suctioning (perhaps as often as every 15 minutes) to keep their airway free of mucus. Use sterile technique to prevent introducing microorganisms, and suction gently yet thoroughly. Ineffective suctioning does not remove obstructive mucus and because of irritation can actually cause more mucus to form. Be certain you know how deeply to suction. Some children need to be suctioned only the length of the tracheostomy tube so that the catheter does not touch and irritate the tracheal mucosa. Others need to be deeply suctioned to reduce the possibility that mucus will become so copious or so thickened that it obstructs the trachea below the tube.

Tracheostomy suctioning technique is shown in Box 40.7. Because suctioning removes air as well as secretions from the trachea, children may become oxygen-deprived during the procedure. Although not evidence-based, preoxygenating them by "bagging" or administering oxygen for approximately 5 minutes before the procedure may help reduce this problem (Pritchard, Flenady, & Woodgate, 2009). Occasionally, a child may have such thick mucus that it is necessary to insert a drop or two of normal saline into the tracheostomy tube before suctioning. This should not be routine, however, as fluid running into the trachea produces a frightening, suffocating feeling.

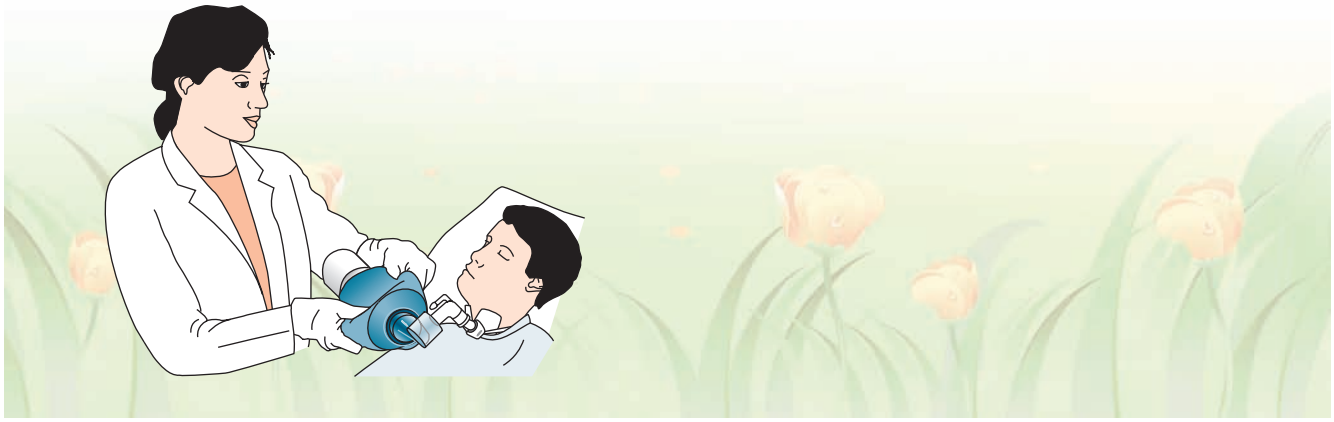
Young children may need to wear elbow restraints while being suctioned to keep their hands away from the sterile catheter. In addition, restraints may be necessary at all times when they are alone to prevent them from fussing with the tracheostomy tube and accidentally removing it.

Check frequently on children with tracheostomies to assess for possible respiratory difficulty. Spend time playing with them or just sitting and rocking them so they can think of you in ways other than as the person who comes to suction them. If parents cannot stay with the child, assure them that you check on their child more frequently than what is necessary for suctioning alone, so they can feel confident if the child should

Box 40.7 Nursing Procedure ✻ Tracheostomy Suction

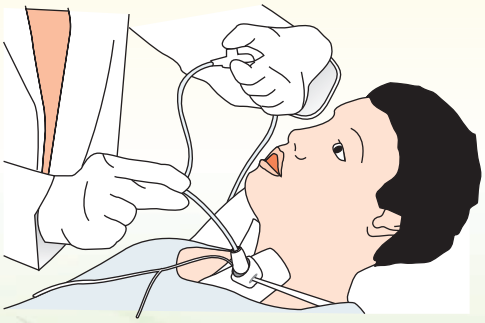
Purpose: To remove mucus from the trachea.

Procedure	Principle
1. Wash hands; identify child; explain procedure to child.	**1.** Handwashing minimizes the risk for spread of microorganisms; identifying the child ensures that you are performing the procedure on the right child; explaining the procedure helps to encourage cooperation and minimize anxiety.
2. Assess child, especially breath sounds; analyze appropriateness of procedure. Plan ways to modify care based on individual circumstances.	**2.** Assessment prior to procedure provides a baseline for future evaluation. Modifications enhance individualization of nursing care based on client need.
3. Assemble supplies: suction source and tubing, sterile suction catheter (#12 or 14F) or sterile suction kit, sterile gloves, bottle of sterile normal saline, sterile medicine dropper or syringe, manual resuscitator. Plan method to keep child from touching sterile catheter (placing a restraint, distraction, or asking assistance from another nurse).	**3.** Organizing supplies will increase efficiency of procedure.
4. Open the bottle of sterile normal saline and suction catheter or kit. Pour a small amount of saline solution into disposable container included in kit. Prepare syringe or dropper with small amount of sterile normal saline; put on sterile gloves.	**4.** Sterile technique is important to prevent introducing microorganisms.
5. Hold suction catheter with one gloved hand, suction tubing with other gloved hand, and attach tubing to sterile catheter; dip tip of catheter into normal saline and suction a small amount through catheter.	**5.** Proper handling of equipment using sterile technique reduces the risk of contamination because once a sterile glove touches suction tubing, it is no longer sterile. Using sterile normal saline to suction through the catheter and tubing ensures patency.
6. If necessary, instruct assistant to hyperoxygenate child with manual resuscitator.	**6.** Hyperoxygenation prevents child from developing hypoxia during suctioning.



(continued)

Box 40.7 Nursing Procedure ✻ Tracheostomy Suction (continued)

Procedure	Principle
7. Hold your breath; introduce sterile catheter into tracheostomy tube to desired length. Apply suction for 5 to 10 sec and gently withdraw, rotating gently.	**7.** Holding your breath helps you not to suction longer than is comfortable. Applying suction only on withdrawal allows the catheter to pass freely without irritating the trachea and prevents oversuctioning. Prolonged suctioning longer than 10 sec can cause hypoxia.
	


8. Rinse catheter by dipping tip in normal saline and applying suction.	**8.** Rinsing catheter ensures that it remains patent.
9. Repeat procedure until airway sounds clear. Be careful not to suction longer than necessary.	**9.** Suctioning is fatiguing to children. Extended suctioning can lead to airway irritation and further mucus production.
10. Assess effectiveness and efficiency of procedure; plan teaching such as importance of procedure to parents; document procedure.	**10.** Comparing initial baseline assessments with postprocedure status provides information about effectiveness of the procedure. Teaching is an important independent nursing care activity for the child and parents.
11. Comfort child; remain with child for support. Provide opportunities for therapeutic play.	**11.** Suctioning is frightening; offering support and comfort after all such procedures helps to decrease fears and anxieties.

have another episode of acute obstruction, someone will be nearby. If the tracheostomy tube is to be left in place after discharge from the hospital, be certain parents have enough experience with changing tubes if that will be necessary or suctioning so they can safely care for their child at home.

Tracheostomy tubes are held in place by cloth ties that fasten at the back of the child's neck. Change ties when they become soiled or loose, and check them frequently to be certain they remain tied. Children may fuss with and untie such things, whereas adults will not. Assess that the ties fit snugly but allow for one finger to be inserted underneath them so they do not rub and cause pain. For preschoolers or younger children, it is a good idea to cover the tracheostomy opening with a gauze square tied to the child's neck like a bib while they eat. This prevents crumbs or spilled liquids from entering the tracheostomy opening. Do not give children small toys that could fit into the lumen of the tube and cause obstruction (Box 40.8).

Each child is considered individually regarding when it is time to remove a tracheostomy tube. Tubes are generally sealed off partially by adhesive tape or a commercial occlusion device for a day or two before removal; then they are completely occluded (but not removed) for another day. This provides a weaning period where suctioning is still possible if it is needed. Occasionally, children cough so forcefully that they dislodge a tracheostomy tube. You might be with a child when this occurs, or you might walk into the room and find the tube lying beside the child on the bedclothes. As long as the child is

BOX 40.8 ✻ Focus on Family Teaching

Preventing Aspiration in a Child With a Tracheostomy

Q. A parent whose child has had a tracheostomy asks you, "How can we prevent something from falling into our child's tracheostomy tube"?

A. Use the following to help prevent aspiration:

- Use a bib tied loosely over the tracheostomy tube when your child is eating to prevent food from entering the tube.
- Avoid buying toys with small parts that could be removed and dropped into the tube.
- Inspect stuffed toys to be certain they are intact and do not shed (fur or stuffing could enter the tube).
- Supervise play with other children to be certain they do not place anything in the tube.
- Stay with your child in the bathtub, to be certain water does not splash into the tube.
- Keep use of sprays such as perfume or room fresheners to a minimum, because they can be irritating to the trachea.
- Avoid cold air, because it can cause tracheal spasm (cover the child's throat with a loose fleece scarf when out in cold weather).

not in distress, this is not an emergency. Because the incision site usually does not close completely to occlude the tracheal opening when a tube is dislodged, the child still has a patent airway. Always keep a new tube and inserter (obturator) at the bedside in case replacement is necessary. Slide the obturator into the tube and gently replace it in the tracheal opening. Remove the obturator and secure the new tube in place. If you do this quickly yet calmly, the average child is not alarmed and so will not protest. If, however, a child senses your excitement or if you indicate that something is terribly wrong, a child may begin to cry and turn away, making it difficult to replace the tube without assistance.

Endotracheal Intubation

Endotracheal intubation (nasal or oral intubation) is the preferred means of bypassing upper airway obstruction and allowing free entry of air to the trachea. There is little difference in efficiency between oral and nasal methods (Spence & Barr, 2009). However, since intubation tubes cause edema and local irritation, they cannot be left in place as a permanent solution. As with tracheostomies, children cannot speak while intubated. Supply those old enough to write with a pencil and paper for effective communication. Preschoolers can point to pictures to indicate what they need. Providing simple drawings or photos (a drink, a straw, a blanket, the television turned on, a urinal) to make needs known is helpful. Endotracheal tubes are held in place by being taped to the face. Make sure tubes are carefully secured, because children can easily dislodge them. As much as possible, limit the number of tape changes to protect the skin on the child's cheeks.

A capnometer is a device that measures the amount of CO_2 in inhaled or exhaled breaths. It uses infrared technology and is attached to the distal end of the endotracheal tube. By measuring the percentage of CO_2 in expired air, the arterial CO_2 (PCO_2) can be estimated. Used in this way, a capnometer can reduce the number of arterial punctures needed for ABG analysis.

Assisted Ventilation

When it is not possible to improve oxygen saturation to sufficient levels by the methods described above, assisted ventilation may be necessary (Carpenter et al., 2008). Positive-pressure machines deliver moistened or nebulized air or oxygen to the lungs under enough pressure and with appropriate timing to produce artificial, periodic inflation of alveoli; they rely on the elastic recoil of the lungs to empty the alveoli.

Depending on the type of ventilator, the inspiration–expiration cycle is determined by a timed interval, a volume limit, or a pressure limit, depending on the child's condition. Ventilators can supply high tidal volumes at a low frequency rate or low tidal volumes at rates as high as 200 to 300 breaths per minute. Hyperinflation of lungs can occur with high-frequency ventilation because there is not enough time for expiration to occur. For this reason, some high-frequency ventilators are set so air is sucked out of the lungs rather than depending on the normal elastic recoil of the lungs. Some commonly used terms associated with ventilator therapy are shown in Table 40.4.

Children who need respiratory assistance are frightened. A great many fight ventilators or refuse to lie quietly and let the ventilator breathe for them. Pancuronium (Pavulon) may be administered intravenously to a point of abolishing spontaneous respiratory action to overcome resistance and allow mechanical ventilation to be accomplished at lower pressures because without normal respiratory action, there is no normal muscle resistance to overcome (Box 40.9). Clearly, children who receive pancuronium have no spontaneous respiratory function and need critical observation and frequent ABG analysis because they depend totally on caregivers at that point.

Mechanical ventilation for a prolonged period requires that children either have a tracheotomy performed or have an endotracheal tube passed (Fig. 40.15). A cuffed tube is used with ventilators so the seal at the trachea is airtight. Infants need a nasogastric tube inserted to prevent stomach distention from air entering the esophagus. Providing adequate nutrition may be difficult for children on ventilators. Enteric (nasogastric) feedings or total parenteral nutrition solves this problem. Providing a balance of rest, stimulation, and assurance for the child is a challenge for nursing personnel and parents.

Once children become accustomed to assisted ventilation, it can be difficult to discontinue a device, even when there is no longer a clinical indication for it. This is most pronounced

TABLE 40.4 ✻ Terms Commonly Used With Ventilator Therapy

Term	Definition	Clinical Application
IMV	Intermittent mandatory ventilation	Number of mandatory breaths the ventilator will deliver each hour. A child may breathe most of the time without assistance, but a set (mandatory) number of breaths per minute is delivered to ensure adequate lung expansion and oxygenation.
PEEP	Positive end-expiratory pressure	Pressure delivered to lungs at the end of each expiration to keep alveoli from collapsing on expiration and to ensure adequate oxygenation
Sigh	A deep inhalation delivered by the ventilator	Method used to fully inflate the lungs several times each minute
CPAP	Continuous positive airway pressure	A constant pressure exerted on the alveoli to keep them from collapsing on expiration
FIO_2	Concentration of oxygen the child is receiving (inspiring)	A child on oxygen therapy will have an FIO_2 from 22% to 100%

BOX 40.9 ✻ Focus on Pharmacology

Pancuronium Bromide (Pavulon)

Classification: Pancuronium bromide is a neuromuscular blocking agent.

Action: Relaxes skeletal muscles during assisted mechanical ventilation or endotracheal intubation (Karch, 2009).

Pregnancy risk category: C

Dosage: 0.03–0.04 mg/kg intravenously initially, then 0.03–0.1 mg/kg intravenously, repeated every 30 to 60 minutes as needed.

Possible adverse effects: Prolonged dose-related apnea; tachycardia, excessive salivation, and sweating.

Nursing Implications

- Keep in mind that the child's respiratory muscles do not function after administration; maintain assisted ventilation.
- Know that the drug's action peaks in approximately 2 to 3 minutes and lasts approximately 1 hour (longer in children with poor renal perfusion).
- Remember that the drug does not alter state of consciousness. Anticipate the need for sedation or analgesia for procedures.
- Keep equipment for emergency resuscitation (Ambu bag) at bedside in case of a power or mechanical ventilator failure.
- Be sure to explain all events and procedures to the child; even though the respiratory muscles may be paralyzed, the child can still hear. Also encourage the parents to talk to the child when they visit.
- Be prepared to reverse the effects of the drug by administering atropine and neostigmine methylsulfate (Prostigmin).
- Monitor all physiologic parameters, including vital signs, heart rate, and blood pressure. Obtain electrolyte levels as ordered, because electrolyte imbalances can potentiate neuromuscular effects.

in adolescents, who are aware of the role of oxygen and proper ventilation for life function. You may need to provide several trial periods free of the ventilator with someone remaining close by so they can be assured that if they do have difficulty breathing, someone is standing by to help. Many children are too afraid to fall asleep on the first night off a ventilator unless someone is with them and has assured them they will be there through the night.

Lung Transplantation

Lung transplantation is a possibility for children with a chronic respiratory illness such as cystic fibrosis (Visner & Goldfarb, 2007). The transplant may involve a single lung, or it can be done in conjunction with heart transplantation if chronic respiratory disease has caused ventricular hypertrophy of the heart. The donor lung can be from a live donor or a cadaver.

FIGURE 40.15 An infant with an endotracheal tube receiving assisted ventilation.

As with any organ transplantation, children need continued immunosuppression therapy with drugs such as cyclosporine or azathioprine (Imuran) following a lung transplant to decrease cell-mediated immunity. Although this level of immunosuppression is the key to successful transplantation, it also makes posttransplant children susceptible to fungal, bacterial, and viral lung infections. In addition, families experience a tremendous psychosocial toll as they wait to see whether the new transplant will be rejected. Children may need to have chest physiotherapy or use a portable spirometry device daily to help mobilize secretions resulting from loss of nerve innervation or a reaction to accumulating mucus in the transplanted lung.

DISORDERS OF THE UPPER RESPIRATORY TRACT

The upper respiratory tract warms, humidifies, and filters the air that enters the body (Fig. 40.16). As such, the structures of the upper respiratory tract constantly come into contact with a barrage of foreign organisms, including pathogens, that can lead to airway irritation and illness. Congenital malformations of respiratory structures also cause some upper respiratory tract disorders.

Upper respiratory illnesses occur universally, making them a concern of parents the world over. Home remedies for such illnesses vary greatly, however. Hanging garlic around a child's neck is a frequent therapy in Mediterranean countries. "Cupping" or applying pressure to the back to "draw out" an infection (which leaves red circular ecchymotic marks on the child's back) may be used in Asian cultures. Although the therapeutic value of these remedies may not be proved, it is important to the nurse–patient and nurse–family relationships to respect family traditions.

Choanal Atresia

Choanal atresia is congenital obstruction of the posterior nares by an obstructing membrane or bony growth, preventing a newborn from drawing air through the nose and down into the nasopharynx (Kelley et al., 2008). It may be either unilateral or bilateral.

Newborns up to approximately 3 months of age are naturally nose-breathers. Infants with choanal atresia, therefore,

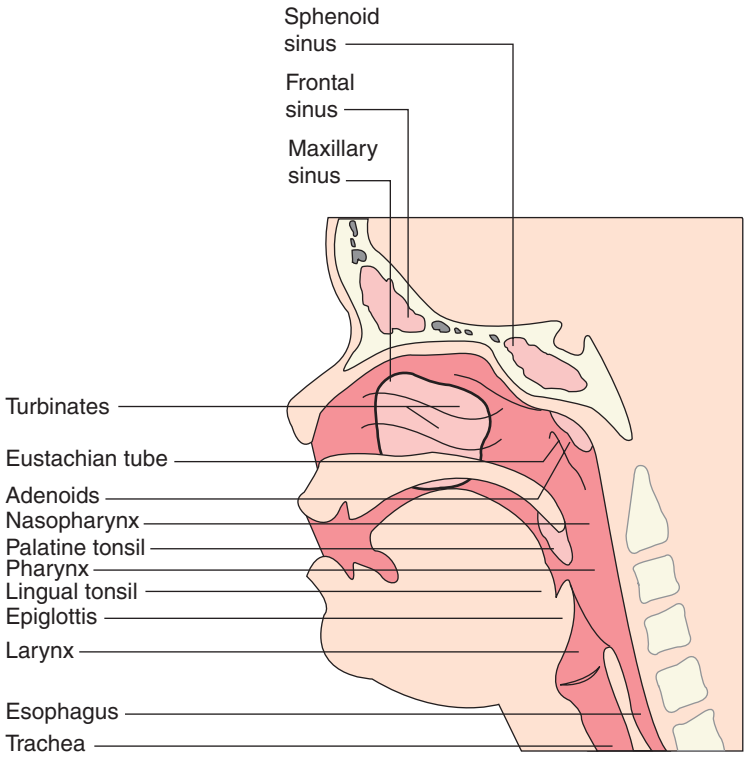


FIGURE 40.16 Structures of the upper respiratory tract.

develop signs of respiratory distress at birth or immediately after they quiet for the first time and attempt to breathe through their nose. Passing a soft no. 8 or 10 French catheter through the posterior nares to the stomach is a part of birthing room procedure in many health care facilities. If such a catheter will not pass bilaterally, the diagnosis of choanal atresia is confirmed immediately at birth.

Choanal atresia can also be assessed by holding the newborn's mouth closed, then gently compressing first one nostril, then the other. If atresia is present, infants will struggle as they experience air hunger when their mouth is closed. Their color improves when they open their mouth to cry. Atresia is also suggested if infants struggle and become cyanotic at feedings because they cannot suck and breathe through the mouth simultaneously.

The treatment for choanal atresia is either local piercing of the obstructing membrane or surgical removal of the bony growth. Because infants with choanal atresia have such difficulty with feeding, they may receive intravenous fluid to maintain their glucose and fluid level until surgery can be performed. Some infants may need an oral airway inserted so they can continue to breathe through their mouths. Following surgery, children have no further difficulty or symptoms.

✔ Checkpoint Question 40.1

Suppose Michael was born with choanal atresia. What would be the best way to assess if this is present?

a. Observe if a newborn can breathe while lying on his stomach.
b. Close the infant's mouth to see if he can breathe through his nose.
c. Assess if the infant's palatine tonsils are blocking his airway.
d. Listen for the sound of either stridor or wheezing on inhalation.

Acute Nasopharyngitis (Common Cold)

The common cold is the most frequent infectious disease in children—in fact, toddlers have an average of 10 to 12 colds a year. School-age children and adolescents have as many as four or five yearly. The incubation period is typically 2 to 3 days. Most occur in the fall and winter (Kelley et al., 2008).

They are caused by one of several viruses, most predominantly by rhinovirus, coxsackievirus, RSV, adenovirus, and parainfluenza and influenza viruses. Children are exposed to colds at school or while playing with other children. If they are in ill health from some other cause, or if their immune system is compromised, they are more susceptible than others to the cold viruses. Although difficult to prove, stress factors also appear to play a role in the development of common colds in children.

Assessment

Symptoms begin with nasal congestion, a watery rhinitis, and a low-grade fever. The mucous membrane of the nose becomes edematous and inflamed, constricting airway space and causing difficulty breathing. Posterior rhinitis, plus local irritation, leads to pharyngitis (sore throat). Upper airway secretions that drain into the trachea lead to a cough. Cervical lymph nodes may be swollen and palpable. The process lasts about a week and then symptoms fade. In some children, a thick, purulent nasal discharge occurs because bacteria such as streptococci invade the irritated nasal mucous membrane and cause a secondary purulent infection.

Infants can be critically ill yet not develop a fever because their temperature-regulating system is still immature. With the common cold, they often develop a fever elevated out of proportion to the symptoms, possibly as high as 102° to 104°

F (38.8° to 40° C). Infants also may develop secondary symptoms, such as vomiting and diarrhea, as a general response. Because they cannot suck and breathe through their mouth at the same time, they refuse feedings. This can lead to dehydration. Older children rarely develop as high a fever, rarely above 102° F (38.8° C). Because older children can breathe through their mouth, nasal congestion does not seem as acute.

Therapeutic Management

There is no specific treatment for a common cold. Although many parents ask to have antibiotics prescribed, because colds are caused by a virus, antibiotics are not effective unless a secondary bacterial invasion has occurred. If a child has a fever, it can be controlled by an antipyretic such as acetaminophen (Tylenol) or children's ibuprofen (Motrin). Help parents understand that these drugs are effective only in controlling fever symptoms; they do not reduce congestion or "cure" the cold. Therefore, they should not be given unless the child has a fever, generally defined as an oral temperature over 101° F (38.4° C). You may need to remind parents that children younger than 18 years should not be given acetylsalicylic acid (aspirin) because this is associated with the development of Reye syndrome, a potentially fatal neurologic disorder (see Chapter 49).

If infants have difficulty nursing because of nasal congestion, saline nose drops or nasal spray may be prescribed to liquefy nasal secretions and help them drain. Removing nasal mucus via a bulb syringe before feedings also allows infants to breathe more freely and be able to suck more efficiently. Caution parents that if they use a bulb syringe, they must compress the bulb first, then insert it into the child's nostril. If they insert the bulb syringe first, then depress the bulb, they will actually push secretions further back into the nose, causing increased obstruction.

There is little proof that oral decongestants relieve congestion to an appreciable degree with the common cold. Cough suppressants are not necessary either as coughing raises secretions, preventing pooling of secretions and the danger of consequent lower respiratory infection. Guaifenesin is an example of a drug that loosens secretions but does not suppress a cough so is safe to use. Parents may use a cool mist vaporizer to help loosen nasal secretions if they wish. The efficiency of home vaporizers is questionable, however, and safe use of a vaporizer, including proper cleaning, must be stressed or it can serve as a reservoir for microorganisms.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Parental health-seeking behaviors related to management of child's upper respiratory symptoms

Outcome Evaluation: Parents state intention to use cool mist vaporizer to loosen secretions, to encourage oral fluid, to administer an antipyretic to reduce fever, and to avoid cough medicine.

Care of the child with a cold is primarily supportive until the infection runs its course. Because they may have a loss of appetite, children may prefer simple liquids to solid food for the first few days of the illness. Parents generally ask whether children should remain on bedrest. Children characteristically restrict their activity when ill, so with acute cold symptoms, children often naturally curl up on the couch and sleep. One of the best ways parents can judge when children are improving is to note they have begun to increase their activity or are "acting like themselves" again.

Because the symptoms in infants are so out of proportion to the seriousness of the disorder, parents may need assurance that a cold in an infant is only a cold and nothing more. A possible complication of a cold is otitis media (middle ear infection). Instruct parents about this possibility and the need to report symptoms suggestive of this infection, such as sudden elevated temperature and ear pain (Yates & Anari, 2008). If otitis media occurs, a child needs further evaluation to protect against hearing impairment (see Chapter 50).

Pharyngitis

Pharyngitis is infection and inflammation of the throat (Kamienski, 2007). The peak incidence occurs between 4 and 7 years of age. It may be either bacterial or viral in origin. It may occur as a result of a chronic allergy in which there is constant postnasal discharge that results in secondary irritation. At least a slight pharyngitis usually accompanies all common upper respiratory infections.

Viral Pharyngitis

The causative agent of pharyngitis is usually an adenovirus (Levin & Weinberg, 2008). The symptoms are generally mild: a sore throat, fever, and general malaise. On physical assessment, regional lymph nodes may be noticeably enlarged. Erythema will be present in the back of the pharynx and the palatine arch. Laboratory studies will indicate an increased white blood cell count.

If the inflammation is mild, children rarely need more than an oral analgesic such as acetaminophen or ibuprofen for comfort. Warm heat applied to the external neck area using a warm towel or heating pad also can be soothing. By school age, children are capable of gargling with a solution such as warm water to help reduce the pain. Before this age, children tend to swallow the solution unless the procedure is well explained and demonstrated to them.

Because children's throats feel so sore, they often prefer liquids to solid food. Infants, especially, must be observed closely until the inflammation and tenderness diminish to be certain that they take in sufficient fluid to prevent dehydration.

Streptococcal Pharyngitis

Group A beta-hemolytic streptococcus is the organism most frequently involved in bacterial pharyngitis in children. All streptococcal infections must be taken seriously because they can lead to cardiac and kidney damage from the accompanying autoimmune process (Ogle & Anderson, 2008).

Assessment. Streptococcal infections are generally more severe than viral infections. The fact that symptoms are mild, however, does not rule out streptococcal infection. With a streptococcal pharyngitis, the back of the throat and palatine tonsils are usually markedly erythematous (bright red); the tonsils are enlarged and there may be a white exudate in the tonsillar

crypts. Petechiae may be present on the palate. A child typically appears ill with a high fever, an extremely sore throat, difficulty swallowing, and overall lethargy. Temperature is usually elevated to as high as 104° F (40° C). The child often has a headache. Swollen abdominal lymph nodes may cause abdominal pain. A throat culture, often completed as a quick office procedure, confirms the presence of the *Streptococcus* bacteria.

Therapeutic Management. Treatment consists of a full 10-day course of an oral antibiotic such as penicillin G or clindamycin. Cephalosporins or broad-spectrum macrolides such as erythromycin may be prescribed if resistant organisms are known to be in the community. Help parents understand the importance of completing the full prescribed days of therapy. The recommended treatment days are necessary to ensure the streptococci are eradicated completely. If they are not, the child may develop a hypersensitivity or autoimmune reaction to group A streptococci that can result in rheumatic fever (although the chance of rheumatic fever occurring is probably as low as 1%) or glomerulonephritis.

Symptoms of acute glomerulonephritis (blood and protein in urine) appear in 1 to 2 weeks after the pharyngitis. For this reason, 2 weeks after treatment, children may be asked to return to the health care facility with a urine specimen to be examined for protein so that developing acute glomerulonephritis can be detected (Steer, Danchin, & Carapetis, 2007).

To ensure that a child receives the full antibiotic course, help parents make a reminder sheet to place on a cabinet or refrigerator door. In addition, instruct them about measures for rest, relief of throat pain, and maintaining hydration, the same actions as for a common cold. Because it is impossible for parents to discriminate between a pharyngitis caused by a virus (and needing no therapy other than comfort measures) and a streptococcal pharyngitis (needing definite therapy to prevent life-threatening illnesses), a child with pharyngitis always should be examined by health care personnel.

✔ Checkpoint Question 40.2

Suppose Michael is diagnosed as having a streptococcal pharyngitis. The chief danger of such an infection is:

a. Lymph nodes will swell and obstruct the airway.
b. Infection may spread and cause a tooth abscess.
c. A small number of children develop kidney disease.
d. Four of five children will develop lung abscesses.

Retropharyngeal Abscess

In infants, the lymph nodes that drain the nasopharynx are located just behind the posterior pharynx wall. These nodes may become infected following an acute nasopharyngitis or pharyngitis. Since these nodes disappear by preschool age, the problem is usually limited to young infants (Page, Bauer, & Lieu, 2008).

Assessment. Typically, infants have an upper respiratory tract infection or sore throat for a few days. Suddenly, they refuse to eat. They develop a high fever and may drool because they cannot swallow saliva past the obstruction in the back of their throat. They "snore" with respirations as the pharynx becomes further occluded. To allow themselves more breathing space, they may hyperextend the head, a very unusual position for infants.

Physical assessment reveals enlargement of the regional lymph nodes. The mass in the posterior pharynx may not be visible if it is below the point of vision. An ultrasound or x-ray study using a swallowed contrast medium will reveal the bulging tissue in the pharynx. Laboratory studies will reveal leukocytosis.

Therapeutic Management. Because the most common cause of retropharyngeal abscess is group A beta-hemolytic streptococcus, benzathine penicillin G or penicillin V is effective. As a result of their poor swallowing, infants' mouths may need to be suctioned to remove secretions. Be careful not to touch the suction catheter to the posterior pharynx because this might rupture the abscess, possibly leading to aspiration of the abscess contents (producing respiratory obstruction or a pneumonia caused by the aspirated purulent material). Blood vessels invade some retropharyngeal abscesses, so rupture of the structure also could lead to profuse bleeding (dangerous to the child both because of the loss of blood from major arteries such as the carotid artery and because the blood could be aspirated).

Place infants in a side-lying position to allow difficult-to-swallow mouth secretions to drain forward. Limit oral intake to fluids. A hard food such as a toast crust (a food often recommended for teething) could rupture the abscess with its hard edges.

Although some postpharyngeal abscesses resolve on their own, some need to be incised by a surgeon to promote drainage. This is done with the child in a Trendelenburg position so that drainage from the abscess can be suctioned away to prevent aspiration. After surgery, maintain the child in a Trendelenburg or a side position as prescribed to encourage further drainage and prevent aspiration. Monitor vital signs closely. Observe any drainage from infants' mouths to detect fresh bleeding. Frequent swallowing is also a sign of postpharyngeal bleeding. Increased respiratory rate suggests airway obstruction.

Oral fluid is introduced as soon as an infant's swallowing and gag reflexes are intact after surgery. Although the throat is undoubtedly still sore, most infants suck eagerly and need supplemental intravenous fluid administration following surgery for only a short time.

On admission to the hospital, parents may have been thoroughly frightened by the extent of the child's symptoms (gurgling or snoring sound, high temperature, dyspnea). Allow parents to give care while in the hospital to help them allay their fears and regain confidence in their ability to care for the child again.

Tonsillitis

"Tonsillitis" refers to infection and inflammation of the palatine tonsils. "Adenitis" refers to infection and inflammation of the adenoid (pharyngeal) tonsils.

Tonsillar tissue is lymphoid tissue that filters pathogenic organisms from the head and neck area. The palatine tonsils are located on both sides of the pharynx; the adenoids are in the nasopharynx. Tubal tonsils are located at the entrance to the eustachian tubes. Lingual tonsils are located at the base of the tongue. All of the tonsils, referred to collectively as Waldeyer's ring, are easily infected because of the bacteria that pass through or are screened through them with lymph.

Assessment

Infection of the palatine tonsils presents with all of the symptoms of a severe pharyngitis. Children drool because their throat is too sore for them to swallow saliva. They may describe swallowing as so painful it feels as if they are swallowing bits of metal or glass. In addition, they usually have a high fever and are lethargic. Tonsillar tissue appears bright red and may be so enlarged the two areas of palatine tonsillar tissue meet in the midline. Pus can be detected on or expelled from the crypts of the tonsils (Millar et al., 2007).

In addition to fever, lethargy, pharyngeal pain, and edema, the symptoms of adenoidal tissue infection also include a nasal quality of speech, mouth breathing, difficulty hearing, and perhaps halitosis or sleep apnea. The mouth breathing, change in speech, and apnea result from the postpharyngeal obstruction by the enlarged tissue. The difficulty with hearing occurs because of eustachian tube obstruction. Long-term obstruction this way can further cause serous and acute otitis media.

Tonsillitis occurs most commonly in school-age children. The responsible organism is identified by a throat culture. In children younger than 3 years of age, the cause is often viral. In school-age children, the organism is generally a group A beta-hemolytic streptococcus (Steer, Danchin, & Carapetis, 2007).

Therapeutic Management

Therapy for bacterial tonsillitis includes an antipyretic for fever, an analgesic for pain, and a full 10-day course of an antibiotic such as penicillin or amoxicillin. If the cause is viral, no therapy other than comfort or fever reduction strategies is necessary. Although the pain of the infection will subside a day or two after the antibiotic administration is begun, remind parents that children need the full 10-day course of antibiotic to eradicate streptococci completely from the back of the throat. After a tonsillar infection, tonsillar tissue may remain hypertrophied, or it may atrophy and appear smaller than it did previously.

Tonsillectomy. Tonsillectomy is removal of the palatine tonsils. *Adenoidectomy* is removal of the pharyngeal tonsils. In the past, tonsillectomy was a common procedure following an episode of tonsillitis, but today it is not recommended unless all other measures to prevent frequent infections prove ineffective. Tonsillar tissue is removed by ligating the tonsil or by laser surgery. Because sutures are not placed, the chance for hemorrhage after this type of surgery is higher than after surgery involving a closed incision. The danger of aspiration of blood at the time of surgery and the danger of a general anesthetic compound the risk.

Chronic tonsillitis is about the only reason for removal of palatine tonsils. Adenoids may be removed if they are so hypertrophied they cause obstruction or sleep apnea. At one time, adenoids and palatine tonsils were always removed together; today, depending on the symptoms and the extent of hypertrophy and infection, children may have a tonsillectomy, an adenoidectomy, or both.

Tonsillectomy or adenoidectomy is never done while the organs are infected, because an operation at such a time might spread pathogenic organisms into the bloodstream, causing septicemia. Parents often ask why an operation to remove tonsils must be delayed until the child is well again. They think that as long as the tonsils are sore, they should be immediately removed. Help them understand why it is safer to schedule surgery for a later date. Most parents report an improvement in their child's general health and performance after tonsillectomy surgery, as this ends the chronic infections.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for fluid volume deficit related to blood loss from surgery

Outcome Evaluation: Child's pulse and blood pressure remain normal for age; there is absence of extensive bleeding; intake and output are within acceptable parameters.

Tonsillectomies are done as ambulatory or 1-day surgery following completion of a complete history and physical examination and laboratory tests, including bleeding and clotting times, complete blood count, and urinalysis. Teach parents to use common sense in their child's care during the week before hospital admission so that the child does not have a cold or recurrent tonsillitis at the time planned for surgery. An important aspect of immediate assessment on the day of surgery is to observe for loose teeth; if present, they could be dislodged during surgery and aspirated. If loose teeth are present, mark this on the front of the child's chart and report it to the anesthesiologist.

After surgery, observe vital signs carefully to make certain the child is not bleeding from the denuded surgical area. Place the child on the side or abdomen with a pillow under the chest so that the head is lower than the chest. This allows blood and unswallowed saliva to drain from the child's mouth rather than back to the pharynx, where it might be aspirated (Fig. 40.17).

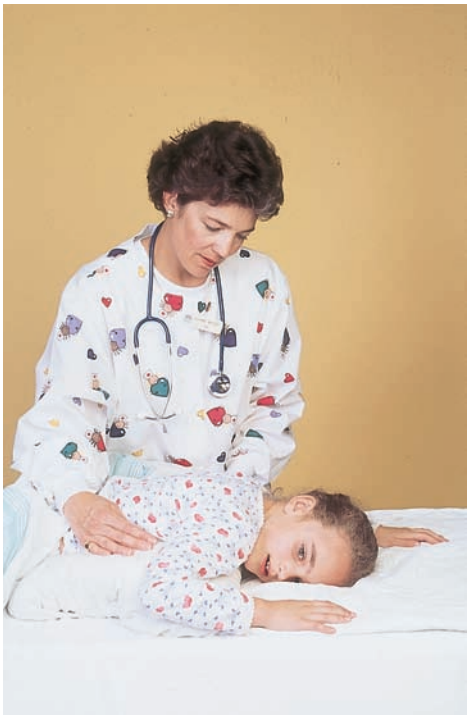

FIGURE 40.17 Positioning a child after tonsillectomy. The pillow under the chest helps secretions flow out of the mouth.

If hemorrhage occurs after tonsillectomy, it can be acute and intense. Because children will swallow any blood that is oozing from the surgical site, a child can be bleeding heavily and yet little blood is apparent. To detect bleeding, assess for subtle signs of hemorrhage, such as an increasing pulse or respiratory rate, frequent swallowing, throat clearing, or a feeling of anxiety. A child's first line of defense against hemorrhage is a nurse who recognizes these subtle signs of bleeding before the bleeding becomes so intense that signs of shock occur.

If you find that the surgical site is bleeding, elevate the child's head to reduce vascular pressure on the operative site. Use a good light to inspect the posterior throat. Have a dental mirror available so the surgeon can thoroughly inspect the bleeding area. If the surgical area is bleeding heavily, the child may need to be returned to surgery for a suture or two to halt bleeding.

The most dangerous periods for a child after a tonsillectomy are the first 24 hours, when the clots covering the denuded surgical area are forming, and days 5 to 7, when the clots begin to lyse or dissolve. If new granulation tissue is not yet present when the clots dissolve, hemorrhage from the denuded surface can occur.

If children have no complications from surgery, are able to swallow fluids, and have voided, they are discharged later the same day of surgery. Parents need careful instructions concerning the danger signs to watch for during the first day home (frequent swallowing, clearing the throat, increasing restlessness). They are usually advised to restrict their child's activity (no gymnastics, swimming) until after the seventh day, when firm healing should have taken place. The child needs a return appointment to a health care facility approximately 2 weeks after surgery for follow-up assessment to make sure the surgical area has healed without complication.

Nursing Diagnosis: Pain related to surgical procedure

Outcome Evaluation: Child states level of pain is tolerable.

Tonsillectomy is an uncomfortable and painful procedure for children. Be sure they receive good preparation for the procedure and for the sensations they will experience afterward. Although tonsils are removed, it is better to talk about tonsils being "fixed" rather than taken out; children may be extremely frightened to know that a body part will be removed, however small it is.

Children's throats are extremely sore following a tonsillectomy. Liquid analgesics are better tolerated than pills or tablets because they are easier to swallow. Rectal administration is a possibility for very young children. Occasionally, a child may require intravenous pain relief.

Most children are thirsty immediately after surgery, and drinking is helpful because swallowing fluid causes active pharyngeal movement, increasing the blood supply to the area and reducing edema and pain. Children commonly are promised by well-meaning people they can have all the ice cream they want after a tonsillectomy. However, because milk products form tenacious secretions that are difficult to swallow, ice cream is not a food of choice. Offer instead frequent sips of clear liquid, Popsicles, or ice chips. Avoid acid juices because these sting the denuded tissue. Carbonated beverages also can irritate the area unless they stand for a time to become "flat." Avoid red fluid such as Kool-Aid, which if vomited can be mistaken for swallowed blood.

Children can then gradually advance after 24 to 48 hours to a diet of soft foods such as gelatin, mashed potatoes, soups, and cooked fruits. They should continue to eat only soft foods for the first week (no toast crusts or other foods that could cause pharyngeal irritation if not chewed well). Be certain parents know whom they should call (clinic, hospital, or pediatrician) if they have a question or concern about their child's condition or care. Caution parents that some children develop a mild earache after tonsillectomy for the first week, probably caused by shifting pressure on the eustachian tube.

✔ Checkpoint Question 40.3

Suppose Michael's 4-year-old roommate spits up dark-red blood following her tonsillectomy. Your best action in relation to this would be:

a. Suction the back of her throat.
b. Encourage her to cough vigorously.
c. Perform a subdiaphragmatic thrust.
d. Continue to observe her for bleeding.

Epistaxis

Epistaxis (nosebleed) is extremely common in children and usually occurs from trauma, such as picking at the nose, from falling, or from being hit on the nose by another child (Burton & Doree, 2009). In homes that lack humidification, the hot dry environment causes children's mucous membranes to dry, feel uncomfortable, and be susceptible to cracking and bleeding. In all children, epistaxis tends to occur during respiratory illnesses. It also may occur after strenuous exercise, and it is associated with several systemic diseases, such as rheumatic fever, scarlet fever, measles, or varicella infection (chickenpox). It can occur with nasal polyps, sinusitis, or allergic rhinitis. Some families show a familial predisposition.

Nosebleeds are always frightening because of the visible bleeding and a choking sensation if blood should run down the back of the nasopharynx. The fear is generally out of proportion to the seriousness of the bleeding.

Keep children with nosebleeds in an upright position with their head tilted slightly forward to minimize the amount of blood pressure in nasal vessels and to keep blood moving forward, not back into the nasopharynx. Apply pressure to the sides of the nose with your fingers (Fig. 40.18). Make every effort to quiet the child and to help stop crying, because crying increases pressure in the blood vessels of the head and prolongs bleeding. If these simple measures do not control the bleeding, epinephrine (1:1000) may be applied to the bleeding site to constrict blood vessels. A nasal pack may be necessary to provide continued pressure.

Every child has an occasional nosebleed. Chronic nasal bleeding, however, should be investigated to rule out a systemic disease or blood disorder.

FIGURE 40.18 Emergency therapy for a nosebleed is to sit the child up and apply pressure to the sides of the nose.

Sinusitis

Sinusitis is infection and inflammation of the sinus cavities. It is rare in children younger than 6 years of age because the frontal sinuses do not develop fully until age 6. It can occur as a primary infection or a secondary one in older children when streptococcal, staphylococcal, or *H. influenzae* organisms spread from the nasal cavity (Revai et al., 2007). Children develop a fever, a purulent nasal discharge, headache, and tenderness over the affected sinus. A nose and throat culture will identify the infectious organism.

Treatment for acute sinusitis consists of an antipyretic for fever, an analgesic for pain, and an antibiotic for the specific organism involved. Oxymetazoline hydrochloride (Afrin), supplied as nose drops or a nasal spray, shrinks the edematous mucous membranes and allows infected material to drain from the sinuses and relieve pain. To avoid a rebound effect, this type of nasal spray should be used for only 3 days at a time; otherwise, it actually causes more nasal congestion than was present originally. Warm compresses to the sinus area may also encourage drainage and relieve pain. Some children need acetaminophen (Tylenol) for pain.

Sinusitis is considered by many adults to be a minor illness. It needs to be treated, however, because it can have serious complications if the infection spreads from the sinuses to invade the facial bone (osteomyelitis) or the middle ear (otitis media). Chronic sinusitis can also interfere with school and social interactions because of the constant pain.

Laryngitis

Laryngitis is inflammation of the larynx. It results in brassy, hoarse voice sounds or inability to make audible voice sounds. It may occur as a complication of pharyngitis or from excessive use of the voice, as in shouting or loud cheering. Laryngitis is as annoying for children as it is for adults. Sips of fluid (either warm or cold, whichever feels best) offer relief from the annoying tickling sensation often present. The most effective measure, however, is for the child to rest the voice for at least 24 hours, until inflammation subsides. For infants with laryngitis, attempt to meet their needs before they have to cry for things. Simply caution older children not to speak. Provide them with a paper and pencil or chalkboard for communication.

Congenital Laryngomalacia/Tracheomalacia

Congenital laryngomalacia means that an infant's laryngeal structure is weaker than normal and collapses more than usual on inspiration (Richter et al., 2008). This produces laryngeal **stridor** (a high-pitched crowing sound on inspiration) present from birth, possibly intensified when the infant is in a supine position or when sucking.

Assessment

The infant's sternum and intercostal spaces may retract on inspiration because of the increased effort needed to pull air into the trachea past the collapsed cartilage rings. Many infants with this condition must stop sucking frequently during a feeding to maintain adequate ventilation and to rest from their respiratory effort, which is exhausting.

Therapeutic Management

Most children with congenital laryngomalacia need no routine therapy other than to have parents feed them slowly, providing rest periods as needed. The condition improves as infants mature and cartilage in the larynx becomes stronger at about 1 year of age. When parents wake at night and listen in a quiet house to the sound of stridor, it seems unbearably loud. This makes it difficult for them to believe it is safe for them to care for the infant at home.

Many parents sleep at night with the child's crib next to their bed or with one hand resting on the infant's chest so they can be assured during the night the child is continuing to breathe. At health care visits, assess whether the parents are receiving enough sleep and are not becoming too exhausted to be able to continue their daily activities. Showing them a weight chart that demonstrates their child is growing and thriving despite this problem can be reassuring.

Be certain parents know the importance of bringing the child for early care if signs of an upper respiratory tract infection develop. If not, laryngeal collapse will be even more intense during these times, and complete obstruction of the trachea could occur. If stridor becomes more intense, advise parents to have the infant seen by their primary care provider, because generally this indicates beginning obstruction and probably the beginning of an upper respiratory tract infection. As parents become more accustomed to the sound their infant makes while breathing, they will become astute reporters of change in their infant's condition; listen to them carefully when they report a change to prevent overlooking this important information.

Croup (Laryngotracheobronchitis)

Croup (inflammation of the larynx, trachea, and major bronchi) is one of the most frightening diseases of early child-

hood for both parents and children. In children between 6 months and 3 years of age, the cause of croup is usually a viral infection such as parainfluenza virus. In previous years, the most common cause was *H. influenzae.* However, since immunization against this organism has been included in a routine immunization series, the incidence of croup from this cause has declined by 90% (Kerby et al., 2008).

Assessment

With croup, children typically have only a mild upper respiratory tract infection at bedtime. Temperature is normal or only mildly elevated. During the night, they develop a barking cough (croupy cough), inspiratory stridor, and marked retractions. They wake in extreme respiratory distress. The larynx, trachea, and major bronchi are all inflamed. These severe symptoms typically last several hours and then, except for a rattling cough, subside by morning. Symptoms may recur the following night. Cyanosis is rarely present, but the danger of glottal obstruction from the laryngeal inflammation and hypoxemia is very real. Pulse oximetry and transcutaneous SaO_2 monitors are helpful measures to document whether hypoxemia is occurring.

Therapeutic Management

One emergency method of relieving croup symptoms is for a parent to run the shower or hot water tap in a bathroom until the room fills with steam, then keep the child in this warm, moist environment. If this does not relieve symptoms, parents should bring the child to an emergency department for further evaluation and care. When a child is seen at an emergency room, cool moist air with a corticosteroid such as dexamethasone, or racemic epinephrine, given by nebulizer, reduces inflammation and produces effective bronchodilation to open the airway. Intravenous therapy may be prescribed to keep the child well hydrated. Maintain accurate intake and output records and test urine specific gravity to ensure that hydration is adequate.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Ineffective airway clearance related to edema and constriction of airway

Outcome Evaluation: Respiratory rate is below 22 breaths per minute; no cyanosis is present; PO_2 is 80 to 100 mm Hg; SaO_2 is over 95%.

Attach a sensor for pulse oximetry monitoring and remain constantly with a child with croup, not only to observe closely for increasing respiratory distress but also to reduce the child's anxiety. Take vital signs as often as every 15 minutes, because extreme restlessness and thrashing, increased stridor, increased heart and respiratory rates, and cyanosis are symptoms of oxygen deprivation. In some children, it is difficult to distinguish between fright from the newness of the experience (and their sense of their parents' fright) and the anxiety that comes from oxygen deprivation. Keep a continuous record of vital signs and activity as a way to demonstrate increasing respiratory rate and restlessness. ABGs may be obtained to assess for sufficient oxygenation if pulse oximetry is not being used. A tracheostomy or endotracheal intubation along with oxygen therapy may be necessary if symptoms do not diminish. (It is difficult to intubate children with croup because of the severe respiratory tract edema.)

Laryngospasm with total occlusion of the airway can occur when a child's gag reflex is elicited or when the child is crying. Therefore, do not elicit a gag reflex in any child with a croupy, barking cough, and provide comfort to prevent crying.

Croup is a frightening disease for parents because their child is suddenly ill with severe symptoms. When the severe symptoms disappear by morning, parents may feel foolish they rushed to a hospital with the child in the middle of the night. Assure them that their initial judgment was correct. When they brought the child in, the child was seriously ill. Parents may be reluctant to see their child discharged in the morning until they are convinced that their child is now well enough to go home (see Focus on Nursing Care Planning Box 40.10).

What if... Michael, who had loud stridor when he was admitted, suddenly has no stridor present? Would you be relieved (his condition must be improving) or worried (his airway may be so blocked that not enough air is entering to make the sound of stridor)? How should you respond?

Epiglottitis

Epiglottitis is inflammation of the epiglottis (the flap of tissue that covers the opening to the larynx to keep out food and fluid during swallowing). Although it is rare, inflammation of the epiglottis is an emergency because the swollen epiglottis cannot rise and allow the airway to open. It occurs most frequently in children from 2 to about 7 years of age (Ogle & Anderson, 2008).

Epiglottitis can be either bacterial or viral in origin. *H. influenzae* type B has been replaced as the most common bacterial cause of the disorder by pneumococci, streptococci, or staphylococci. Echovirus and RSV also can cause the disorder.

Assessment

Symptoms begin as those of a mild upper respiratory tract infection. After 1 or 2 days, as inflammation spreads to the epiglottis, the child suddenly develops severe inspiratory stridor, a high fever, hoarseness, and a very sore throat. Children may have such difficulty swallowing that they drool saliva. They may protrude their tongue to increase free movement in the pharynx.

If a child's gag reflex is stimulated with a tongue blade, the swollen and inflamed epiglottis can be seen to rise in the back of the throat as a cherry-red structure. It can be so edematous, however, that the gagging procedure causes complete obstruction of the glottis and shuts off the ability of the child to inhale. Therefore, in children with symptoms of epiglottitis (dysphagia, inspiratory stridor, cough, fever, and hoarseness), *never attempt to visualize the epiglottis directly with a tongue blade or obtain a throat culture* unless a means of providing an

BOX 40.10 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Child With Laryngotracheobronchitis (Croup)

Michael is a 4-year-old who is brought to the emergency department by paramedics who responded to an emergency call by his grandmother at his home. He has a sharp, barking cough, is crying loudly, and is obviously short of breath. His grandmother shouts at you. "I gave him some chocolate. Is he allergic to that?" Michael is diagnosed as having laryngotracheobronchitis (croup) and admitted to an ambulatory care unit.

Family Assessment ✻ Child lives with two parents in four-bedroom suburban home. Father works as a bartender at local restaurant; mother works part-time as a beautician. Parents are out of town on vacation. Were notified of child's condition and gave oral permission for therapy by telephone to W. Burton, M.D. (witnessed by C. Finacca, R.N.); will fax consent and signatures from vacation hotel.

Client Assessment ✻ Child was born with choanal atresia. Is allergic to seafood, especially shrimp (develops hives and shortness of breath). Age-acceptable parameters for height and weight. Has had a "slight head cold" for last 2 days; woke from nap this afternoon gasping for breath. Has audible stridor. Tympanic temperature 102.2° F (39.0° C); pulse 146; respirations 40. Nasal flaring and intercostal retractions noted. Sharp, frequent, nonproductive cough.

Nursing Diagnosis ✻ Fear related to inability to breathe without effort, heightened by absence of parents.

Outcome Criteria ✻ Respiratory rate, oxygen saturation, and arterial blood gas levels are within age-acceptable parameters without the use of supplemental oxygen. No stridor is present on auscultation. Child states he can breathe more easily; is aware parents are concerned although absent.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Assess if child is able to complete any self-care despite fatigue and shortness of breath.	Place the child in a semi-Fowler's to high Fowler's position. Reposition the child frequently.	An upright position facilitates breathing and promotes optimal lung expansion by lowering diaphragm. Frequent repositioning prevents pooling and stasis of secretions.	Child cooperates with procedures to extent possible, given degree of fatigue and fear.
		Consultations		
Nurse practitioner	Assess if anesthesiologist is available.	Consult with anesthesiologist about the possibility that intubation or tracheostomy may be necessary.	If tracheolaryngeal edema occludes airway, intubation or tracheostomy can be life-saving.	Anesthesiology team examines child; prepares equipment for emergency intubation if necessary.
		Procedures/Medications		
Nurse	Assess temperature by tympanic thermometer.	Administer acetaminophen liquid orally as prescribed.	Oral temperature would be inaccurate because of rapid respirations.	Child's temperature decreases one degree per hour until it reaches 98.6° F.
Nurse	Assess if child has experience with vital sign procedures or breath sound assessment.	Assess pulse, respirations, and lung sounds every 15 minutes.	An increasing pulse or respiratory rate or increased stridor can signal decreasing oxygenation.	Child agrees to allow chest leads to be applied to monitor heart rate. Pulse and respiratory rate do not increase any further.

Nurse	Assess if child has ever received medicine by nebulizer or humidifier.	Administer racemic epinephrine by nebulizer every 3 hours as prescribed. Keep room infused with cold humidification.	Epinephrine causes bronchodilation, widening lumen of airway. Cold moisture helps reduce inflammation and moisten mucus.	Child cooperates with nebulizer therapy to extent possible, given fear. Respiratory rate and stridor decrease following treatment.
Nurse	Assess which method of oxygen administration (face mask or nasal prongs) would be most acceptable to child.	Administer humidified oxygen at prescribed rate. Obtain arterial blood gases (ABGs) as ordered and monitor oxygen saturation levels via pulse oximetry.	Humidified oxygen improves ventilation without drying the mucous membranes, to reduce hypoxemia. ABGs and pulse oximetry provide objective evidence of the child's oxygenation.	Child chooses method for oxygen administration; cooperates with oxygen administration; Po_2 and Sao_2 improve to adequate levels.
		Nutrition		
Nurse	Assess what is child's favorite fluid to drink.	Offer the child sips of fluid frequently. Maintain intravenous fluid as prescribed.	Dehydration can occur from rapid respirations. Adequate hydration can help keep mucus moist.	Child drinks 80% of fluid offered; IV is maintained at correct rate.
		Patient/Family Education		
Nurse	Assess grandparent's knowledge of child's condition.	Review that croup is a viral infection, not an allergic disorder.	Understanding why a disease occurs can help grandparent to cooperate with therapy.	Grandparent states that she understands the cause of croup, its usual course, and its prognosis.
		Psychosocial/Spiritual/Emotional Needs		
Nurse/nurse practitioner	Assess if child has had prior experiences with hospitalization. Ask child to state if he feels afraid or anxious of procedures.	Use play to encourage child to cough, deep breathe, and drink fluid. Involve the grandparent in these activities.	Games and play are effective methods for encouraging fluid intake in a child. Involving the grandparent promotes participation in child's care.	Child states he understands the nebulizer, oxygen mask, etc. are to help him breathe, not punishment for eating candy.
		Discharge Planning		
Nurse	Assess if grandparent is comfortable with taking child home.	Review child's condition and careful watching grandparent will need to continue.	Croup is a frightening illness. Grandparent needs good preparation to continue care at home.	Grandparent states she is prepared to take child home; will telephone if child's symptoms return.
Nurse	Assess if grandparent knows action to take if child should develop croup again.	Review how to flood bathroom with warm moist steam.	Warm steam can help reduce airway inflammation.	Grandparent states she is prepared to initiate home therapy if a second incidence of croup should occur. Knows to call 911 if child's condition does not improve.

artificial airway, such as tracheostomy or endotracheal intubation, is readily available. This is especially important for the nurse who functions in an expanded role and performs physical assessments and routinely elicits gag reflexes.

When epiglottitis is present, laboratory studies will show leukocytosis (20,000 to 30,000 mm^3), with the proportion of neutrophils increased. A blood culture to evaluate for septicemia and ABGs to evaluate respiratory sufficiency may be ordered. However, because excessive crying can precipitate entrapment of the epiglottis and obstruction, such tests may be delayed in preference to a lateral neck x-ray film or ultrasound, which will show the enlarged epiglottis. Do not allow a child with possible epiglottitis to go to these departments accompanied only by parents or a nursing aide, in case obstruction occurs in the radiograph or ultrasound room.

Therapeutic Management

Children need moist air to reduce the epiglottal inflammation. If cyanosis is present, they need oxygen. An antibiotic, such as a third-generation cephalosporin such as cefotaxime, may be prescribed until a throat culture indicates a specific antibiotic drug. Because they cannot swallow, children need intravenous fluid therapy to maintain hydration. They may need a prophylactic tracheostomy or endotracheal intubation to prevent total airway obstruction, although it is often difficult to intubate children with epiglottitis because the tube cannot be passed beyond the edematous epiglottis. After antibiotic therapy begins, the epiglottal inflammation recedes rapidly. By 12 to 24 hours, it has reduced enough that the airway may be removed. Antibiotic administration will continue for a full 7 to 10 days. Siblings of the ill child may be prescribed prophylactic antibiotic therapy to prevent them from developing the same symptoms.

Initially, the symptoms of epiglottitis are not unlike those of croup. As a result, parents may not realize the extent of the occlusion in their child, especially if the child has had croup on other occasions. They may question why a prophylactic tracheostomy was necessary this time when it was not used when the child had croup. Explain to them the difference between the two diseases (Table 40.5).

Some infants with epiglottitis die because obstruction occurs before a tracheotomy can be accomplished. If this should happen, parents can be assured they could not realize the seriousness of their child's symptoms. This may make them overcautious, bringing other children to health care settings repeatedly for symptoms that are obviously not serious. It will take time for them to regain confidence in themselves as parents and in their ability to judge a child's health.

✔ Checkpoint Question 40.4

Michael has a barking cough, sore throat, and high fever. You want to see if his throat looks sore. Your best procedure to do this would be:

a. Gag him with a tongue blade to inspect his tonsils.
b. Ask him to press down on his tongue with a finger.
c. Elicit a gag reflex using only one gloved finger.
d. Inspect his throat visually only.

Aspiration

Aspiration (inhalation of a foreign object into the airway) occurs most frequently in infants and toddlers. When a child aspirates a foreign object such as a coin or a peanut, the immediate reaction is choking and hard, forceful coughing. Usually, this dislodges the object. However, if the airway becomes so obstructed that coughing is impossible (no sound with cough), or if there are signs of increased respiratory difficulty accompanied by stridor, some intervention is essential. A series of subdiaphragmatic abdominal thrusts are recommended for children, the same as for adults. This recommendation does not extend to infants, however, because of the great risk of rupturing the liver (American Heart Association, 2008).

For this maneuver, stand behind the child and place a fist just under the child's diaphragm (a point immediately below the anterior rib cage). Embrace the child, grip your fist with your other hand, and pull back and up with a rapid thrust. The pressure created by this action of pushing up on the diaphragm forces the aspirated material out of the trachea (Fig. 40.19).

TABLE 40.5 ✻ Comparison of Laryngotracheobronchitis (Croup) and Epiglottitis

Assessment	Laryngotracheobronchitis	Epiglottitis
Causative organism	Usually viral	Usually pneumococci or streptococci
Usual age of child	6 mo–3 years	3–6 years
Seasonal occurrence	Late fall and winter	None
Onset pattern	Preceded by upper respiratory infection; cough becomes worse at night	Preceded by upper respiratory infection; suddenly very ill
Presence of fever	Low grade	Elevated to about 103° F
Appearance	Retractions and stridor; prolonged inspiratory phase of respirations; not very ill-appearing	Drooling; very ill-appearing; neck hyperextended to breathe. (Do not attempt to view enlarged epiglottis, or immediate airway obstruction can occur.)
Cough	Sharp, barking	Muffled cough
Radiographic findings	Lateral neck radiograph showing subglottal narrowing	Lateral neck radiograph showing enlarged epiglottis
Possible complications	Asphyxia because of subglottic obstruction	Asphyxia because of supraglottic obstruction

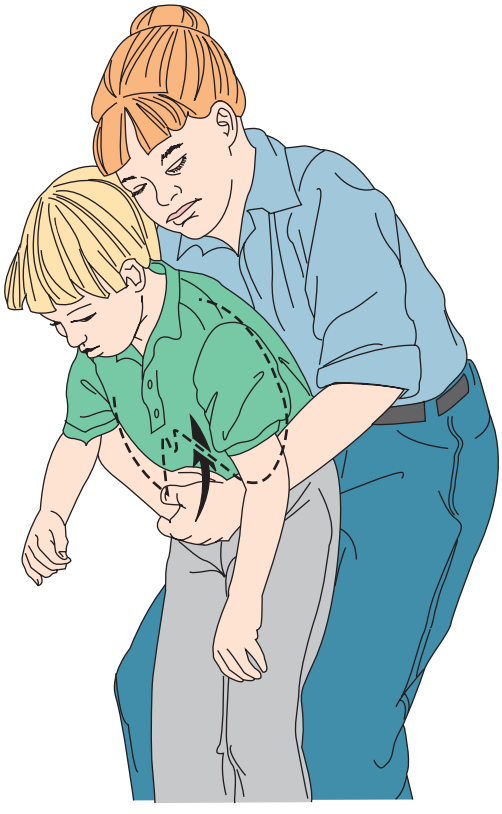

FIGURE 40.19 Subdiaphragmatic abdominal thrust on a school-age child.

If a child is lying on his or her back at the time of the aspiration, stand at the head of the bed or table, place your hands in the same position as described above, and exert the same inward and upward thrust. A subdiaphragmatic abdominal maneuver may cause a child to vomit as well as expel an aspirated object. Turn the child's head to the side to prevent aspiration of vomitus.

For infants, use back thrusts to dislodge an aspirated object. Turn the infant prone over your arm and administer up to five quick back blows forcefully between the infant's shoulder blades, using the heel of the hand (Fig. 40.20A). If the object is not expelled, turn the infant while carefully supporting the head and neck and hold the infant in a supine position draped over your thigh. Be sure to keep the infant's head lower than his or her chest. Provide up to five quick downward thrusts in the lower third of the sternum (Fig. 40.20B; American Heart Association, 2008). This is generally enough to dislodge the foreign object. However, if this does not occur, rescue breathing may then be attempted.

Bronchial Obstruction

The right main bronchus is straighter and has a larger lumen than the left bronchus in children older than 2 years of age. For this reason, an aspirated foreign object that is not large enough to obstruct the trachea may lodge in the right bronchus, obstructing a portion or all of the right lung. The alveoli distal to the obstruction will collapse as the air remaining in them becomes absorbed (atelectasis), or hyperinflation and pneumothorax may occur if the foreign body serves as a ball valve, allowing air to enter but not leave the alveoli (see later discussion on disorders of the lower respiratory tract).

Assessment

After aspirating a small foreign body, the child generally coughs violently and may become dyspneic. If the article is not expelled, hemoptysis, fever, purulent sputum, and leukocytosis will generally result as infection develops. Localized wheezing (a high whistling sound on expiration made by air passing through the narrowed lumen) may occur. Because this is localized, it is different from the generalized wheezing of a child with asthma.

A chest radiograph will reveal the presence of a radiopaque object. Objects most frequently aspirated include bones, popcorn, nuts, and coins. As a rule, nuts or popcorn should not be given to children younger than school age. These objects are coated with oil, and as they swell with moisture in the respiratory tract, they cause not only obstruction but also lipid pneumonia, a persistent and difficult-to-treat type of pneumonia. Foreign bodies that are inhaled this deeply are rarely coughed

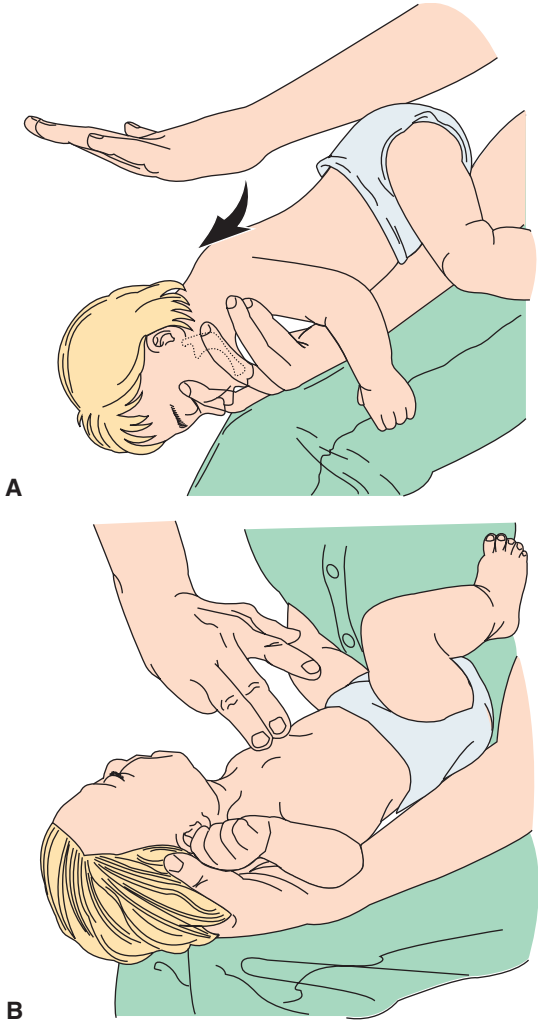

FIGURE 40.20 Back blows (**A**) and chest thrusts (**B**) to relieve complete foreign body airway obstruction in an infant. (From American Heart Association. [2008]. *Resuscitation in the newborn.* Dallas, TX: Author.)

up spontaneously, despite the severe coughing that ensues. Because objects such as plastic and nuts cannot be visualized well on x-ray film, an x-ray study may be inconclusive.

Therapeutic Management

Children who are seen in emergency departments after aspirating a foreign body are in distress from pain and are choking and coughing. Their parents are frightened by the degree of distress. Parents may feel bad about having offered the child (or allowed the child to reach) a food such as a peanut. Children need quick orientation to the treatment environment, as they move from the emergency department to radiography and then possibly to surgery or a treatment room. If possible, allow the parents to go with them. Throughout, be vigilant in observing the child for coughing up the foreign body or developing increasing respiratory distress.

A bronchoscopy may be necessary to remove the foreign body (Rosbe, 2008). Children are often given conscious sedation for a bronchoscopy (for details of a bronchoscopy procedure and conscious sedation, see Chapter 37). After bronchoscopy, assess the child closely for signs of bronchial edema and airway obstruction that occurs from mucus accumulation because of the bronchus manipulation. Obtain frequent vital signs (increasing pulse and respiratory rates suggest increased edema and obstruction).

Keep a child NPO for at least an hour after a bronchoscopy. Check for return of the gag reflex. Once the gag reflex is present, offer the first fluid cautiously to prevent additional aspiration. Cool fluid may feel more soothing than warm fluid and also helps to reduce the soreness in the throat. Breathing cool, moist air or having an ice collar applied may further reduce edema.

Obviously, parents need to be cautioned about the dangers of aspiration to keep this from happening again. Do not lecture them, however. Parents whose child has just been through this experience already recognize the danger of aspiration and realize they need to be more careful in the future.

DISORDERS OF THE LOWER RESPIRATORY TRACT

The structures of the lower respiratory tract are subject to infection by the same pathogens that attack the upper respiratory tract. Inflammation and infection of the lungs or bronchi is particularly troublesome: it occurs in various forms and is caused by several organisms. Other illnesses that occur in the lower respiratory tract, such as bronchiastasis, can lead to secondary pneumonia infections and chronic illness.

Influenza

Influenza involves inflammation and infection of the major airways. It is caused by the orthomyxovirus influenza type A, B, or C. It is marked by a cough, fever, fatigue, aching pains, a sore throat, and often accompanying gastrointestinal symptoms such as vomiting or diarrhea. The disease spreads readily through a home or a classroom because children are contagious on the day before symptoms appear and for about the next 5 days.

Children usually need an antipyretic such as acetaminophen (Tylenol) to control fever. Oseltamivir (TamiFlu), a new antiviral drug that halts viral proliferation, can be taken by children over 1 year of age (Deglin & Villerand, 2008). Because TamiFlu only halts virus replication, and does not kill viruses, it needs to be taken at the first sign of illness before replication can begin. Although most children recover without incident, influenza can lead to bronchitis or pneumonia. The condition can be largely prevented by yearly influenza vaccine. Because the influenza virus mutates yearly, the influenza vaccine is specific for only that year and must be readministered yearly (Zimmerman, 2007).

Bronchitis

Bronchitis, or inflammation of the major bronchi and trachea, is one of the more common illnesses affecting preschool and school-age children. It is characterized by fever and cough, usually in conjunction with nasal congestion. Causative agents include the influenza viruses, adenovirus, and *Mycoplasma pneumoniae*, among others.

Assessment

Children usually have a mild upper respiratory tract infection for 1 or 2 days; they then develop a fever and a dry, hacking cough, which is hoarse and mildly productive in older children. The cough is serious enough to wake a child from sleep. These symptoms may last for a week, with full recovery sometimes taking as long as 2 weeks.

On auscultation, rhonchi and coarse crackles (the sound of rales) can be heard. A chest radiograph will reveal diffuse alveolar hyperinflation and some markings at the hilus of the lung.

Therapeutic Management

Therapy is aimed at relieving respiratory symptoms, reducing fever, and maintaining adequate hydration. An antibiotic is prescribed for bacterial infections. If mucus is viscid, an expectorant may be necessary to help the child raise sputum. It is important that children with bronchitis cough to raise accumulating sputum. Cough syrups to suppress coughing, therefore, are rarely indicated.

Bronchiolitis

Bronchiolitis is inflammation of the fine bronchioles and small bronchi. It is the most common lower respiratory illness in children younger than 2 years, peaking in incidence at 6 months of age. The infection occurs most often in the winter and spring. Many children who develop asthma later in life have numerous instances of bronchiolitis during their first year of life. Viruses, such as adenovirus, parainfluenza virus, and RSV, in particular, appear to be the pathogens most responsible for this illness (Quintero & Gershan, 2007).

Assessment

Typically, infants have 1 or 2 days of an upper respiratory tract infection, then suddenly begin to demonstrate nasal flaring, intercostal and subcostal retractions on inspiration, and an increased respiratory rate. They may have a mild fever, leukocytosis, and an increased erythrocyte sedimentation rate, indicating the amount of bronchial inflammation present. Both accumulating mucus and inflammation block the small bronchioles, so air can no longer enter or leave alve-

oli freely. Most infants develop alveolar hyperinflation because air enters more easily than it leaves inflamed, narrowed bronchioles. This increases the expiratory phase of respiration and can create wheezing. After initial hyperinflation, areas of atelectasis in alveoli may occur as the air that cannot be expired is absorbed. Tachycardia and cyanosis develop from hypoxia. Infants soon become exhausted from rapid respirations. A chest radiograph may show pulmonary infiltrates caused by a secondary infection or collapse of alveoli (atelectasis). Pulse oximetry shows low oxygen saturation. A throat culture will identify the offending organism.

Therapeutic Management

For children with less severe symptoms, antipyretics, adequate hydration, and maintaining a watchful eye for progression to more serious illness is all that is necessary. Hospitalization is warranted for children in severe distress such as when an infant is tachypneic, has marked retractions, seems listless, or has a history of poor fluid intake.

Antibiotics are not commonly used in the treatment of bronchiolitis, because bacteria are rarely a causative factor (Spurling et al., 2009). Children with chronic pulmonary disease may receive anti-RSV immunoglobulin if RSV (respiratory syncytial virus) was identified as the causative agent.

If symptoms are severe, children need humidified oxygen to counteract hypoxemia and adequate hydration to keep respiratory membranes moist. Nebulized bronchodilators, epinephrine, and anti-inflammatory medications such as nebulized budesonide (a glucocorticoid steroid) may be used, although there is little evidence they make a major difference in reducing symptoms. Some children need ventilatory assistance to achieve adequate ventilation. All infants with bronchiolitis need to be carefully observed because if RSV is the cause, apnea may occur. In some infants, extracorporeal membrane oxygenation (the same as that used for heart surgery) is necessary to maintain adequate oxygenation.

Feeding is often a problem because infants tire easily and therefore cannot finish a feeding. Intravenous fluids may be given for the first 1 or 2 days of illness to eliminate the need for oral feeding.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Parental anxiety related to respiratory distress in child

Outcome Evaluation: Parents state that their anxiety level is tolerable as signs and symptoms of disease decrease.

Be certain that parents receive a good explanation of their child's condition. Most parents are aware of bronchi but are unfamiliar with the word *bronchiole*. This leaves them unsure how a simple cold has become so severe. They wonder whether they should have sought medical attention sooner. This may cause them to lose confidence in themselves as parents. Assure them that bronchiolitis begins as only a cold and that it was impossible to know that this cold would take a more serious turn but their child is now safe for discharge (Box 40.11).

The acute phase of bronchiolitis lasts 2 or 3 days. After this time, the child's condition improves rapidly. Although mortality from bronchiolitis is less than 1%, it is a serious disorder of infancy; without treatment, a larger number of infants certainly would die. Some children develop an increased incidence of airway hyperreactivity that may persist for years and be manifested later as asthma (Boguniewicz, 2008).

BOX 40.11 ✻ Focus on Evidence-Based Practice

How do you know when it is safe to discharge an infant with bronchiolitis from the emergency room?

During 2004 and 2006, researchers studied the outcome of 1456 infants under 2 years of age seen in 30 U.S. emergency departments with a diagnosis of bronchiolitis. Of these children, 57%, or 837, were discharged home. Factors that predicted a safe discharge to home (the child's condition improved on home care) were infant was over 2 months of age, there was no history of intubation, respiratory rate was specific for age (under 45 breaths per minute for 0–1.9 months, under 43 breaths per minute for 2–5 months, and under 40 breaths per minute for 6–23.9 months), there were no or only mild retractions, initial oxygen saturation was at or greater than 94%, few albuterol or epinephrine treatments were needed in the first hour, and the infant took in an adequate oral intake.

Based on the above research, suppose a parent of an infant, diagnosed with bronchiolitis, who is 1 month of age, has a respiratory rate of 55, moderate retractions, and an oxygen saturation level of 94.5% tells you she cannot wait in the emergency department any longer. Would you advise her that it is safe to leave and take her infant home?

Source: Mansbach, J. M. (2008). Prospective multicenter study of bronchiolitis: predicting safe discharges from the emergency department. *Pediatrics, 121*(4), 680–688.

Respiratory Syncytial Virus Bronchiolitis

RSV is a pathogenic RNA virus that is the most common cause of bronchiolitis in young children. Symptoms begin as a mild upper respiratory infection that quickly extends to include the bronchioles. The infant becomes lethargic and possibly cyanotic. Dehydration occurs as the child becomes too fatigued to suck. Respiratory distress with nasal flaring, retractions, grunting, rales, rhonchi, and expiratory wheezing noted on auscultation occur. All infants with an RSV infection must be monitored closely because the virus tends to cause apnea or periodic halting of respirations. The diagnosis is confirmed by throat or nasal culture.

Therapy is supportive (supplemental oxygen and hydration therapy), although life-threatening apnea may require ventilatory support with mechanical ventilation. Ribavirin, an antiviral agent, is effective against RSV, but ribavirin aerosol treatment is controversial as the drug is teratogenic

and could be harmful to pregnant caregivers (Ventre & Randolph, 2009). Because RSV infection spreads readily from one child to the next, infants should be isolated for care. Nursing care should be organized so nurses do not care for other infants than those infected with RSV.

The disease peaks in severity between 48 to 72 hours. Recurrent apneic episodes are rare, so home monitoring for apneic episodes is usually not necessary. Two products are available for the prevention of RSV infection: RSV immune globulin intravenous (RSV-IGIV), made from RSV antibody–positive donor serum, and Palivizumab, a humanized monoclonal antibody produced by recombinant DNA technology. These may be given prophylactically to premature infants during the winter months (Kerby et al., 2008).

Asthma

Asthma, an immediate hypersensitivity (type I) response, is the most common chronic illness in children, accounting for a large number of days of absenteeism from school and many hospital admissions each year. It tends to occur initially before 5 years of age, although in these early years it may be diagnosed as frequent occurrences of bronchiolitis rather than asthma (Table 40.6). The condition may be intermittent, with symptom-free periods, or chronic, with continuous symptoms.

Asthma tends to occur in children with atopy or those who tend to be hypersensitive to allergens. Mast cells release histamine and leukotrienes that result in diffuse obstructive and restrictive airway disease because of a triad of inflammation, bronchoconstriction, and increased mucus production. Most children with asthma can be shown to have sensitization to inhalant antigens such as pollens, molds, or house dust. Food also may be involved. Severe bronchoconstriction can also occur because of exposure to cold air or irritating odors, such as turpentine or smog, as well as inhalation of a known allergen. Air pollutants such as cigarette smoke may lower the threshold for hypersensitivity reactions and worsen the condition. Although there may be a seasonal factor responsible for a particular child's symptoms, most children have multiple sensitivities and are affected all year long. Aspirin can be a trigger, so caution adolescents with asthma that if they begin to take aspirin as an adult, it may initiate an attack.

Mechanism of Disease

Asthma primarily affects the small airways and involves three separate processes: bronchospasm, inflammation of bronchial mucosa, and increased bronchial secretions (mucus). All three processes act to reduce the size of the airway lumen, leading to acute respiratory distress. Bronchial constriction occurs because of stimulation of the parasympathetic nervous system (cholinergic mediated system), which initiates smooth muscle constriction. Inflammation and mucus production occur because of mast cell activation to release leukotrienes, histamine, and prostaglandins. Once viewed as a long-term, poorly controlled disorder, newer therapy makes this a reversible or manageable disorder (Boguniewicz, 2008).

Assessment

The word *asthma* is derived from the Greek word for "panting," a description of the child's distress. Typically, after exposure to an allergen or trigger, an episode begins with a dry cough, often at night as bronchoconstriction begins. Because bronchioles are normally larger in lumen on inspiration than expiration even with bronchoconstriction, children may inhale normally or have little difficulty. They develop increasing difficulty exhaling, however, as it becomes more and more difficult to force air through the narrowed lumen of the inflamed bronchioles filled with mucus. This causes the typical dyspnea and wheezing (the sound caused by air being pushed forcibly past obstructed bronchioles) typically associated with the disorder. Wheezing is heard primarily on expiration. However, when severe, it may be heard on inspiration as well. Hearing it on inspiration means a child is having extreme breathing difficulty. If a child coughs up mucus, it is generally copious and may contain white casts bearing the shape of the bronchi from which it was dislodged.

History. Assessment should include a thorough history of the development of a child's symptoms—for example, what the child was doing at the time of the attack, and what actions were taken by the parents or child to decrease or arrest the symptoms. When an acute attack has passed, ask the parent or child to describe the home environment, including any pets, the child's bedroom, outdoor play space, classroom environment, and type of heating in the house, to see whether more environmental control could reduce future occurrences.

Physical Assessment. A physical assessment includes examining for the specific symptoms of asthma. In many children, the initial wheezing is so loud it can be heard without a stethoscope. In others, it is evident only by auscultation. Asthma affects all lobes of the lungs, so although the wheezing may be more prominent in one lobe than in another, it is generally audible in all lung fields. Audible wheezing in only one lobe suggests that only one bronchus is plugged, which suggests that a foreign body such as a peanut is more likely responsible than asthma. Cyanosis may be present. The eosinophil count is elevated.

Bronchospasm leads to CO_2 trapping and retention; therefore, arterial oxygen saturation monitored by a pulse oximeter will begin to decrease because of the child's inability to fully aerate the lungs. The child becomes frightened because of an acute feeling of suffocation. A peak flow meter shows decreased ability to exhale (Fig. 40.21).

Air-filled lungs are hyperresonant to percussion or they make a louder, hollower noise on percussion than usual. With normal respiration, the inspiration phase of breathing is longer than the expiration phase. During an asthma attack, however, a child must work so hard to exhale that the expiration phase becomes longer than the inspiration phase. Time the two phases to demonstrate this. Also observe for retractions (the chest wall is drawn inward with breaths) because children have to use intercostal accessory muscles to achieve full breaths.

As constriction becomes acute, the sound of wheezing may decrease because so little air can leave the alveoli. Hypoxemia and possibly cyanosis will become severe. When blood gases show an increased P_{CO_2} level and the sound of wheezing suddenly stops, respiratory failure is imminent.

During attacks, children with asthma are generally more comfortable in a sitting or standing position rather than lying down. If seated in a chair, they lean forward and raise their shoulders to give themselves more breathing space. Do not urge children to "lie down and relax," as this can cause severe anxiety and increased difficulty in breathing. Children who

FIGURE 40.21 Here a child with asthma practices using a peak flow meter to track her peak expiratory flow readings on a daily basis.

do agree to lie down are either at the end of an attack and beginning to feel less threatened by the dyspnea or are so exhausted by the paroxysms of coughing they no longer have the strength to sit upright.

Over time, as children have many bouts of asthma, they develop a shield-like or barrel-shaped chest from constant overinflation of air in alveoli. Clubbing of the fingers (from the growth of excess capillaries initiated when oxygen deprivation is sensed in distal parts) may be noticeable. If children are treated for a long period with high doses of steroids, they may fall behind in growth.

Pulmonary Function Studies

Good pulmonary function depends on good ventilation (both drawing adequate air into the lungs and expelling it again), adequate transfer of gases across the alveolar capillary membranes, and adequate volume and distribution of pulmonary capillary blood flow to transport oxygen to body cells. In children with asthma, the vital capacity (air that they are able to exhale) may be low or the capacity may be normal, but, because of narrowed bronchioles as a result of bronchospasm, the expiratory rate will be abnormally long (more than 10 seconds, rather than the normal 2 or 3 seconds). If a child has bronchial plugging, the vital capacity will be low because of air absorption behind blocked bronchi. A gross measure of vital capacity is to ask a child to blow out a match. A child with an average vital capacity should be able to do this when the match is held at 6 inches. Children with asthma may not have the expiratory pressure to do this.

Peak Expiratory Flow Rate Monitoring. Children with asthma often use a home peak flow meter daily to measure gross changes in peak expiratory flow over time and help in planning an appropriate therapeutic regimen (Fig. 40.21). Children with asthma should be able to tell you their usual reading and personal best score.

To use a peak flow meter, a child places the indicator on the apparatus at the bottom of the numbered scale, and takes a deep breath. A child then places the meter in the mouth and blows out as hard and fast as possible. The child then repeats this two more times and records the highest number achieved as the peak flow meter result. During a 2-week period when a child feels well, this should be done daily. The highest number achieved during this time is recorded as the child's personal best.

Children are assigned "zones" to rate their expiratory compliance:

- Green zone (80% to 100% of their personal best) means no asthma symptoms are present, and they should take their routine medications.
- Yellow zone (50% to 80% of personal best) signals caution. An episode of asthma may be beginning.
- Red zone (below 50% of personal best) indicates an asthma episode is beginning. Children should immediately take their prescribed medication such as an inhaled beta-2–agonist, then repeat the peak flow assessment. If the second reading is not in the green zone, their parents should alert their primary care provider of the impending asthma attack.

Therapeutic Management

Therapy for children with asthma involves planning for the three goals of all allergic disorders: avoidance of the allergen by environmental control; skin testing and hyposensitization to identified allergens; and relief of symptoms by pharmacologic agents. Parents need good instructions to be able to continue to address all three concerns over an extended period of time (McMullen et al., 2007).

Cough suppressants are contraindicated with asthma because, as a rule, as long as children can continue to cough up mucus, they are not in serious danger. When they stop coughing up mucus, thick plugs form that then may lead to pneumonia, atelectasis, and further acidosis.

A child with mild but persistent asthma usually is prescribed an inhaled anti-inflammatory corticosteroid such as fluticasone (Flovent) daily. Children who have moderate persistent symptoms usually are prescribed a long-acting bronchodilator at bedtime in addition to the inhaled anti-inflammatory daily corticosteroid. Children who have severe persistent asthma symptoms take a high dose of both an oral corticosteroid and an inhaled corticosteroid daily as well as a long-acting bronchodilator at bedtime. In addition, children may be prescribed a short-acting beta-2–agonist bronchodilator, such as albuterol or terbutaline, to use if an attack should begin (see Box 40.6). Cromolyn sodium is a mast cell stabilizer given by a nebulizer or metered-dose inhaler (see Figures 40.6 and 40.12A,B). This can prevent bronchoconstriction and thereby prevent the symptoms of asthma (Box 40.12). Cromolyn sodium is not effective once symptoms have begun.

Another group of drugs used in the treatment of asthma are leukotriene receptor antagonists such as montelukast (Singulair) (Scow, Luttermoser, & Dickerson, 2007). These drugs are used for prophylaxis and chronic treatment of

BOX 40.12 ✻ Focus on Pharmacology

Cromolyn Sodium (Intal)

Classification: Cromolyn sodium is a mast cell inhibitor.

Action: Inhibits the release of histamine, slow-releasing substance of anaphylaxis, and leukotriene, thereby decreasing the overall allergic response. In asthma, it is used prophylactically to prevent severe bronchospasms (Karch, 2009).

Pregnancy risk category: B

Dosage: Initially, 20 mg inhaled (via spinhaler inhalant or as nebulized solution) 4 times daily at regular intervals; one ampule orally 4 times daily 1/2 hour before meals and at bedtime (ampule is not recommended for use in children under the age of 5 years)

Possible adverse effects: Dizziness, headache, nausea, dry and irritated throat, cough, nasal congestion, epistaxis, sneezing

Nursing Implications

- Instruct parents and child that this drug is not effective in an acute attack.
- Caution child and parents to take the drug exactly as prescribed and to continue other agents, such as bronchodilators.
- Instruct child and parents in the use of metered-dose inhaler or nebulizer for administration of cromolyn sodium.
- If the oral form is prescribed, instruct parents to open the ampule and pour the contents into a glass of water and to wait for the medication to dissolve. Caution parents not to substitute the oral form for the inhalant form and vice versa.
- Instruct parents and child to watch for a possible recurrence of asthma symptoms if dosage is decreased.
- Know that this drug is only given once the acute episode is over and the child's airway is clear, to prevent a further episode.
- Caution child and parents not to exceed the number of ordered puffs via inhaler, to prevent possible tolerance to drug.
- If more than one inhalation is ordered, advise child to wait 1 to 2 minutes before taking the second puff.
- If the child is also receiving an inhaled bronchodilator, advise the child and parents to have the child use the bronchodilator first to open the airways and then wait approximately 5 minutes before using the cromolyn sodium, to maximize its effectiveness.

asthma in children over 6 years of age. They are not effective in an acute attack.

If children are to receive medication by nebulizer or inhaler, be certain they know how to use these properly. It is easy for children to take this type of medication lightly (the belief it is "not really medicine" because it is not swallowed). As a result, overdose from constant use of nebulizers or metered-dose inhalers can occur.

Dehydration occurs rapidly in children during an asthma attack because they have decreased oral intake (children stop drinking because they are coughing, or coughing makes them vomit and parents stop offering fluid) as well as increased insensible loss that occurs from tachypnea. Dehydration may contribute to increased mucus plugging and further airway obstruction. Encourage children to continue to drink fluids (ask about favorite beverages and offer small sips of them). Avoid milk or milk products because they cause thick mucus and difficulty swallowing. In an emergency setting, an intravenous line is established to supply continuous fluid therapy and also provide a route for emergency drug administration.

Nursing Diagnoses and Related Interventions ✻

Nursing Diagnosis: Fear related to sudden onset of asthma attack

Outcome Evaluation: Parents and child express confidence in their ability to prevent attacks and effectively manage any that occur.

Asthma is a frightening disease. At the time it is diagnosed, parents may have already gone through a long period of wondering why their child was always tired and had episodes of difficulty with breathing. After diagnosis, parents may be afraid to allow a child to sleep overnight away from them or leave the child alone with a babysitter. Help parents find a middle ground: to allow a child enough freedom for growth and development while still being certain the child is safe. Taking steps to slow breathing, better emptying alveoli through pursed-lip breathing, and administering medications to prevent symptoms are key measures for children to learn. Many children have long periods without attacks. When a new one occurs after a long absence, it is almost as frightening as the original attack because everything seems so new again.

Nursing Diagnosis: Health-seeking behaviors related to prevention of and treatment for asthma attacks

Outcome Evaluation: Parents and child accurately state triggers that cause an attack; child correctly demonstrates breathing exercises, use of inhaler, and peak expiratory flow meter.

Children need to learn how to avoid possible triggers through environmental control. If foods are a trigger, children need to learn to be responsible for their own diets so they can avoid these foods. Children as young as 6 years can learn what foods they cannot eat and can take responsibility for telling a friend's parent or a schoolteacher that they must not eat certain foods. They must learn to use a metered-dose inhaler or nebulizer if prescribed. At the same time, they must not become inhaler-dependent or use the inhaler constantly, afraid to go anywhere without it. This will invariably result in their using the inhaler much more often than is necessary.

To prevent children with asthma from losing chest mobility and to decrease their tendency to develop a barrel chest, they can be taught several breathing or mobility exercises to do daily at home. Such exercises are aimed at increasing expiratory function (diaphragmatic or side expansion breathing). Recommended activities include bending side to side, bending forward and touching the left foot with the right hand, and swinging the arms rhythmically in front of the body like a windmill (jumping jacks). These exercises can be incorporated into a bedtime or after-school routine. (Parents [and nurses] who do mobility exercises with children find the exercises are helpful to them as well, as they help tighten the abdominal muscles.) Using an incentive spirometer daily is another method for children to use to exercise the lungs and keep chest muscles supple.

The prognosis in children who develop asthma is good if they adhere to their treatment regimen. Children do not outgrow asthma, although most of them may become symptom-free as adults, probably because the lumens of major airways enlarge with adulthood.

Do not convey to parents the impression that asthma is a disease that will be simply outgrown, however. Although asthma may not always last into adulthood, parents need to maintain careful environmental control, conscientious administration of medication, and hyposensitization, if indicated, to keep the child free of symptoms during childhood.

Status Asthmaticus

Under ordinary circumstances, an asthma attack responds readily to the aerosol administration of a bronchodilator such as albuterol, terbutaline, levalbuterol (Xopenex), or salmeterol (Serevent). When children fail to respond and an attack continues, they are in *status asthmaticus*. This is an extreme emergency because, if the attack cannot be relieved, a child may die of heart failure caused by the combination of exhaustion, atelectasis, and respiratory acidosis from bronchial plugging.

Assessment

A child with status asthmaticus is in acute respiratory distress. Both heart rate and respiratory rate are elevated. Both oxygen saturation and P_{O_2} are low; P_{CO_2} is elevated because the bronchi are so constricted the child cannot exhale, resulting in CO_2 accumulation. The rising P_{CO_2} rapidly leads to acidosis. In contrast to the loud wheezing initially heard in an asthma attack, children with status asthmaticus may have so little air able to pass in or out of their lungs that breath sounds are limited. Pulse oximetry will reveal the low oxygen saturation level.

Status asthmaticus is often initiated by a respiratory infection, which acts as the triggering mechanism for the prolonged attack. If this occurs, obtain cultures from coughed sputum, and be prepared to administer a broad-spectrum antibiotic until the culture results are available. Be certain the sputum obtained for culture was coughed from deep in the respiratory tract and not just from the back of the child's throat.

Therapeutic Management

By definition, a child in status asthmaticus has failed to respond to first-line therapy (Mannix & Bachur, 2007). Continuous nebulization with an inhaled beta-2-agonist and intravenous corticosteroids may be necessary to reduce symptoms. Oxygen is given by face mask or nasal prongs to maintain the P_{O_2} at more than 90 mm Hg. These methods supply good oxygen concentrations and yet leave the child's face unobscured for easy observation. To prevent drying of pulmonary secretions, always give oxygen with humidification. It is best administered at a concentration of 30% to 40%, not 100%. If concentrations greater than 40% are needed, a Venturi mask that allows for rebreathing may be used. Some children in severe status asthmaticus have such a carbon dioxide buildup (because they cannot exhale properly) that they develop carbon dioxide narcosis with no stimulation for inhalation. The child's respiratory stimulus, therefore, is hypoxia, or lack of oxygen. If 100% oxygen were administered, the oxygen lack would disappear, and respirations would cease. The idea "if a little is good, a lot is better" does not apply here. After it has been ascertained that the child is not in acidosis (from blood gas and pH studies), oxygen levels may be increased, but for initial therapy, unless prescribed otherwise, keep the level at 40%.

During the acute stage of status asthmaticus, children need increased fluid to combat dehydration and keep airway secretions moist. Drinking tends to aggravate coughing, so an intravenous infusion such as 5% glucose in 0.45 saline is usually prescribed to supply fluid. If a child can drink, do not offer cold fluids because these tend to aggravate bronchospasm.

Monitor intake and output; measure the specific gravity of urine. Under stress, antidiuretic hormone is released, so fluid retention and overhydration may occur.

An increasing P_{CO_2} is a danger sign because it indicates the degree of hypoventilation. In severe attacks, endotracheal intubation and mechanical ventilation may be necessary to maintain effective respirations (Carpenter et al., 2008).

Bronchiectasis

Bronchiectasis is chronic dilatation and plugging of the bronchi. It may follow pneumonia, aspiration of a foreign body, pertussis, or asthma.

Children develop a chronic cough with mucopurulent sputum (Kerby et al., 2008). Young infants may have accompanying wheezing or stridor. If a large area of lung is involved, children may have cyanosis. As the disease becomes chronic, children develop symptoms of chronic lung disease, such as clubbing of the fingers and easy fatigability. Their physical growth may become restricted. Their chest may become enlarged from overinflation of alveoli caused by the air trapped behind inflamed bronchi.

Inhaled mucolytic agents or bronchodilators and chest physiotherapy may be necessary to raise the tenacious sputum. An antibiotic will be necessary if infection is present. The cause of the bronchiectasis such as an aspirated seed or nut must be identified and relieved before the chronic process can be relieved. In rare instances, surgery to remove the affected lung portion may be necessary.

Pneumonia

Pneumonia (infection and inflammation of alveoli) occurs at a rate of 2 to 4 children in 100. It may be of bacterial origin (pneumococcal, streptococcal, staphylococcal, or chlamydial) or viral in origin, such as RSV. Aspiration of

TABLE 40.6 ✻ Comparison of Bronchiolitis, Pneumonia, and Asthma

Assessment	Bronchiolitis	Pneumonia	Asthma
Cause	Usually respiratory syncytial virus	Possibly bacterial (pneumococcal, or *H. influenzae*), viral, or mycoplasmal; possibly secondary to aspiration	Hypersensitivity type I immune response
Age of child	Under 2 years	All through childhood	Onset 1–5 years
Onset pattern	Follows an upper respiratory infection	Follows an upper respiratory infection	Follows initiation by an allergen
Appearance	Fatigued, anxious, shallow respirations, increasing anteroposterior diameter of chest	Fatigued, anxious, shallow respirations	Wheezing, exhausted, frightened
Cough	Paroxysmal, dry	Productive, harsh cough	Paroxysmal, with thick mucus production
Fever	Low grade	Elevated	None
Auscultatory sounds	Barely audible breath sounds, rales, expiratory wheezing	Decreased breath sounds, rales	Wheezing

lipid or hydrocarbon substances also causes pneumonia. The disease is commonly divided into two types: hospital acquired (pneumococcal or streptococcal pneumonia) and community acquired (chlamydia, viral pneumonias). It is the most common pulmonary cause of death in infants younger than 48 hours of age. It occurs most often in late winter and early spring. Newborns who are born more than 24 hours after rupture of the amniotic membranes and those who aspirated amniotic fluid or meconium during birth are particularly prone to developing pneumonia in their first few days of life (Raab, 2007). When it is known that the fetal membranes have been ruptured for more than 24 hours before birth, prophylactic broad-spectrum antibiotics may be given to prevent pneumonia. The differences between bronchiolitis, asthma, and pneumonia are summarized in Table 40.6. *Pneumocystis carinii* pneumonia, the type seen almost exclusively with HIV/AIDS infection, is discussed in Chapter 42.

Pneumococcal Pneumonia

The onset of pneumococcal pneumonia is generally abrupt and follows an upper respiratory tract infection. In infants, pneumonia tends to remain bronchopneumonia with poor consolidation (infiltration of exudate into the alveoli). In older children, pneumonia may localize in a single lobe, and consolidation may occur. With this, children may have blood-tinged sputum as exudative serum and red blood cells invade the alveoli. After 24 to 48 hours, the alveoli are no longer filled with red blood cells and serum but fibrin, leukocytes, and pneumococci. At this point, the child's cough no longer raises blood-tinged sputum but thick purulent material.

Assessment. Children develop a high fever, nasal flaring, retractions, chest pain, chills, and dyspnea. Some children report the pain as being abdominal. The fever with pneumococcal pneumonia may rise so high and fast a child has a febrile seizure (see Chapter 49).

Children with pneumococcal pneumonia appear acutely ill. Tachypnea and tachycardia develop. Because the lung space is filled with exudate, respiratory function will be diminished. Breath sounds become bronchial (sound transmitted from the trachea) because air no longer or only poorly enters fluid-filled alveoli. Crackles (rales) may be present as a result of the fluid. Dullness on percussion over a lobe indicates that total consolidation has occurred. Chest radiographs will usually show this type of lung consolidation in older children but only patchy diffusion in young children. Laboratory studies will indicate leukocytosis.

Therapeutic Management. Therapy for pneumococcal pneumonia is antibiotics (Awasthi et al., 2008). Either ampicillin or a third-generation cephalosporin is effective against pneumococci. Amoxicillin-clavulanate (Augmentin) may be prescribed for penicillin-resistant organisms. Children need rest to prevent exhaustion. Plan nursing care carefully to conserve the child's strength. At the same time, turn and reposition a child frequently to avoid pooling of secretions. Intravenous therapy may be necessary to supply fluid, especially in infants, because infants tire so readily with sucking they may not be able to achieve a good oral intake. They may need an antipyretic such as acetaminophen to reduce fever.

Humidified oxygen may be necessary to alleviate labored breathing and prevent hypoxemia. Assess oxygen saturation levels frequently via pulse oximetry. Chest physiotherapy encourages the movement of mucus and prevents obstruction. Older children may need to be encouraged to cough so that secretions do not pool and become further infected.

Before antibiotic therapy was available for pneumonia, it was almost always a fatal disease, especially in infants, so parents may be more worried about a child's condition than is warranted (Box 40.13).

Following pneumonia, children usually have a period of at least a week when they tire easily and need frequent, small feedings. Parents need to be cautioned that this degree of fatigue is an expected outcome and not a complication in itself.

BOX 40.13 ✻ Focus on Communication

B. J. Silver is a 2-year-old who has been admitted to your hospital unit with pneumonia. His mother called home to tell the grandmother about the diagnosis. Since she returned from the telephone, Mrs. Silver seems tearful and visibly upset.

Less Effective Communication

Nurse: Is something wrong, Mrs. Silver? You seem upset.
Mrs. Silver: I am. I didn't realize pneumonia was so serious until I talked to my mother.
Nurse: Because it's serious is the reason that B.J.'s been admitted to the hospital.
Mrs. Silver: She told me my brother had pneumonia when he was a baby. Is this oxygen? My mother said to check B.J.'s getting oxygen.
Nurse: It sure is. He's also going to get an antibiotic. Why don't you stay with him while I get the equipment for that?

More Effective Communication

Nurse: Is something wrong, Mrs. Silver? You seem upset.
Mrs. Silver: I am. I didn't realize pneumonia was so serious until I talked to my mother.
Nurse: Because it's serious is the reason that B.J.'s been admitted to the hospital.
Mrs. Silver: She told me my brother had pneumonia when he was a baby. Is this oxygen? My mother said to check B.J.'s getting oxygen.
Nurse: Let's talk about everything your mother told you about pneumonia. Because the treatment has changed so much, what happened years ago is not the same as what happens now.

Before the advent of antibiotics, a diagnosis of pneumonia in a young child was almost automatically a fatal diagnosis. Ask enough questions to be certain parents understand that pneumonia, although serious, is not the fatal diagnosis of years ago.

Children with chronic illness, those who have had a splenectomy, or those who are immunocompromised should receive a pneumococcal vaccine to prevent pneumococcal pneumonia.

Chlamydial Pneumonia

Chlamydia trachomatis pneumonia is most often seen in newborns up to 12 weeks of age because the chlamydial organism is contracted from the mother's vagina during birth. Symptoms usually begin gradually with nasal congestion and a sharp cough; infants fail to gain back their birth weight. Symptoms progress to tachypnea, with wheezing and rales audible on auscultation. Laboratory assessment will show an elevated level of immunoglobulin IgG and IgM antibodies, peripheral eosinophilia, and a specific antibody to *C. trachomatis.* Such an infection is treated with a macrolide antibiotic such as erythromycin with good results (Kerby, 2008).

Viral Pneumonia

Viral pneumonia is generally caused by the viruses of upper respiratory tract infection: the RSVs, myxoviruses, or adenoviruses. Symptoms begin as an upper respiratory tract infection. After a day or two, additional symptoms such as a low-grade fever, nonproductive cough, and tachypnea begin. There may be diminished breath sounds and fine rales on chest auscultation. RSV may cause apnea. Chest radiographs will show diffuse infiltrated areas.

Because this is a viral infection, antibiotic therapy usually is not effective. The child needs rest and, possibly, an antipyretic for the fever; intravenous fluid may be necessary if a child becomes exhausted or is dehydrated and refusing fluids. After recovery from the acute phase of illness, a child will have a week or two of lethargy or lack of energy, the same as occurs with bacterial pneumonia. Parents may be confused because their child is not receiving an antibiotic, despite the diagnosis of pneumonia. Explain the difference between viral and bacterial infections so they can better understand their child's therapy and plan of care.

Mycoplasmal Pneumonia

The mycoplasma organisms are similar to yet larger than viruses. Mycoplasmal pneumonia occurs more frequently in older children (over 5 years) and more often during the winter.

The symptoms of mycoplasmal pneumonia make it difficult to differentiate from other pneumonias. The child has a fever and a cough and feels ill. Cervical lymph nodes are enlarged. The child may have a persistent rhinitis.

Mycoplasmal organisms generally are sensitive to erythromycin or tetracycline. Erythromycin is the preferred drug for children younger than 8 years of age, because tetracycline tends to stain teeth brown and possibly stunt long bone growth (Karch, 2009).

Lipid Pneumonia

Lipid pneumonia is caused by the aspiration of an oily or lipid substance. It is much less common than it once was because children are not given oil-based tonics, such as castor oil or cod liver oil anymore, as they were in the past. Today it is most often caused by aspirated oily foreign bodies such as peanuts or popcorn. A proliferative inflammatory response occurs when lung lipases act on the aspirated oil. This is then followed by diffuse fibrosis of the bronchi or alveoli. The area then becomes secondarily infected.

A child may have an initial coughing spell at the time of aspiration. A period follows during which the child is symptomless; then a chronic cough, dyspnea, and general respiratory distress occur. A chest radiograph shows densities at the affected site.

Antibiotic therapy is ineffective unless a secondary bacterial infection has occurred. Surgical resection of a lung portion may be necessary to remove a lung segment if the pneumonitis does not heal by itself.

Hydrocarbon Pneumonia

Several common household products such as furniture polish, cleaning fluids, turpentine, kerosene, gasoline, lighter fluid, and insect sprays have hydrocarbon bases. These

products are a common cause of childhood poisonings and result in hydrocarbon pneumonia.

Assessment. Children who swallow a hydrocarbon-based product usually exhibit gastrointestinal symptoms such as nausea and vomiting. Next, they become drowsy and develop a cough from inhalation as vapors from the stomach rise and are inhaled. As bronchial edema occurs from irritation and inflammation, respirations become increased and dyspneic.

Physical assessment shows an increased percussion sound caused by the presence of air trapped in the alveoli beyond the point of inflammation. Rales may be heard as air passes through collecting mucus. Because air cannot reach and inflate the alveoli fully, breath sounds may be diminished.

Therapeutic Management. Irritation from fumes of hydrocarbon ingestion may occur when children initially swallow the fluid. If they are given an emetic to induce vomiting, it can cause them to aspirate vomitus or cause additional irritation. Parents should telephone a poison control center to ask for advice if their child has swallowed any poison, rather than induce vomiting to prevent this secondary complication. In the emergency room, gastric lavage may be done by health care personnel with great care to remove the substance from the stomach and help prevent inhalation.

The child is usually admitted to a hospital observation unit for a short time. Obtain vital signs and observe the child's general appearance carefully for evidence of increased respiratory tract obstruction or increasing drowsiness or other symptoms of CNS involvement from CNS intoxication. Cool, moist air administered by a nebulizer with supplemental oxygen may be prescribed to decrease lung inflammation. If febrile, a child needs an antipyretic. Frequent changes of position will prevent pooling of secretions, which could lead to a secondary infection. Chest physiotherapy will help to move secretions and reduce areas of stasis.

The initial inflammation reaction from hydrocarbon aspiration may lead to such occlusion that emphysema (pocketing of air in alveoli) occurs, causing rupture of the alveoli into the pleural space, with consequent pneumothorax and atelectasis.

Often, children who swallow a household cleaner or other substance are aware they should not have been handling substances kept under the sink. As a result, they cannot help but interpret the hospitalization, blood drawing, and other uncomfortable procedures as punishments for their action. They may benefit from therapeutic play with puppets or dolls that will help alleviate their guilt and anger at being "punished" so severely.

Hydrocarbon pneumonia is slow to resolve, so the child will be ill for some time. After the illness, reinforce with parents the need to keep poisons in a safe place. Offer a listening ear so they can explain they were unaware of the extreme danger of these everyday household products.

Atelectasis

Atelectasis is the collapse of lung alveoli. It may occur in children as a primary or secondary condition. It must be considered as a possibility in all children with respiratory distress.

Primary Atelectasis

Primary atelectasis occurs in newborns who do not breathe with enough respiratory strength at birth to inflate lung tissue or whose alveoli are so immature or so lacking in surfactant that alveoli cannot expand. This is seen most commonly in immature infants or in infants with CNS damage. It may occur if infants have mucus or meconium plugs in the trachea.

When atelectasis occurs, the newborn's respirations become irregular, with nasal flaring and apnea. After a few minutes, a respiratory grunt and cyanosis may occur. The sound of a respiratory grunt is caused by the newborn's glottis closing on expiration. At first, this is a helpful action because it increases pressure in the respiratory tract, keeps alveoli from collapsing, and allows for better alveoli exchange surfaces. This action is also tiring, however, and as the infant tires, hypoxemia will increase, and the infant will become hypotonic and flaccid. The Apgar score will invariably be low.

As infants cry or are administered oxygen, more alveoli become aerated and cyanosis may decrease. The cause of the atelectasis must be established, however, so that therapy directed to the specific cause can be initiated.

Secondary Atelectasis

Secondary atelectasis occurs in children when they have a respiratory tract obstruction that prevents air from entering a portion of the alveoli. As the residual air in the alveoli is absorbed, the alveoli collapse. The causes of obstruction in children include mucus plugs that may occur with chronic respiratory disease or aspiration of foreign objects. In some children, atelectasis occurs because of pressure on lung tissue from outside forces, such as compression from a diaphragmatic hernia, scoliosis, or enlarged thoracic lymph nodes (Fig. 40.22).

The signs of secondary atelectasis depend on the degree of collapse. Asymmetry of the chest may be noticed. Breath sounds on the affected side are decreased. If the process is extensive, tachypnea and cyanosis will be present. A chest radiograph will show the collapsed alveoli (a "whiteout").

Children with atelectasis are prone to secondary infection because mucus, which provides a good medium for bacteria, becomes stagnant without air exchange.

Therapeutic Management. Atelectasis caused by inspiration of a foreign object will not be relieved until the object is removed by bronchoscopy. Atelectasis caused by a mucus plug will resolve when the plug resolves or is moved or expectorated. Children may need oxygen and assisted ventilation to maintain adequate respiratory function until this time (Groeben et al., 2008).

Make certain the chest of a child with atelectasis is kept free from pressure so that lung expansion is as full as possible (to allow as much breathing space as possible). If restraints are being used to keep an infant positioned, make certain that body restraints are not crossing the chest area and interfering with chest expansion. Check clothing to be certain it is loose and nonbinding. Make certain the child's arms are not positioned across the chest, where their weight could interfere with deep inspiration.

A semi-Fowler's position generally allows for the best lung expansion because it lowers abdominal contents and increases chest space. Increase the humidity of the child's environment to prevent further bronchial plugging; suction and chest physiotherapy may be necessary to keep the respiratory tract clear and free of mucus. Observe closely for increased respirations or cyanosis, as these indicate failing oxygenation.

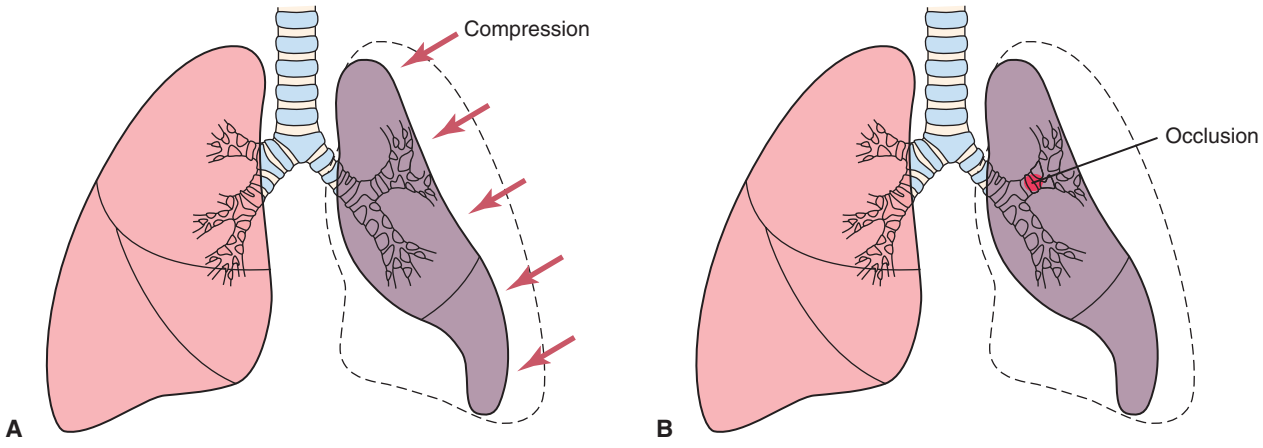

FIGURE 40.22 (**A**) Atelectasis caused by compression of lung tissue. (**B**) Atelectasis caused by obstruction.

Pneumothorax

Pneumothorax is the presence of atmospheric air in the pleural space; its presence causes the alveoli to collapse (atelectasis) (Fig. 40.23). Pneumothorax in children usually occurs when air seeps from ruptured alveoli and collects in the pleural cavity. It also can occur when external puncture wounds allow air to enter the chest (Chauvin, Chen, & Anthony, 2007).

Pneumothorax occurs in approximately 1% of newborns, probably because of rupture of the alveoli from the extreme intrathoracic pressure needed to initiate a first inspiration. The infant develops tachypnea, grunting respirations, flaring of the nares, and cyanosis. Auscultation reveals absent or decreased breath sounds on the affected side. Percussion may not be revealing, despite the hollow air space; as so much air is present, this may be hyperresonant. A more revealing sign may be the shift of the apical pulse (mediastinal shift) away from the site of the pneumothorax and the resulting atelectasis. A chest film will show the darkened area of the air-filled pleural space.

A child with a pneumothorax needs oxygen therapy to relieve respiratory distress. A thoracotomy catheter or needle may be placed in the pleural space and atmospheric air aspirated or low-pressure suction with water-seal drainage applied to remove accumulated air. In most children with pneumothorax, symptoms are relieved within 24 hours after suction is begun. The use of water-seal drainage with children is discussed in Chapter 41.

If the air in the pleural space is from a puncture wound such as a stab wound, cover the chest wound immediately with an impervious material, such as petrolatum gauze, to prevent further air from entering and help decrease the possibility of atelectasis. In an emergency, an impervious object can be your gloved hand.

Pneumothorax is always a potentially serious respiratory problem. The extent of the symptoms and the outcome will depend on the cause of entry of air into the pleural space and whether it can be removed.

Bronchopulmonary Dysplasia

Bronchopulmonary dysplasia (BPD) is chronic pulmonary involvement that occurs in 10% to 40% of infants who are treated for acute respiratory distress in the first days of life (Yost & Soll, 2009). The condition most often occurs in

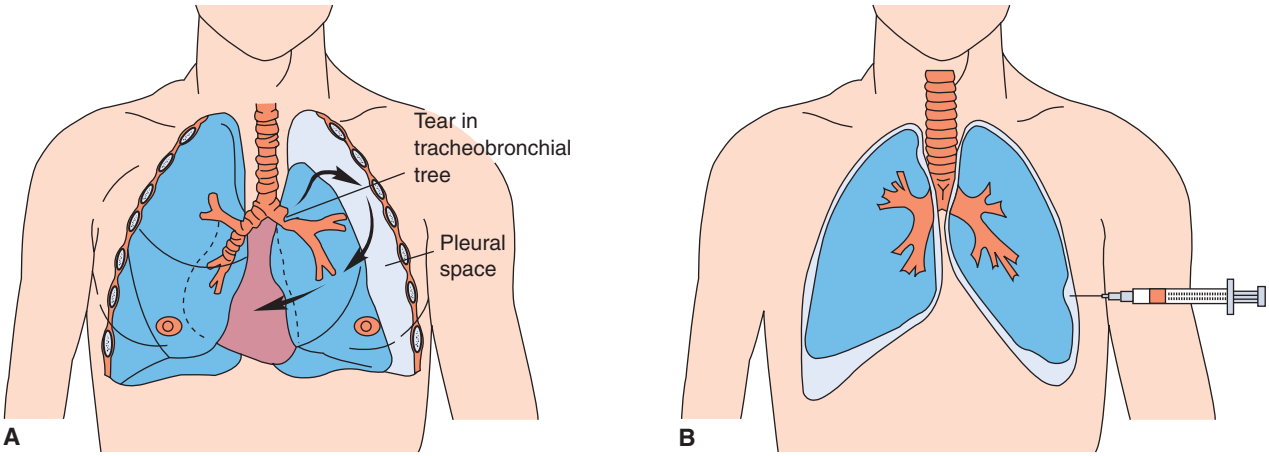

FIGURE 40.23 (**A**) Pneumothorax. A tear in the tracheobronchial tree has caused air to move into the pleural space; the lung collapses and the mediastinum shifts to the unaffected side. (**B**) Aspiration of air from the pleural space allows lung to re-expand after a pneumothorax.

infants who received mechanical ventilation for respiratory distress syndrome at birth. The condition is thought to occur from a combination of surfactant deficiency (decreased from lung trauma), barotrauma (lung damage from ventilator pressure), oxygen toxicity (from high levels needed to counteract the original respiratory distress), and continuing inflammation. It occurs most often in infants born weighting less than 1000 g.

Infants with BPD develop tachypnea, retractions, nasal flaring, tachycardia, oxygen dependence, and abnormal radiograph findings that show areas of overinflation, inflammation, and atelectasis. As the inflamed surfaces heal, they are left with fibrotic scarring. On auscultation, decreased air movement can be detected.

The clinical course ranges from a mild need for increased oxygen requirements that will gradually resolve over a few months to severe disease requiring chronic tracheostomy and mechanical ventilation for as long as the first 2 years of life. A respiratory infection greatly compromises the infant's ability to breathe.

Administration of a corticosteroid to reduce inflammation and a bronchodilator by nebulizer greatly improves respiratory function. Infants need to be monitored carefully for nutrition and fluid intake, especially if ventilator dependent. Because of the long hospitalization involved, parents need support to continue to visit and care for the child as what seemed to be a miracle at birth (their very small newborn survived) becomes years of specialized and expensive health care.

Tuberculosis

Tuberculosis is a highly contagious pulmonary disease. The causative agent is *Mycobacterium tuberculosis* (tubercle bacillus). The mode of transmission is inhalation of infected droplets. The incubation period is 2 to 10 weeks (Starke, 2007).

Children generally contract this disease from someone in the immediate family. When any member of a family contracts tuberculosis, all family members must be tested (a Mantoux skin test) to screen for the disease. In some children, the contact is not known, and the disease is first detected when symptoms appear. Children who are homeless or severely impoverished or who have chronic illness or malnutrition tend to be more susceptible than others because of their overall susceptibility to infection. It also occurs at a higher incidence in internationally adopted children (Long & Boffa, 2007).

When *M. tuberculosis* invades a child's lung, there is primary inflammation. The child develops a slight cough. As the disease progresses, anorexia, weight loss, night sweats, and a low-grade fever occur.

Leukocytes and lymphocytes invade the lung area to attack the tuberculosis organism and wall off the primary infection. This wall surrounding the bacteria then calcifies and confines the organism permanently. The development of a primary focus this way is the most usual form of tuberculosis in children. If a child is in poor health or does not have adequate calcium intake for the body to confine the infection, tuberculosis may spread to other lung areas or to other parts of the body (miliary tuberculosis). Common body sites that may be affected are bones and joints, lymph nodes, kidneys, and the subarachnoid space (tuberculous meningitis).

Assessment

All children should have a tuberculin test as part of basic preventive health care at 9 to 12 months of age, and yearly thereafter if they live in an area in which there is a high risk of tuberculosis. The test should not be done immediately after measles immunization or the test can read falsely negative (a child with tuberculosis will be considered free of the disease). Also, the measles vaccine can cause a primary tuberculosis focus to become miliary; it is important, therefore, to have a negative tuberculin result before administering this vaccine.

For a Mantoux test, also called a purified protein derivative (PPD) test, 5 units of protein derivative vaccine is injected intradermally, usually on the left lower arm. A health care professional inspects the area in 72 hours and notes the reaction. A positive reaction (the formation of 5 to 15 mm of reddened induration) indicates the child has been exposed to tuberculosis or has developed antibodies to the foreign products of the tuberculosis organism. Children with positive reactions need follow-up with a chest radiograph to ascertain the importance of the reaction; that is, whether a current infection exists. Skin testing should not be done on children who are known to have had tuberculosis. Such a child will have such an intense reaction that the skin at the site of the test may slough and necrose.

In the early course of tuberculosis, because the initial focus of the tuberculosis is so small, it may not be evident on a chest radiograph. As local inflammation occurs, however, cloudiness in the inflamed area will be noticeable on the film, as will calcification as it occurs.

To confirm a diagnosis of active disease, sputum may be analyzed. Make certain children understand that you want them to expectorate mucus raised from the lungs, not just from the back of the throat. Have a child demonstrate a deep cough to you so you can be sure you are both talking about the same thing. Infants and children younger than 5 years do not raise sputum but swallow it. In young children, therefore, gastric lavage may be necessary to obtain the sputum specimen (because tuberculosis bacteria are acid-fast, they are not destroyed by gastric secretions). Schedule this test early in the morning before the child eats. This prevents vomiting and also allows for the collection of large numbers of organisms because the child has been coughing sputum and swallowing it all night. To collect the specimen, a nasogastric tube is passed either nasally or orally. The stomach contents are then aspirated and placed in a sterile container for laboratory processing. Analysis is generally done for 3 consecutive days because individual specimens may not contain organisms.

Having a large tube passed into the stomach is uncomfortable, and the concept itself is frightening. Offer support during the procedure. Encourage children to express their feelings about the procedure afterward. They may enjoy playing with a plastic catheter and a doll into which a tube can be inserted after the procedure (therapeutic play). It is revealing to see the force and the anger they use to insert the tube into the doll. This helps you to understand how they envision the procedure.

Children who have primary tuberculosis are not infectious because they have a minimal pulmonary lesion and little or no cough. They need not be isolated. As soon as drug therapy has been started, they can return to regular activities, including school.

Before drug therapy was available, a diagnosis of tuberculosis meant a hospital stay of approximately a year. Parents who believe that tuberculosis is still treated this way will need assurance that it is all right for their child to return home and attend regular school as soon as their child begins taking medication.

Therapeutic Management

Several medications are effective against tuberculosis. Isoniazid (INH) is the drug of choice. INH may produce peripheral neurologic symptoms if pyridoxine (vitamin B_6) is not administered concurrently. Rifampin is a secondary drug often used in combination with INH. Para-aminosalicylic acid (PAS) is bacteriostatic to *M. tuberculosis* and for a long time served as the mainstay of therapy. However, PAS administration may lead to such gastrointestinal disturbances in children that it is not used as much as in the past. If it is prescribed, it should be administered after meals, never on an empty stomach.

Ethambutol is used with older children. It must be used with caution with infants because one side effect is optic neuritis; the inability to do adequate eye examinations in children under school age to discover this side effect can make ethambutol unsafe for long-term use.

In addition to drug therapy, children should ingest a diet high in protein, calcium, and pyridoxine, especially if INH is being used as they help supply nutrients necessary to wall off organisms in lung tissue.

Because tuberculosis therapy can last up to 18 months, a major concern during treatment is that the tuberculosis organism will become resistant to commonly used drugs. Children should have periodic chest radiographs for the rest of their life to make certain their disease does not become active again later in life. A woman who had tuberculosis as a child should tell her primary care provider about this when she becomes pregnant; lung changes that occur in pregnancy as a result of the pressure of the growing uterus against the lungs can break down calcifications and reactivate tuberculosis. Children who develop another chronic disease that interferes with appetite, and therefore with calcium intake, also have a high risk of reactivation of calcium-contained tuberculosis.

Because children will be taking medicine for a long time, they need periodic health care visits to evaluate the extent of drug adherence. Assess that they receive regular childhood immunizations so they do not contract a second disease until they have fully recovered from tuberculosis. It is most important to prevent pertussis (whooping cough) because the paroxysmal cough caused by this illness could easily reactivate tuberculosis lesions.

The Bacille Calmette-Guérin (BCG) vaccine is available against tuberculosis, but it is not used routinely in the United States. A skin test will be strongly positive after effective BCG vaccination. For this reason, most people advocate placing children on prophylactic INH when there is known tuberculosis in the home rather than vaccinating them against tuberculosis. With this method, as long as a repeat PPD test remains negative, you know that they are disease-free. After BCG vaccine is administered, the value of skin testing would be lost.

Cystic Fibrosis

Children with cystic fibrosis (CF) have a generalized dysfunction of the exocrine glands (Gardner, 2007). Mucus secretions of the body, particularly in the pancreas and the lungs, are so tenacious that they have difficulty flowing through gland ducts. There is also a marked electrolyte change in the secretions of the sweat glands (chloride concentration of sweat is two to five times above normal). The cause of the disorder is an abnormality of the long arm of chromosome 7. This results in the inability to transport small molecules across cell membranes; this leads to dehydration of epithelial cells in the airway and pancreas and dried secretions.

The disorder is inherited as an autosomal recessive trait. It occurs in approximately 1 in 2500 live births. It occurs most commonly in Caucasian children and rarely in black or Asian children. Although the disease can be fatal in early life, as many as 50% of children now live to be more than 30 years of age. With the availability of lung transplants, full life expectancy is possible. Because the gene that causes the disorder can be isolated, chorionic villi sampling or amniocentesis can be done early in pregnancy to detect fetuses who have the disease. All newborns can be screened at birth by a simple heel puncture blood sample for the disorder (Merelle et al., 2009). In the future, it is expected that gene therapy will be available to reverse the effect of the involved gene.

Boys with CF may not be able to reproduce because they have persistent plugging and blocking of the vas deferens from tenacious seminal fluid. Girls may have such thick cervical secretions that sperm penetration is limited. Artificial insemination or in vitro fertilization can be accomplished if they desire to become pregnant.

Pancreas Involvement

The acinar cells of the pancreas normally produce lipase, trypsin, and amylase, enzymes that flow into the duodenum to digest fat, protein, and carbohydrate. With CF, these enzyme secretions become so thickened that they plug the ducts; eventually, there is such back-pressure on the acinar cells that they become atrophied and then are no longer capable of producing the enzymes. The islets of Langerhans and insulin production are little influenced by this process until late in the disease because they have endocrine (ductless) activity.

Without pancreatic enzymes in the duodenum, children cannot digest fat, protein, and some sugars. The child's stools become large, bulky, and greasy **(steatorrhea).** The intestinal flora increases because of the undigested food; this, when combined with the fat in the stool, gives the stool an extremely foul odor, often compared to that of a cat's stool. The bulk of feces in the intestine leads to a protuberant abdomen. Because children are benefiting from only about 50% of the food they ingest, they show signs of malnutrition—emaciated extremities and loose, flabby folds of skin on their buttocks. The fat-soluble vitamins, particularly A, D, and E, cannot be absorbed because fat is not absorbed, so children develop symptoms of low levels of

these vitamins. These four symptoms—malnutrition, protuberant abdomen, steatorrhea, and fat-soluble vitamin deficiencies—are the same four symptoms that are part of celiac disease (malabsorption syndrome), so they are referred to as a celiac syndrome (see Chapter 45).

Meconium in a newborn is normally thick and tenacious. In approximately 10% of children with CF, it may be so thick, because pancreatic enzymes are lacking, that it obstructs the intestine (meconium ileus). The newborn develops abdominal distention with no passage of stool. Meconium ileus should be suspected in any infant who does not pass a stool by 24 hours of life (Jawaheer et al., 2007). Rectal prolapse from straining to evacuate hard stool is another common finding in infants with CF.

Lung Involvement

Thickened mucus pools in bronchioles. Pockets of infection then begin in these secretions. The organisms most frequently cultured are *Staphylococcus aureus, Pseudomonas aeruginosa,* and *H. influenzae.* Secondary emphysema (overinflated alveoli) occurs because air cannot be pushed past the thick mucus on expiration, when all bronchi are narrower than they are on inspiration. Bronchiectasis and pneumonia occur. Respiratory acidosis may develop because obstruction interferes with the ability to exhale carbon dioxide. Atelectasis occurs as a result of absorption of air from alveoli behind blocked bronchioles. The child's fingers become clubbed because of the inadequate peripheral tissue perfusion. The anterior-posterior diameter of the chest becomes enlarged.

Sweat Gland Involvement

Although the sweat glands themselves do not appear to be changed in structure, the electrolyte composition of perspiration is changed. The level of chloride to sodium is increased two to five times above normal. Some parents report they knew their newborn had the disease before they had laboratory tests done because when they kissed their child, they could taste such strong salt in the perspiration.

Assessment. If CF is not diagnosed by a screening blood sample at birth, it can be diagnosed by documenting the chromosomal abnormality, or by the history and the combination of the abnormal concentration of chloride in sweat, the absence of pancreatic enzymes in the duodenum, the presence of immunoreactive trypsinogen in the blood, and pulmonary involvement.

CF may be suspected in a newborn when a newborn loses the normal amount of weight at birth (5% to 10% of birth weight), but then, because the infant cannot make use of the fat in milk, does not gain it back at the usual time of 7 to 10 days and perhaps not until 4 to 6 weeks of age. Nurses often weigh newborn babies and infants at well child health visits so may be the first to detect this lack of weight gain. Nurses may also be the first health care provider to suspect CF because meconium is so tenacious an infant is unable to pass stool (meconium ileus). Chromosome analysis or analysis of serum immunoreactive trypsin (IRT) in the stool, which is elevated because obstruction in the pancreas occurs as early as during fetal life, confirms the diagnosis.

Children who are not diagnosed at birth may be seen in a health care setting at about 1 month of age because of a feeding problem. Using only about 50% of their intake because of their poor digestive function, they are always hungry. This causes them to eat so ravenously they tend to swallow air. This leads to colic or abdominal distention and vomiting. The appearance of typical CF stools (large and greasy) is an important finding because children with simple colic do not show these changes in stool consistency.

Respiratory infections develop at 4 to 6 months of age. Even at this early stage of the disease, wheezing and rhonchi may be heard on chest auscultation.

By the time a child with CF is a preschooler, a cough is a prominent finding. On percussion, the chest is hyperresonant, reflecting the emphysema present. Rales and rhonchi are heard. Clubbing of the fingers may already be apparent. It is rare for a child to go undiagnosed beyond this time because the symptoms of the illness have become so persistent and evident.

Sweat Testing. Sweat testing is a time-honored method for detecting the abnormal concentrations in sweat in children with CF. Sweat is collected by placing a filter paper on the skin and analyzed for sodium chloride content. With chromosomal determination available, sweat tests are no longer necessary, but parents may ask about the procedure if they hear about it from friends. A normal concentration of chloride in sweat is 20 mEq/L. A level of more than 60 mEq/L chloride in children is diagnostic of CF.

Duodenal Analysis. Analysis of duodenal secretions for detection of pancreatic enzymes reveals the extent of the pancreatic involvement. This is done by passing a nasogastric tube into the duodenum and then aspirating secretions for analysis. This test may take a considerable amount of time because the tube is allowed to pass through the pylorus and into the duodenum by natural peristaltic action. You can tell that a tube has passed from the stomach into the duodenum by aspirating secretions from the tube and testing them for pH. Stomach secretions are acid (pH less than 7.0); duodenal secretions are alkaline (pH more than 7.0). The initial insertion of the tube typically is frightening to children because they may choke and gag as it passes the pharynx. Children, however, are generally surprised that once the initial insertion is done, the tube is not uncomfortable. They need a great deal of support during the procedure, however, because it is so unusual for them and initially so uncomfortable. Duodenal analysis may also be done by endoscopy; for this, children usually receive conscious sedation (Lee et al., 2008).

The secretions removed from the duodenum are sent to the laboratory for analysis of trypsin content, the easiest pancreatic enzyme to assay. Keep the secretions cold during transport. They should be analyzed immediately for accurate results.

Stool Analysis. Stool may be collected and analyzed for fat content and lack of trypsin, although description of the large greasy appearance may be all that is necessary.

Pulmonary Testing. A chest radiograph generally confirms the extent of the pulmonary involvement (pockets of emphysema and perhaps beginning pneumonia infiltration are present). Pulmonary function tests may be done to determine if atelectasis and emphysema are present.

Therapeutic Management. Therapy for children with CF consists of measures to reduce the involvement of the pancreas, lungs, and sweat glands. Because so many organs are involved, care works best if it is a collaborative process (Rideout, 2007).

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Imbalanced nutrition, less than body requirements, related to inability to digest fat

Outcome Evaluation: Child's height and weight follow percentile growth curves; quantity of stool decreases; signs and symptoms of vitamin deficiency are absent.

Children with CF are placed on a high-calorie, high-protein, moderate-fat diet. Water-miscible forms of vitamins A, D, and E are supplemented. Medium-chain triglycerides are used with the diet because these are more readily digested than other oils. During the hot months of the year, extra salt may be added to food to replace that lost though perspiration.

Generally, infants with CF cannot be totally breast-fed because there is not enough protein in breast milk for them (they need large amounts because they cannot make use of all the protein they ingest). Breast-feeding with supplementary formula is required. Some of these children, unfortunately, are initially diagnosed as having a milk allergy and are treated by being placed on a soybean formula. This does not contain enough protein either, and their malnutrition increases greatly while they are taking this formula. A high-protein formula, such as Probana, is generally recommended as a supplement.

Because children with CF have a ravenous appetite, they eat well. Before each meal or snack, they need to take a synthetic pancreatic enzyme, pancreatic lipase (Cotazym or Pancrease), to replace the enzyme they cannot produce (Box 40.14). These synthetic enzymes are supplied in large capsules that must be opened for young children because they cannot swallow such a big capsule; infants, in particular, may not have enough gastric acids to dissolve the capsule. The powder from the capsule is then added to a small amount (no more than a teaspoonful) of food. It should not be added to hot food, or a large portion of enzyme activity can be destroyed. Also, it must not be added to the infant's bottle of formula, because the infant may not drink the entire bottle and therefore will not receive the total benefit of the enzyme. When children are taking a synthetic source of pancreatic enzyme this way, the size of stools and the accompanying foul odor decreases. Children begin to gain weight. In adolescence, children may have a great deal of difficulty eating enough to maintain weight, even with enzyme therapy, because their growth spurt requires so many additional calories.

If children with CF become overheated, they begin to lose excessive sodium and chloride through perspiration and become dehydrated. Caution parents to keep their house temperature at 72° F or below and to offer water frequently. They also need to supervise outside play to guard against overexertion or heat exposure.

Nursing Diagnosis: Ineffective airway clearance related to inability to clear mucus from the respiratory tract

Outcome Evaluation: Child's temperature is below 100.4° F (38.0° C); P_{O_2} is 80 to 90 mm Hg; P_{CO_2} is less than 40 mm Hg.

Unfortunately, the pulmonary effects of CF progress despite supplementation with pancreatic enzyme; infection from plugged airways is always a possibility. Therefore, it is important to try to keep bronchial secretions as moist and freely flowing as possible so they can drain from the bronchial tree. This is done by frequent nebulization or aerosol therapy followed by chest physiotherapy.

Be certain to observe children with CF frequently because their condition can change rapidly. If a portion of a lung becomes obstructed from a plug of mucus, a child can quickly experience respiratory difficulty. The right side of the heart tends to enlarge in children with chronic respiratory disease because the congestion in the lungs increases pressure in the pulmonary artery and the right ventricle. After a period of stress or exercise, children may begin to show signs of cardiac failure because their already enlarged heart cannot compensate any further.

Humidified Oxygen. Oxygen is supplied to children by mask, prongs, ventilators, or nebulizers. Mist can be supplied by an ultrasonic compressor and delivered through a nebulizer mask, which makes the

BOX 40.14 Focus on Pharmacology

Pancrelipase (Cotazym)

Classification: Pancrelipase is an enzyme replacement.

Action: Used to aid digestion in children with cystic fibrosis (Karch, 2009).

Pregnancy risk category: C

Dosage:

- Children 6 months to 1 year of age: 2000 U orally per meal
- Children 1 to 6 years of age: 4000 to 8000 U orally with each meal and 4000 U with snacks
- Children 7 to 12 years of age: 4000 to 12,000 U orally with each meal and with snacks

Possible adverse effects: Nausea, abdominal cramps, diarrhea, hypersensitivity

Nursing Implications

- Administer the drug before or with meals and snacks. Instruct parents and child to do the same.
- Caution child and parents to avoid inhaling powder or spilling it on the hands, because it may irritate the skin or mucous membranes.
- Do not crush or let the child chew the enteric form of the drug.
- Instruct the child and parents about possible adverse effects and encourage them to contact their health care provider should any become severe.

droplet size so small the mist reaches the smallest bronchial spaces.

Aerosol Therapy. Three or four times a day, children may be given aerosol therapy by means of a nebulizer to provide antibiotics or bronchodilators. Antibiotics are specifically determined by culture. A mucolytic, such as acetylcysteine (Mucomyst), can be added to the mist to aid in diluting and liquefying secretions. Children's coughs will become loose and productive after using aerosol therapy. Provide a box of tissues so a child can cough up these loose secretions. Observe children to ensure that they can cough and keep the airway clear. Never give cough syrups to suppress a cough, because getting secretions out is essential for air exchange and to prevent infection. Likewise, question an order for codeine as an analgesic, because codeine suppresses the cough reflex.

Chest Physiotherapy. Because the bronchial secretions with CF are so tenacious, even with liquefaction by mist or aerosol therapy, children may be unable to raise them. To aid drainage of secretions, children need chest physiotherapy frequently, approximately three or four times a day.

Activity. Children with CF need to maintain their usual activities as much as possible. When in bed, they need frequent position changes so that, at various times of the day, all lobes of their lungs will be encouraged to drain by being in a superior position. Be certain they sit up part of each day to drain the upper lobes. This change in position also helps to prevent skin breakdown over bony prominences.

Respiratory Hygiene. The sputum that a child coughs up may have a disagreeable taste or odor. Offer frequent mouth care, toothbrushing, and a good-tasting mouthwash to make the child's mouth feel fresh.

Nursing Diagnosis: Risk for impaired skin integrity related to acid stools

Outcome Evaluation: Child's skin does not exhibit areas of erythema or ulceration; rectal prolapse is not present.

Until children are regulated on pancreatic enzymes, their stool is particularly irritating because of its high fat content. Children who are not toilet-trained need to have their diapers changed immediately after they wet or pass stool so that they do not develop skin irritation and breakdown in the diaper area.

After a bowel movement, check the rectum for rectal prolapse. Because of weak musculature of the rectal area, this is a common complication. A prolapse of rectal mucosa appears as a bright-red mass protruding from the anal sphincter. This mucosa must be replaced promptly before its blood supply is compromised. Place the child on the slant board used for chest physiotherapy with the head lower than the buttocks; then, with a lubricated, gloved hand, gently replace the prolapsed rectal mass. Afterward, compress the buttocks together to maintain gentle pressure on the anus for a few minutes. This is much less of a problem in children who are receiving pancreatic enzymes than in those who are not, because the incidence of rectal prolapse decreases with better nutrition.

Nursing Diagnosis: Risk for compromised family coping related to chronic illness in a child

Outcome Evaluation: Family members state they have adequate resources to cope with current circumstances.

The parents of children with CF are asked to assume a great deal of responsibility for care of their child. Begin discharge planning when a child is first admitted to a hospital in terms of what changes need to be made to accommodate the child at home and to familiarize parents with the necessary care measures. For example, many children with this disorder sleep with oxygen by cannula at night when they are at home. Parents need to be taught the functions of oxygen and how to regulate the flow. This type of learning is most effective if a little is taught every day (for example, "Could you turn the oxygen on for me, Mrs. Smith? I'm ready to tuck Brian in to sleep" rather than a sit-down, let-me-tell-you-how-oxygen-works lecture given close to the day of discharge). Teach parents how to do chest physiotherapy the same way.

The family will have to think through how the care of this child will affect their home life. They are going to be spending a great deal of time caring for the child, so they will need to balance work, care of the child, and care of the rest of the family. Many parents become fatigued after the first week of having the child at home; they may believe that if they fall soundly asleep at night, they may not hear their child call to them if in distress. As they grow more confident in their ability to evaluate their child's condition before bedtime, their apprehension will lessen, but real confidence may not come for months, even years. This may always be a problem for some parents.

Be sure that parents have the telephone number of the health care provider they should call if they feel overwhelmed. Encourage parents to join a support group, so that there are other people available who understand and to whom they can voice their concerns. At these times, one of the most important needs they have is to verbalize to someone what it feels like to be the parent of a child with CF, including feelings of guilt they may be experiencing because the disease is inherited.

Adequate Rest and Comfort. Any child who has compromised lung function has a degree of dyspnea that leads to exhaustion. To counteract this, provide periods of rest during the day, but do not group too many activities or procedures together all at once, as this could exhaust a child. Plan a rest period before meals so that a child is not too tired to eat. Also plan for a long rest period before chest physiotherapy so that a child will be able to tolerate it better. Achieving a balance between allowing periods of rest and yet not doing all procedures at once is not an easy task.

Growth and Development. Children need to be exposed to as many normal life experiences as possible. This may be difficult because it is important not to tire the child out or expose the child to crowds of peo-

ple (possibly increasing the risk for infection). Assist parents with planning age-appropriate activities with the child.

Children should attend regular school if at all possible so they are provided with socialization experiences with other children. If this is not possible, a home tutor can be arranged for them. Urge children to participate to the extent they can in physical fitness activities in school or with friends. Use a reminder sheet as necessary so they can remember to take pancreatic enzymes with them if they are going to be eating lunch in the school cafeteria or outside the home.

Continuing Care. Ensure that children with CF receive periodic health assessments and routine childhood immunizations. It is not unusual for children with a chronic disease to fall behind in routine checkups and immunizations if they are hospitalized at the times these are routinely done. It is particularly important that children with CF receive the pertussis and measles vaccines, because these two infections cause severe respiratory complications. Children also should receive influenza, meningococcal, and pneumococcal vaccines.

As children with CF reach adolescence, they are candidates for lung transplants. Some of these are done as lower lobe transplants from a living donor. People who donate a single lobe in this manner report that they feel little loss of lung capacity afterward. A lung transplant is advantageous for children with CF because the new lung does not possess the defective gene that caused mucus to be so thick. Life span can greatly improve.

✔ Checkpoint Question 40.5

Children with cystic fibrosis take the pancreatic enzyme pancrelipase before each meal. You would prepare this by:

a. Opening the capsule and adding it to warm tea.
b. Adding it to at least 8 ounces of milk to drink.
c. Sprinkling it on a small amount of applesauce.
d. Teaching the child how to swallow large capsules.

Key Points for Review

- Respiratory tract disorders tend to occur more frequently in children than adults, because the lumens of children's bronchi are narrow and obstruction and infection can occur more easily.
- Infants with respiratory illness need extremely close observation because they cannot describe oxygen deprivation. Young children do not comprehend the fact that oxygen supports combustion. Observe them more frequently than adults to be certain that no flames, such as birthday candles, are brought within 10 feet of an oxygen source.
- Acute nasopharyngitis (common cold) is the most common infectious disease in children. There is no specific therapy for a common cold other than comfort measures.
- Tonsillitis is infection and inflammation of the palatine tonsils. Adenitis is infection and inflammation of the adenoid tonsils. Children with recurring infections may have their tonsils surgically removed.
- Laryngotracheobronchitis (croup) is inflammation of the larynx, trachea, and major bronchi. Epiglottitis is inflammation of the epiglottis. Both of these conditions can cause severe impairment of the airway. Children with epiglottitis should never be assessed for a gag reflex with a tongue blade because the elevated epiglottis can completely occlude the airway.
- Bronchitis is inflammation of the major bronchi and trachea. Bronchiolitis is inflammation of the fine bronchioles. Both conditions are caused by bacterial or viral invasion.
- Respiratory syncytial virus infection is an infection that accounts for the majority of lower respiratory infections in young children. Infants with RSV infections must be observed closely because they are prone to apnea.
- Pneumonia may occur from a variety of organisms (viral, pneumococcal, chlamydial, mycoplasmal, lipid, and hydrocarbon). Except for viral pneumonia, children need specific antibiotics, depending on the organism present.
- Asthma, a type I hypersensitivity reaction, is a diffuse and obstructive airway disease with wheezing as the most common symptom. Newer drugs such as leukotriene receptor antagonists and careful environmental control have aided in the management of this disorder.
- Tuberculosis is a lung infection that is growing in incidence, with some strains becoming very resistant to the usual therapy. The entire family needs drug therapy if one member develops a primary lesion.
- Cystic fibrosis is a disease in which there is generalized dysfunction of the exocrine glands. This results in malabsorption and tenacious pulmonary secretions, leading to infection and pneumonia. Lung transplantation can be used to replace the diseased lung tissue and increase the child's life span.

CRITICAL THINKING EXERCISES

1. Michael is the 4-year-old you met at the beginning of the chapter. His grandmother brought him to the emergency room because his respirations were rapid and he had a sharp, barking cough. He is diagnosed as having laryngotracheobronchitis (croup). He was crying loudly. What about Michael's actions would lead you to believe his airway is not yet extremely constricted? Would you encourage him to lie down and rest? What emergency care does Michael need?
2. One of Michael's observation unit roommates has a permanent tracheostomy tube in place from pulmonary dysplasia as an infant. Her parents are going to enroll her in kindergarten starting next month. What

precautions would you want to review with her parents to keep this experience safe?

3. When the 4-year-old in the ambulatory bed next to Michael returns from tonsillectomy surgery, what observations would be most important to make? Why is the 7th day after tonsillectomy surgery a particularly important day for close observation?
5. Examine the National Health Goals related to respiratory disorders in children. Most government-sponsored funds for nursing research are allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to Michael's family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to respiratory disorders in children. Confirm your answers are correct by reading the rationales.

Chapter 41

Nursing Care of a Family When a Child Has a Cardiovascular Disorder

KEY TERMS

- acyanotic heart disease
- afterload
- balloon angioplasty
- cardiac catheterization
- congestive heart failure
- contractility
- cyanosis
- cyanotic heart disease
- diastole
- innocent heart murmur
- left-to-right shunt
- organic heart murmur
- polycythemia
- postcardiac surgery syndrome
- postperfusion syndrome
- preload
- right-to-left shunt
- systole
- vasculitis

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe the common cardiovascular disorders of childhood.
2. Identify National Health Goals related to children with cardiovascular disorders that nurses could help the nation achieve.
3. Use critical thinking to analyze ways that nursing care of children with cardiovascular disorders could be more family centered.
4. Assess a child with a cardiovascular dysfunction.
5. Formulate nursing diagnoses for a child with a cardiovascular disorder.
6. Identify appropriate outcomes based on the priority needs of a child with a cardiovascular disorder.
7. Plan nursing care for a child with a cardiovascular disorder.
8. Implement nursing care for a child with a cardiovascular disorder such as teaching about the importance of taking prescribed medication.
9. Evaluate expected outcomes for achievement and effectiveness of care.
10. Identify areas related to the care of children with cardiovascular disorders that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of cardiovascular disorders with nursing process to achieve quality maternal and child health nursing care.

Megan is a newborn who was born with tetralogy of Fallot. By 1 hour of age, she developed rapid respirations, tachycardia, and cyanosis. An echocardiogram revealed the typical four structural defects of the syndrome. Megan's parents will be taking her home for a month to await cardiac surgery. They tell you their doctor instructed them to "watch her carefully" during that time. "What does that mean?" they ask you. Will they be able to take her outside in a stroller? Should she sleep in their bedroom? Exactly what should they watch for?

Previous chapters described the growth and development of well children. This chapter adds information about the child who is ill with a cardiovascular disorder and the stress that such a serious diagnosis places on families. Such information builds a base for care and health teaching for children with these disorders.

What advice would you give Megan's parents?

The cardiovascular system, the body system on which all other systems depend, consists of the heart, which acts as a pump; the blood, which provides the fluid and cells for transport of oxygen and nutrients; and the blood vessels, which provide the means and routes for transport throughout the body. The regular pumping of the heart propels oxygen and needed nutrients through the bloodstream to cells and allows waste products to be removed from cells and transported to the lungs or kidneys for excretion. The cardiovascular system also transports regulatory materials such as hormones, enzymes, and antibodies to the body systems. It can adapt to changing body needs by adjusting the rate and force of heart pumping, modifying the size of the blood vessels, and altering the volume and composition of the blood (Bashore & Granger, 2009).

Most cardiovascular disorders in children occur as a result of a congenital anomaly; either the heart developed inadequately in utero, or the heart cannot adapt to extrauterine life for some reason. Open-heart surgery often is the only treatment that will correct the primary congenital problem. Children also may experience acquired cardiovascular disorders, such as rheumatic fever or Kawasaki disease. All these disorders can lead to inadequate heart function.

Cardiovascular disorders are frightening for both children and parents, as even small children realize the importance of their hearts in sustaining life, and they recognize the seriousness of any illness that undermines the heart's activity. For the families of children with a cardiovascular disorder, understanding the functioning of the heart and circulation is an important first step toward coping with the illness. Cardiac disorders are a major focus of health promotion and disease prevention measures in both adults and children. National Health Goals related to cardiovascular illness and children are shown in Box 41.1.

BOX 41.1 ✻ Focus on National Health Goals

Cardiovascular illness is a major health problem in adults. However, the illness and its effects can be prevented or at least minimized by instituting measures early in childhood. A number of National Health Goals address ways that children should modify nutrition or exercise to achieve better cardiovascular health:

- Increase the proportion of adolescents who engage in vigorous physical activity that promotes cardiorespiratory fitness 3 or more days per week for 20 or more minutes per occasion from a baseline of 65% to at least 85%.
- Increase the proportion of persons aged 2 years and older who consume less than 10% of calories from saturated fat from a baseline of 36% to a target level of 75%.
- Reduce the proportion of children and adolescents who are overweight or obese from a baseline of 11% to a target level of 5% (http://www.nih.gov).

Nurses can help the nation achieve these goals by educating parents and children about the importance of reducing obesity and planning exercise and nutrition programs for sound cardiovascular health. It is equally important for nurses to caution parents not to start their children on reduced-fat diets until they are 2 years old, to allow for myelination of nerve cells.

Nursing research is needed to determine what weight loss programs are the most effective for children, what reduced-fat foods make the best finger foods for preschoolers, what snacks schools could provide in snack machines that would have a reduced fat content and would also be eaten by children, and what are effective ways to increase physical activity in adolescents who do not participate in any type of organized sport or exercise program.

Nursing Process Overview

For Care of a Child With a Cardiovascular Disorder

Assessment

Assessment of a child with a cardiovascular disorder includes both careful history taking and physical examination, because many of the signs and symptoms of heart disease in children are subtle. A variety of diagnostic studies such as echocardiography or electrocardiography or cardiac catheterization may be used to confirm the diagnosis and prepare a child for surgery. Teaching about these tests and providing psychological support to children and their families are two major responsibilities of nurses throughout the assessment process.

Remember that hypertension, hypercholesterolemia, and congenital heart disorders occur at higher incidences in some families than others because these disorders tend to be familial. Hypertension, for example, occurs at a higher rate in African Americans than in other groups. Nurses have a responsibility to educate adolescents about the importance of maintaining a sensible weight and sodium intake and reducing saturated fat and cholesterol intake, in an attempt to minimize these familial disorders. Be knowledgeable about cultural preferences in foods when planning preventive health care.

Nursing Diagnosis

Nursing diagnoses associated with heart disease in children usually speak to the effect of poor circulation on body tissues or the effect a serious disorder can create on the child or parents. Examples are:

- Decreased cardiac output related to congenital structural disorder
- Ineffective tissue perfusion related to inadequate cardiac output
- Deficient knowledge related to care of the child pre- and postoperatively
- Fear related to lack of knowledge about child's illness
- Interrupted family processes related to stresses of the diagnosis and care responsibilities
- Ineffective coping related to lack of adequate support people
- Impaired parenting related to inability to bond with critically ill newborn

If the concerns in the latter three diagnoses are not identified when a child is ill, they may continue long after a child is treated and returns home.

If a child will be undergoing surgery or cardiac catheterization, nursing diagnoses will focus on the psychological needs of the child and family for preparation and postprocedure care in addition to physical concerns after the procedure such as hypothermia related to cooling during surgery; powerlessness related to conscious sedation during cardiac catheterization.

Outcome Identification and Planning

Nursing planning is essential to help parents and children understand heart anatomy. A sound knowledge base will help them understand the need for diagnostic testing. Additional teaching is necessary to prepare parents and children for procedures or surgery and recovery at home. Teaching parents to conscientiously administer cardiac medications is another area where planning plays an important role. Part of this planning includes establishing appropriate outcomes to help a child and parents adjust to a serious diagnosis, now and in the future, such as coping with their present fears and caring for the child at home. Parents may wish to contact the American Heart Association (www.americanheart.org) for educational materials and family support groups in their area.

Implementation

Nursing interventions in the care of children with a cardiovascular disorder include teaching, providing an opportunity for children and their families to express fears about a child's illness and treatment plan, providing physiologic and psychological support such as comfort measures after surgery, and caring for a child in cardiac failure. An equally important role is teaching prevention of heart disease. Measures such as promoting nonsmoking and exercise, maintaining appropriate weight, and eating a low-fat diet are discussed in Chapter 32.

Outcome Evaluation

Outcome evaluation should be both short and long term for the child and family. It is important for families to receive adequate immediate support during procedures and treatment. If long-term care is necessary, evaluating the family's ability to think of their child not in terms of illness but in terms of wellness is also key. Provide opportunities for parents to express their concerns about their child at follow-up visits to help address any misconceptions about their child's future.

Examples suggesting achievement of outcomes are:

- Child's heart rate remains within accepted parameters for age.
- Child demonstrates age-appropriate coping skills related to diagnosis and possible surgery.
- Parents demonstrate competence with procedures required for care of their child.
- Parents exhibit positive coping skills related to their child's diagnosis and required care to foster optimal growth and development in their child.
- Parents verbalize positive aspects about their child.

THE CARDIOVASCULAR SYSTEM

Embryologic development of the heart is described in Chapter 9. Cardiac adaptations at birth are described in Chapter 18. After these adaptations, the heart can be thought of as consisting of two pumps: the right side pumps blood to the lungs, where it is oxygenated before returning to the left side of the heart; the left side pumps the oxygenated blood to the peripheral tissues through systemic arteries. After supplying nutrients and collecting wastes, the blood returns through the veins to the right side of the heart, where the cycle begins again. Contraction of the chambers is termed **systole**; relaxation is termed **diastole**. Normal heart anatomy is shown in Figure 41.1.

Most heart disease in children occurs because embryonic structures necessary for fetal life did not close at birth or the heart originally formed inappropriately. For example, a septal defect between the right and left sides of the heart may remain open. Because pressure and volume on the left side of the heart are greater than on the right side, blood will flow through the connecting opening left to right, or from the area of stronger heart action to the area of weaker heart action, compromising right-sided function.

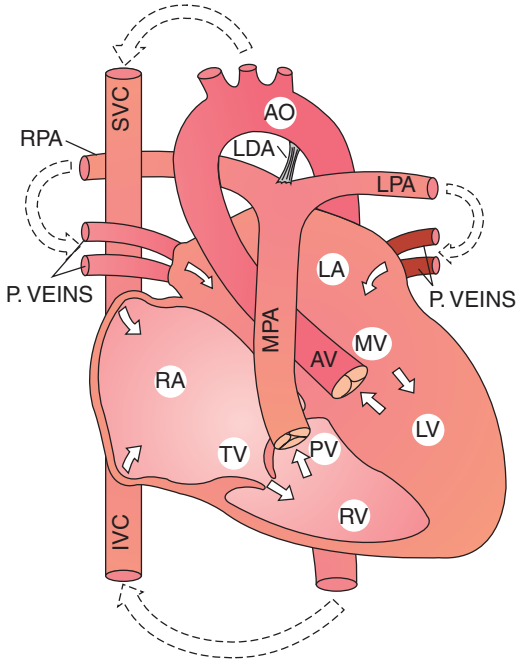
Cardiac output (CO) is the volume of blood pumped by the ventricles each minute. It is calculated by multiplying stroke volume (the volume of blood a ventricle ejects during systole) by the heart rate (beats per minute). CO is affected by three main factors: preload, contractility, and afterload. **Preload** is the volume of blood in the ventricles at the end of diastole (the point just before contraction). **Afterload** refers to the resistance against which the ventricles must pump. **Contractility,** the ability of the ventricles to stretch, refers to the force of contraction generated by the myocardial muscle. The Frank-Starling law predicts that the stroke volume can be increased by increasing the stretch of the fibers. Excessive stretch, however, results in a decrease in cardiac output as the heart tires. Much of the therapy of heart disease is aimed at reducing preload and afterload and increasing contractility to promote better cardiac output.

ASSESSMENT OF HEART DISORDERS IN CHILDREN

The assessment of heart disease in children begins with a thorough history and a physical assessment. More specific diagnostic studies, such as electrocardiography or echocardiography, are ordered as indicated. Because all children with heart disorders have an increased risk of poor tissue perfusion, which may affect growth and development, developmental testing also is incorporated into the assessment.

History

Some congenital heart disorders, such as atrial septal defects, may have a polygenic inheritance pattern. Because the heart arises from the same embryonic origin as the kidney, heart disorders often occur in conjunction with renal disease. Heart disorders also occur as an anomaly in chromosomal disorders such as Down syndrome (Marian, Brugada, & Roberts, 2008).



AO–Aorta
AV–Aortic valve
IVC–Inferior vena cava
LA–Left atrium
LPA–Left pulmonary artery
LV–Left ventricle
MPA–Main pulmonary artery
MV–Mitral valve
LDA–Ligamentum ductus arteriosus
PV–Pulmonary valve
P. Vein–Pulmonary vein
RA–Right atrium
RPA–Right pulmonary artery
RV–Right ventricle
SVC–Superior vena cava
TV–Tricuspid valve

FIGURE 41.1 Anatomy of the normal heart.

As a result of technological advances in prenatal health care, such as prenatal ultrasound, which can show poor heart action or a enlarged heart, heart disease may be recognized as early as fetal life. However, even with these advances, heart disease may not be detected before birth. In the newborn period, because the newborn heart rate is so rapid that extra sounds of abnormal circulation may not be heard, heart disease still may not be detected. Because of relatively high pulmonary resistance, defects of the septum may not be readily apparent until about 2 weeks after birth. Infants with heart disease generally have tachycardia and tachypnea. The infant who is breathing rapidly has to stop sucking on a bottle or breast frequently to breathe. The infant who is easily fatigued because of ineffective heart action has to stop sucking to rest before finishing a feeding. Heart disease may be first discovered, therefore, when an infant is brought to a primary care setting at 1 or 2 weeks of age because the child is so fatigued the child is unable to suck long enough to obtain adequate calories or fluid.

A history should include a thorough pregnancy history to try to determine whether an intrauterine insult could have led to poor fetal formation. Cardiac anomalies can occur as a result of intrauterine infections such as toxoplasmosis, cytomegalovirus, or rubella. Also ask whether the mother took any medication during pregnancy, whether nutrition was adequate, or whether she was exposed to any radiation, because these may also contribute to congenital heart disorders.

A mark of older children with heart disease is that they become easily fatigued. When obtaining the history, ask how much activity it takes before a child becomes tired: an hour of strenuous play? A short walk? Be sure parents are not confusing sedentary activities (the child who prefers to sit and read) with activities that are the result of fatigue such as coming home from school and falling asleep day after day.

Ask about a child's usual position when resting. Some infants with congenital heart disease prefer a knee–chest position, whereas older children often voluntarily squat. These positions are unusual in children but trap blood in the lower extremities because of the sharp bend at the knee and hip, allowing the child to oxygenate the blood remaining in the upper body more fully and easily. Also ask about frequency of infections, because children with heart disease have a higher incidence of lower respiratory tract infections than do other children, probably due to less than usual pulmonary circulation. Children with left-to-right shunts tend to perspire excessively because of sympathetic nerve stimulation. Ask if there is an indication of this. Urine is produced only when cardiac function is adequate to perfuse the kidneys. Ask if an infant is wetting diapers or if an older child is voiding normally to discover this. Edema from retained fluid is a late sign of heart disease in children. If it does occur, periorbital edema generally occurs first. **Cyanosis** (a blue tinge to the skin) may occur if a shunt allows deoxygenated blood to enter the arterial system. Such infants generally fail to thrive and are below usual height and weight on a standard growth chart. Children with coarctation of the aorta, discussed below, who have high blood pressure in the head and upper extremities, have a history of nosebleeds and headaches. Because of corresponding low blood pressure in the lower extremities, such children may have pain in the legs on running (reported as "growing pains").

Physical Assessment

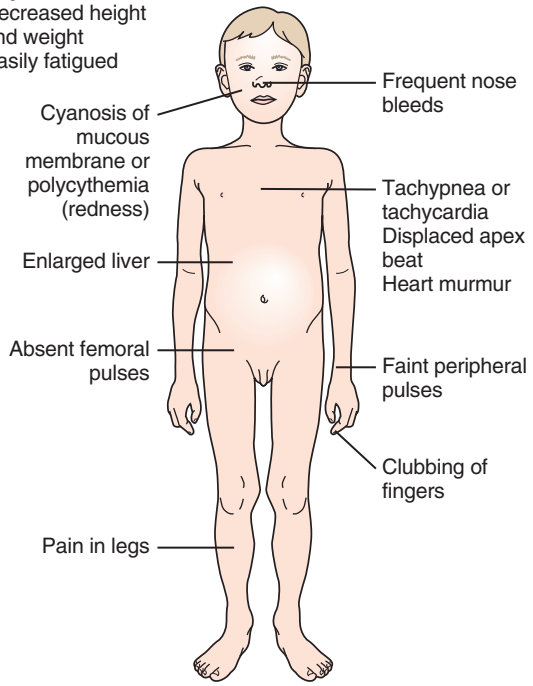
Physical assessment of a child with a suspected heart disorder begins with measuring height and weight and comparing these findings against standard growth charts. A thorough physical examination should then be done, with particular emphasis on certain body parts or systems (Box 41.2).

Because a major part of the physical assessment will include inspection, palpation, and auscultation of the chest for heart function, it is best if a child is relaxed and not crying. Provide age-appropriate toys that can distract a child readily.

Box 41.2 Assessment
Assessing a Child With a Cardiovascular Disorder

History
Chief concern: Fatigue, cyanosis, frequent upper respiratory infections, feeding difficulty, poor weight gain, growth failure.
Past medical history: Infection during pregnancy, difficulty with resuscitation at birth.
Family history: Other members with heart disorders.

Physical examination
Decreased height and weight
Easily fatigued



A bottle of formula or breast milk (or asking the mother to breastfeed) can help comfort an infant. Play with both children and infants if possible before an examination so they are acquainted and are not afraid of you.

General Appearance

Inspect toes and fingers (particularly the thumbs) for clubbing and color. Assess capillary refill time by applying slight pressure on a fingernail and quickly releasing. The nailbed will blanch white and then quickly return to pink in a child with good circulation and oxygenation. In a child with poor tissue perfusion, the pink color returns slowly (more than 5 seconds).

The mucous membranes of the mouth are the most likely place for cyanosis to be visible, so always assess the buccal membrane and lips for a blue color. Any time hemoglobin is reduced below 4 to 6 g per 100 mL, cyanosis may not be evident because the severe anemia masks it. Cyanosis persisting for over 20 minutes after birth (except for acrocyanosis) suggests serious cardiopulmonary dysfunction. If the cyanosis increases with crying, cardiac dysfunction is suggested, as this implies the infant cannot meet the increased circulatory demands of extrauterine life. If the cyanosis decreases with crying, pulmonary dysfunction is suggested because crying deepens respirations and aerates more lung tissue.

A ruddy complexion may be present in some children with heart disease because the body overproduces red blood cells **(polycythemia)** in an attempt to better oxygenate body cells. Also observe for lethargy and rapid respirations, symptoms that the heart is an ineffective pump.

Inspection of the chest may reveal a prominence of the left side and obvious heart movement (the apex beat, or point of maximum impulse). If a chest is extremely flat, loud innocent murmurs, accentuated heart sounds, and palpable cardiac activity may be very noticeable because of the proximity of the heart to the chest wall.

Pulse, Blood Pressure, and Respirations

The techniques for assessing pulse and blood pressure are described in Chapter 37. Normal findings for children of different ages are shown in Appendix G. Abnormal pulse patterns that tend to occur in children with heart disorders are shown in Table 41.1. Tachycardia is a pulse rate more than 160 beats per minute in an infant and more than 100 beats per minute at 3 years of age or older. An increase in pulse rate over these standards needs further investigation. Tachycardia is particularly significant if it persists during sleep, when the possibility of excitement and activity is removed.

Murmurs of no significance are termed functional, insignificant, or innocent murmurs. In discussing such murmurs with parents, the term **innocent heart murmur** is best to use because it most clearly describes that the sound heard is not important or is nothing to worry about. Such murmurs probably reflect a normal variation of vibration in the heart or pulmonary artery.

Although innocent murmurs are of no consequence, parents need to be told when their child has one because this finding will undoubtedly be discovered again at a future health assessment. Activities need not be restricted when a child has an innocent murmur and the child requires no more frequent health appraisals than other children. Innocent murmurs do not turn into serious murmurs so parents should not view them as a prelude to heart disease. Innocent murmurs may become more pronounced during

TABLE 41.1 ✻ Abnormal Pulse Patterns

Pulse Pattern	Description
Water hammer	Very forceful and bounding pulse (Corrigan's pulse); capillary pulsations possibly apparent even in the fingernails; suggestive of cardiac insufficiency, as in patent ductus arteriosus
Pulsus alternans	A pulse of one strong beat and one weak beat; suggestive of myocardial weakness
Dicrotic	A double radial pulse for every apical beat; symptomatic of aortic stenosis
Thready	Weak and usually rapid pulse; suggestive of ineffective heart action

TABLE 41.2 ✻ Comparison of Innocent and Organic Murmurs

Characteristic	Innocent	Organic
Timing	Systolic	Systolic or diastolic
Duration	Short	Longer
Quality	Soft, musical	Harsh, blowing
Intensity	Soft	Loud
Position in which heard	Usually supine position	Heard in all positions
Affected by exercise	Yes	No

febrile illness, anxiety, or pregnancy. This is why they may be audible for the first time at a hospital admission or at a sick-child visit. At future health assessments, parents may need to be reassured again that a murmur is innocent.

If a murmur occurs as the result of heart disease or a congenital defect, it is an **organic heart murmur.** The characteristics of innocent and organic murmurs are compared in Table 41.2.

To help differentiate innocent from organic murmurs, describe any murmur that you hear according to:

- Its position in the cardiac cycle, that is, early systolic, midsystolic, late diastolic, etc.
- Duration (how long the sound lasts)
- Quality (blowing, rasping, rumbling)
- Pitch (high- or low-sounding noise)
- Intensity (loudness)
- Location (where it is heard best or the point of maximum intensity)
- Presence of a thrill (a palpable purring sensation)
- The response of the murmur to exercise or change of position.

The intensity, or loudness, of the murmur is graded according to standard criteria shown in Table 34.9, Chapter 34.

Diagnostic Tests

The diagnostic studies performed on a child with suspected heart disease vary with the specific lesion suspected.

Electrocardiogram

An *electrocardiogram* (ECG) is a written record of the electrical voltages generated by the contracting heart. It provides information about heart rate, rhythm, state of the myocardium, presence or absence of hypertrophy (thickening of the heart walls), ischemia or necrosis due to inadequate cardiac circulation, and abnormalities of conduction. It also can provide information about the presence or effect of various drugs and electrolyte imbalances (Morelli, Biancaniello, & Chandran, 2007).

On an ECG waveform tracing, an upward pattern indicates a positive voltage, whereas a downward pattern indicates a negative voltage. The heartbeat is initiated by the sinoatrial (SA) node in the right atrial wall near the entrance of the superior vena cava. From the SA node, the electrical impulse spreads over the atria, reaching the atrioventricular (AV) node in the lower right atrium. From there, it spreads through the AV bundle (bundle of His) and the Purkinje fibers to the walls and septum of the ventricles. At the point that the ventricles have filled, the electrical flow has reached a peak, causing the ventricles to contract.

A normal ECG consists of an atrial wave (the P wave, denoting atrial contraction), a brief hesitation before the AV node is activated, then the prominent peak as the ventricles contract (the QRS spike), another brief hesitation, and then a large slow wave caused by ventricular recovery (the T wave) and often an incompletely understood additional slow wave (the U wave; Fig. 41.2). A longer-than-normal P wave suggests that the atria are hypertrophied and it is taking longer than usual for the electrical conduction to spread over the atria. A lengthened P-R interval suggests that there is difficulty in coordination between the SA and AV nodes (first-degree heart block). A heightened R wave indicates that ventricular hypertrophy is present. An R wave that is decreased in height means that the ventricles cannot contract fully, as happens if they are surrounded by fluid (pericarditis).

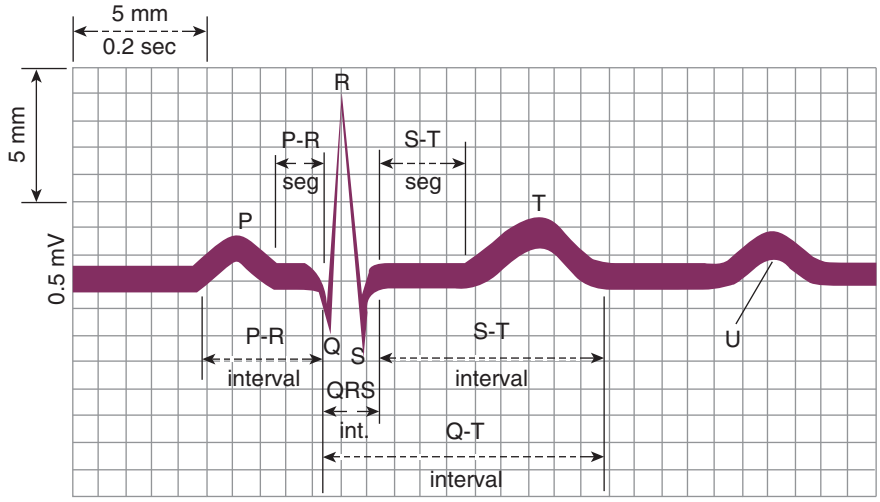


FIGURE 41.2 A normal ECG configuration.

Elongation of the T wave occurs in hyperkalemia; depression of the T wave is associated with anoxia; depression of the ST segment is associated with abnormal calcium levels.

✔ Checkpoint Question 41.1

Megan has a heart murmur from tetralogy of Fallot, a congenital heart disorder. This type of murmur is termed:

a. Innocent
b. Functional
c. Organic
d. Symmetrical

Radiography

X-ray examination can furnish an accurate picture of the heart size and the contour and size of the heart chambers. It can reveal fluid collecting in the lungs or pulmonary artery from cardiac failure. It also can be used to confirm the placement of pacemaker leads. In a posteroanterior view (in children over 1 year of age), if the cardiac width is more than half the chest width, it indicates that the heart is unusually enlarged. In infants, because of the more horizontal position of the heart, this ratio must be increased to more than half.

In addition to a chest radiograph, an upper gastrointestinal (UGI) series may be done. This is because the esophagus is located so close to cardiac chambers that when it is visualized with barium, it can help define cardiovascular structures. Even with this technique, interpretation of atrial or ventricular hypertrophy in infants and children by radiography is difficult. X-ray findings are therefore usually complemented by ECG, a more sensitive and accurate measure of ventricular enlargement.

Fluoroscopy, a form of x-ray, provides a permanent motion-picture record of the size and configuration of the heart and great vessels, lungs, thoracic cage, and diaphragm. Because prolonged observation is necessary to record this information, special precautions must be taken to protect a child and health care personnel from radiation during an assessment.

In radioangiocardiography, a radioactive substance such as technetium is injected intravenously into the bloodstream. As the substance circulates through the heart, it may be traced and recorded on videotape. The procedure involves a low dose of radiation and may be used to demonstrate, in particular, septal shunts.

Generalized angiography, or instillation of dye followed by x-rays, has little value in demonstrating pediatric heart defects. Selective angiocardiography, however, performed as part of a cardiac catheterization, allows identification of specific heart abnormalities if followed by serial x-ray films. After a contrast medium has been introduced into a specific heart chamber, closed-circuit video equipment records fluoroscopy pictures. Although an excellent diagnostic technique, angiocardiography is not without hazard: deaths have been reported from sensitivity to the dye used, cardiac arrhythmias, and pulmonary edema.

Echocardiography

Echocardiography, or ultrasound cardiography, has become the primary diagnostic test for heart disease (Marijon et al., 2007). High-frequency sound waves, directed toward the heart, are used to locate and study the movement and dimensions of cardiac structures, such as the size of chambers, thickness of walls, relationship of major vessels to chambers, and the thickness, motion, and pressure gradients of valves. This technique is referred to as M-mode, a single beam that reveals chamber contractility; two-dimensional, a technique used to reveal chamber and vessel size; and Doppler technique, which reveals the velocity of blood flow. Remind parents that echocardiography does not use x-rays so it can be repeated at frequent intervals without exposing children to the possible risk of radiation. It may be done using a transesophageal probe to better reveal heart chambers (Lim et al., 2007). Fetal echocardiography can reveal heart anomalies as early as 18 weeks into a pregnancy. This can alert staff to be prepared with immediate resuscitation or other needed equipment at the baby's birth (DeMaria & Blanchard, 2008).

Phonocardiography and Magnetic Resonance Imaging

A *phonocardiogram* is a diagram of heart sounds translated into electrical energy by a microphone placed on the child's chest and then recorded as a diagrammatic representation of heart sounds. The technique can measure the timing of heart sounds that occur too quickly or at too high or too low a sound frequency for the human ear to detect by direct auscultation. Magnetic resonance imaging (MRI) may also be used to evaluate heart structure or size or blood flow (Laifer-Narin et al., 2007).

Exercise Testing

Exercise tests using treadmill walking to demonstrate that the pulmonary circulation can increase to meet the increased respiratory demands of exercise may be performed with children, although these tests are not used as extensively with children as they are with adults. With children who have heart defects that obstruct the flow of blood to the lungs (such as pulmonary stenosis), accommodation to exercise is not possible, and such a test can cause extreme exertional dyspnea. Such tests are difficult to perform successfully with young children because they require the child's cooperation.

Laboratory Tests

Children with heart disease usually undergo a number of blood tests to support the diagnosis of heart disease or to rule out anemia or clotting disorders. Hematocrit or hemoglobin studies are usually obtained to assess the rate of erythrocyte production, which may increase in an attempt to produce more oxygen-carrying red blood cells. If the increase in the number of red blood cells is extreme (polycythemia), there will be a corresponding increase in blood volume and possibly an increase in blood viscosity. Newborns are normally slightly polycythemic. In a newborn, polycythemia is defined as a hemoglobin level over 25 g per 100 mL or a hematocrit level over 70%. In an older child, polycythemia is defined as a hemoglobin level over 16 g per 100 mL or a hematocrit level over 55%. An elevated erythrocyte sedimentation rate (ESR) denotes inflammation and is useful in documenting that an inflammatory process, such as occurs with rheumatic fever, Kawasaki disease, or myocarditis, is present (Smith, 2008).

Blood gas levels also are determined. To test for this, a child is given 100% oxygen for about 15 minutes. If the child

still has a P_{O_2} less than 150 mm Hg after this time, a shunt directing deoxygenated blood into oxygenated blood can be suspected. Oxygen saturation levels also are assessed; children with a deoxygenated to oxygenated shunt will have a lower-than-normal oxygen saturation level in arterial blood. Normally, arterial blood oxygen saturation is 95% to 100%; oxygen saturation is usually less than 92% when venous arterial shunts are present.

Before cardiac catheterization or surgery, blood clotting must be assessed. Expect prothrombin and partial thromboplastin times and platelet count studies to be completed before the procedure. Some children with polycythemia from heart disease have an associated reduced platelet count (thrombocytopenia). Because platelet formation is necessary for blood coagulation, the platelet count must be corrected before cardiac surgery.

In children with heart failure, a serum sodium level may be obtained to ensure that an increased sodium level is not causing edema. All children receiving diuretics should have serum potassium levels determined periodically because diuretics tend to deplete the body of potassium. Low serum potassium levels potentiate or increase the effect of cardiac glycosides, such as digoxin. For this reason, serum potassium levels are also usually obtained in children receiving these medications.

HEALTH PROMOTION AND RISK MANAGEMENT

Cardiac disease prevention in adults has received extensive attention in health literature. Because the risk factors that lead to adult heart disease, such as obesity, high cholesterol serum levels, and lack of consistent exercise, involve health habits that begin in childhood, prevention of cardiac disease has shifted from an adult to a child focus. Early interventions to reduce risk factors in early life should have a major impact on reducing the incidence of heart disease in the next generation.

Risk Management for Congenital Heart Disease

The cause of congenital heart disease often cannot be documented, although it is associated with familial patterns of inheritance and possibly triggers such as infection during pregnancy. All women of childbearing age should be immunized against rubella (German measles) and varicella (chickenpox) because these viruses are known to cause heart damage in a fetus if the mother contracts them during pregnancy. Because some types of congenital heart disorders have a familial incidence, parents who have a family member born with a heart defect need to alert their primary care provider so that other children can be carefully screened prenatally and at birth for a similar disorder.

Risk Management for Acquired Heart Disease

Acquired heart diseases in children that have identified risk factors include rheumatic fever, hypertension, and hyperlipidemia. Rheumatic fever is an autoimmune response that follows a group A beta-hemolytic streptococcal infection. Ensuring that all parents know that children with streptococcal infections from otitis media, streptococcal pharyngitis, and impetigo should receive adequate antibiotic therapy is essential for disease prevention (Chakko & Bisno, 2008).

Although hypertension (elevated blood pressure) occurs mainly because of a genetic predisposition, a high intake of sodium (such as table salt), lack of exercise, and obesity increase the chances that a susceptible child will develop the disorder by late childhood (Sondheimer, Yetman, & Miyamoto, 2008). If infants are never introduced to high-sodium foods, perhaps by the time they are selecting their own meals they will continue to eat a low-sodium diet, helping to prevent the development of hypertension in later life. For this reason, baby food manufacturers have stopped adding salt and monosodium glutamate to infant food. Urging school-age children and adolescents to reduce their intake of canned soups, cheese, lunch meats, and hot dogs, all foods with high sodium content, can reduce salt intake in these age groups. School nurses can play an important role in this effort by monitoring the foods served daily in school cafeterias and advocating for more nutritious menus. Beginning when a child is 3 years of age, blood pressure should be included as part of routine assessment to detect hypertension as early as possible (AAP, 2009).

Although the tendency toward hyperlipidemia is inherited as an autosomal dominant trait, a diet high in saturated fat has been implicated in the development of the syndrome. It is important that fat intake not be restricted in infants because they need fat and the calories it provides for brain growth. School-age children and adolescents, however, should reduce their fat intake to 30% of total calories (the same recommendation as for adults). The use of vegetable oils in place of saturated fat should begin when children begin solid food. Children from high-risk families (a family member has had an early myocardial infarction or hyperlipidemia) should be regularly screened for elevated cholesterol and triglyceride levels beginning at about 3 years of age. Children with low-density lipoprotein (LDL) levels greater than 130 mg/dL on two successive tests should receive nutritional counseling and instruction about a regular exercise program to enhance their health (Sondheimer, Yetman, & Miyamoto, 2008).

NURSING CARE OF THE CHILD WITH A CARDIAC DISORDER

Most parents have many questions about how to care for a child with heart disease. Encourage them to learn as much as possible about their child's disorder. Encourage them to handle and feed their newborn in the hospital so they can feel secure in caring for the infant at home. Be certain parents recognize that not all children with heart disease have the same disease or need the same degree of restriction. If this is not made clear to parents, they may unnecessarily limit their child's activity, assuming that because another child was told not to do some activity, their child should not do it either.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Parental health-seeking behaviors related to desire to be informed about child's disorder

Outcome Evaluation: Parents accurately state the nature of their child's illness and unique needs of the child; can name primary care providers who will follow child's progress; state they will telephone or e-mail if they have any questions.

Provide Information About Care. Parents generally ask whether it is safe to let a baby with heart disease cry. If the infant has a cardiac disorder such as tetralogy of Fallot in which hypercyanotic episodes tend to develop, the baby should not be allowed to cry for long periods of time (no baby should). However, crying for a few minutes while a parent warms formula or fully awakens at night will, as a rule, not harm the baby.

Another common question is, "Does our child need special nutrition?" As with all newborns, breastfeeding is the preferred method of feeding, and the average infant with heart disease can be successful at this. Salt is rarely restricted during early life because infants need sodium to regulate water balance. Because anemia stresses the heart, infants are generally given an iron supplement, either with formula or separately, to prevent iron deficiency anemia during the first year. They may be prescribed supplemental vitamins with formula or when breastfeeding is stopped. Because some infants with congenital heart disease tire readily, frequent small feedings during the day may be necessary. If a child is an extremely poor eater, a high-calorie formula or enteral or gastrostomy feedings may be necessary to supply enough calories for growth.

"How much activity can we allow the baby?" This answer depends on the type and extent of the heart disorder. As a rule, infants or young children naturally limit their own activity. Parents may need guidance, however, in setting sensible limits. Roughhousing with infants, such as tossing them up in the air and watching them squeal and laugh, or playing games such as chasing a ball, may not be advisable. Encourage parents to observe their infant carefully to recognize the first signs of respiratory distress and the point at which a child's activity is beginning to exceed tolerance. Caution parents to observe a child carefully and thoughtfully as new activities are introduced and new interests are gained, so that the child's activity is limited to what the heart can accommodate.

"What do we do if our child becomes ill?" Although children with congenital heart disorders are usually seen by a cardiologist for health supervision, it is important that they are also seen by health care personnel for routine care who can ensure they are receiving normal childhood immunizations and health guidance. As a rule, infants with heart disorders need prompt treatment for minor illnesses. The fever that accompanies a cold, for instance, can increase the metabolic rate of a child who has a severe congenital heart disorder to beyond the point at which the child's heart can compensate. Dehydration must be avoided in children with polycythemia or the polycythemia may become so severe that clotting or thrombophlebitis may result. It is also important that infections be treated vigorously to avoid infectious endocarditis.

Children with congenital heart disorders or rheumatic fever need prophylactic antibiotic therapy before they have oral surgery (tooth extractions or tonsils removed). This is because the streptococcal organisms generally present in the mouth can lead to infectious endocarditis if the organisms enter the bloodstream during surgery (Sykes & Farrington, 2007). It is a good rule for parents of children with structural heart defects to ask that their children be given prophylactic antibiotics before they visit the dentist at all, because they cannot always anticipate what procedures the dentist will do at any one visit. Oral penicillin is the preferred prophylactic antibiotic; erythromycin can be used for a child sensitive to penicillin. Some parents need reassurance that their child will not become immune to penicillin if it is taken this way over long periods. Children with congenital heart disorders should receive routine immunizations and influenza vaccines and should be considered for pneumonia vaccine.

Review Steps for Follow-Up Care and Emergencies. Before parents leave the hospital with a newborn who has a congenital heart disorder, be certain they have the name and number of the person to call if they have a question about their infant's health (their primary care provider and an emergency telephone number as a back-up). Review with them the steps to take if their child should become cyanotic, such as placing the child in a knee–chest position. Be certain they have an appointment for a first health assessment. This helps to reassure them that the responsibility of caring for this child will not be theirs alone but will be shared by concerned health care personnel. In many instances, parents are first-time parents. If they are unsure whether their child is in distress or ill, urge them to err on the side of caution by telephoning or bringing the child to their primary care setting. Everyone who cares for infants or children with heart disease appreciates the responsibility parents feel and the difficulty they can have in making health judgments about their child.

Most parents feel relieved to know they can have home follow-up after a hospitalization. In addition to providing opportunities for child and family assessment, home visits allow parents to discuss the frightening responsibility they feel and to obtain a second opinion about their child's health. Teach cardiopulmonary resuscitation (CPR) and how to activate the community's emergency medical system (EMS) before they leave the hospital. It may be reassuring for the parents to visit their closest EMS station so they know the staff is acquainted with their child should an emergency call be necessary.

The Child Having Cardiac Catheterization

Cardiac catheterization, a procedure in which a small radiopaque catheter is passed through a major vein in the arm, leg, or neck into the heart to secure blood samples or inject dye, helps to evaluate cardiac function (Sondheimer, Yetman, & Miyamoto, 2008). Diagnostic cardiac catheterization is used to help diagnose specific heart disorders in

anticipation of surgery. Interventional cardiac catheterization is used to correct an abnormality, such as dilating a narrowed valve by the use of a balloon catheter or other device. With both types, the pressure of blood flow in all heart chambers and total cardiac output can be evaluated. Blood specimens can be obtained to determine oxygen saturation levels, or a contrast dye can be injected for angiography. Electrodes can be introduced to record electrical activity and diagnose arrhythmias.

This procedure is usually completed as ambulatory or 1-day surgery using conscious sedation. Children must have a recent chest radiograph, ECG, and electrolyte levels, and blood must be typed and cross-matched before the procedure. Take and record pedal pulses for a baseline assessment. Also measure and record height and weight. This information is used to determine catheter size and the amount of sedation to be administered. Because the vessel site chosen for catheterization must not be infected at the time of catheterization (or obscured by a hematoma), do not draw blood specimens from the projected catheterization entry site before the procedure (generally a femoral vein). Children scheduled for the procedure are usually kept NPO for 2 to 4 hours beforehand to reduce the danger of vomiting and aspiration during the procedure.

In the cardiac catheterization room, ECG and pulse oximetry leads are attached. The site for catheter insertion is locally anesthetized with EMLA cream or intradermal lidocaine, and a catheter is threaded through a large-bore needle into a blood vessel. The specific vessel used differs according to the technique being planned. In neonates, an umbilical artery can be catheterized. For right-side heart catheterization, a right femoral vein or a vein in the antecubital fossa usually is used. Left-side heart catheterization can be performed using either a venous or an arterial approach. If done by the arterial route, a catheter is inserted into either the femoral or brachial artery. If a venous route is used, the catheter is inserted into the right femoral vein. Under fluoroscopy, the catheter is advanced to the right atrium and then through the foramen ovale. Once the catheter is in a selected heart chamber, radiopaque dye can be injected to outline the heart configuration (Fig. 41.3).

Cardiac catheterization has a mortality rate of under 0.1% when done as an elective procedure and approximately 2% to 5% when performed in a severely distressed child (Kern & King, 2008). Arrhythmias may occur while the catheter is being passed through the heart chambers or when contrast dye is being injected. Such arrhythmias generally are transitory or stop abruptly with withdrawal of the catheter. Inadvertent perforation of the heart may occur during passage of the catheter. Other complications include bleeding from the insertion site (secondary to heparin introduced into the catheter to reduce the possibility of clot formation) and thrombophlebitis (from platelet aggregation due to irritation by the catheter, a foreign body). Because cardiac catheterization may be necessary so that the cardiac surgeon can visualize and plan a cardiac repair, the key to making cardiac surgery safe, the benefit of the procedure outweighs these risks.

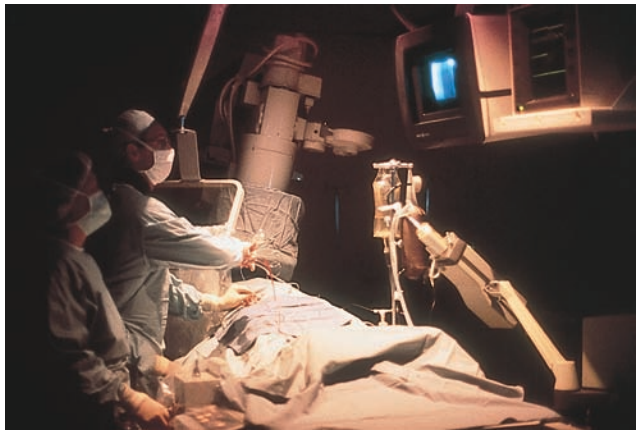

FIGURE 41.3 A child undergoing a cardiac catheterization. (© Hough/Custom Medical Stock Photograph.)

Nursing Diagnosis and Related Interventions: Preprocedure Phase

Nursing Diagnosis: Anxiety related to lack of knowledge about cardiac catheterization procedure

Outcome Evaluation: Parents and child state goal of procedure and reasons for preparation and aftercare measures; state that anxiety is less after teaching.

Because most cardiac catheterizations are done with children under conscious sedation, children may need more information about what is going to happen during this procedure than they will need for cardiac surgery, when they will be fully anesthetized. Provide explanations about the procedure for the child with the parents present, if possible. This allows parents to help reinforce the information. After this explanation, provide parents with a more detailed explanation of the procedure and allow time to ask any questions they do not want to ask in the child's presence.

Parents often need a review of heart anatomy. Although the cardiologist may have already done this, many parents appreciate reinforcement and a review of this information. Show them the pathway the catheter will take during the procedure.

Be aware that consenting to a cardiac catheterization experience brings with it the realization that cardiac surgery may be necessary. As a result, parents may be so concerned with what the procedure may reveal that they cannot listen well to preprocedure explanations. Allow them to accompany their child to the catheterization room and, if possible and appropriate, to remain there for support during the procedure if they choose.

Review with children what they will see in the catheterization room. Small children can become overwhelmed by seeing the actual equipment. Therefore, try building a facsimile room out of small cardboard boxes (representing the x-ray machine, the fluoroscopy screen, the ECG machine, and so forth). A puppet or small doll can serve as the patient in the miniature room. Dress the puppets in surgery suits and masks like those worn by cardiac catheterization personnel and act out what the child can expect to happen. Older children prefer a tour of the cardiac catheterization area and the opportunity to meet the personnel.

If children have never seen ECG leads or restraints before, let them touch and feel the equipment. Caution them the total procedure may be as long as 3 to 4 hours and that they will need to lie still during this time. Help them master imagery or another stress-reduction technique to help reduce apprehension.

Do not underestimate what children know about their heart's purpose and function; even preschoolers know their heart is vital to their body. Reassure them that the doctors are only taking a look at their heart during this procedure, not cutting it or removing any part of it.

Teach children of all ages that when the catheter is inserted, it will not hurt. Caution them, however, that they may feel a momentary speeding up of their heart, a feeling that is uncomfortable. When dye is inserted, they may feel a stinging sensation. Do not use the word "dye," which young children may misinterpret as "die." Instead, say "medicine." Caution them that the lights will be turned off after the medicine is injected so a doctor can watch the medicine on a television screen (fluoroscopy) as it passes through the heart. Let children know that after the procedure, a pressure dressing will be placed over the catheter insertion site to reduce the risk of bleeding. They will need to keep that extremity flat and unbent to prevent the dressing from loosening.

Nursing Diagnoses and Related Interventions: Postprocedure Phase

Nursing Diagnosis: Risk for ineffective cardiopulmonary and peripheral tissue perfusion related to cardiac catheterization

Outcome Evaluation: Child's vital signs remain within established parameters; absence of arrhythmia; absence of bleeding or hematoma formation at catheter insertion site; pedal pulse is present distal to catheter insertion site.

When a child returns from the procedure, assess the pressure dressing over the catheter insertion site to be certain the dressing is snug and intact and no bleeding is present. Instruct the child not to bend the hip (if the femoral site was used) or the elbow (if the brachial site was used) to keep the pressure dressing secure and to prevent hematoma formation. This is particularly important when an artery was used for catheterization; a loose dressing on an artery will cause a large blood loss in a very short time. Palpate pulses and assess color, temperature, and circulation (blanch the toe or fingernail and watch to see that it turns pink again readily) distal to the insertion site to ensure that blood flow in the extremity is unobstructed. If there is bleeding at the insertion site, apply firm, continuous pressure and notify the physician who performed the procedure immediately.

Children often appreciate being asked to describe their experience afterward. Saying out loud how frightened they were—by the x-ray machine being pushed in over them or by the thought of a tube going all the way into their heart—helps alleviate their fear and allows better acceptance of the procedure. Praise them for their cooperation during a very stressful experience. Introduce therapeutic play if needed.

Keep the child flat in bed for 2 to 3 hours until the child is completely awake from conscious sedation. This helps to prevent not only oozing at the insertion site but also postural hypotension, which may occur when a child rises suddenly after lying flat while under sedation for such a long period. In the immediate postcatheterization period, a child's blood pressure may be 10% to 15% lower than the precatheterization level because of the hypotensive effect of the radiopaque dye.

Cardiac arrhythmias and bradycardia may occur from the mechanical action of the catheter having touched the conduction nodes of the heart. Assess pulse, blood pressure, and respirations at frequent intervals (about every 15 minutes) for the first several hours to help detect if this has occurred. Monitor the pulse for a full minute to aid in recognizing abnormalities. Be alert for signs of arrhythmias. Small children cannot describe the odd feeling that accompanies an arrhythmia. Older children might describe it as their heart "fluttering" or "skipping beats." Therefore, be alert for signs of increasing anxiety in children after a catheterization; this may be a child's way of reporting these feelings.

Infants may need intravenous (IV) fluid during the procedure and for several hours afterward to prevent dehydration, which could result from being NPO for a long period of time. If an infant is polycythemic, IV fluid helps minimize the risk of vessel thrombi. Regulate IV fluid carefully to prevent heart failure from fluid overload.

Assess temperature immediately after the procedure to determine a baseline. Some children have a transient elevation in temperature already due to physiologic dehydration as a result of having been NPO or as a reaction to the dye. Others have slightly subnormal temperature readings from lying in a cool procedure room for a lengthy period. This below-normal body temperature quickly compromises respiratory and heart action because, to raise body temperature, infants must increase their metabolic rate. This requires rapid breathing and increased heart action, which can lead to exhaustion. Infants may need to be placed under radiant heat warmers to help regain and maintain normal body temperature and also to allow accurate temperature determinations.

The adverse effects of cardiac catheterization may be episodes of apnea, sternal retractions, or dyspnea. If oxygen was administered during the catheterization procedure, it may be continued for a period of time after the procedure to reduce the stress of respirations. Like arrhythmias, dyspnea, bradycardia, and blood pressure anomalies may be transient, but all should be reported so they can be evaluated.

Nursing Diagnosis: Risk for infection related to presence of cardiac catheterization incision site

Outcome Evaluation: The child's temperature remains less than 100.4° F (38.0° C) axillary; the catheter insertion site appears free of erythema or drainage.

If the dressing for a cardiac catheterization is over the femoral artery or vein, keep it clean of stool and urine. Waterproofing the dressing with plastic may be necessary. Also check the insertion site for signs of infection, because any opening in the skin is a portal of entry for bacteria. Alert parents to observe the catheter insertion site daily for redness. Most parents are advised to monitor their child's temperature daily for about 3 days and to omit tub baths and strenuous exercise for their child for 2 to 3 days to aid healing.

✔ Checkpoint Question 41.2

Megan is scheduled for a cardiac catheterization. Why might a child develop cardiac arrhythmias after this procedure?

a. The dye inserted can create inflamed heart chambers.
b. The many radiographs taken lead to a weakened heart muscle.
c. The catheter can irritate nerves in the heart septum.
d. Latex allergy can cause symptoms of unusual heart rate.

The Child Scheduled for Cardiac Surgery

There are many different types of congenital heart disorders, and many different procedures are available to correct them. Open-heart or intra-catheter surgery, however, remains the chief cure for congenital heart disease (Fulton & Freed, 2008). Open-heart surgery is made possible by the use of cardiopulmonary bypass or extracorporeal membrane oxygenation (ECMO). With this, the venous return to the heart is diverted from the right atrium or inferior and superior vena cava to a heart–lung machine, where it is artificially oxygenated. It is returned to the body's arterial system by way of the aorta, bypassing the heart. The heart, practically bloodless, now can be opened and operated on. Blood returns to the coronary and pulmonary capillary beds under pressure from the aorta so that even though blood bypasses the heart, it still receives an adequate blood supply for self-maintenance during the bypass procedure (Fynn-Thompson & Almond, 2007). Very ill infants may be maintained on ECMO using the same technique after surgery.

During surgery, hypothermia (reducing the child's body temperature to 68° to 79° F [20° to 26° C]) is used to reduce the child's metabolic needs and slow the heart rate. If extreme hypothermia is used (59° to 68° F [15° to 20° C]), usually in an infant, the body temperature drops so low that the heart stops beating and the surgeon can work in a quiet and bloodless field. Measuring temperature to be certain the infant is rewarmed is a major responsibility afterward.

Preoperative Care

Before surgery, obtain vital signs (blood pressure, temperature, pulse, and respirations) to establish baselines. Count pulse and respiratory rates for a full minute for accuracy. Some children may need baseline pulse determinations done at several pulse points or blood pressures taken in both upper and lower extremities. Before obtaining a blood pressure, have a child rest for about 15 minutes and take the recording with the child lying down so it closely mimics what the child's position will be following surgery. Also record height and weight, because these parameters are necessary for the estimation of blood volume for the heart–lung machine and for medication dosages. Weighing also is helpful in estimating blood loss or edema after surgery. In children receiving digoxin, it is usually withheld 24 hours before surgery because cardiac surgery may cause arrhythmias in the presence of cardiac glycosides.

The immediate surgical preparation of children varies from one institution to another but usually includes preparing the skin incision site. The skin over the surgical incision area is scrubbed with an antiseptic solution to ensure as clean a surgical field as possible. Most children and parents are startled to learn that cardiac surgery may be performed through the sternal bone or the back, not over the left side of the chest, and may question the area being prepared for the incision. An enema also may be given to keep children from straining to pass stool in the immediate postoperative period and placing additional strain on the newly operated heart.

Nursing Diagnoses and Related Interventions: Preoperative Phase

Nursing Diagnosis: Deficient knowledge related to cardiac surgery and its outcome

Outcome Evaluation: Parents and child accurately state the reason for surgery and expected outcome.

Bringing a child to the hospital for cardiac surgery is a large responsibility for parents. They want their child to be made well, but they are also aware there is a definite risk from this surgery. They may have been protecting and guarding their child for months or years, and they feel no less protective the morning of surgery. For this reason, parents of children being readied for cardiac surgery may watch preoperative procedures more carefully than usual. Review with them what they already know about the surgery to correct any misconceptions and inform them what laboratory tests will be scheduled. Prepare them for the amount of equipment that will surround their child after surgery, such as cardiac monitors, oxygen and IV equipment, chest tubes, and a ventilator. Parents usually appreciate visiting the intensive care unit (ICU) where their child will be cared for after surgery. Be certain they have an opportunity to meet the ICU staff, especially if those nurses are not the same ones who are caring for the child preoperatively.

Prepare Child for Surgery and Postoperative Care. It is best if a child is prepared for surgery with the parents present. This allows parents the opportunity to reinforce your teaching and shows children that their parents approve and feel secure with these surgery plans. Parents will then need additional time to discuss the surgical procedure with you and ask questions they might not have wished to ask in the presence of their child.

Children can be very frightened about cardiac surgery (Fig. 41.4). Remember when caring for them preoperatively (or any time) not to make careless remarks so children can maintain confidence in health care personnel. For example, statements such as, "These syringes never work right" (when all you mean

FIGURE 41.4 Orientation for cardiac surgery includes time for talking and learning more about the heart. (© Lesha Photography.)

is you prefer another brand) or "Amy [an ICU nurse] is a real clown" (when you mean she is not only a competent nurse but has a good sense of humor besides) could be interpreted by anxious parents or children to mean a child is in less-than-competent hands. Because many children having cardiac surgery have had previous cardiac catheterizations, talking to them about their previous hospitalization experiences is helpful. Talking will reveal the things they fear the most this time. Any misconceptions they have about past experiences can then be discussed and clarified.

Both parents and children may have questions about the difference between cardiac catheterization and cardiac surgery. One important difference is that children are sedated but awake for the former but anesthetized for the latter. For some children, knowing they will be fully asleep is more reassuring; for others, it is more frightening. When they were awake, they knew that they were all right; asleep, how can they know? Encourage them to express these feelings so they can receive reassurance that anesthetized sleep is a special sleep from which they will have no difficulty waking. Meeting the anesthesiologist and receiving reassurance directly from the person who will be watching over them while they are asleep is often helpful.

As with cardiac catheterization, it may help to make models of the equipment that will surround the child postoperatively. Parents and older children can be taken to the ICU where they will return after surgery and be shown the actual equipment and setting.

After surgery, a child will need to cough and deep-breathe and use incentive spirometry to help the lungs expand. Introduce these exercises preoperatively to let a child know what will be expected. Familiarize children with chest tubes. Caution both children and parents that chest tubes must stay in place until it is time for them to be removed. If children want to turn over with tubes in place, they need to ask for help to prevent the tubes from being dislodged. Caution parents that a chest-tube drainage reservoir must remain below the level of the child's chest and must not be raised for any reason. If children are not familiar with ECG leads, introduce these as part of preoperative preparation. Comparing these tubes or leads to being "hooked up" like an astronaut is often appealing to children. In addition, introduce children to the form of oxygen therapy they will receive after surgery (mask, cannula, or ventilator) to avoid surprises. Orienting children to oxygen equipment is discussed in Chapter 40.

Postoperative Care

After surgery and before leaving the operating room, an x-ray film is taken and the child is weighed. Future estimates of lung expansion and weight, to reveal whether edema is accumulating from poor heart function, will be checked against these two measurements.

Nursing Diagnoses and Related Interventions: Postoperative Phase

Nursing Diagnosis: Risk for ineffective cardiopulmonary tissue perfusion related to cardiac surgery

Outcome Evaluation: Vital signs are within normal limits; central venous pressure (CVP) or pulmonary artery wedge pressure is within established parameters.

Taking accurate vital signs, as often as every 15 minutes, is essential in the immediate postoperative period following cardiac surgery. Continuous cardiac monitoring and assisted ventilation with endotracheal intubation also are usually necessary. Blood pressure will probably be monitored directly by means of an intra-arterial catheter or indirectly with an automated blood pressure recording device. Hemodynamic monitoring by way of a pulmonary artery or central venous catheter will reveal information on chamber pressures and oxygen saturation (Fig. 41.5).

Adequate voiding after surgery indicates that the kidneys are receiving an adequate blood flow or the heart is working effectively. An indwelling urinary (Foley) catheter is usually inserted at the time of surgery so urine output can be carefully recorded postoperatively (it should be 1 mL/kg/hr). Be certain to mark the amount of urine drainage present when children first return from surgery so that lack of or diminished urinary output will not be missed or misinterpreted. Individual samples may be tested for specific gravity and pH. A specific gravity below 1.010 implies that the kidneys are not concentrating urine well, perhaps because of the stress of surgery. The pH should remain slightly acid; however, extreme acidity may indicate respiratory acidosis from poor pulmonary perfusion.

FIGURE 41.5 Because children after cardiac surgery typically have a myriad of wires and tubes attached to monitors, pumps, and equipment, parents need to be prepared for how their child will look. As the child's condition improves, use of the equipment is discontinued. Here, an infant is 2 days post-cardiac surgery. Note his level of alertness and the use of only a few monitoring devices and equipment. (© Caroline Brown, RNC, MS, DEd.)

Carefully record all IV fluid administered to the child after surgery. Fluid overload can pose a severe threat to the heart during the immediate postoperative period. Use an infusion control device to regulate the amount and rate of infusion.

Laboratory tests such as arterial blood gases (Po_2 and Pco_2), hemoglobin, hematocrit, clotting time, and electrolytes (particularly sodium and potassium) will be monitored closely to assess cardiac and pulmonary function postoperatively. Oxygen saturation levels may be monitored by pulse oximetry or transcutaneous oxygen monitoring. A drug such as dopamine may be administered to improve cardiac output.

Central Venous Pressure Monitoring. CVP may be recorded by inserting a catheter into a brachial, jugular, or subclavian vein, and ultimately into the right atrium (Fig. 41.6). CVP is an excellent way to evaluate a child's fluid volume status. CVP will rise with heart failure, indicating that the heart cannot handle the blood arriving at the atria.

Pulmonary Artery Pressure Monitoring. To assess pressure in the left side of the heart parallel to CVP measurement, a multilumen pulmonary artery catheter, such as a Swan-Ganz catheter, can be threaded through the venous circulation through the right side of the heart and into the pulmonary artery. The pressure, registered there as a waveform on a cardiac monitor, reflects both the resistance of the lungs to the passage of blood (pulmonary artery resistance) and the ability of the left side of the heart to handle the circulating fluid volume. Such catheters must be kept from clotting with frequent irrigations or with a constant infusion system. When withdrawing blood specimen samples from the catheter, make sure no air is allowed to enter, because this would immediately flow into the left side of the heart and possibly to a cerebral artery as an embolus.

Nursing Diagnosis: Impaired gas exchange related to unexpanded lung space and collection of lung excretions.

Outcome Evaluation: Child's respiratory rate remains within age-appropriate parameters; absence of rales or other adventitious breath sounds; chest tubes function normally.

Measures to Prevent Pooling of Secretions in Lungs. Suction as necessary while a child is receiving ventilatory assistance to prevent pooling of secretions in the respiratory tract. As soon as the endotracheal

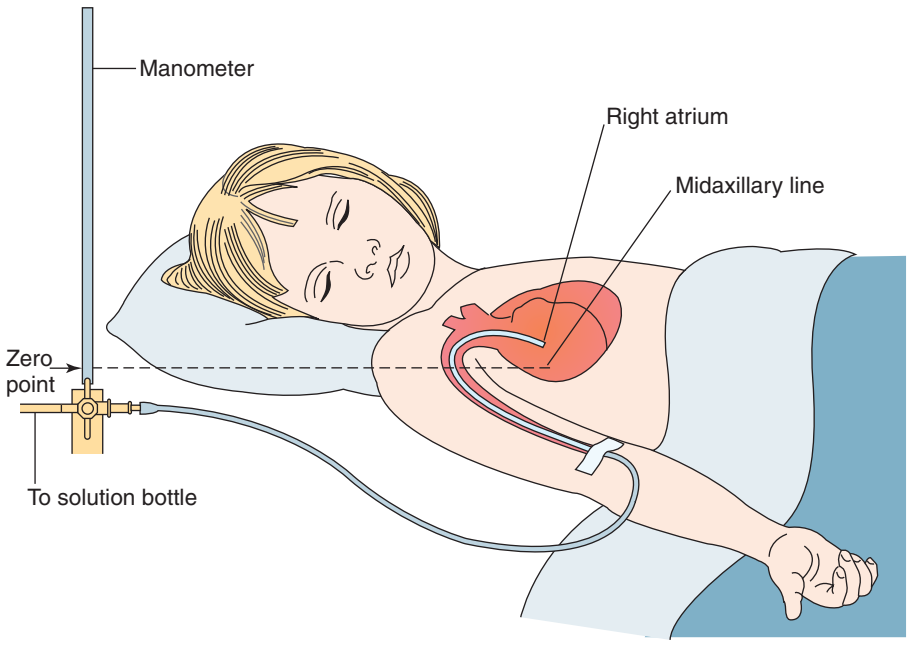

FIGURE 41.6 A CVP catheter may be inserted after cardiac surgery to monitor fluid volume. The zero point on the scale is at the level of the right atrium.

tube and ventilator are removed, encourage the child to cough and deep-breathe or use an incentive spirometer at hourly intervals to help mobilize secretions. Although children may have practiced such procedures preoperatively, they may have difficulty carrying them out now because, unless continuous epidural anesthesia is used for pain relief, coughing or deep-breathing can be very painful. To minimize pain, administer the prescribed analgesia or alert the child to use the patient-controlled analgesia (PCA) pump 10 to 15 minutes before it is time to deep-breathe. For optimal effectiveness, demonstrating coughing again, sometimes deep-breathing with the child, may be necessary. Chest physiotherapy with percussion and vibration may be prescribed to keep lung secretions mobile. Be certain parents understand that games such as blowing cotton balls or blowing up a balloon are not really games but important exercises to help achieve lung expansion. Otherwise, they may interpret these exercises as too tiring for the child and discourage them.

Most children have two thoracotomy chest tubes inserted following surgery. The upper tube drains air to aid lung re-expansion and the lower one drains fluid to encourage lung expansion and decrease the possibility of infection. These tubes are connected to a water-seal drainage apparatus (a Pleur-Evac; Fig. 41.7).

Pleur-Evacs consist of three chambers: one to collect drainage, one to furnish a water seal, and one that can be attached to suction. A thoracotomy tube connects to the first drainage compartment. Because of the water seal, atmospheric air cannot enter the tube and flow back into the pleural space. Note how much drainage is occurring and if the level of fluid fluctuates (proof that the apparatus is airtight). On the third or fourth postoperative day, the fluctuation will cease, indicating that the lungs are fully expanded. Then it is time for the tubes to be removed.

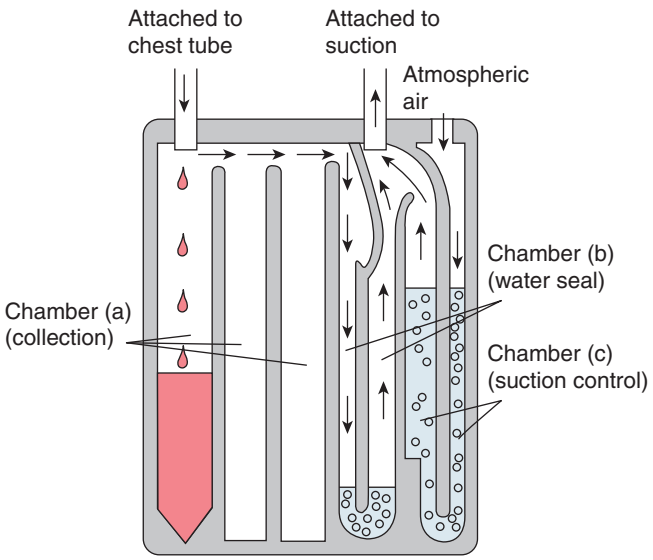

FIGURE 41.7 Pleur-Evac system for chest tube drainage.

Maintain children with chest tubes in place in a semi-Fowler's position because thoracotomy tubes drain best in this position; often there is less dyspnea as well, because the chest is elevated and the abdominal contents do not press on the lungs. Always keep thoracotomy chest tube drainage systems below the level of the child's chest so that fluid does not flow back into the pleural space. Check that tube connections are secure and that the Pleur-Evac is not cracked or broken. Otherwise, air can enter the chest cavity and collapse the lungs (pneumothorax).

Mark the fluid level in the collecting chamber immediately after surgery. Continue to mark the level of fluid in the drainage chamber every hour so the hourly amount of drainage can be evaluated (approximately 5 mL/kg/hr is typical). Also note the color and the presence of any clots in the drainage. Drainage fluid may be blood-tinged but should not contain fresh blood. If it does, this suggests active bleeding.

A chest radiograph taken on the third or fourth postoperative day will confirm that full lung expansion has returned. The tubes are then removed by a physician or nurse practitioner while an impervious dressing is simultaneously applied to the puncture wound. Provide emotional support during thoracotomy tube removal. Children know these tubes are important for their well-being. Aside from worrying about the momentary pain of removal, they may believe that something bad will happen after the tubes are removed. Do not change any dressings over former thoracotomy tube sites, because lifting them to change them could allow air to enter.

Occasionally, despite being cautioned not to, children may turn so suddenly after surgery that they pull a thoracotomy tube out accidentally. This creates an emergency situation because air rushing into the child's chest can cause a pneumothorax with sudden dyspnea, tachycardia, cyanosis, and perhaps sharp chest pain. If a tube is only loosened or air is leaking slowly through a connection, the symptoms may be less dramatic but include restlessness and apprehension accompanying gradually increasing dyspnea. If the air entering the chest is the result of air leaking into the tubing, clamp the tube close to the child's chest with a large clamp to prevent further air from entering the chest. If the tube actually has been pulled out, immediately close the puncture wound to the chest by covering it with petrolatum gauze, a type of dressing that is impervious to air. If such gauze is not immediately available, place your gloved hand over the puncture wound and hold it snugly in place until help arrives. The child may need emergency oxygen administration to counteract the decreased amount of air exchange space experienced as a result of partial lung collapse. Remaining calm will help a child remain calm, which will avoid increasing respiratory rate and oxygen demand.

Nursing Diagnosis: Risk for infection related to surgical incision and tube sites

Outcome Evaluation: Child's temperature remains at or below 100.4° F (38.0° C) axillary; incision site is clean, dry, and without evidence of erythema or foul drainage.

Some children are begun on a prophylactic course of a broad-spectrum antibiotic before surgery. If so, this will be continued for 24 to 48 hours postoperatively. Frequently monitor temperature postoperatively to assess for infection. Frequently assess the dressing over the surgical incision and the points of insertion of the thoracotomy tubes for drainage and erythema. Use strict aseptic technique when changing the incisional dressing to avoid introducing pathogens.

Nursing Diagnosis: Hypothermia related to cooling during surgery

Outcome Evaluation: Child's temperature is above 96.8° F (36.0° C) axillary. Capillary refill is less than 5 seconds.

If hypothermia was induced for surgery, the child's temperature will be low postoperatively and a hyperthermia blanket, warm blankets, or radiant heat may be necessary to elevate the temperature to normal. Alternatively, a child's temperature may be above normal because of an inflammatory response to hypothermia. Unless infection is developing, these temperature readings will gradually return to normal in a few days.

Nursing Diagnosis: Risk for excess or deficient fluid volume related to fluid shifts accompanying cardiac surgery

Outcome Evaluation: Child maintains weight; skin turgor is good; central venous pressure or pulmonary artery pressure is within established parameters.

Children tend to develop hypervolemia after cardiac surgery because of increased production of aldosterone by the adrenal glands and an increase in antidiuretic hormone secretion by the pituitary gland in response to stress. Also, if cardiopulmonary bypass was used, some fluid may have been shifted from the intravascular system to the interstitial spaces during surgery. After surgery, this fluid returns by osmosis to the vessels, causing hypervolemia. On the other hand, an individual child may have experienced excessive bleeding because of the heparin used during surgery and may subsequently develop hypovolemia.

Monitor central venous or pulmonary artery pressure to evaluate a child's hemodynamic status. Monitor IV fluid administration carefully to prevent fluid overload. Typically, oral fluid intake is withheld for at least the first 24 hours after surgery. Once bowel sounds have returned, oral fluids can be introduced gradually.

Nursing Diagnosis: Parental anxiety related to lack of knowledge of postoperative routine and exercises

Outcome Evaluation: Family members accurately state plans for child's postoperative recovery; relate less anxiety after teaching and support.

Most children recover quickly from heart surgery. Passive range-of-motion exercises may be prescribed the day of surgery. By 24 hours, children are out of bed and ambulating. Encourage parents to do whatever they want to do for their child's care during this period. It is difficult for them to accept the fact the surgery is over and their child is now a well child (or will be at the end of the recovery period).

Offering the child sips of water or helping the child with bathing (under supervision) helps parents see that their child is returning to usual activities and doing well. Be certain that in the midst of the postoperative excitement, the child receives adequate rest the first postoperative days. You may need to monitor and regulate visits by staff and outside visitors to make sure a child is undisturbed for sustained rest periods. Urge parents to read to children or play music for them as a way to provide quiet rest periods. Caution parents not to pick up an infant under the arms, because this pulls on the chest incision. Show them how to lift an infant by placing their hands under the shoulders and buttocks instead.

Once the immediate postoperative period has passed, the child will be moved from the ICU to a routine patient unit. This may be a difficult move for both the child and the parents because they have developed confidence in the ICU staff and are reluctant to entrust the child to new personnel (even if the patient unit is the one to which the child was initially admitted before surgery). It helps the transition if the regular nursing staff visits the child daily in the ICU. Generally, place children returning from the ICU in a room near the nursing station, and place the bed so it can be easily seen from the hallway. Although you are not providing the constant attendance that the child received in the ICU, you can show that you are very observant and aware of individual needs. Stopping to look in every time you pass the room reassures the family that you are always close by. Allow parents an opportunity to voice their concern over the change in personnel and surroundings. Accepting this change can help prepare them for the day of hospital discharge, when they will be observing and caring for their child on their own.

At hospital discharge, parents need clear explanations of the activities in which the child will and will not be able to participate. Be sure they have an appointment for a checkup for the child and the telephone number they should call if they have any questions regarding their child's care. The protectiveness they felt for the child before surgery does not diminish instantly, even though surgery has been completed. They may find themselves saying, "Don't run" for months after the child has been allowed full activity. They may appreciate a listening ear for their concerns, which may include feeling they are not as important to their child as they were when the child was ill. Emphasize that well children also need continued parental supervision and guidance (Box 41.3).

Complications of Cardiac Surgery

A number of complications can arise after cardiac surgery because of the use of cardiopulmonary bypass and the extent of the surgery (Box 41.4). The first of these is hemorrhage, because heparin is used to prevent blood coagulation during the cardiopulmonary bypass. Although protamine sulfate (the antidote for heparin) is administered IV immediately after surgery, some heparin is still present in the

BOX 41.3 ❊ Focus on Communication

Megan is a 3-month-old infant who is being discharged after cardiac surgery. You stop at her hospital room to give discharge instructions to her mother.

Less Effective Communication

Nurse: Good morning, Mrs. Carver. Let me review a few instructions with you.
Mrs. Carver: The most important thing you can tell me is how to keep a baby on bedrest.
Nurse: Most infants are so exhausted from surgery, they automatically reduce their activity, so that's not a problem. You can let her return to her usual activities at as near normal a level as possible.
Mrs. Carver: She likes to kick a mobile. It'll be hard to keep her from doing that.
Nurse: Her appetite should be back to normal in a few days. Check back with the clinic if it doesn't improve.
Mrs. Carver: I don't understand how she'll eat well if she has to be in bed all the time.
Nurse: Megan will need to continue to take digoxin until she returns for her checkup in 1 week. Do you have any questions about the dose?
Mrs. Carver: No. It'll be hard to get her to cooperate, though, when she's unhappy about having to stay in bed all the time.
Nurse: You'll need to check the incision daily and report any redness or increasing pain.
Mrs. Carver: I can do that. The thing I'll have trouble with is keeping her on bedrest.
Nurse: Infants generally limit their own activity, so that shouldn't be a problem. Wait here, now, until I call transportation to take you downstairs.

More Effective Communication

Nurse: Good morning, Mrs. Carver. Let me review a few instructions with you.
Mrs. Carver: The most important thing you can tell me is how to keep a baby on bedrest.
Nurse: Most infants are so exhausted from surgery, they automatically reduce their activity, so that's not a problem. You can let her return to her usual activities at as near normal a level as possible.
Mrs. Carver: She likes to kick a mobile in bed. It'll be hard to keep her from doing that.
Nurse: You'll need to check the incision daily and report any redness or increasing pain.
Mrs. Carver: I can do that. The thing I'll have trouble with is keeping her on bedrest.
Nurse: You've mentioned bedrest several times. Megan doesn't have to stay on bedrest. Let's talk about what activities she can do.

Because cardiac surgery is such serious surgery, most parents assume that it will take their child a very long time to recover from it. In the above scenarios, the mother has overestimated the time it will take her child to return to normal activities. Only when really listening to what the mother is saying, rather than just continuing to review discharge instructions, does the nurse recognize that the mother has not heard the first instruction—let the child return to activities at as near normal a level as possible.

child's system. Monitor the coagulation time and vital signs and observe thoracotomy tube drainage to identify early signs of bleeding.

Shock, another possible complication, is revealed by hypotension, oliguria, acidosis, and cyanosis. It may result from hypovolemia or cardiac tamponade (bleeding into the heart muscle or pericardium, interfering with the heart's ability to contract forcibly), or it may be a reaction to prolonged extracorporeal perfusion. It is treated according to individual needs, including plasma volume expanders, continued mechanical ventilation, and perhaps a return to surgery to stop the bleeding. Heart block or arrhythmias may occur as the result of edema or trauma compromising the effectiveness of the bundle of His. An artificial pacemaker may be inserted to correct these problems. If the child had congestive heart disease before surgery, this may persist for a week or more after surgery. If it occurs as a new entity, it suggests that the surgery has caused a stricture to circulation at some point, causing either the right or left side of the heart to become overwhelmed. Measures for treating postoperative congestive heart failure are the same as those in children who have this syndrome from any cause. Neurologic symptoms, also a possible complication, may occur if the child experienced hypoxia during surgery.

A **postcardiac surgery syndrome** may develop at the end of the first postoperative week. This is a febrile illness with pericarditis and pleurisy (fluid collecting in the pleural space) that appears to be a benign inflammatory response to the surgical procedure. Anti-inflammatory therapy and bedrest reduce the symptoms. The symptoms may recur months after surgery.

Postperfusion syndrome may occur 3 to 12 weeks after surgery. The child develops a fever, an enlarged spleen, general malaise, and a maculopapular rash. Increased liver size also may be present. The white blood count reveals a leukocytosis, with lymphocytes as the predominant cell type. Such a reaction is usually caused by a cytomegalovirus infection contracted from the donor blood used in the cardiopulmonary bypass machine. The illness runs a short course, with no permanent effect.

✔ Checkpoint Question 41.3

Megan will be scheduled for open-heart surgery. What type of fluid imbalance is apt to occur after cardiac surgery?

a. Hypervolemia from aldosterone production.
b. Hypercalcemia from calcium release from bones.
c. Hypernatremia from excess sodium retention.
d. Hypokalemia from excess urine diuresis.

BOX 41.4 ✻ Focus on Evidence-Based Practice

Do parents rate their child's quality of life as improved following cardiac surgery?

Because children's physical abilities improve following cardiac surgery, it is usually assumed that both children and parents will be happier afterward. To investigate whether parents reported that as being true, researchers asked the parents of 110 children (mean age, 10.4 years) to rate their children's health-related quality of life on a questionnaire. The mean age of the children's surgery was 2.3 years, and the mean duration of cardiopulmonary bypass was 95 minutes. Circulatory arrest had been performed in 9% of the children. Parents reported that most dimensions of quality of life including autonomy and motor, social, emotional, and cognitive functioning were impaired. Factors such as the duration of cardiopulmonary bypass, the length of hospitalization, the need for current cardiac medication, and adverse family relationships all had negative impacts on the parent's ratings of their child's quality of life.

Based on the above study, would you promise parents that their child will be "perfect" following cardiac surgery?

Source: Landolt, M. A., Valsangiacomo Buechel, E. R., & Latal, B. (2008). Health-related quality of life in children and adolescents after open-heart surgery. *Journal of Pediatrics, 152*(3), 349–355.

The Child with an Artificial Valve Replacement

A number of congenital heart anomalies, such as aortic stenosis, and diseases, such as rheumatic fever or Kawasaki disease, can require artificial heart valve replacement. Valve replacement is technically more complicated in children than adults because children's hearts are smaller. Because children have a longer life expectancy than adults, valve durability also is a prime consideration. In addition, the advantage of the long-term anticoagulation therapy necessary to prevent clots from forming at the valve site must be weighed against the problem of extensive bleeding from normal childhood accidents.

Artificial valves were first obtained from pigs (porcine) or cows (bovine), but synthetic material (prosthetic) or human donors (homografts) are most often used today because synthetic materials or a child's own tissue provide the best long-term replacement. After surgery to place an artificial valve, a child is given either anticoagulation or antiplatelet therapy to prevent thrombi from forming at the valve implantation site. The drugs prescribed most commonly for anticoagulation therapy are heparin or warfarin sodium (Coumadin). Antiplatelet therapy also may be used, most often acetylsalicylic acid (aspirin) and dipyridamole (Persantine). Aspirin decreases platelet aggregation; dipyridamole decreases platelet adhesiveness. The dosage for these drugs must be periodically monitored by blood analysis to ensure they remain adequate as the child grows.

If a child should develop a bacterial infection with an artificial valve in place, organisms tend to cluster and colonize at the valve site. For this reason, a child generally is prescribed prophylactic antibiotic therapy to prevent this from becoming endocarditis. Additional therapy with amoxicillin will be prescribed if a child is scheduled for dental work or any other invasive procedure (Sykes & Farrington, 2007).

Adolescent girls need counseling about avoiding pregnancy until they become adults because the artificial valve may be unable to accommodate the increased blood volume associated with pregnancy and support the adolescent's growth as well. In addition, because warfarin is teratogenic, any girl contemplating pregnancy needs to be changed to a heparin regimen before conception. Girls with artificial valves in place should not use an estrogen-based birth control pill, because this can increase blood coagulation and possibly lead to thrombi. They also should not use an intrauterine device (IUD) because IUDs have been associated with an increased rate of pelvic inflammatory disease, which could spread to the valve site.

Hemolytic anemia may occur as a complication of artificial valve replacement. The extreme turbulence of blood through the prosthetic valve apparently results in breakage of red blood cells. Blood replacement may be necessary if the hemolytic process persists.

The Child Undergoing Cardiac Transplantation

Children who have a hypoplastic left ventricle or extensive cardiomyopathy from any cause are candidates for heart transplantation (Schroeder et al., 2008). Children are usually maintained on extracorporeal membrane oxygenation (ECMO) or a trial ventricular assist device while waiting for surgery (Fynn-Thompson & Almond, 2007).

Children who will be having heart transplants may be at home or in the hospital when their family is notified that a donor heart is available. After removal from the donor, the transplant heart is perfused with a balanced electrolyte solution and chilled immediately. It can be maintained this way for 2 to 3 hours using cardiopulmonary bypass technique before being transplanted. For the procedure, the aorta of the child who will be receiving the heart is cross-clamped, and the original heart is removed except for the upper portion of the right atrium, which contains the SA node. Once the new heart is transplanted and the major cardiac vessels are reattached, intrathoracic hemodynamic monitoring lines and ventricle pacing wires are implanted. Transplanted hearts beat normally except for autonomic nervous system control. This means the transplanted heart varies its rate in response to the amount of blood arriving at it and the response to catecholamines rather than by nervous system control. An ECG will show two P waves (one from the residual original heart and one from the donor heart) because both SA nodes are intact.

Postoperative care is similar to that for any child undergoing cardiac surgery. The child has the same potential problems: decreased cardiac output, impaired gas exchange, risk for infection, imbalanced nutrition, and ineffective family coping. Children are prone to arrhythmias because of possible injury to the SA node during transport or transplant.

Although a long-term consequence of cardiac transplantation is severe atherosclerosis, apparently as a result of inflammation, rejection of the transplant is the number one cause of death in cardiac transplant patients (Law, 2007). An antithymocyte antibody preparation and drugs such as cyclosporine A, prednisone, and azathioprine are commonly used for immunosuppression in an attempt to reduce the risk of rejection. However, rejection still can occur in hyperacute, acute, or chronic forms. Hyperacute rejection occurs immediately and is manifested by coronary thrombosis. Acute rejection occurs in about 7 days and is manifested by low-grade fever, tachycardia, edema, and ECG changes. Cardiac catheterization is usually performed a week after transplant to obtain a biopsy sample from the heart muscle to evaluate for signs of acute rejection (tissue necrosis will have started to occur). Long-term or chronic rejection may begin as early as 6 months. At any point that rejection is beginning, additional antithymocyte globulin (ATG) or monoclonal antibodies to CD3T-lymphocytes (OKT-3) may be infused to help stop the process.

Once past the rejection period, most children adjust well to cardiac transplant. They can participate in normal growth and development activities after the procedure. Depending on the specific protocol, they return to the transplant center about once yearly for a repeat cardiac catheterization and evaluation of progress.

The Child with a Pacemaker

A child whose heart has ineffective SA node function or has difficulty in transmitting impulses from the SA node to the ventricles may have an artificial pacemaker inserted to control the heartbeat by stimulating the ventricles electronically (Karpawich, 2007). The pacing system consists of two components: a pulse generator that contains the battery and programmed instructions, and wire leads that connect to the heart. Most leads placed in children are an epicardial type and are attached to the epicardium (the outside wall of the heart) by suture. The generator is placed under the skin in the subxiphoid or mid- or lower abdomen. Heart disorders that will need pacing can be detected during intrauterine life by fetal monitoring. In these children, pacemakers can be implanted as soon as they are born.

Commonly, the type of pacemaker and its functions are denoted by either a three- or five-letter code. With the three-letter system, the first letter identifies the chamber paced, the second the chamber sensed, and the third the pacemaker's response to the intrinsic activity of the heart. If a fourth letter is used, it denotes whether rate modulation is possible; a fifth letter denotes whether antitachyarrhythmia function, such as the ability to produce a shock to defibrillate, is possible (Vijayaraman & Ellenbogen, 2008). For example, a pacemaker that is set to pace the *v*entricle, sense the *v*entricle, and be *i*nhibited (cannot modify the rate and does not respond as long as the heart initiates a normal beat) is a VVI pacemaker.

Teach the parents of the child with a pacemaker how to take the child's pulse accurately. They will need to do this daily at home and report any alterations in the pulse rate to their primary care provider until it is certain that the paced rate is appropriate. They also may need to telephone the health care center periodically and transmit a recording of the child's heart action to the center by means of a telephone attachment to ensure that the paced rate remains accurate.

Some parents stay awake at night worrying that the pacemaker batteries will suddenly stop operating and their child will die. Because of this fear, they may be afraid to take vacations or allow the child to go away to camp. How long a pacemaker battery lasts depends on the percentage of time pacing is needed (continuous or intermittent), the battery energy output in amplitude (the amount of battery voltage needed to create each pacing impulse), and the pulse width (the length of time the impulse is being delivered). With usual pacemaker parameters, such as an intermittent pattern, low amplitude, and narrow pulse width, a battery can last 12 to 15 years. In all instances, parents can be reassured that pacemaker batteries lose power slowly, not abruptly. They will have ample time to recognize weakening batteries through signs in their child such as dizziness, fatigue, fainting, or a slow pulse rate and arrange to have the pacemaker replaced before the child's heart would fail.

Occasionally, pacemaker leads in the right ventricle of infants lie in such close proximity to the diaphragm that they stimulate the diaphragm to contract with each ventricular contraction. This causes constant hiccupping. If this occurs, the leads may need a position adjustment. Another problem with infants is that there is not room to implant the generator deeply, so it can trigger airport security systems.

Help parents learn to evaluate whether toys are safe. As a rule, magnets should be avoided. Toys that emit an electrical current can interfere with a pacemaker's operation and so are not recommended. Also question the use of MRI (which involves the use of magnets) or electrocautery (which involves the use of electricity) with these children. Children should not participate in contact sports such as football that could injure the pacemaker. Sports such as gymnastics and basketball that involve a high degree of shoulder action could dislodge pacemaker leads.

CONGENITAL HEART DISORDERS

About 8% of term newborns are born with a congenital cardiovascular abnormality (Fulton & Freed, 2008). This rate is even higher in preterm infants. Overall, these disorders affect equal numbers of male and female infants, but specific defects show a tendency toward sex differences. Patent ductus arteriosus and atrial septal defect, for example, are found more commonly in girls. Conditions such as valvular aortic stenosis, coarctation of the aorta, tetralogy of Fallot, and transposition of the great vessels occur more often in boys.

The usual cause of congenital heart disorders is failure of a heart structure to progress beyond an early stage of embryonic development. Maternal rubella is an example of an infection known to lead to disorders such as patent ductus arteriosus, pulmonary or aortic stenosis, atrial or ventricular septal defects, or pulmonary stenosis. Atrial and ventricular septal defects can also be familial. If a parent has an aortic stenosis, atrial septal defect, ventricular septal defect, or pulmonic stenosis, the incidence of this occurring also in the child is about 10% to 15% (Fulton & Freed, 2008).

Classification

Formerly, congenital heart disorders were classified based on the physical sign of cyanosis, or these disorders were classified as either cyanotic or acyanotic disorders.

Acyanotic heart disease involves heart or circulatory anomalies that involve either a stricture to the flow of blood or a shunt that moves blood from the arterial to the venous system (oxygenated to unoxygenated blood, or **left-to-right shunts**). These disorders cause the heart to function as an ineffective pump and make the child prone to heart failure. **Cyanotic heart disease** occurs when blood is shunted from the venous to the arterial system as a result of abnormal communication between the two systems (deoxygenated blood to oxygenated blood, or **right-to-left shunts**). Although helpful, this classification system led to difficulties because children with acyanotic heart disease can develop cyanosis, and children with cyanotic disease may not exhibit cyanosis until they are seriously ill.

To solve this problem, a second classification system has been established that addresses the hemodynamic and blood flow patterns of the disorders rather than their effect, allowing a more uniform and predictable set of signs and symptoms. As identified by this system, the four classifications identify disorders with:

- Increased pulmonary blood flow
- Obstruction to blood flow leaving the heart
- Mixed blood flow (oxygenated and deoxygenated blood mixing in the heart or great vessels)
- Decreased pulmonary blood flow

Disorders With Increased Pulmonary Blood Flow

Congenital heart disorders associated with increased pulmonary blood flow involve blood flow from the left side of the heart, which is under greater pressure, to the right side of the heart, which is under less pressure, through some abnormal opening or connection between the two systems or the great arteries. Disorders of this type include ventricular septal defect (VSD), atrial septal defect (ASD), atrioventricular canal (AVC) defect, and patent ductus arteriosus (PDA).

Ventricular Septal Defect

VSD, the most common type of congenital cardiac disorder seen, accounts for about 30% of all instances of congenital heart disease, or about 2 in every 1000 live births (Fulton & Freed, 2008). With this defect, an opening is present in the septum between the two ventricles. Because pressure in the left ventricle is greater than that in the right ventricle, blood shunts from left to right across the septum (an acyanotic disorder). This impairs the effort of the heart because blood that should go into the aorta and out to the body is shunted back into the pulmonary circulation, resulting in right ventricular hypertrophy and increased pressure in the pulmonary artery (Fig. 41.8).

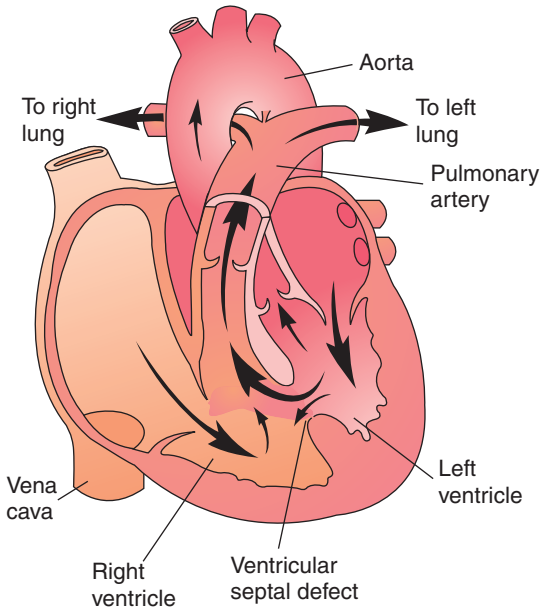

FIGURE 41.8 A ventricular septal defect.

Assessment. A VSD may not be evident at birth. With incomplete opening of the alveoli, there is still high pulmonary artery resistance, so little blood is shunted through the defect. At about 4 to 8 weeks of age, as shunting begins, the infant demonstrates easy fatigue, and a loud, harsh pansystolic murmur becomes evident along the left sternal border at the third or fourth interspace. This typical murmur is generally widely transmitted. A thrill (vibration) also may be palpable. The diagnosis of VSD is based on examination by echocardiography with color flow Doppler or MRI, which reveals right ventricular hypertrophy and possibly pulmonary artery dilatation from the increased blood flow. An ECG will also reveal right ventricular hypertrophy.

Therapeutic Management. Up to 85% of VSDs are so small they close spontaneously (Sondheimer, Yetman, & Miyamoto, 2008). Those that are moderate in size may be closed during cardiac catheterization. Larger ones (over 3 mm) require open-heart surgery. This is usually scheduled before 2 years of age to prevent pulmonary artery hypertension. Closure is important because if the defect is left open, cardiac failure from the artery hypertension can result. The heart can become infected (endocarditis) because of the recirculating blood flow.

Surgery requires the use of extracorporeal circulation and a quiet heart. In surgery, after cardiopulmonary bypass, the edges of the septal opening are approximated and sutured. If the defect is exceptionally large, a Silastic or Dacron patch can be sutured into place to occlude the space. With time, septal tissue will grow across the synthetic patch and knit it firmly into place. Postoperatively, be alert for arrhythmias because edema in the septum can interfere with ventricular conduction. Children may receive prophylactic antibiotics to prevent bacterial endocarditis for 6 months afterward. If there are no complications, children can expect to participate in normal activities after the repair.

Atrial Septal Defect

An ASD is an abnormal communication between the two atria, allowing blood to shift from the left to the right atrium (an acyanotic defect). It is more common in girls than boys (Fulton & Freed, 2008). Blood flow is from left to right (oxygenated to deoxygenated) because of the stronger contraction of the left side of the heart. This causes an increase in the

volume in the right side of the heart and generally results in ventricular hypertrophy and increased pulmonary artery blood flow, the same as with a VSD (Fig. 41.9). There are two types of ASDs: ostium primum (ASD1), where the opening is at the lower end of the septum, and ostium secundum (ASD2), where the opening is near the center of the septum. ASD2 defects may be asymptomatic and not discovered until infection from recirculating blood occurs.

Assessment. A harsh systolic murmur is heard over the second or third interspace (the pulmonic area) because of the extra amount of shunted blood that crosses the pulmonic valve. As the volume of blood crossing it causes the pulmonic valve to close consistently later than the aortic valve, the second heart sound will be auscultated as split (fixed splitting). Such a sound is almost always diagnostic of ASD.

Echocardiography with color flow Doppler will generally reveal the enlarged right side of the heart and the increased pulmonary circulation. Cardiac catheterization, although rarely needed for diagnosis, would reveal the separation in the atrial septum and the increased oxygen saturation in the right atrium.

Therapeutic Management. Surgery to close the defect is done electively between 1 and 3 years of age. Closure is important because without it, a child is at risk for infectious endocarditis and eventual heart failure. It is particularly important that ASDs be repaired in girls, because they can cause emboli during pregnancy. Surgery in which the edges of the opening in the septum are approximated and sutured may be completed with cardiac catheterization technique if the defect is small (Lim & Matherne, 2007). Large defects may still require open heart surgery and cardiopulmonary bypass. As with VSDs, if the defect is very large, a Silastic or Dacron patch may be sutured into place to occlude the space. Postoperatively, carefully observe the child for arrhythmias because edema of the right atrium could interfere with SA node function. With uncomplicated surgery, children can expect a normal quality and length of life.

Atrioventricular Canal Defect

AVC, also called an endocardial cushion defect, results from incomplete fusion of the endocardial cushion, which is the septum of the heart at the junction of the atria and the ventricles (Fig. 41.10). Usually there is a low ASD continuous with a high VSD and distortion of the mitral and tricuspid valves (Keller, Wessels, & Markwald, 2008). Although blood flow is generally left to right, blood may flow between all four heart chambers with this defect. Although rare in the general population, as many as 50% of children with trisomy 21 (Down syndrome) who have heart disease have this type of congenital cardiac defect (Marian, Brugada, & Roberts, 2008). The defect leads to the same symptoms as other ASDs (right ventricular hypertrophy, increased pulmonary blood flow, and fixed S2 splitting). An ECG often will reveal first-degree heart block as impulse conduction is halted before the AV node. Echocardiography will confirm the diagnosis. Pulmonary artery banding may be done palliatively in selected infants. This increases pressure in the pulmonary artery and right side of the heart, reducing the amount of shunting. Surgery, however, is always necessary for a final repair because these defects are too large to close spontaneously. Because surgery may involve a valve repair as well as a septal repair, mitral and tricuspid insufficiency from poor valve function may occur at a later date. Postoperatively, closely observe children for jaundice resulting from red blood cell destruction as red cells are destroyed by the newly constructed valves. Both prophylactic anticoagulation and antibiotic therapy may be necessary postoperatively, but with these drugs, the artificial valve should help ensure the child can lead an active life.

Patent Ductus Arteriosus

The ductus arteriosus is an accessory fetal structure that connects the pulmonary artery to the aorta. If it fails to close at birth (closure begins with the first breath, and is usually

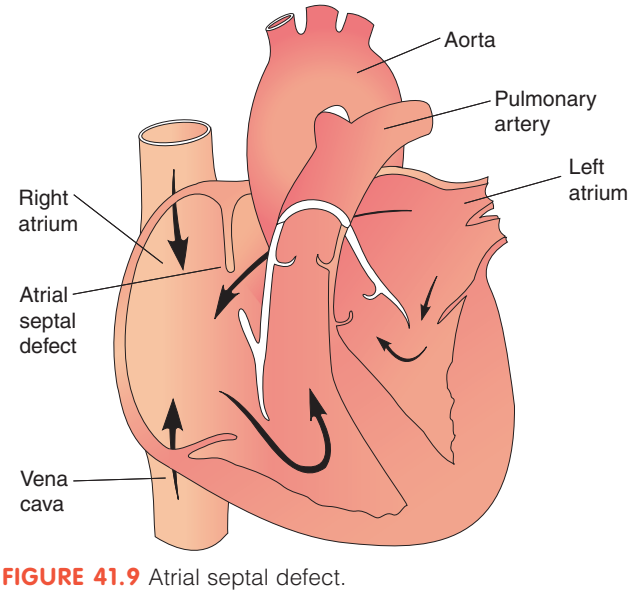

FIGURE 41.9 Atrial septal defect.

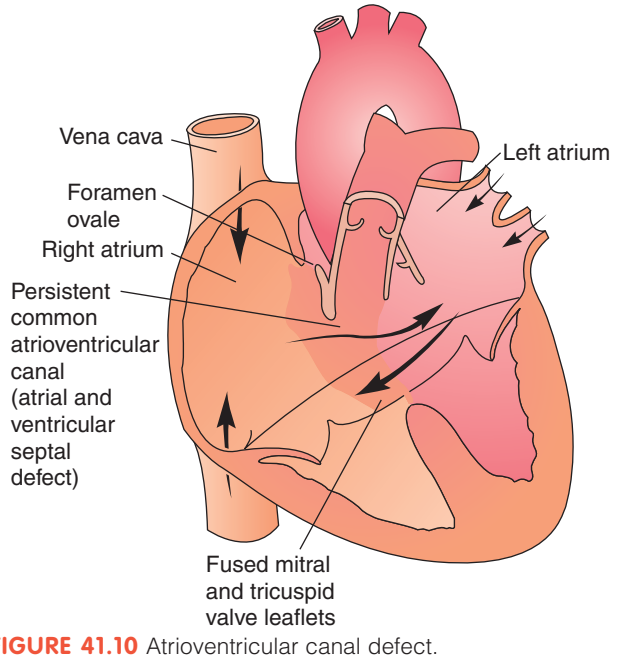

FIGURE 41.10 Atrioventricular canal defect.

complete between 7 to 14 days of age, although full closure may not occur until 3 months of age), blood will shunt from the aorta (oxygenated blood) to the pulmonary artery (deoxygenated blood) because of the increased pressure in the aorta (Thilo & Rosenberg, 2008). The shunted blood returns to the left atrium of the heart, passes to the left ventricle, out to the aorta, and shunts back to the pulmonary artery (Fig. 41.11). This causes increased pressure in the pulmonary circulation from the extra shunted blood; this leads to right ventricle hypertrophy and ineffective heart action.

Assessment. PDAs are twice as common in girls as boys and occur at a higher incidence at higher altitudes. In preterm infants, the incidence may be as high as 20% to 60% and accounts for about 10% of all heart disease. On physical examination, the child usually has a wide pulse pressure (the difference between systolic and diastolic blood pressures). The diastolic pressure, a measure of peripheral resistance, is low because of the shunt or runoff of blood, which reduces resistance. A typical continuous (systolic and diastolic) "machinery" murmur can be heard at the upper left sternal border or under the left clavicle in older children. In newborns, the murmur may not be quite so characteristic, perhaps a short grade II or III harsh systolic sound. An ECG is generally normal, although it may show ventricle enlargement if the shunt is large. Echocardiography provides good visualization of the patent ductus. Cardiac catheterization is generally not necessary for diagnosis but may be performed to rule out associated defects.

Therapeutic Management. One reason that the ductus arteriosus remains open in fetal life is stimulation by prostaglandins, particularly PGE_1, from the placenta and the low oxygen level of fetal blood. After birth, when the PGE_1 level falls and the oxygen level increases, the ductus arteriosus is stimulated to close. If it does not close spontaneously, an infant may be prescribed IV indomethacin or ibuprofen, prostaglandin inhibitors. These lower the PGE_1 level and encourage ductus closure. If indomethacin is given, assess for possible side effects, including reduced glomerular filtration, impaired platelet aggregation, and diminished gastrointestinal and cerebral blood flow (Box 41.5). Because it has much fewer side effects, ibuprofen is becoming the drug of choice; it can even be used as prophylaxis in preterm infants (Thilo & Rosenberg, 2008).

If medical management fails to bring about closure of the ductus arteriosus, the disorder can be closed by insertion of Dacron-coated stainless-steel coils by interventional cardiac catheterization when the child is 6 months to 1 year of age. Exceptionally large defects can be closed surgically by ductal ligation. This involves major surgery because opening the chest (thoracotomy) and manipulating the great vessels is necessary. However, it is not open-heart surgery and so does not involve the use of extracorporeal circulation; rather, it may be performed using only three small thoracotomy incisions on the chest. If surgery is not done by one of these techniques, the child is at risk for heart failure from the increased amount of blood pouring back into the pulmonary artery and infectious endocarditis developing from the recirculating blood and potential stasis in the pulmonary artery.

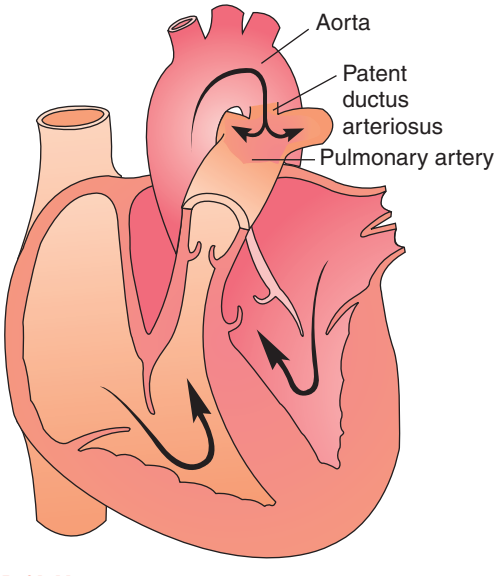

FIGURE 41.11 Patent ductus arteriosus.

BOX 41.5 ✻ Focus on Pharmacology

Indomethacin (Indocin)

Classification: Nonsteroidal anti-inflammatory agent

Action: Inhibits prostaglandin synthesis. Its exact mechanism of action is unknown.

Pregnancy risk category: B (D in third trimester)

Dosage: 0.2 mg/kg intravenously for the first dose, followed by 0.1 mg/kg (if child is less than 48 hours old), 0.2 mg/kg (if child is 2 to 7 days old), or 0.25 mg/kg (if child is over 7 days old) for second and third doses, given at 12- to 24-hour intervals.

Possible adverse effects: Headache, dizziness, somnolence, nausea, gastrointestinal bleeding, constipation, rash, apnea, and increased bleeding problems

Nursing Implications

- Administer reconstituted solution intravenously over 5 to 10 seconds.
- Space doses at specified intervals.
- Educate the parents about the rationale for using the drug.
- Observe the child closely for adverse effects. Check the infusion site carefully for signs of oozing or bleeding indicative of impaired clotting. Also assess vomitus or urine for bleeding (Karch, 2009).

✔ Checkpoint Question 41.4

Suppose Megan has a simple ventricular septal defect. With this condition, in which direction would blood shunt?

a. From the left to the right ventricle
b. From the right ventricle to the aorta
c. From the right to the left ventricle
d. From the left ventricle to the left atria

Disorders With Obstruction to Blood Flow

A number of congenital anomalies cause the blood flow leaving the heart to be obstructed because a vessel or a valve is narrower than usual. Pressure from blood flow increases prior to the narrowing and decreases after the narrowing. These are problematic defects in that they prohibit enough blood from reaching its intended site, the lungs or the rest of the body; they threaten to overwhelm the heart because of back-pressure. Obstructive defects of this category include pulmonary stenosis, aortic stenosis, and coarctation of the aorta.

Pulmonary Stenosis

Pulmonary stenosis is narrowing of the pulmonary valve or the pulmonary artery just distal to the valve (Fig. 41.12). It accounts for about 10% of congenital heart anomalies (Fulton & Freed, 2008). Inability of the right ventricle to evacuate blood by way of the pulmonary artery because of the obstruction leads to right ventricular hypertrophy.

Assessment. Infants with pulmonary artery stenosis may be asymptomatic or have signs of mild (right-sided) heart failure. If the narrowing is severe, cyanosis may be present from inability of adequate blood to reach the lungs for oxygenation or right-to-left shunting across the foramen ovale because of the increased right-sided heart pressure. A typical systolic ejection murmur, grade IV or V crescendo–decrescendo in quality, can be heard, usually loudest at the upper left sternal border. It may radiate to the suprasternal notch. A thrill may be present in the upper left sternal area or at the suprasternal notch. The second heart sound may be widely split because of late closure of the pulmonary valve. An ECG or echocardiography will reveal right ventricular hypertrophy. Cardiac catheterization is rarely necessary for diagnosis but is used for interventional enlargement of the stenosed valve.

Therapeutic Management. Management of the defect depends on the severity of the stenosis and the child's age. **Balloon angioplasty** by way of cardiac catheterization is the procedure of choice. With this procedure, a catheter with an uninflated balloon at its tip is inserted and passed through the heart into the stenosed valve. As the balloon is inflated, it breaks valve adhesions and relieves the stenosis. Following the procedure, although children may always have a residual heart murmur, they can expect a normal life span.

Aortic Stenosis

Stenosis, or stricture, of the aortic valve prevents blood from passing freely from the left ventricle of the heart into the aorta. Because the heart cannot force blood through the strictured valve, increased pressure and hypertrophy of the left ventricle occur (Fig. 41.13). If the left ventricular pressure becomes acute, pressure in the left atrium also increases, resulting in back-pressure in pulmonary veins and possibly pulmonary edema. Aortic stenosis accounts for about 7% of congenital cardiac abnormalities (Fulton & Freed, 2008).

Assessment. Most children with aortic stenosis are asymptomatic, but physical assessment generally reveals a typical murmur, a rough systolic sound heard loudest in the second right interspace (the aortic space). The murmur may be transmitted to the right shoulder, clavicle, and up the vessels of the neck; it may also be transmitted to the heart's apex. A thrill may be present, particularly at the suprasternal notch. If severe, decreased cardiac output evidenced by faint pulses, hypotension, tachycardia, and inability to suck for long periods may be present. When the child is active, chest pain similar to angina occurs, because the coronary arteries receive inadequate blood. Sudden death can occur when the amount of oxygen needed by the heart muscle on exertion far exceeds what is available.

ECG or echocardiography will reveal left ventricular hypertrophy. Cardiac catheterization is rarely necessary unless interventional therapy by this route is planned.

Therapeutic Management. Stabilization with a beta-blocker or a calcium channel blocker may be necessary to reduce cardiac

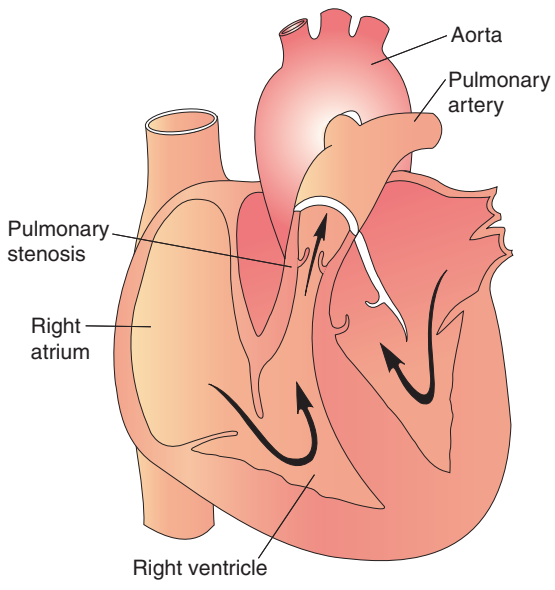

FIGURE 41.12 Pulmonary stenosis.

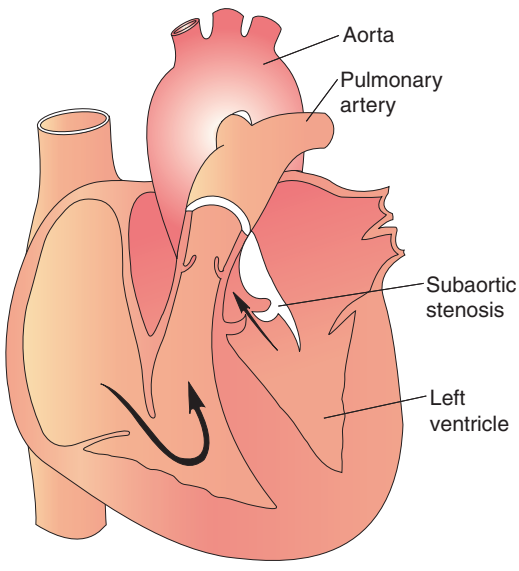

FIGURE 41.13 Aortic stenosis.

hypertrophy before the defect is corrected. Balloon valvuloplasty is the surgical treatment of choice. Surgery that involves dividing the stenotic valve or dilating an accompanying constrictive aortic ring can be used for severe defects. Such a repair may lead to aortic valve insufficiency in later life, at which time further surgery may be needed. Some children will need artificial valve replacement for correction. If a prosthetic valve is used, children generally continue to receive anticoagulation or antiplatelet therapy and antibiotic prophylaxis against endocarditis. In addition, children need exercise testing before participating in competitive sports if an artificial valve is in place.

Coarctation of the Aorta

Coarctation of the aorta, a narrowing of the lumen of the aorta due to a constricting band (Fig. 41.14), accounts for about 6% of instances of congenital heart disease (Keller, Wessels, & Markwald, 2008). It occurs more frequently in boys than in girls and is the leading cause of congestive heart failure in the first few months of life. There are two locations in which this commonly occurs. In the first, termed "preductal," the constriction occurs between the subclavian artery and the ductus arteriosus. In the second, postductal, the constriction is distal to the ductus arteriosus.

Because it is difficult for blood to pass through the narrowed lumen of the aorta, blood pressure increases proximal to the coarctation and decreases distal to it. This results in increased blood pressure in the heart and upper portions of the body as pressure in the subclavian artery increases. Elevated upper-body blood pressure produces headache and vertigo. Because a child under 3 years of age has difficulty describing these sensations, exceptional irritability may be the main clue that these symptoms are present. Epistaxis (nosebleed) and cerebrovascular accident, an event not generally associated with children, can occur from this dangerously elevated blood pressure.

Assessment. If the coarctation is slight, absence of palpable femoral pulses may be the only symptom. For this reason, always include evaluation of femoral pulses in all initial newborn assessments and admission inspections to newborn nurseries. Children who have an obstruction proximal to the left subclavian artery may have absent brachial pulses as well. As children with coarctation of the aorta grow older, they may experience leg pain on exertion because of the diminished blood supply to their lower extremities. Because collateral circulation is necessary to allow blood to flow around the constriction, collateral arteries enlarge and may be seen on the ribs as obvious nodules as the child grows older.

The diagnosis of coarctation of the aorta may be made on the basis of the history and physical assessment. On examination, the blood pressure in the arms will be at least 20 mm Hg higher than in the legs, a reversal of the normal pattern. Echocardiography, ECG, MRI, or x-ray examination of older children will reveal left-sided heart enlargement from back-pressure and also notching of the ribs from the enlarged collateral vessels. Occasionally, a murmur is present, but this is variable in position, intensity, and character. The most frequent type is a soft or moderately loud systolic murmur, especially prominent at the base of the heart and transmitted to the left interscapular area. The absence of a murmur, however, does not rule out coarctation of the aorta.

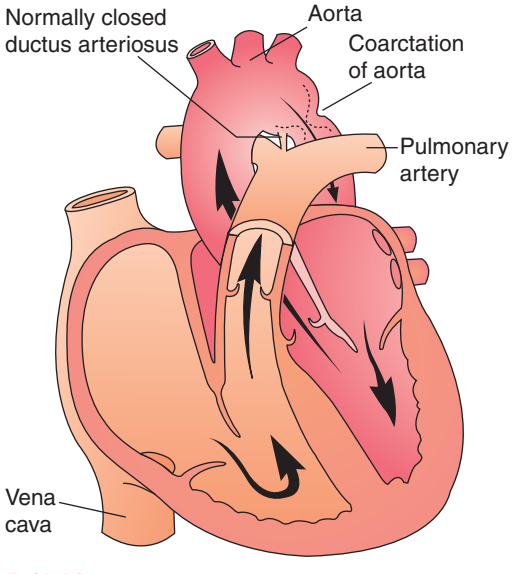

FIGURE 41.14 Coarctation of the aorta.

Therapeutic Management. Management of coarctation of the aorta is by interventional angiography (a balloon catheter) or surgery. With surgery, the narrowed portion of the aorta is removed and the new ends of the aorta are anastomosed. A graft of transplanted subclavian artery may be necessary if the narrowed section is so extensive that an anastomosis cannot be accomplished readily.

Many infants with coarctation of the aorta require therapy with digoxin and diuretics in the time before surgery can be performed. This drug therapy aims to reduce the severity of the congestive heart failure from hypertension.

Planning a time for correction of the condition is important. It would be ideal if children could achieve the greater part of their adult height before surgical correction, as this might prevent a strain on the incision line as they grow. At the same time, in terms of self-image, correction is best done before children begin to think of themselves as chronically ill or before they develop a complication, such as chronic hypertension. Girls must have the defect repaired before childbearing age, or the extra blood volume during pregnancy can cause heart failure. Surgical repair is usually scheduled, therefore, by 2 years of age. If the surgery is successful, the child can expect to live a normal life. After surgery, abdominal vessels receive more blood than they did previously. This may result in abdominal pain or generalized abdominal discomfort, but this is a short-term problem. Some children continue to have elevated upper body hypertension after the repair. They need continued treatment with antihypertensive agents. Some children require repeat balloon angioplasty at adolescence to reenlarge the aortic lumen and help reduce this upper body hypertension.

Disorders With Mixed Blood Flow

Mixed disorders are cardiac anomalies that involve mixing of blood from the pulmonary and systemic circulation in the heart chambers. This mixing results in a relative deoxygenation of systemic blood flow, although cyanosis is not always

visible. Mixed defects include transposition of the great arteries, total anomalous pulmonary venous return, truncus arteriosus, and hypoplastic left heart syndrome.

Transposition of the Great Arteries

In transposition of the great arteries, the aorta arises from the right ventricle instead of the left, and the pulmonary artery arises from the left ventricle instead of the right. Blood enters the heart from the vena cava to the right atrium, then flows to the right ventricle, and goes out into the aorta to the body completely deoxygenated; it returns again by the vena cava. A secondary source of blood enters the heart from the pulmonary veins, goes to the left atrium, left ventricle, and out the pulmonary artery to the lungs to be oxygenated, and returns to the left atrium, a second closed circulatory system (Fig. 41.15). This severe a defect is incompatible with life. In most instances, atrial and ventricular septal defects occur in connection with this transposition, making the entire heart one mixed circulatory system. It tends to occur in large newborns (9 to 10 lb) and occurs more often in boys than in girls. This disorder accounts for about 5% of congenital heart anomalies (Fulton & Freed, 2008).

Assessment. Infants with this defect are usually cyanotic from birth. There may be no murmur, or there may be various murmurs, depending on the shunting of blood through atrial or ventricular defects or through the ductus arteriosus, which usually remains open. Echocardiography generally reveals an enlarged heart. An ECG may or may not reveal heart changes. Cardiac catheterization will reveal the low oxygen saturation resulting from the mixing of blood in the heart chambers.

Therapeutic Management. If no septal defect exists or if the defect is too small to allow enough mixing of blood to sustain life, PGE_1, a prostaglandin, will be administered to keep the ductus arteriosus patent. A balloon atrial septal pull-through operation to enlarge the septal openings may also need to be done in the infant's first few days. With this procedure, done by cardiac catheterization, a deflated balloon catheter is passed from the right atrium through the foramen ovale into the left atrium. The balloon is then inflated, and the catheter is drawn back into the right atrium. This enlarges the opening of the foramen ovale and creates an artificial ASD.

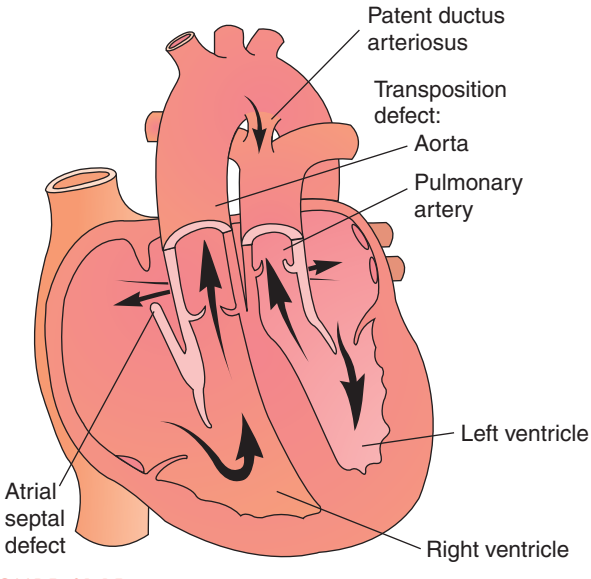

FIGURE 41.15 Transposition of the great vessels.

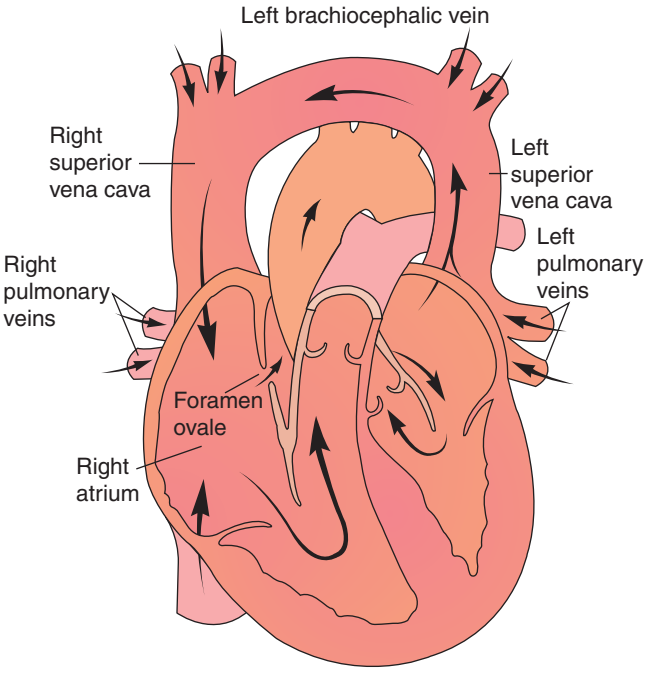

FIGURE 41.16 Total anomalous pulmonary venous return.

Surgical correction of transposition of the great vessels, done at 1 week to 3 months of age, involves an arterial switch procedure in which the major vessels are switched in position (DeBord, Cherry, & Hickey, 2007). The child will be transported to a major center for the surgery and care as soon as a disorder of this magnitude is diagnosed. The survival rate following surgery is as high as 95%.

Total Anomalous Pulmonary Venous Return

In this disorder, the pulmonary veins return to the right atrium or the superior vena cava instead of to the left atrium as they normally would. For blood to reach the systemic circulation, it must shunt across a patent foramen ovale or a PDA (Fig. 41.16). This disorder accounts for only 2% of all congenital heart disorders. An absent spleen is often associated with the disorder. These infants are mildly cyanotic and tire easily. If the ductus closes or the septal defect is small, cyanosis increases in amount; right-sided heart failure develops.

Surgery involves reimplanting the pulmonary veins into the left atrium. Until this can be carried out, a balloon atrial septal pull-through procedure may be necessary to enlarge a small foramen ovale. The child may be maintained on a continuous IV infusion containing PGE_1 to help keep the ductus arteriosus open (Fulton & Freed, 2008).

Truncus Arteriosus

In truncus arteriosus, a rare defect (approximately 1% of initial cardiac lesions), one major artery or "trunk" arises from the left and right ventricles in place of separate aorta and pulmonary

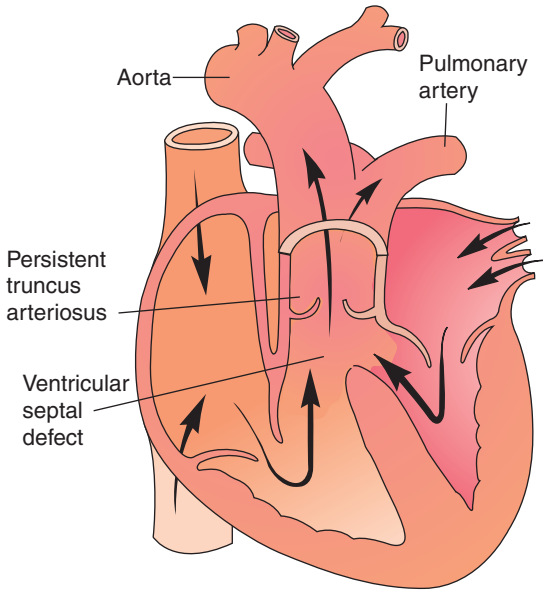

FIGURE 41.17 Truncus arteriosus.

artery vessels (Fig. 41.17). There is usually an accompanying VSD. The child is cyanotic and may have a typical VSD murmur. Repair involves restructuring the common trunk to create separate vessels. Some children need a second surgical procedure by school age as the graft inserted to separate the aorta and pulmonary artery is outgrown.

Hypoplastic Left Heart Syndrome

In hypoplastic left heart syndrome, a rare disorder accounting for only 1% to 3% of congenital heart disease, the left ventricle is nonfunctional. There may be accompanying mitral or aortic valve atresia. The nonfunctioning left ventricle lacks adequate strength to pump blood into the systemic circulation. This causes the right ventricle to hypertrophy as it tries to maintain the entire heart action (Alsoufi et al., 2007). The disorder may be detected by ultrasound prenatally (Rasiah et al., 2008). At birth, mild to moderate cyanosis develops as deoxygenated blood is shunted across the foramen ovale because of the greater pressure on the right. Echocardiography effectively diagnoses this condition. Prostaglandin therapy to maintain a PDA will be initiated to increase blood supply to the aorta. Inhaled nitrogen combined with oxygen may be prescribed to decrease P_{O_2}; this increases pulmonary resistance and allows the right heart to shift more blood into the left heart and aorta. Surgery has limited success in this syndrome, although a great deal of research is being done in this area and a two- or three-stage procedure (restructuring of the heart; a Norwood procedure) is possible. Heart transplantation is the ultimate answer for prolonging the child's life, but the number of donor hearts available for newborns is limited (Tjang et al., 2007).

Disorders With Decreased Pulmonary Blood Flow

As the category implies, disorders with decreased pulmonary blood flow involve some type of obstruction to blood flow in the pulmonary artery. Because of the obstruction, pressure increases in the right side of the heart. If an ASD or VSD also is present, deoxygenated blood shunts from right to left. This results in deoxygenated blood invading the systemic circulation. Common disorders include tricuspid atresia and tetralogy of Fallot.

Tricuspid Atresia

Tricuspid atresia is an extremely serious disorder because the tricuspid valve is completely closed, allowing no blood to flow from the right atrium to the right ventricle (Bartlett et al., 2007). Instead, blood crosses through the patent foramen ovale into the left atrium, bypassing the lungs and the step of oxygenation. It reaches the lungs for oxygenation by being shunted back through a PDA (Fig. 41.18). As long as the foramen ovale and ductus arteriosus remain open, the child can obtain adequate oxygenation. At the point they close, however, the infant will develop extreme cyanosis, tachycardia, and dyspnea. An IV infusion of PGE_1 is begun to ensure that the ductus remains open. Surgery consists of the construction of a vena cava-to-pulmonary artery shunt, which deflects more blood to the lungs, or a Fontan procedure (sometimes termed a Glenn Shunt baffle), which restructures the right side of the heart.

Tetralogy of Fallot

Tetralogy of Fallot, one of the first types of congenital heart disease described, occurs in about 10% of children with congenital cardiac disease (Dambro, 2008). It is called a tetralogy because four anomalies are present: pulmonary stenosis, VSD (usually large), dextroposition (overriding) of the aorta, and hypertrophy of the right ventricle. Because of the pulmonary stenosis, pressure builds up in the right side of the heart. Blood then shunts from this area of increased pressure into the left ventricle and the overriding aorta. The extra effort involved to force blood through the stenosed pulmonary artery causes the fourth deformity, hypertrophy of the right ventricle (Fig. 41.19). A number of children with this disorder show a

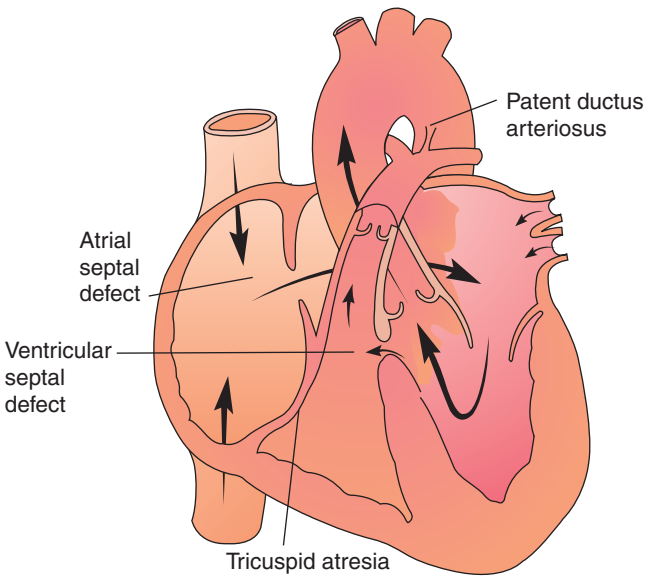

FIGURE 41.18 Tricuspid atresia.

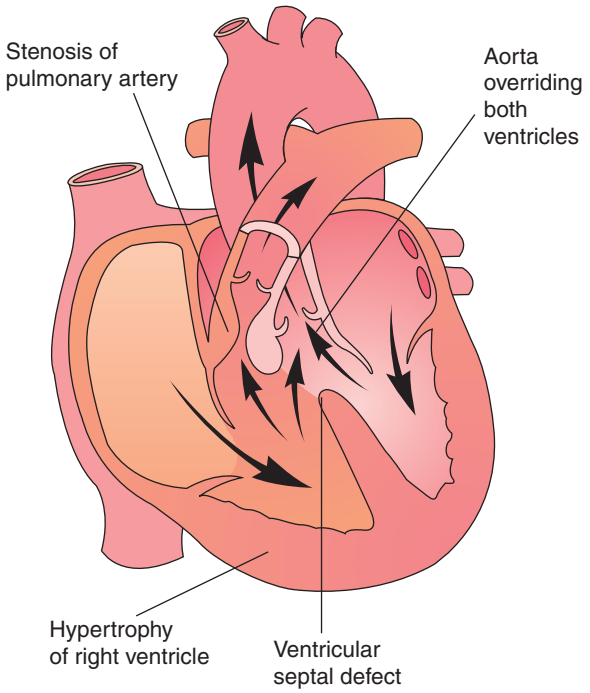

FIGURE 41.19 Tetralogy of Fallot.

deletion abnormality of chromosome 22 (22q11.2), or the disorder can result from a documented chromosome disorder.

Assessment. Although this is an extremely serious form of heart disease, newborns may not exhibit a high degree of cyanosis immediately after birth. As they become more active, however, their skin acquires a bluish tint as cyanosis begins. Polycythemia (an increase in the number of red blood cells) occurs as the body attempts to provide enough red blood cells to supply oxygen to all body parts. This is an additional potential danger because the increased concentration of red blood cells causes the blood to become thick (increased viscosity), and clots in blood vessels may occur, with complications such as thrombophlebitis, embolism, or cerebrovascular accident.

If the condition is not corrected, a child will generally develop severe dyspnea, growth restriction, and clubbing of the fingers. The child tends to assume a squatting or a knee–chest position when resting. Squatting gives physiologic relief to an overstressed heart by trapping blood in the lower extremities. Unless they do this, children's hearts can be overwhelmed, leaving an insufficient amount of total circulating blood for the body to oxygenate and deliver to major body organs (Hovels-Gurich et al., 2007).

Children may develop syncope (fainting) and hypercyanotic episodes (sometimes called tet spells) caused by decreased blood and oxygen supply to the brain. These usually follow prolonged crying or exertion. They can be so extreme, if long term, that children develop cognitive challenge.

Tetralogy of Fallot is diagnosed based on the history and physical symptoms, echocardiography, ECG, cardiac catheterization and laboratory findings that reveal polycythemia, increased hemoglobin, hematocrit, and total red blood cell count as well as reduced oxygen saturation. A loud, harsh, widely transmitted murmur or a soft, scratchy, localized systolic murmur in the left second, third, or fourth parasternal interspace may be present. It is so widely transmitted that it is often heard as well in the left clavicular area or posteriorly, in the interscapular space. Splitting of the second heart sound rarely occurs with tetralogy of Fallot because blood is forced through the shunt; the pulmonic valve does not, therefore, close later than the aortic valve.

Echocardiography and ECG both show the enlarged chamber of the right side of the heart. Echocardiography also shows the decrease in the size of the pulmonary artery and the reduced blood flow through the lungs. Cardiac catheterization and angiography will permit a definitive evaluation of the extent of the defect, particularly the pulmonary stenosis and the VSD.

Therapeutic Management. Management of tetralogy of Fallot is surgery to correct the heart defects, done at 1 to 2 years of age. Parents need to try to keep hypercyanotic episodes to a minimum during this waiting time. If a baby begins to have a hypoxic episode, administering oxygen, placing the baby in a knee–chest position (to trap blood in the lower extremities and keep the heart from being overwhelmed), and administering morphine sulfate generally reduces symptoms. If not, propranolol (Inderal, a beta-blocker) may be given orally to aid pulmonary artery dilation. A temporary or palliative surgical repair, called the Blalock-Taussig procedure, can create a shunt between the aorta and the pulmonary artery (creating a ductus arteriosus). This will allow blood to leave the aorta and enter the pulmonary artery, oxygenate in the lungs, and return to the left side of the heart, the aorta, and the body. Because the subclavian artery is used in a Blalock-Taussig procedure, a child will not have a palpable pulse in the right arm after this procedure. For this reason, blood pressure and venipunctures should be avoided in the affected arm.

A full repair that relieves the pulmonary stenosis, VSD, and overriding aorta will then be scheduled (a Brock procedure). Postoperatively, observe for arrhythmias, which may result from any ventricular septal repair, edema, and conduction interference.

What if... You noticed Megan, who has tetralogy of Fallot, always draws her knees up tightly against her chest? Would this be a concern for you? Why or why not?

ACQUIRED HEART DISEASE

The most commonly acquired heart disease in children is congestive heart failure (CHF), or a condition where the heart is overwhelmed and unable to effectively pump blood forward.

Congestive Heart Failure

Congestive heart failure (CHF) usually occurs as a result of a congenital heart disorder or a disease such as rheumatic fever, Kawasaki disease, or infectious endocarditis. This occurs when the myocardium of the heart cannot pump and circulate enough blood to supply oxygen and nutrients to body cells (Fenton & Burch, 2007). Blood pools in the heart (excessive preload) or in the pulmonary or venous systems. This may result from a congenital disorder that lessens the effectiveness of the heart's pumping action, or it may

occur after cardiac surgery or rheumatic fever, when the myocardium is weakened. Severe anemia, hypocalcemia, and myocarditis may contribute to the heart's inability to function effectively. CHF is most apt to occur in children under 1 year of age (Fulton & Freed, 2008).

The heart can compensate in several ways to move blood forward and attempt to increase cardiac output. The muscle fibers can lengthen, causing the ventricles to enlarge in an attempt to handle more blood with each heart stroke (ventricular hypertrophy). The heart can also increase the number of beats per minute. As long as these mechanisms allow for adequate cardiac output, the signs of heart failure are not apparent. However, the heart's capacity for compensation is limited, particularly in infants, an age group in which hypertrophy is restricted. Eventually, in children of all ages, the heart can no longer compensate and becomes overwhelmed by the amount of blood present, which cannot be pushed forward effectively.

Sympathetic nervous system stimulation causes the frequently seen symptoms of excessive sweating and pallor. As blood flow to the kidneys decreases, the glomerular filtration rate slows, resulting in stimulation of the renin-angiotensin system, which causes fluid and sodium retention. Aldosterone secretion by the adrenal glands further promotes sodium retention in an attempt to increase blood flow to the kidneys. Antidiuretic hormone secretion by the pituitary is also increased to help retain fluid. This additional fluid results in dependent edema.

Assessment

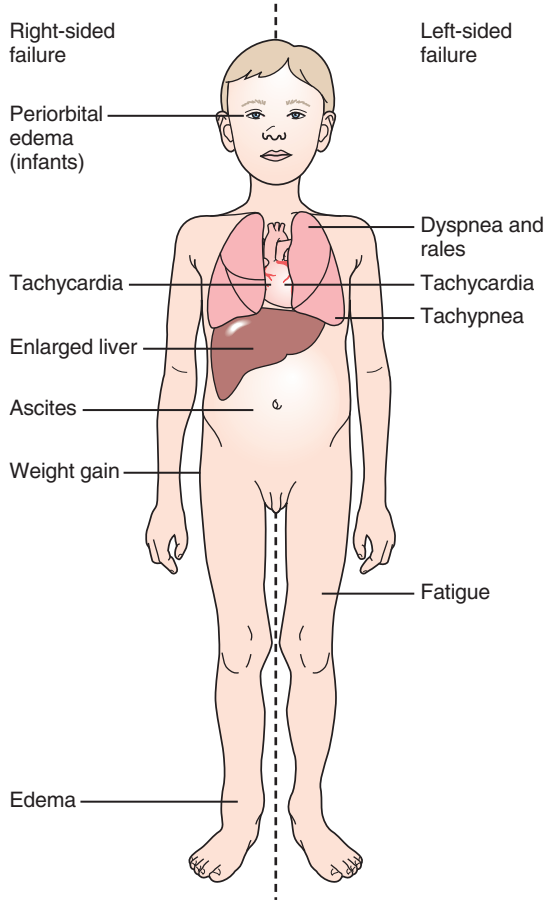
One of the first signs of CHF is tachycardia as the heart attempts to beat faster to move blood forward more effectively; this is quickly followed by tachypnea or rapid breathing. When a child has primary right heart failure, increased venous pressure and hepatomegaly (enlarged liver) occur from back-pressure in the portal circulation. The child may feel irritable and restless from the abdominal pain caused by the liver distention. Lower extremity edema, usually a primary sign in adults, is often a late sign of heart failure in children (Box 41.6).

With left-sided heart failure, back-pressure causes blood to accumulate in the pulmonary system. Dyspnea is usually the dominant symptom, especially when a child lies flat (this is orthopnea or difficulty breathing except in an upright position; it occurs due to increased pulmonary congestion). A child may have rales and may produce bloody sputum on coughing (from lung capillaries broken under increased pulmonary blood pressure). A child may appear cyanotic from interference with gas exchange in the alveoli, which begin to fill with fluid (pulmonary edema). Left-sided heart failure can ultimately lead to right-sided heart failure as extensive pressure in the pulmonary system prevents blood from leaving the right ventricle.

In an infant, heart failure is often difficult to detect because it presents with very subtle signs. The infant becomes breathless from rapid respirations, tires easily, and has difficulty feeding because of the exhaustion and dyspnea present. Often an infant becomes diaphoretic from the effort of feeding. If edema is present, it is generalized rather than dependent and often is first noticed as periorbital edema. An abrupt gain in weight may be the most obvious indication that extra fluid is accumulating. On physical examination, an infant will have an enlarged liver (a liver palpable more than 2 cm below the right costal margin) and may have ascites or fluid in the peritoneal space.

The apical heartbeat is displaced laterally and downward. As a rule, if the width of the heart is more than half the width of the chest (in a child over 1 year of age), the heart is enlarged. In addition, a galloping heart rhythm or an accentuated third heart sound may be heard because of the sudden distention of the ventricle during the rapid filling phase. Heart failure may be confirmed by echocardiography, which reveals the enlarged heart. Ventricular hypertrophy can be confirmed by ECG.

Box 41.6 Assessment
Assessing a Child With Heart Failure



Therapeutic Management

Therapy for heart failure consists of reducing the workload of the heart by measures such as evacuating the accumulated fluid (reduces preload) with diuretics, slowing the heart rate and strengthening cardiac function (increases contractility) by administering an inotropic (heart-strengthening) drug, and reducing afterload with a vasodilator.

Commonly used diuretics include furosemide (Lasix) and spironolactone (Aldactone). The most common drug used to increase contractility and slow tachycardia is digoxin. Drugs that decrease afterload include hydralazine, an arterial

vasodilator; nifedipine, a calcium channel blocker; nitroprusside, a direct-acting vasodilator; and captopril, an angiotensin-converting enzyme (ACE) inhibitor (Karch, 2009).

Nursing Diagnoses and Related Interventions

Be certain that outcomes established for the care of a child with congestive heart disease are realistic in light of the child's condition as well as individualized for each child. Interventions focus on helping support heart function and helping parents deal with this crisis until the child's heart is again strong enough to maintain strong heart action (see Focus on Nursing Care Planning Box 41.7).

Nursing Diagnosis: Ineffective cardiopulmonary and peripheral tissue perfusion related to inadequate heart function

Outcome Evaluation: Child's pulse, blood pressure, and respiratory rate are within acceptable parameters for age group; abnormal heart sounds, edema, and ascites are absent.

Provide for Rest Periods. Rest, a major aspect of care for a child with heart failure, reduces the metabolic rate, decreasing myocardial and body oxygen demand. Most children with heart failure feel more comfortable in a semi-Fowler's position than in a supine position. This chest-elevated position lowers the abdominal contents, enlarging the thoracic cavity and allowing for easier, more comfortable lung expansion. Babies are most comfortable in an infant seat, which supports them in a semi-Fowler's position. Sedation with morphine may be necessary to encourage bedrest in some children. Most children with heart failure, however, automatically limit their activity, so the need for sedation must be considered on an individual basis.

Organize nursing care to allow periods of sustained rest. At the same time, do not attempt to perform too many procedures at once or you will exhaust the child. Be certain that both you and the child's parents understand how much rest the child is to have each day. The term "complete bedrest" is often loosely used and has different meanings to different people. Does it mean a child may eat by herself, or must she be fed? Does it mean bathroom privileges or not? Playtime or not? Unless children are exceptionally exhausted, most children need to be entertained or played with to remain on bedrest. Activities such as watching television, being read to, or listening to music can quiet a child and promote better rest than if the child is expected to rest quietly without any diversion.

Provide Oxygen as Necessary. If a child has dyspnea, hypoxemia, or cyanosis, supplemental oxygen by way of hood, mask, or nasal prongs is usually necessary.

Remember that oxygen is considered to be a drug so must be prescribed according to amount or oxygen parameters except when associated with resuscitation, and oxygen saturation should be monitored with pulse oximetry. Assess the nostrils of the child receiving oxygen with nasal prongs every 4 hours to prevent pressure and subsequent irritation and breakdown of the interior nostrils (this is a major problem in newborns). For a child with heart failure, it is a strain to be submitted to strange, frightening equipment. Orient a child to oxygen equipment before it is brought to the bedside. Children generally experience such relief from dyspnea when they are receiving oxygen that their apprehension quickly disappears.

Administer Drugs as Prescribed to Improve Heart Action. Digoxin, a cardiac glycoside made from digitalis, acts directly on the heart to increase the contractility of the myocardium (and the force of contraction). It also slows the ventricular response in atrial arrhythmias. Digoxin is a potent drug, so doses must be prepared with extreme accuracy. For safest administration, digoxin should be prescribed with the dose designated in both milligrams and milliliters. When this is done, the milligram dose can be checked against the milliliter dose to be certain the decimal point of the milligram dose has not been inadvertently misplaced (0.03 mg, not 0.3 mg, for example). Digoxin may also be ordered in micrograms or μg (0.02 mg = 20 μg). Digoxin preparations are typically administered IV first in a large dose (the digitalizing dose). Six to 8 hours later, one fourth of the initial dose is given; another one fourth is given again in 6 to 8 more hours. An ECG and serum digoxin level are generally obtained before the second or third dose of digoxin to assess the adequacy of the dose. Following this, maintenance doses are given once daily. For children under 10 years of age, the dosage could be divided into two doses given at 12-hour intervals.

Before administering a dose of digoxin, to be certain that the child's heart rate is not abnormally low, always obtain a child's apical pulse. As a rule, the pulse rate should be above 100 beats per minute in infants and above 70 beats per minute in older children. When effective, digoxin improves the strength of the heart's contraction. Diuresis begins and relieves any edema present. Changes in the ECG (a lengthening of the P-R interval or a depression of the S-T segment) confirm that digitalization has taken place.

The "window" between effective digitalization and digoxin toxicity is very narrow. Monitor serum digoxin levels closely as prescribed. Symptoms of toxicity include anorexia, nausea and vomiting, dizziness, diarrhea, headache, and arrhythmia.

Many children are discharged on long-term administration of digoxin (Lanoxin). If parents will be administering the drug after their child's discharge from the hospital, be certain they understand the drug's correct dose and frequency of administration. Help them choose a specific time for administration to which they can adhere faithfully. Make out a reminder sheet to

BOX 41.7 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for an Infant With Congestive Heart Failure

Megan is a newborn who was born with tetralogy of Fallot. By 1 hour of age, she developed rapid respirations, tachycardia, and cyanosis. An echocardiogram revealed the typical four structural defects of the syndrome. An hour later, Megan is in heart failure.

Family Assessment ✻ Child's parents were divorced 1 month ago; dual custody of infant granted. Child will spend weekdays with mother, weekends with father. Father is a city bus driver; mother is a paralegal. Father to pay child support; with child support, mother rates finances as "workable."

Client Criteria ✻ One-hour-old infant girl who appears pale to cyanotic, tachycardic, and dyspneic. Child born by vaginal birth; Apgars 9 and 6. Afebrile; pulse 150 bpm; respirations 36. Oxygen saturation via pulse oximetry 90 mm Hg. Apical heart rate displaced down and laterally. S3 heart sound noted. Lungs with harsh rhonchi and rales on auscultation. Generalized edema with hepatomegaly.

Nursing Diagnosis ✻ Ineffective cardiopulmonary tissue perfusion related to impaired cardiac function and increased cardiac workload

Outcome Evaluation ✻ Child's vital signs are within age-acceptable parameters; skin color pink and warm; dyspnea seems lessened. Absence of S3 heart sound; oxygen saturation more than 95 mm Hg. Lungs clear to auscultation.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Assess vital signs as prescribed. Auscultate heart and lung sounds. Monitor arterial blood gas values and oxygen saturation levels via pulse oximetry.	Place infant in infant seat to elevate head and chest 30° to 60°.	Elevating the head and chest relieves pressure on the diaphragm, enhancing lung expansion and heart function.	Child's vital signs remain within prescribed parameters. O_2 saturation is at 95%. Po_2 is 80–100 mm Hg.
Nurse	Assess actions that appear to allow the infant to be most comfortable.	Remove any constricting clothing from child's chest. Limit procedures to those that are necessary to provide adequate rest periods.	Constricting clothing interferes with chest expansion. Activity increases metabolic and myocardial oxygen demands, further impairing cardiopulmonary tissue perfusion.	Infant appears to rest comfortably in infant seat.
		Consultations		
Physician	Determine whether additional consultation will be necessary.	Consult with cardiac specialist on call as necessary.	Infants with congestive heart failure have few resources to use to compensate for failing heart action.	Cardiac specialist consults as necessary to better stabilize infant's condition.
		Procedures/Medications		
Nurse	Assess apical pulse before administering digoxin. Obtain serum digoxin levels as ordered.	Administer digoxin as prescribed.	Digoxin improves myocardial contractility.	Infant receives digoxin based on adequate heart rate and serum level.
Nurse	Obtain baseline weight. Assess electrolytes for hypokalemia before administering diuretics.	Monitor weight daily at same time. Administer diuretics, such as furosemide, as ordered.	Weight is an indicator of fluid balance. Diuretics reduce edema and diminish afterload. Potassium can be removed with urine.	Infant receives diuretics as prescribed, based on weight and potassium status.

(continued)

BOX 41.7 ✻ Focus on Nursing Care Planning (continued)

Nurse/ respiratory therapist	Assess O_2 saturation with continuous pulse oximetry.	Administer oxygen by infant hood.	Oxygen enhances tissue perfusion; Infant hoods provide oxygen without obscuring infant's face.	Infant's O_2 saturation remains at 95% or above.
		Nutrition		
Nurse	Assess child's intake and output for adequacy.	Feed 1 oz commercial formula q4h as prescribed. Allow to rest halfway through feeding.	Eating requires energy expenditure, which could compromise heart function and interfere with nutrition.	Infant takes in prescribed formula without evidence of undue tiredness.
Nurse	Determine when mother will be present in hospital.	Urge mother to feed infant at least once daily.	Feeding can promote mother–child interaction.	Mother visits and feeds at least one feeding daily. States she is comfortable feeding ill infant.
		Patient/Family Education		
Nurse	Assess parents' understanding of child's condition.	Educate parents as needed about congenital heart disease and congestive heart failure.	Parents need an understanding of child's illness to respect need for rest and medications.	Parents both state that they understand child's condition; necessary because both will be caregivers.
		Psychosocial/Spiritual/Emotional Needs		
Nurse/nurse practitioner	Assess whether parents feel they have enough emotional support to care for an ill infant at home.	Discuss necessity for vigilance and keeping infant free of infection.	Respiratory infection could quickly worsen child's condition.	Parents state that they understand the strain caring for an ill infant can cause. Have made arrangements for continuous care.
		Discharge Planning		
Nurse	Assess whether parents have any further questions about child's condition or needs.	Review care necessary for infant. Give parents written instructions.	Parents will be taking responsibility for a potentially ill infant.	Parents state that they feel confident in their ability to care for infant prior to corrective surgery.
Nurse	Assess whether parents are familiar with CPR technique for infants.	Teach parents infant CPR technique using CPR mannequin.	Well-prepared parents can be the child's first line of defense.	Parents correctly demonstrate infant CPR technique on CPR mannequin.
Nurse	Assess whether parents will be able to return infant in 1 week for follow-up visit.	Schedule appointment for 1-week follow-up visit.	Weekly evaluation will help ascertain that child's condition remains stable until corrective surgery.	Parents state that they understand importance of follow-up visit and will keep appointment.

help them remember to give the drug. Additional instructions for home administration of digoxin are shown in Box 41.8.

Diuretics such as furosemide (Lasix) may be administered to decrease pulmonary edema, which will reduce afterload. This choice appears to be more effective than restricting salt and fluid in young children. Daily weights are a good way to gauge the diuretic's effectiveness. Be certain children are weighed at the same time, with the same scale, in the same clothing (or nude) every day so measurements are as accurate as possible and any weight loss can be noted easily. As large quantities of fluid can be lost through diuretics, so can potassium, which could lead to hypokalemia

BOX 41.8 ✻ Focus on Family Teaching

Giving Digoxin Safely at Home

Q. Megan's mother says to you, "The doctor has prescribed our daughter digoxin to take at home. Are there any special things we should do?"

A. Use the guidelines below to ensure safe digoxin administration at home:

- Always assess an apical pulse before administration; do not administer the drug if your child's heart rate is below 100 beats per minute (or as specifically instructed as she grows older).
- Always use the same measuring device (spoon or dropper) each time, so the dose given remains consistent.
- Do not change the amount or timing of the dose without specific instructions from your primary care provider.
- If you omit a single dose, give the next dose on time as prescribed.
- If you omit more than one dose, telephone your primary care provider for further instructions.
- Give digoxin 1 hour before or 2 hours after feeding, to avoid a dose being lost if the child spits up.
- If a dose is vomited, do not repeat the dose. Give the next dose at the scheduled time. If the child vomits the next dose, call your primary care provider.
- Notify your primary care provider if the child vomits more than once each day, because vomiting is a sign of digoxin overdose (toxicity).
- Notify your primary care provider if administration of the medicine or the timing of the dose is difficult for your lifestyle.

(low serum potassium levels). For these reasons, monitor urine output and serum electrolyte levels, including the potassium level. Normal urine output is 1 to 2 mL/kg/hr. If hypokalemia occurs, the risk for digoxin toxicity increases. Hydrochlorothiazide (HCTZ) is a typical diuretic used for long-term therapy. Because HCTZ, a thiazide diuretic, also promotes potassium excretion, a diet high in potassium and perhaps oral potassium supplementation may be prescribed to maintain potassium levels. Liquid potassium is irritating to the gastrointestinal tract and should be given mixed with fruit juice.

Nursing Diagnosis: Risk for imbalanced nutrition, less than body requirements, related to fatigue

Outcome Evaluation: Child maintains percentile curve on growth chart; skin turgor is good.

Maintaining proper nutrition may be a problem for children with heart failure because they tire easily. Eating six to eight small meals daily is often less tiring than eating three large meals. Smaller meals also prevent the child's stomach from pressing upward on the diaphragm and compromising an enlarged heart. Sucking is hard work, so infants may need to drink smaller amounts frequently to maintain adequate fluid intake or receive a higher-calorie formula to allow for adequate calories without added fluid volume. Using soft "preemie" nipples may be helpful because they make sucking easier. If an infant is breastfed, the mother may need to consult a lactation consultant to coordinate a program of frequent feedings.

Nursing Diagnosis: Fear related to child's ill appearance and possible disease outcome

Outcome Evaluation: Parents and child openly discuss fears and concerns, actively question, and express confidence in treatment plan and health care team.

By school age, children with heart failure are usually aware of the seriousness of their condition. They learn this from the frequent procedures and visits to cardiologists and from the exhaustion they feel because their heart is not working well. They may lie stiffly in bed, afraid to move, afraid to burden their already overtaxed heart with even simple activities such as turning pages in a book. Offer reassurance that although their heart is a little behind in its action, the oxygen and medication they are receiving are helping. Reassure them that people are checking on them frequently and observing them closely in between as well as during procedures. Give them time to talk and use play to express their fears.

Parents of a child with heart failure need the same reassurance (provided, of course, the statements are true). They are as frightened by what the physician has told them as by their child's obviously ill appearance. It is often helpful to point out subtle signs of improvement in their child that they may not notice on their own, such as a slower heart rate or slower, less distressed respirations.

If the child will be cared for at home, review CPR technique to be certain parents know what to do in an emergency. Be certain they have a follow-up appointment scheduled and a telephone number they can call if they have any concerns about their child's condition.

Persistent Pulmonary Hypertension

Persistent pulmonary hypertension (PPH) results when the pulmonary vascular resistance present at birth because of unopened alveoli fails to fall to normal. The disorder occurs most often in full-term infants who have experienced perinatal asphyxia from conditions such as postterm birth (Hernandez-Diaz et al., 2007). PPH occurs because hypoxia and acidosis from respiratory difficulty cause vasoconstriction of the pulmonary artery. The infant develops tachypnea. Pulse oximetry shows a low P_{O_2} from inability of blood to perfuse the lungs because of the pulmonary artery constriction. The resulting hypoxia and acidosis cause even greater vasoconstriction of the pulmonary artery. An echocardiogram slows right-to-left shunting across the patent ductus or foramen ovale.

Treatment consists of supportive therapy such as oxygen, high-frequency oscillatory ventilation, IV glucose to provide calories, antibiotics to combat infection, medications to reduce pulmonary resistance, and other drugs, such as low-dose dopamine, to elevate systemic blood pressure. Sildenafil citrate has promising effects for vasodilation and reduced resistance

(Leibovitch, Matok, & Paret, 2007). Sodium bicarbonate may be necessary to relieve acidosis and to help reverse pulmonary vasoconstriction. Inhaled nitric oxide may be administered to promote pulmonary vasodilatation (Tanaka et al., 2007). Infants who do not respond to these usual measures may require ECMO to allow the lungs to rest until adequate pulmonary vasodilatation and the return of alveoli perfusion can be achieved.

PPH is a serious threat to newborns, both because of the original insult from respiratory distress that produced the syndrome and the prolonged therapy course. Because of this, a newborn may be left with neurologic challenge from severe hypoxia and inadequate brain cell oxygen perfusion.

Rheumatic Fever

Rheumatic fever is an autoimmune disease that occurs as a reaction to a group A beta-hemolytic streptococcal infection (Bashore & Granger, 2009). Inflammation from the immune response leads to fibrin deposits on the endocardium and valves, in particular the mitral valve, as well as in the major body joints. The disease often follows an attack of pharyngitis, tonsillitis, scarlet fever, "strep throat," or impetigo, because the organism common to these infections is a group A beta-hemolytic streptococcus. In 95% of children with acute rheumatic fever, an elevation of one or more antistreptococcal antibodies, an indication of a recent streptococcal infection, can be documented. Although the incidence of rheumatic fever has declined greatly in recent years, the disease has not been eradicated, and in some inner cities and developing countries, the incidence is rising (Carapetis, 2007). It occurs most often in children 6 to 15 years of age, with a peak incidence at 8 years. It is seen most often in poor, crowded urban areas. Because children do not develop immunity to streptococcal infections, streptococcal infections recur; rheumatic fever also recurs.

The symptoms of the original streptococcal infection subside in a few days with or without antimicrobial therapy. Children appear well again. After 1 to 3 weeks, however, if the child was not treated with an appropriate antibiotic for the original infection, the onset of rheumatic fever symptoms can begin. Because nurses are the primary people who advise parents when to seek health care and how to adhere to medicine administration, nurses have contributed greatly to the decline of this disorder.

Assessment

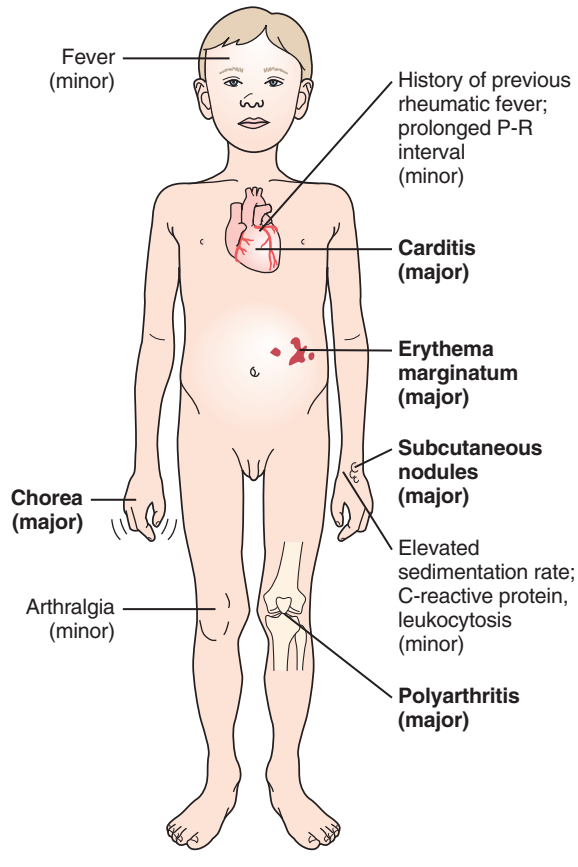
The signs and symptoms of rheumatic fever are divided into major and minor symptoms according to the Jones criteria (Box 41.9). Of these, the heart involvement is the most serious. The child usually has a systolic murmur from mitral insufficiency and prolonged P-R and Q-T intervals on the ECG that reflect inflammation and slowing of impulse conduction. Sydenham's chorea (sudden involuntary movement of the limbs) is a striking symptom (Weiner & Normandin, 2007). This loss of voluntary muscle control due to inflammation of basal ganglia occurs most often in children between 7 and 14 years of age (rarely after age 20). It occurs more frequently in girls than boys. Dysfunctional speech from chorea may be demonstrated by asking the child to count rapidly. Children with chorea begin with clear speech, but then suddenly the sounds become garbled or they cannot speak for several seconds. If asked to protrude the tongue, children cannot keep from making undulating, jerky movements. If asked to extend their arms in front of them, they soon hyperextend their wrists and fingers. Hand grasp may be weak or may consist of spasmodic contractions and relaxation. If asked to smile, the facial expression may change rapidly from a "Cheshire cat" grin to a flat, expressionless affect or grimace. Erythema marginatum, a macular rash found predominantly on the trunk, subcutaneous nodules or painless lumps on tendon sheaths by the joints, and tender swollen large joints (polyarthritis) are additional manifestations. Important laboratory findings include the presence of an antibody antistreptococcal titer (ASO) and an increased ESR and C-reactive protein levels (Smith, 2008).

Therapeutic Management

The full course of rheumatic fever is 6 to 8 weeks. Children are maintained on bedrest only during the acute phase of illness or until congestive heart disease is not present, the ESR decreases, and the C-reactive protein level and pulse rate return to normal. Because pulse rate is a valuable sign of improvement, monitoring vital signs is essential during the acute phase. Obtaining an apical pulse for a full minute is preferred. It may be ordered when the child is asleep as well

Box 41.9 Assessment

Assessing a Child With Rheumatic Fever



as when the child is awake to measure the effect of activity on the pulse rate.

A course of penicillin therapy or a single intramuscular injection of benzathine penicillin is used to eliminate group A beta-hemolytic streptococci completely from the child's body. Oral ibuprofen is prescribed to reduce inflammation and joint pain. Corticosteroids may be prescribed to reduce inflammation in children who are not responding to ibuprofen therapy alone. Possible side effects of corticosteroid therapy include hirsutism, a round moon face (Cushing's syndrome), and an increased susceptibility to infection.

Phenobarbital and diazepam are both effective in reducing the purposeless movements of chorea. If heart failure is present, measures to reduce heart failure such as digoxin and diuretics will be prescribed.

The prognosis for the child with rheumatic fever depends on the extent of myocardial involvement. Valve destruction from formation of Aschoff's bodies (fibrin deposits) may result in permanent valve dysfunction, especially of the mitral valve. With severe myocarditis the heart dilates, but when it cannot maintain this compensation, it eventually fails to contract effectively. Children may be left with mitral valve insufficiency, which is especially hazardous for girls, because this may lead to heart failure during pregnancy. Some children need mitral valve replacement to restore heart function. Usually, there are no residual effects from joint or chorea involvement.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for nonadherence to drug therapy related to knowledge deficit about importance of long-term therapy

Outcome Evaluation: Child takes oral penicillin daily; absence of symptoms of throat infection; vital signs are within age-acceptable parameters.

Therapy for Initial Attack. A child who has had rheumatic fever is at great risk for a recurrence (Sondheimer, Yetman, & Miyamoto, 2008). To eliminate the bacteria from the upper respiratory tract, either amoxicillin or penicillin is prescribed. To be effective, a drug level must be maintained for 10 to 14 days. Erythromycin is used in children sensitive to penicillin; it, too, must be continued for at least 10 days. One intramuscular injection of a long-acting penicillin, such as benzathine penicillin (Bicillin), can be used with children if there is a question whether the parent will give, or the child will take, the full course of oral penicillin. Be sure to repeat prescription instructions for parents in ambulatory settings so they understand how often and how much of a drug is to be given and the need to give the drug for the full 10 to 14 days. Usually a child's symptoms will fade before then, and if the parents are not cautioned about the importance of the drug, they may give the drug for only 2 or 3 days and then discontinue it.

Prevent Recurrent Attacks. Children who have had rheumatic fever must be prevented from contracting the disease again to prevent valve damage from occurring a second time. To do this, they must take prophylactic antibiotic therapy for at least 5 years after the initial attack, or until they are 18 years of age. If some valve involvement is present, many physicians advocate maintaining the child on penicillin indefinitely. Penicillin may be prescribed as monthly injections of benzathine penicillin G or daily oral doses of aqueous penicillin (penicillin V).

Additional prophylactic measures should be instituted when dental or tonsillar surgery is planned, because most children have streptococci in their throats (Sykes & Farrington, 2007). With an open incision in the mouth, the risk of streptococcal invasion of the bloodstream increases.

Nursing Diagnosis: Situational low self-esteem related to chorea movements secondary to rheumatic fever

Outcome Evaluation: Child expresses frustration with inability to control movements; continues to feed and dress self with help as needed.

Children may have difficulty feeding themselves because of chorea. They may also be emotionally unstable and cry easily. Emphasize the transitory nature of the chorea; stress that it is frustrating to have to be fed and to be unable to use your hands meaningfully, but that this lack of coordination will pass without permanent effects. Provide toys and games that do not require fine coordination, because it may be frustrating to try to do something such as move checkers or chessmen on a board (a typical low-activity game). Children with chorea who are on bedrest may need to have the bedrails padded so they do not injure themselves from thrashing movements.

Kawasaki Disease

Kawasaki disease (mucocutaneous lymph node syndrome) is a febrile, multisystem disorder that occurs almost exclusively in children before the age of puberty. It has replaced rheumatic fever as the most likely cause of acquired heart disease in children. The peak incidence is in boys under 4 years of age. The incidence is higher in late winter and spring. **Vasculitis** (inflammation of blood vessels) is the principal (and life-threatening) finding because it can lead to formation of aneurysm and myocardial infarction (Rowley & Shulman, 2007).

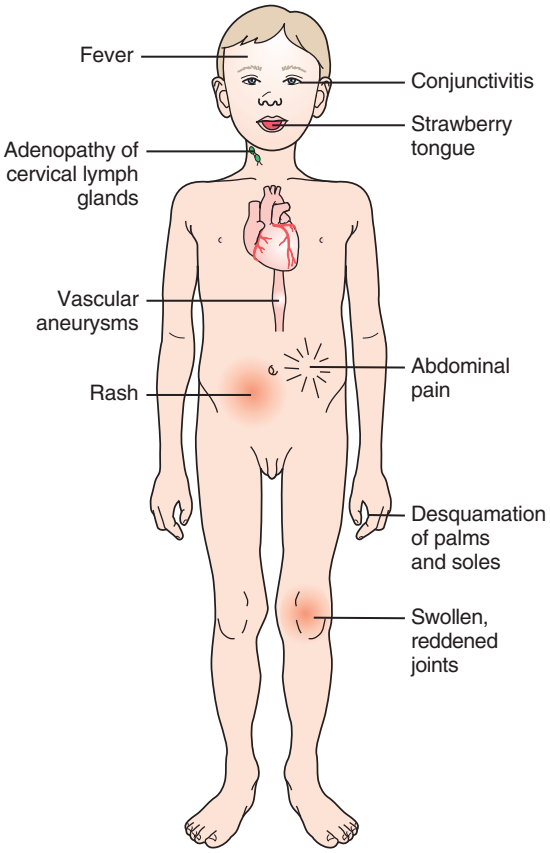
The cause of Kawasaki disease is unknown, but it apparently develops in genetically predisposed individuals after exposure to an as-yet-unidentified infectious agent. After the infection (perhaps an upper respiratory infection), altered immune function occurs. An increase in antibody production creates circulating immune (antibody–antigen) complexes that bind to the vascular endothelium and cause inflammation. The inflammation of blood vessels leads to aneurysms, platelet accumulation, and the formation of thrombi or obstruction in the heart and blood vessels.

Assessment

Kawasaki disease begins with an acute phase (stage I) of high fever (102° to 104° F [39.0° to 40.0° C]) that does not respond to antipyretics (Box 41.10). The child acts lethargic or irritable and may have reddened and swollen hands and feet.

Box 41.10 Assessment

Assessing a Child With Kawasaki Disease



Soon the bulbar mucous membranes of the eyes become inflamed (conjunctivitis) and the child develops a "strawberry" tongue and red, cracked lips. A variety of rashes occur, often confined to the diaper area. Cervical lymph nodes become enlarged. As internal lymph nodes swell, children may develop abdominal pain, anorexia, and diarrhea. Joints may swell and redden, simulating an arthritic process. White blood cell count and the ESR are both elevated.

About 10 days after the onset, a subacute phase begins. The skin desquamates, particularly on the palms and soles. The platelet count rises; this increases the possibility of clotting, which could result in necrosis of distant body cells, particularly the fingertips, if they no longer receive adequate blood. Aneurysms may form in coronary arteries, compromising heart activity. Sudden death from accumulating thrombi or rupture of an aneurysm may occur, making this the most dangerous phase.

The convalescent phase (stage II) begins at about the 25th day and lasts until 40 days. Stage III lasts from 40 days until the ESR returns to normal. To be diagnosed with Kawasaki disease, a child must manifest fever and four of the typical symptoms shown in Box 41.11, plus echocardiographic confirmation of artery disease. Children are followed by sequential echocardiograms to monitor for development of aneurysms.

BOX 41.11 ✻ Criteria for Diagnosis of Kawasaki Disease

1. Fever of 5 or more days' duration
2. Bilateral congestion of ocular conjunctivae
3. Changes of the mucous membrane of the upper respiratory tract, such as reddened pharynx; red, dry, fissured lips; or protuberance of tongue papillae ("strawberry" tongue)
4. Changes of the peripheral extremities, such as peripheral edema, peripheral erythema, desquamation of palms and soles
5. Rash, primarily truncal and polymorphous
6. Cervical lymph node swelling

Therapeutic Management

The administration of acetylsalicylic acid (aspirin) or ibuprofen decreases inflammation and blocks platelet aggregation. Abciximab is a platelet receptor inhibitor specific for Kawasaki disease (Karch, 2009). IV immune globulin (IVIG) can also be administered to reduce the immune response (Oates-Whitehead et al., 2009). Caution parents that children should not receive routine immunizations while taking IVIG or the immunization will be ineffective. Steroids, which may increase aneurysm formation, are contraindicated. If the child is left with coronary artery disease from stenosis of the coronary arteries, coronary artery bypass surgery may be necessary in the future.

Nursing Diagnoses and Related Interventions ✻

Nursing Diagnosis: Risk for ineffective peripheral tissue perfusion related to inflammation of blood vessels

Outcome Evaluation: Child's pulse, blood pressure, and respiratory rate are within age-established parameters; capillary filling time is less than 5 seconds.

Observe for signs of heart failure such as tachycardia, dyspnea, rales, and edema. Inspect the extremities for color and palpate for warmth and capillary filling in toes and fingers to evaluate peripheral tissue perfusion. If a child is developing myocarditis, be alert for chest pain, arrhythmias, and ECG changes. All these are findings that need to be reported and documented.

Nursing Diagnosis: Pain related to swelling of lymph nodes and inflammation of joints

Outcome Evaluation: Child states level of pain is tolerable; rates it below 2 on a standard scale.

A child with Kawasaki disease is uncomfortable from the joint involvement, edema, pruritic rash, abdominal discomfort, and the frequent blood sampling necessary to monitor the platelet count. The high fever can lead to dry, cracked lips. Ibuprofen, administered for its anti-inflammatory action, helps reduce both the

pain and itchiness (which is a low level of pain). Provide additional comfort measures such as rocking and holding. Protect edematous areas from pressure; make certain clothing is not constricting and irritating areas of rash. Applying lip balm protects lips from drying and cracking.

Because the fever remains high, offer extra fluid to help maintain hydration and reduce mouth tenderness. Keep the child free of heavy blankets or clothing and prevent overexertion. Monitor IV fluid to prevent fluid overload.

Children with Kawasaki disease lose their appetite and generally eat poorly because of the systemic illness, mouth soreness from cracks and fissures, and abdominal pressure from swollen lymph nodes. Carefully monitor and record the child's intake and output. Encourage the child to continue brushing his or her teeth (use a soft toothbrush or a padded tongue blade), even though the oral mucous membrane is tender. Soft, nonirritating foods such as gelatin (Jell-O) may be better tolerated than foods that require chewing and acidic fluids, such as orange juice, that might sting. Observe for signs of gastrointestinal obstruction, such as vomiting.

Most children with Kawasaki disease recover fully, but a few will need cardiac bypass surgery to treat aneurysms that developed in the coronary arteries.

What if... A child with Kawasaki disease has ibuprofen ordered every 4 hours but tells you she no longer has pain or fever? Should you continue to give it?

Endocarditis

Endocarditis is inflammation and infection of the endocardium or valves of the heart (Tulathimutte, 2008). It may occur in a child without heart disease but more commonly occurs as a complication of congenital heart disease such as tetralogy of Fallot, VSD, or coarctation of the aorta. The infection is generally caused by streptococci of the viridans type, although staphylococcal or fungal organisms may be at fault. The streptococcal infection tends to invade the body during oral surgery, such as with dental extractions. It also can enter from a urinary tract infection or a skin infection, such as impetigo. As the disease progresses, vegetation composed of bacteria, fibrin, and blood appears on the endocardium of the valves and heart chambers. This tends to occur more commonly on the left side of the heart, although if a heart defect is present the erosion begins at the site of the defect. Over a period of time, the invading process destroys the endocardial lining of the heart, underlying muscle and valves (Sondheimer, Yetman, & Miyamoto, 2008).

Assessment

The onset of the illness is insidious. Children often appear pale, with anorexia and weight loss. Arthralgia (pain in joints), malaise, chills, or periods of sweating, especially at night, occur. As the vegetative process begins to erode the heart's valves, significant murmurs become audible. Signs of heart failure appear. Petechiae of the conjunctiva or oral mucosa or hemorrhages of the fingernails or toenails (that simulate a splinter inserted under the nail) may be present. The child may notice left upper quadrant abdominal pain from infarction of the spleen; on physical assessment, the spleen may be enlarged. Laboratory studies may reveal proteinuria or hematuria; a normochromic, normocytic anemia may also be present. There may be leukocytosis and an increased ESR. An echocardiogram shows vegetative growths on the heart valves. The diagnosis is confirmed by a blood culture that reveals the presence of the invading organism.

Therapeutic Management

All children with congenital heart disease and those who have had rheumatic fever should have prophylactic administration of an antibiotic before ear, nose, throat, tonsil, or mouth surgery (and before childbirth) to prevent infectious endocarditis. If it does occur despite these preventive measures, therapy is directed toward the underlying infection and also includes supportive measures to reduce heart failure. Because the invading organism is generally a streptococcus, a penicillinase-resistant penicillin such as nafcillin (Unipen) is prescribed and given IV through a central venous access device. Giving the drug into a large vessel allows quick dilution and distribution. Children need long-term follow-up care to be certain the invading organism is eliminated and the disease process has halted. Prognosis is good unless an embolus from the vegetations on the valves causes a complication such as renal occlusion or cerebrovascular accident.

Arrhythmias

Children have fewer cardiac arrhythmias than do adults, but the number of these is increasing as more and more children survive cardiac surgery for congenital heart disease but are left with a cardiac arrhythmia due to septal trauma (Prystowsky & Foge, 2008). Better means of monitoring cardiac rhythm patterns through the use of Holter monitors has also made detection of cardiac arrhythmia easier. Remember that most children show a normal sinus arrhythmia or a slowing of the heart rate during inspiration (increased lung size slows lung perfusion, putting enough back-pressure on the heart to slow the heartbeat), with the normal rate resuming on expiration.

Ventricular tachycardia and atrial fibrillation are syndromes that occur because of multiple or abnormal initiation of the heartbeat and can occur following surgery for congenital heart disease. These can cause episodes of syncope, palpitations, and exercise intolerance. If bradycardia occurs, it can be treated with a drug such as atropine to counteract vagal stimulation; digoxin is commonly used for decreasing and strengthening the heart rate if needed. A few children may require pacemakers implanted to maintain a steady heart rhythm.

Cryo- or radioablation are nonsurgical transvenous catheter techniques that can permanently disrupt an abnormal arrhythmia focus (Tuzcu, 2007).

Hypertension

Although primary hypertension may occur in children, hypertension in children usually occurs as a secondary manifestation of another disease such as a kidney disorder. It has a

higher incidence among black children than other ethnic groups and occurs in about 1% of schoolchildren and adolescents. As obesity in children is increasing, the incidence of hypertension in children is also increasing.

It is difficult to define hypertension in children because normal blood pressure varies with the age of the child. A systolic pressure reading above the 95th percentile for a given age may be used as a practical criterion (AAP, 2009).

Assessment

Beginning at 3 years of age, blood pressure should be included as a part of routine health assessment. Normal blood pressure and the technique of blood pressure recording in children are discussed in Chapter 34. To ensure accuracy, be sure a child is relaxed, after at least 1 or 2 minutes of rest, before taking a blood pressure. When children are discovered on routine physical assessment to have hypertension, the reading should be repeated at a successive visit to confirm that the abnormal reading was not a reaction to the stress of the examination or some other emotional event of that day. Only when the blood pressure is still elevated on a third occasion is hypertension diagnosed.

When a child has hypertension, a number of additional studies are performed to discover underlying disease conditions. The most common diseases associated with hypertension in children are renal and cardiac diseases such as coarctation of the aorta, Cushing's syndrome, primary hyperaldosteronism, adrenogenital syndrome, pheochromocytoma (a tumor of the adrenal gland), and brain tumor. If blood pressure is elevated, record a blood pressure in both lower extremities and upper extremities to help rule out coarctation of the aorta (which results in low pressure in the lower extremities). Obtain a urine specimen for analysis of microalbuminuria, a finding that accompanies hypertension. If red blood cells are present in urine, this suggests glomerulonephritis, a kidney disease that increases blood pressure. Children with suspected hypertension should have a funduscopic examination of their eyes to determine the presence of papilledema or spasm, or hemorrhage of the retinal arteries from the consistently elevated blood pressure. If papilledema is present, children need immediate care to prevent optic nerve damage. Further studies to rule out adrenal or renal disease may be ordered if these preliminary assessment procedures do not reveal a cause for the hypertension (Armstrong, 2007).

Therapeutic Management

Therapy for hypertension depends on the underlying primary disease. Although the underlying disease conditions that lead to hypertension are serious disorders, they are also ones that can respond to therapy. Therefore, hypertension must not be dismissed lightly.

If essential hypertension (elevated blood pressure for no identifiable reason) is present and a child is obese, a child is placed on a reducing diet and urged to increase the level of exercise to reduce weight. Salt intake is rarely limited, but it may be if salt intake has been excessive; girls are advised not to use oral contraceptives, which elevate blood pressure. Unfortunately, because mild hypertension produces few symptoms, often children do not adhere to nutritional suggestions or suggested exercise programs well. For these children, a single medication such as an angiotensin-converting enzyme (ACE) inhibitor such as captopril [Capoten] may be prescribed. A diuretic such as furosemide (Lasix) or vasodilators such as hydralazine (Apresoline) may also be added.

Children with hypertension need continued counseling at health care visits. Educate them and their parents about the long-term effects of hypertension (increased risk of heart and blood vessel disease). Only if children understand these long-term consequences can they see the benefits of taking medication today.

Dyslipidemia

Dyslipidemia (increased lipids in blood serum) can involve cholesterol or triglycerides. Risk factors include familial hypercholesterolemia, a dominantly inherited disease occurring in 5% to 25% of children; obesity; a sedentary lifestyle; and a high-fat diet (Pignone & McPhee, 2009). For this reason, all children of parents with premature coronary artery disease (disease before the age of 55) or a family history of hypercholesterolemia (parents with blood cholesterol levels above 200 mg/dL or low-density lipoprotein [LDL] levels above 130 mg/dL) should be screened for total serum cholesterol, because there is an association between high total cholesterol and LDL and the incidence of coronary artery disease. This is particularly important if the child smokes, is obese, or has a sedentary lifestyle.

Acceptable levels of total cholesterol and LDL in children are less than 170 mg/dL and less than 110 mg/dL, respectively. Levels are borderline if they are 170 to 199 mg/dL and 110 to 129 mg/dL. They are high if over 200 mg/dL and 130 mg/dL (AAP, 2009).

If the total triglyceride, cholesterol, or LDL level is found to be elevated, the child's diet should be regulated in an attempt to lower these levels. Exercise also should be increased. Adolescents may be placed on the American Heart Association's step 1 diet (total fat no more than 30% of calories; cholesterol less than 300 mg/day) to attempt to bring them into adulthood with sound nutritional habits. Children rarely are placed on low-fat diets because they need calories for growth. Use of low-fat diets in infants under 2 years of age is even less common because fat is needed for myelinization of nerves.

If the child becomes an adolescent and the diet has not been effective, one of the many cholesterol-reducing agents such as cholestyramine (Questran) may be prescribed. These agents reduce the cholesterol level by binding bile acids and decreasing their reabsorption. Side effects of these drugs include large, bulky stools and possible gastrointestinal discomfort. If this therapy is ineffective, an HMG-CoA inhibitor such as atorvastatin (Lipitor) may be prescribed.

Because hypercholesterolemia has no symptoms, it is difficult to motivate children to continue a special diet and take medication unless the entire family changes to a lower fat diet (Poustie & Rutherford, 2009). They need continued counseling at health care visits so they understand the damage that excess lipids can cause.

Cardiomyopathy

The term "cardiomyopathy" refers to a structural or functional abnormality of the ventricular myocardium that occurs following an infection such as adenovirus, cytomegalovirus, or

HIV/AIDS infection and results in severe dilation of the left or both ventricles (Colam et al., 2007). This impairs systolic function and leads to heart failure. Idiopathic dilated cardiomyopathy (IDC) is a rare form that presents before 2 years of age, usually after a viral respiratory or gastrointestinal illness. Hypertrophic cardiomyopathy (HCM) is a relatively common autosomal dominant disease that occurs at an incidence of about 1 in 500 young adults (Marian, Brugada, & Roberts, 2008).

In the older child, symptoms appear gradually. Physical examination reveals an ill-appearing child with severe respiratory distress. Peripheral pulses are weak and blood pressure is decreased. Pulsus alternans (beat-to-beat variation) is a common finding. The liver is enlarged from backflow pressure. A chest radiograph, echocardiogram, and ECG all reveal the enlarged heart.

Therapy is directed at controlling the heart failure by bedrest, fluid restriction, and pharmacologic agents to decrease the cardiac load, improve myocardial contractility, and decrease afterload. Immune globulin may help reverse the process. If a child fails to respond to medical therapy, the prognosis is poor unless the child is eligible for cardiac transplantation.

CARDIOPULMONARY ARREST

Children with heart disease are at high risk for cardiopulmonary arrest, although this may occur in any child for reasons such as airway obstruction, trauma, anaphylactic reaction, central nervous system depression, drowning, or electrocution. Management of cardiopulmonary arrest may vary according to the cause of the arrest and the age of the patient, but the basic considerations are the same.

Many health care facilities and public buildings provide automated external defibrillators (AEDs) for use in cardiac resuscitation. Nurses who respond to emergencies need to familiarize themselves with this equipment as well as CPR technique (AHA, 2008).

Assessment

Respiratory failure is the most frequent cause of cardiac arrest because anoxia in the heart muscle quickly leads to cardiac arrest. When cardiac arrest occurs, no audible heart sounds or pulses can be obtained. No blood pressure can be recorded (do not waste time trying to obtain one). If a cardiac monitor was attached before the arrest, it will show no ECG complex. This is a helpful assessment if available, but again do not waste time attaching monitor leads if they are not already in place. The outcome for the child in arrest will depend to a great extent on the speed with which resuscitation is begun, so it is better to err on the side of unnecessary resuscitation rather than delayed resuscitation. The steps for resuscitation can be remembered as "ABCs" (*airway, breathing, and circulation*).

Airway

The first step in resuscitation is to shake the child and call the child's name to verify that a child is not just sound asleep. If a child does not respond to this action, call for help. Turn the child onto the back and open the mouth. Tip the child's head backward slightly to a neutral position or place a rolled towel or other fairly firm object under the neck to hyperextend the head slightly (a "sniffing" position). Do not overextend the neck, however, or you will occlude, not clear, the airway (AHA, 2008).

Breathing

Emergency equipment such as an Ambu-bag should be readily available in all health care settings so that mouth-to-mouth resuscitation is not necessary. If no breathing bag is available, use a protective one-way valve mask for mouth-to-mouth resuscitation to protect yourself from body secretions.

For small infants, place the bag mask over the infant's mouth and nose, creating a seal. For larger infants and children, make a bag-to-mouth seal, pinching the child's nose tightly with the thumb and forefingers. Provide two slow breaths (1 to 1.5 seconds per breath). It may be necessary to adjust the head-tilt chin position to obtain optimal airway patency, although this should not be done if neck or spine trauma is suspected (AHA, 2008).

If oxygen is available, attach it to the resuscitation bag, running at a rate of about 4 L/min. However, do not wait for oxygen if it is not available. Room air's oxygen content is about 21%, so additional oxygen is helpful but not necessary for resuscitation.

Observe the child's chest with each breath you administer to see if it rises. If it does not, the airway is obstructed and air cannot reach the lungs; you need to alert the EMS system for help. Perform back blows and chest thrusts for an infant or subdiaphragmatic abdominal thrusts for an older child to help relieve the obstruction (see Chapter 40). Continued breaths should be given at the rate of normal respirations (20/min) in both infants and older children. When respiratory arrest has occurred and mechanical ventilation is anticipated, the child can be intubated to provide an open airway, as discussed in Chapter 40.

Circulation

After the two initial ventilations, feel for a carotid pulse (in an infant, the brachial pulse) or assess for other signs of circulation, such as adequate color (Fig. 41.20). It is better to use the carotid than a peripheral pulse as an indicator of cardiac function in older children, because with shock, the peripheral pulses may be absent while the heart is still beating. The carotid pulse is also the easiest to assess from your position near the child's head. In an infant, however, the neck may be too chubby for you to easily palpate a carotid pulse, so the brachial pulse is easiest to assess.

If you feel no pulse, begin chest compressions. In a newborn, enough pressure will be generated by two fingers pressed on the midsternum about a fingerbreadth below the nipple line to a depth of ½ to 1 inch (Fig. 41.21). Midsternal compression is used with newborns and infants to prevent excessive pressure on the ribs and the possibility of breaking either a rib or the xiphoid process (which then might puncture the heart or liver). In the older child, you need to apply the heel of your palm over the sternum (measure one or two fingerbreadths up from the sternal-costal notch and place the palm there) and compress 1 to 1½ inches (Fig. 41.22). Compress the chest at a rate of 100 beats per minute in both infants and older children (AHA, 2008).

Breathing and cardiac compression must be carried out concurrently but not exactly at the same time. If there are two

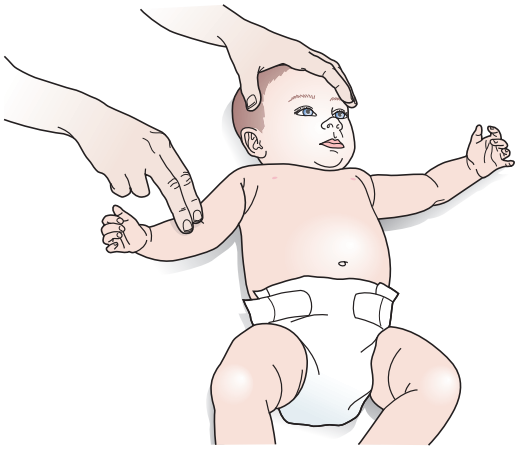


FIGURE 41.20 Assessing a brachial pulse in an infant.

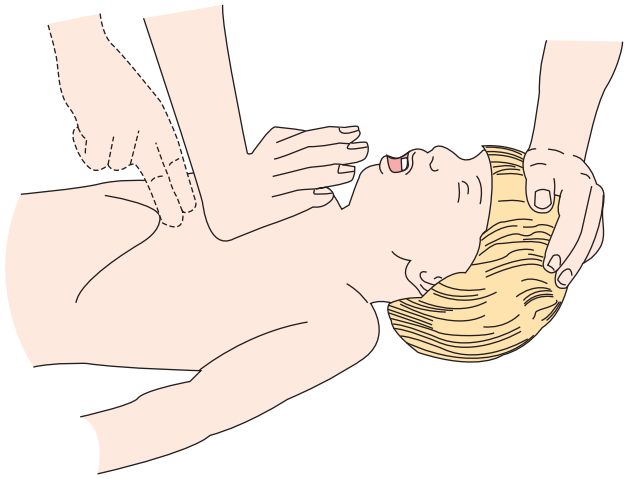

FIGURE 41.22 Locating hand position for cardiac compression in an older child.

people available for resuscitation, one can administer breaths to the child while the other compresses the chest. If you are by yourself, you must do both. For infants, administer two breaths, then compress the chest 30 times; administer another two breaths, then compress the chest 30 more times, and so forth. This 2:30 ratio of ventilations to compressions is necessary to effectively ventilate and circulate blood for this size child. For older children, use a 2:15 ratio as with adults. A 2:15 ratio reduces the number of times compressions must be interrupted for breaths. Be certain that you release the pressure on the chest between compressions; this allows the heart to fill more readily. Do not lift your fingers or hands off the chest, however, because doing so requires time spent to properly reposition them. Also make sure to maintain a patent airway by using the head-tilt chin lift using the hand not performing the compressions. If the resuscitation attempt is successful, the child's color will improve (especially the oral mucous membrane, which is readily visible) and the carotid pulse will become palpable.

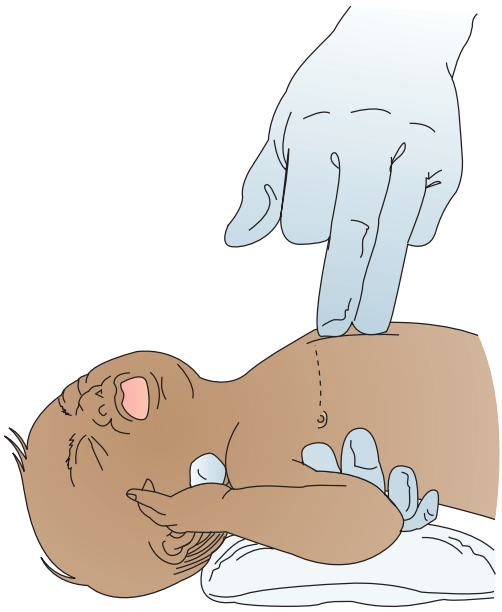

FIGURE 41.21 With cardiac resuscitation in a newborn or infant, chest compression is best done by pressing two fingers on the midsternum. Notice the slight extension of the infant's head to maintain a patent airway.

These three techniques (clearing the airway, ventilating the lungs, and circulating blood by cardiac compression) will provide adequate oxygenation to major body organs for several minutes until additional personnel arrive who can then initiate further resuscitation measures. The outcome of these secondary measures depends on how well and promptly the initial measures were performed.

Secondary Measures

IV access for drug administration must be accomplished as a fourth step. If it is not possible after several attempts to locate an accessible vein, an intraosseous catheter can be inserted (see Chapter 38). Drugs administered through an intraosseous route reach the circulation as rapidly as IV administration because of the rich blood supply in bone. Drugs such as epinephrine, lidocaine, and atropine also may be given by an endotracheal tube. An endotracheal dose is calculated by multiplying the IV dose by 2 or 3. The drug is then diluted with normal saline, administered by a catheter inserted deeply into the tube, and followed by an additional 1 or 2 mL of normal saline and several positive-pressure breaths to move the drug into the lungs.

Common drugs helpful in resuscitation procedures that should be available on a pediatric emergency resuscitation cart include:

- *Atropine:* Reduces bronchial secretions, keeping the airway clear during resuscitation attempts. It also reduces vagus nerve effects, relieving bradycardia.
- *Calcium chloride:* Increases heart contractility. A contraindication to its use is the presence of digitalis toxicity.
- *Epinephrine:* Strengthens or initiates cardiac contractions; increases heart rate and blood pressure; bronchodilates
- *Adenosine:* Relieves arrhythmias
- *Lidocaine:* Counteracts ventricular arrhythmias
- *Amiodarone (Cordarone):* An antidysrhythmic
- *Bretylium tosylate:* Like lidocaine, counteracts ventricular arrhythmias

- *Dopamine:* Increases cardiac output. It acts on alpha-receptors to cause vasoconstriction.
- *Dobutamine:* Acts as a direct-acting beta-agonist that increases contractility and heart rate

Psychological Support

A cardiopulmonary arrest is an acute emergency, and everyone who arrives at the scene should know what course of action to take. Even after heart action has been initiated, ventricular fibrillation may occur, requiring defibrillation. As soon as children begin to respond to resuscitation, be aware that they begin to hear. Children are obviously frightened by the number of people and all the equipment surrounding them, such as cardiac monitor leads, IV tubing, and possibly an endotracheal tube. A child may have vivid memories of frightening body sensations just before going into cardiac arrest. A child may regain consciousness, therefore, struggling and fighting. Assure the child that everyone is there to help. It is extremely frightening for parents to see their child suddenly cease breathing. Although it is comforting to see emergency personnel arrive promptly and efficiently, parents are frightened to realize their child is ill enough to need such skilled personnel. Assist, inform, and comfort parents, therefore, as well as the child.

Provide specific information on the child's condition as soon as it is available, and update the parents often. Allow them to see their child as soon as possible after the resuscitation attempt is complete so they can assure themselves their child is breathing and has heart function once again. Be certain they know that follow-up procedures such as ECG monitoring or blood-gas measurements are being scheduled to prevent another emergency. In contrast, offer support to help them begin grieving if the child does not survive.

✔ Checkpoint Question 41.5

You need to teach CPR to Megan's parents before hospital discharge. What is the ratio of ventilation to compressions used for resuscitating an infant (one person rescue)?

a. 2:30
b. 1:10
c. 2:15
d. 3:15

Key Points for Review

- Cardiovascular disorders in children may be either structural, such as congenital heart disease, or acquired, such as Kawasaki disease, rheumatic fever, or cardiomyopathy. Assessment of children with heart disease includes history and physical examination. Echocardiogram, magnetic resonance imaging, and cardiac catheterization are procedures used frequently for diagnosis.
- Children with cardiac disease may fall behind in development because they do not have the energy to play usual childhood games. Help parents to think of games that are intellectually or developmentally stimulating without being physically exhausting.
- Limiting saturated fat intake and following a consistent exercise program are important strategies for children to prevent heart disease in later life.
- A number of therapies are available for children with cardiac disease. For example, children born with a septal defect undergo open-heart surgical repairs; those with hypoplastic left heart syndrome may undergo cardiac transplant. Children born with ineffective sinoatrial node function may have pacemakers implanted to improve heart function.
- The families of children undergoing cardiac surgery need a great deal of support from health care personnel so they can cope well enough with this major event to provide effective support to their child.
- Postcardiac surgery syndrome and postperfusion syndrome are two complications that may occur after cardiac surgery. They are related to the extracorporeal circulation used during the procedure.
- Congenital heart disorders are classified as those associated with increased pulmonary blood flow, decreased pulmonary blood flow, obstruction to blood flow, and mixed blood flow.
- Common signs of heart failure seen in children include tachycardia, tachypnea, enlarged liver, dyspnea, and cyanosis. Signs tend to be subtle in infants and may be manifested chiefly by difficulty in feeding from exhaustion and dyspnea.
- Rheumatic fever is an autoimmune disease that occurs after a group A beta-hemolytic streptococcal infection. Common signs and symptoms include fever, chorea, arthralgia, polyarthritis, erythema marginatum, subcutaneous nodules, and an elevated ESR. Taking prophylactic penicillin after the illness until age 18 helps prevent further recurrence and cardiac involvement. Some children with congenital heart disease may also need this same protective routine.
- Kawasaki disease results from altered immune function. An inflammation of blood vessels leads to platelet aggregation and formation of thrombi and aneurysms.
- Infectious endocarditis is an infection of the endocardium of the heart. It may be a complication of congenital heart disease.
- Hypertension in children usually occurs as a result of a secondary disorder. A diet that is moderate in cholesterol content along with regular exercise and maintenance of weight proportional to height can help prevent this condition.
- Children with heart disease are at high risk for cardiopulmonary arrest. Nurses and parents need to know how to perform CPR to be prepared for this emergency.

CRITICAL THINKING EXERCISES

1. Megan is the newborn with tetralogy of Fallot whom you met at the beginning of the chapter. Her parents are taking her home for a month while they wait for cardiac surgery to be scheduled. They asked you what "watch her

carefully" means and how much exercise they should allow her. What advice would you give them about how to care for Megan?

2. Megan is admitted to the hospital with beginning heart failure. Her most important need is to have sustained periods of rest. How would you schedule your nursing care to avoid tiring her? What advice would you give to her parents at hospital discharge about home care?
3. Megan will need to take prophylactic penicillin until she is an adolescent. She will be living with her mother during the week and visiting her father on weekends. What steps would you take to ensure adherence over this long period?
4. Examine the National Health Goals related to heart disease in children. Most government-sponsored funds for nursing research are allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to Megan's family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to cardiovascular disorders in children. Confirm your answers are correct by reading the rationales.

Chapter

42 Nursing Care of a Family When a Child Has an Immune Disorder

KEY TERMS

- allergen
- anaphylaxis
- antigen
- autoimmunity
- cell-mediated immunity
- chemotaxis
- complement
- cytotoxic response
- delayed hypersensitivity
- environmental control
- humoral immunity
- hypersensitivity response
- hyposensitization
- immune response
- immunity
- immunogen
- immunoglobulins
- lymphokines
- lysis
- macrophage
- phagocytosis
- tolerance

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe the immune process as it relates to childhood illnesses.
2. Identify National Health Goals related to immune disorders in children that nurses could help the nation achieve.
3. Use critical thinking to analyze ways that nursing care for a child with an immune disorder can be more family centered.
4. Assess a child with a disorder of the immune system.
5. Formulate nursing diagnoses for a child with a disorder of the immune system.
6. Establish outcomes for a child with a disorder of the immune system.
7. Plan nursing care pertinent to a child with an immune system disorder.
8. Implement nursing care for a child with an immune disorder such as teaching about environmental control.
9. Evaluate expected outcomes for achievement and effectiveness of care.
10. Identify areas related to care of a child with an immune disorder that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of immune disorders and the nursing process to achieve quality maternal and child health nursing care.

Dexter Goodenough is a 6-year-old boy you meet in an ambulatory setting. He had atopic dermatitis (infantile eczema) as an infant. Today, his eyes look reddened and are watering; his nose is draining a clear discharge. His mother tells you he is constantly listless and other children make fun of him because of his appearance. His grades are "terrible" because the minute he gets to school, his symptoms begin. Dexter is diagnosed as having atopic rhinitis (hay fever). "Thank heavens," his mother exclaims. "I thought when I heard he had an immune system disease he had AIDS. What a relief to know it's only an allergy."

Previous chapters described normal growth and development of children. This chapter adds information about the dramatic changes, both physical and psychosocial, that can occur when a child is born with or develops a disorder of the immune system.

In light of the effect this condition is having on Dexter's life, is this "only" an allergy? What additional information would you want his mother to know about his condition? Knowing his problem is worse at school, what environmental control measures would you want to suggest for Dexter?

The immune system consists of a complex network of cells interacting to protect the body against invasion by foreign substances. The study of the immune system has grown immensely over the past several years, and almost every day brings new findings. More diseases are being attributed at least in part to malfunctioning of the immune system, all of which makes an understanding of how the immune system works in health and disease essential for safe nursing care.

Disorders of the immune system include deficiencies of immune substances and function that affect the body's ability to ward off infection (immunodeficiency disorders); abnormal and excessive immune response to foreign substances (hypersensitivity disorders, or allergies); and abnormal and excessive immune response to self (autoimmune disorders). Immune disorders are a focus of much research and study because they may hold the key to understanding why major illnesses such as HIV/AIDS and possibly cancer occur. Immunodeficiencies and examples of allergic disorders are described in this chapter. Autoimmune disorders, which include a wide range of illnesses, often affect a particular body system. These are addressed in the chapters that discuss the affected system (rheumatoid arthritis, which affects the joints, for example, is discussed in Chapter 51). National Health Goals related to immune disorders and children are shown in Box 42.1.

Nursing Process Overview

For a Child With an Immune Disorder

Assessment

The immune system provides protection for the body from invading organisms or antigens. A deficiency of *immunocompetent* cells (cells capable of resisting these types of foreign invaders) or alteration in their function can limit this protection. Assessment focuses on analysis of blood components, particularly the white blood cells, to determine exactly what components are altered, missing, or not functioning properly. When the immune system reacts excessively or inappropriately to the invasion of certain antigens, a thorough history and analysis of presenting symptoms is usually the best way to identify the problem and develop appropriate interventions.

Nursing Diagnosis

Several nursing diagnoses associated with immune dysfunction are:

- Risk for infection related to altered immune response
- Impaired skin integrity related to inadequate lymphocyte protection
- Activity intolerance related to chronic illness

Nursing diagnoses for children experiencing allergic responses focus on their particular allergic symptoms. Examples of these are:

- Situational low self-esteem related to effects of contact dermatitis
- Ineffective breathing pattern related to bronchospasm of anaphylaxis
- Anxiety related to continued allergic response
- Powerlessness related to difficulty determining cause of allergy
- Risk for delayed growth and development related to chronicity of HIV/AIDS

Outcome Identification and Planning

Outcome identification and planning for a child with an immune disorder focus both on present and future concerns.

BOX 42.1 * Focus on National Health Goals

Allergies affect at least 25% of the population so efforts to reduce them are reflected in several National Health Goals:

- Reduce indoor allergen levels such as dust mites from a baseline of 46.2% to 37% of homes.
- Increase or maintain the number of territories or states that monitor diseases that can be caused by exposure to environmental hazards from a baseline of 6 to 25.

Of the immunologic disorders, human immunodeficiency virus (HIV) infection is the most serious, not only because it is still ultimately fatal but also because its spread has been so difficult to contain. National Health Goals that address HIV/AIDS are:

- Increase the proportion of adolescents who abstain from sexual intercourse or use condoms if sexually active from a baseline of 72% to at least 83%.
- Reduce occupational needlestick injuries among health care workers from a baseline of 600,000 per year to 420,000 per year, a 30% improvement.
- Reduce AIDS among adolescents and adults from a baseline of 19.5 new cases per 100,000 of the population to a target level of 1.0 per 100,000.
- Reduce the incidence of new cases of perinatally acquired HIV infection from 82 to 75 yearly.
- Increase the proportion of middle, junior high, and senior high schools that provide education on HIV and AIDS from a baseline of 65% to a target level of 90% (http://www.nih.gov).

Nurses can help the nation achieve these goals by initiating educational programs for children that include teaching children and adolescents about the way HIV is transmitted (sexual relations and unclean intravenous needles) and protective measures they can take to avoid contracting the disease (using safer sex practices and not using intravenous drugs).

Nursing research that could add helpful information to the area includes research that attempts to answer questions such as: How can school nurses best help children with food allergies select a nutritious meal from a cafeteria menu? How can parents of school-age children be persuaded that safer sex practices should be part of usual school-age health awareness curricula? What methods work best to educate adolescents about the danger of unprotected sex?

Relief of immediate symptoms is the first priority. This is followed by planning for long-term care and prevention of future attacks. Looking into organizations that could supply information for parents or children could be key. Informational and support organizations that can be helpful are Eczema Association for Science and Education (http://www.nationaleczema.org), The Asthma and Allergy Foundation of America (http://www.aafa.org/), and the Elizabeth Glaser Pediatric AIDS Foundation (http://www.pedaids.org).

Implementation

A major nursing intervention in the care of children with immune disorders is client and family teaching. The family of a child with an immunodeficiency may need help in identifying ways to keep the child from contracting life-threatening infections while at the same time providing enough stimulation and social contact to promote normal growth and development. A similar teaching goal must be established for a child with a chronic allergic disorder. Parents need to learn ways to help their child avoid triggers or situations that provoke allergy, but they must not keep the child so isolated or fearful that the child misses out on important experiences.

Outcome Evaluation

Outcome evaluation with immune disorders must be ongoing because new triggers for allergies can arise at any time. New therapies for HIV/AIDS are constantly being suggested. Because the field of immunology is continually evolving, theories about immune diseases and associated treatments may change from visit to visit. Be certain parents are kept abreast of developments in the field, especially those that will affect their ability to provide an environment that is safest for their child.

Examples of outcomes suggesting achievement of goals include:

- Child voices high self-esteem even if contact dermatitis rash has not completely faded.
- Child's respiratory rate is maintained at 20 breaths per minute with minimal wheezing.
- Child and parents state they can cope with their present level of anxiety.
- Child lists three actions she takes daily to help feel a greater sense of control.
- Child demonstrates achievement of developmental milestones within age-acceptable parameters despite chronic illness.

THE IMMUNE SYSTEM

The immune system functions to protect the body from invasion by foreign substances by several mechanisms. First, body surfaces such as the skin, cilia, and mucous membranes act as physical protective barriers. When an invading pathogen does get through this barrier, the process of **phagocytosis** (destruction of invaders) begins. **Macrophages** (mature white blood cells) engulf, ingest, and neutralize the pathogen. At the same time, an inflammatory response creates vascular and cellular changes that help to rid the body of dead tissue and the inactivated antigens. The immune system maintains cells ready to attack this way whenever necessary, directing the efforts of macrophages and supplementing the inflammatory response as necessary. It also singles out specific antigens for interactions (antibody–antigen reactions). This immune response not only furnishes immediate protection but also creates a template for how to destroy that particular antigen again in the future.

Immune Response

The **immune response** is the body's action plan devised to combat invading organisms or substances by leukocyte and antibody activity. An **antigen** is any foreign substance (molecule) capable of stimulating an immune response. Most antigens are proteins, but other large molecules such as polysaccharides may also function as antigens. Penicillin, although not antigenic by itself, may become antigenic when it combines with a higher-weight molecule, usually a protein (a process called *hapten formation*; this explains why penicillin reactions occur). If an antigen is one that can be readily destroyed by an immune response, and **immunity** (the ability to destroy like antigens) results, the antigen may be referred to as a simple **immunogen.** If, during the immune response, mediating substances are released that cause tissue injury and allergic symptoms, the antigen is termed an **allergen.** Allergens may enter the body through a variety of routes. They may be ingested (foods such as eggs or wheat), inhaled (pollen, dust, or mold spores), injected (drugs), or absorbed across the skin or mucous membranes (poison ivy).

Immune System Organs and Cells

The organs of the immune system consist of the lymph nodes, bone marrow, thymus, spleen, and tonsils. Bone marrow produces two types of lymphocytes, *B lymphocytes* and *T lymphocytes*. After being produced, lymphocytes travel throughout the lymphoid system and are stored in the lymph nodes and spleen. Both T and B lymphocytes recognize invading organisms and provide for attack of specific antigens (Fig. 42.1).

B Lymphocytes

Originating in the bone marrow (the reason for their name), the B lymphocytes develop into *plasma cells* and *memory cells* when exposed to antigens. Plasma cells secrete large quantities of immunoglobulins or antibodies, which bind to and destroy specific antigens (termed *humoral immunity*). When an antibody is formed in response to a particular antigen this way, it is specific to that antigen. An antibody against the pertussis antigen, for instance, will not have any effect on the tetanus antigen. Memory cells are responsible for retaining the formula or ability to produce specific **immunoglobulins.** Immunoglobulins are classified as IgG, IgA, IgM, IgD, and IgE. Those involved in immunity are IgG, IgA, and IgM. IgM reaches adult levels at approximately 1 year of age, IgG at 4 years, and IgA at adolescence. IgE is primarily responsible for allergic or hypersensitivity responses. It is present at proportions capable of extreme response early in infancy. The functions of the immunoglobulins are summarized in Table 42.1.

T Lymphocytes

T lymphocytes account for 70% to 80% of blood lymphocytes and are responsible for *cell-mediated immunity*. They

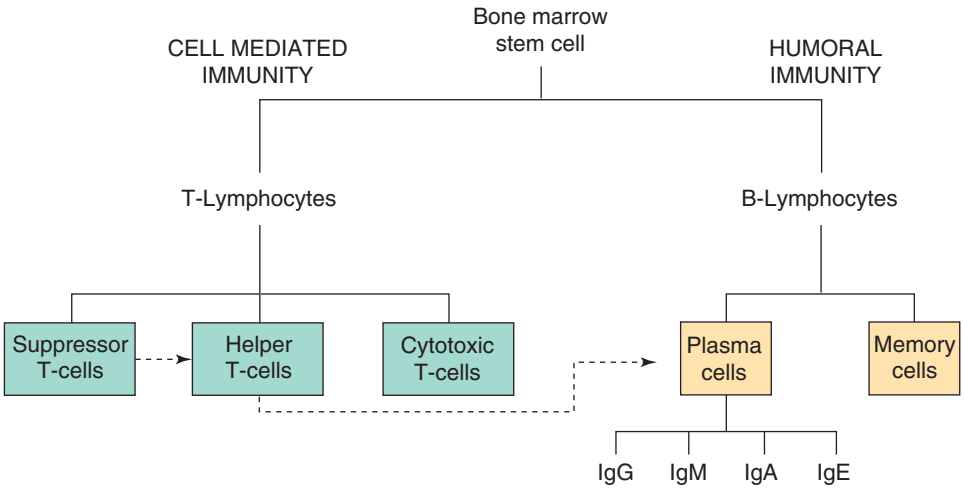

FIGURE 42.1 Lymphocyte production. From the bone marrow stem cell, T and B lymphocytes are formed. T-lymphocyte action leads to cell-mediated immunity. B-lymphocyte action results in humoral immunity.

are produced by the bone marrow but mature under the influence of the thymus gland (hence their name). When mature, T lymphocytes leave the thymus to enter specific body regions (thymus-dependent zones), mostly in the lymph nodes and spleen; there, they react specifically to viruses, fungi, and parasites but have an effect on all antigens. T cells can be differentiated into three subtypes.

The first type, *cytotoxic (killer) T cells*, are T lymphocytes that have the specific feature of binding to the surface of antigens and directly destroying the cell membrane and therefore the cell (phagocytes). As a part of this process, cytotoxic cells secrete **lymphokines;** lymphokines contain or prevent migration of antigens and call other lymphocytes into the area. Interferon is an example of a lymphokine important in preventing viral spread and helping to call leukocytes into the area (the property of **chemotaxis**).

The second type, *helper T cells* (CD4 cells), stimulate B lymphocytes to divide and mature into plasma cells and begin secreting immunoglobulins. The IgA antibody response, especially, depends on stimulation by helper T cells. Helper T cells can be identified in blood because of specific markers on their surface. Analysis of these (CD4 counts) is an important assessment of the competency of the immune system (Kishiyama & Adelman, 2009).

The third type, *suppressor T cells*, are T cells that reduce the production of immunoglobulins against a specific antigen and prevent their overproduction.

Types of Immunity

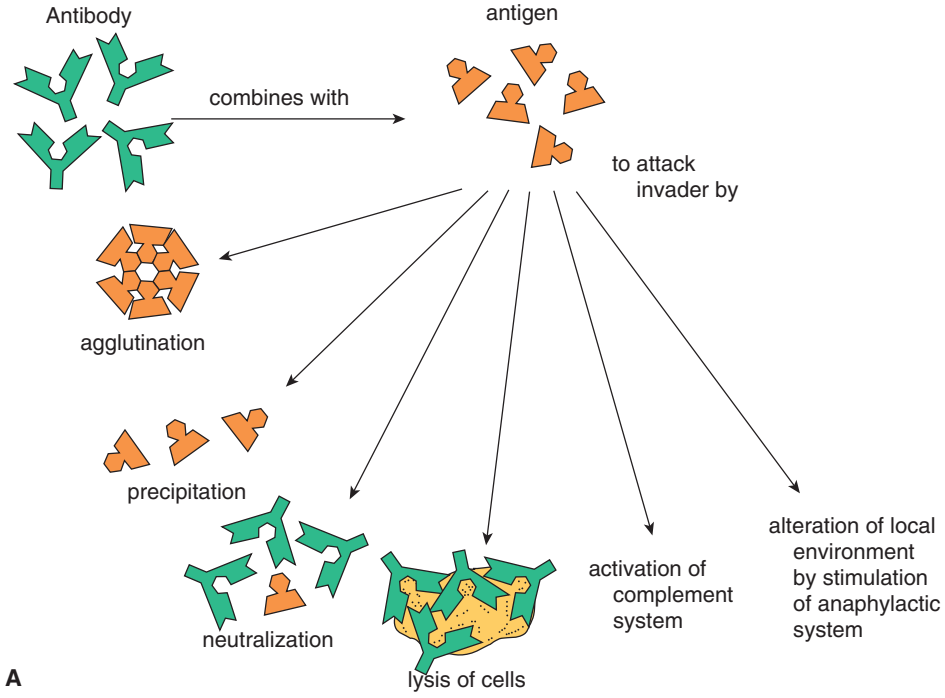
The action of B and T lymphocytes leads to two different types of immunity: humoral and cell-mediated immunity.

TABLE 42.1 ✻ Location and Function of Immunoglobulins

Immunoglobulin	Description
IgM	Effective in agglutinating antigen as well as lysing cell walls; discovered early in the course of an infection in the bloodstream
IgG	Most frequently occurring antibody in plasma; during secondary response, it is the major immunoglobulin to be synthesized; it freely diffuses into extravascular spaces to contact antigens; in prenatal life, it diffuses across the placenta to supply passive immune protection to the fetus and until the infant can effectively produce immunoglobulins; it has the major responsibility for neutralizing bacterial toxins and in activating phagocytosis (destruction of bacteria)
IgA	Found in external body secretions such as saliva, sweat, tears, mucus, bile, and colostrum; provides defense against pathogens on exposed surfaces, especially those of the gastrointestinal tract and respiratory tract, apparently by preventing adherence of pathogens to mucosal cells
IgD	Found in plasma; may be the receptor that binds antigens to lymphocyte surfaces
IgE	Involved in immediate hypersensitivity reactions; exists bound to mast cells on tissue surfaces; when contacted by an antigen, cellular granules are released; associated with allergy and parasitic infections

Humoral Immunity

Humoral immunity refers to immunity created by antibody production or B-lymphocyte involvement. The process begins when helper T cells recognize an antigen and cause activation of B lymphocytes (possibly by an intermediary macrophage). The specific B lymphocytes differentiate into plasma cells and begin creation of specific immunoglobulins that mark the antigen for destruction (Fig. 42.2). A few antigens (*Escherichia coli*) are capable of activating a B-lymphocyte response without recognition by T lymphocytes.



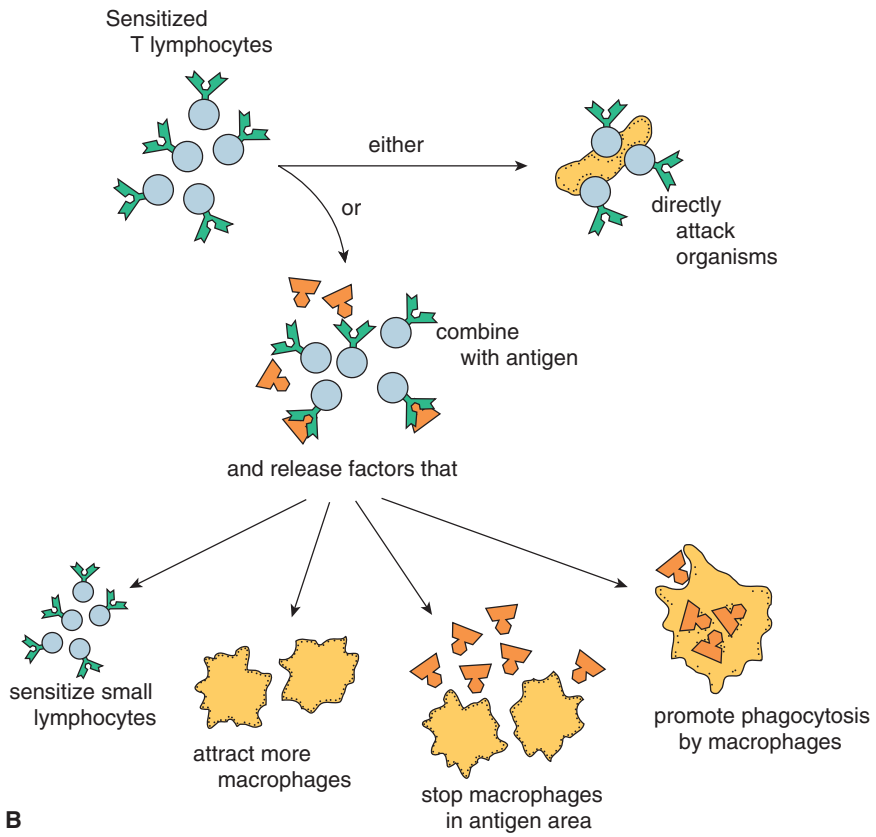


FIGURE 42.2 Mechanism of immunity response. (**A**) Humoral immunity. (**B**) Cell-mediated immunity.

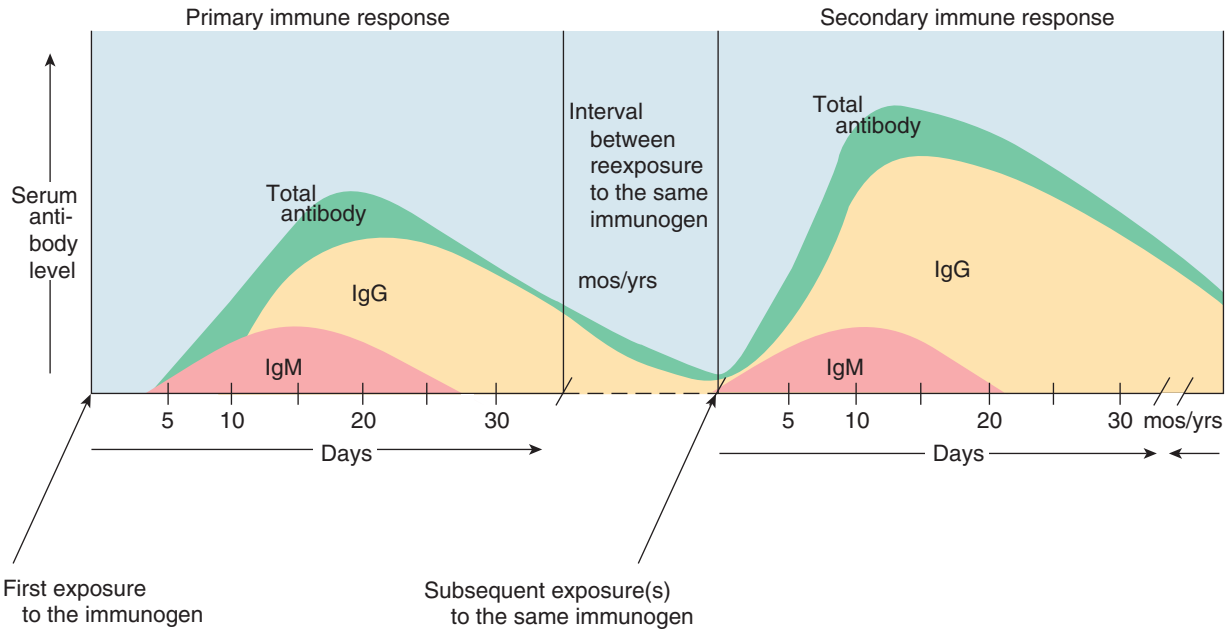

FIGURE 42.3 Primary and secondary humoral responses. IgM is the first immunoglobulin to appear in the serum.

Primary Response. The first time a specific antigen enters the body and is identified by T lymphocytes, B-cell differentiation and growth begin. Within 6 days, IgM antibodies specific to the antigen can be measured in the bloodstream. The production of IgM antibodies peaks at 14 days and then declines until, within a few weeks, few are any longer present. At approximately day 10, IgG production begins and remains high for several weeks (Fig. 42.3).

Secondary Response. When a specific antigen enters the body a second or additional time, antibody production begins immediately because of memory cells. The main type of immunoglobulin produced in a secondary response is IgG (see Fig. 42.3).

Complement Activation. **Complement** is composed of 20 different proteins that are normally nonfunctional molecules; however, when activated by antigen–antibody contact, these molecules begin a cascade response that leads to increased vascular permeability, smooth muscle contraction, chemotaxis ("calling" leukocytes into the area), phagocytosis, and **lysis** (killing) of the foreign antigen. The affected area feels warm and looks reddened and swollen, indicating an inflammatory reaction. Although an inflammatory reaction causes some local injury to tissue around the antigen, it is helpful overall because it produces an environment harmful to the antigen. Complement reactions that persist beyond the usual time for resolution (2 to 3 days) may be responsible for many of the autoimmune disorders.

Cell-Mediated Immunity

Cell-mediated immunity is the type of immune response caused by T-lymphocyte activity. Cytotoxic T cells attack and directly destroy invading antigens through the release of chemical compounds on the antigen membrane, injection of a toxin directly into the antigen, or secretion of lymphokines. A wheal-and-flare response occurs because of accumulation of lymphocytes around small blood vessels, resulting in minor destruction of blood vessels (see Fig. 42.2). This response is termed **delayed hypersensitivity** if the T-lymphocyte activity occurs solely without an accompanying humoral response. It is this response that causes transplant rejection.

Autoimmunity

Autoimmunity results from an inability to distinguish self from nonself, causing the immune system to carry out immune responses against normal cells and tissue. Autoimmune responses may be organ-specific or limited to one organ, as happens with attachment to the thyroid gland in Hashimoto's disease (see Chapter 48), or generalized and systemic (not organ-specific), as in rheumatoid arthritis and systemic lupus erythematosus (see Chapter 20). There is currently much research oriented toward the study of autoimmune responses and their possible implications in a wide variety of disorders, such as multiple sclerosis. Autoimmune disorders occur at a greater rate in some families than in others and in girls and women more than boys and men.

HEALTH PROMOTION AND RISK MANAGEMENT

As many as 15% to 30% of children today have some form of allergy or involvement of the immune system (Boguniewicz, 2008). Preventing allergies, therefore, could have a major impact on the health of children. Early prevention can begin with encouraging women to breastfeed so that infants are not exposed to cow milk protein. Delaying the introduction of solid food until 6 months of age, once thought to reduce the development of allergies, may not be as beneficial as once thought (Filipiak et al., 2007). Delaying solid

food because infants' gastrointestinal tracts are not ready for digestion, however, is still a valid reason to delay early feeding. Environmental control to reduce the number of allergens in a home can drastically reduce allergy symptoms. This should begin when parents choose furniture for a child's room, such as eliminating wool blankets, choosing toys carefully, and keeping the room free of dust. Teach parents to use a minimum of washing compounds so that children are exposed to as few chemical products as possible. Avoiding spray products such as perfumes and air fresheners and discontinuing cigarette smoking also help (Box 42.2). These are sensible rules for parents to follow beforehand, rather than waiting for a child to develop allergic rhinitis or atopic dermatitis and then having to put more extreme measures into effect. Latex is a common substance which causes allergy in children. Avoiding the use of latex gloves for health care procedures can help reduce the incidence of this (Rapp, 2008). Environmental pollutants such as exhaust from automobile or ash from forest fires are other triggers for atopic diseases (Box 42.3).

Because some families are more prone to allergies than others, some communities have a higher incidence of children with allergies than others. As a result, these communities may have more services and specialists to treat these children, a situation that develops a "community culture" of allergy acceptance and treatment. Children typically may leave school early for immunotherapy. School cafeterias commonly offer allergy-free foods. In other communities where fewer children have allergies, a child with an allergy is viewed as unique or not typical, so may need additional support.

Allergies are a type of disorder that typically causes chronic rather than acute symptoms. For this reason, children who develop allergies often need to be encouraged to be vigilant in taking their medicine. For the same reason, once parents begin a child on an immunotherapy program, they may need to be encouraged to continue it. It helps if children and their parents understand how allergic reactions lead to symptoms and how important it is for them to play a role in their own therapy.

Although it is probably impossible to keep children with atopic allergies free of reactions and manifestations of allergies, parents who know of familial allergy patterns can take some preventive steps in this direction. If parents are going to prepare allergy-free foods, be sure they consider the child's likes and dislikes and think through the child's weekly intake to ensure the child receives all essential nutrients. If a child eats at school or has a meal prepared every day at a child care center, remind parents to make sure the center, babysitter, or school dietitian is aware of the child's allergies. If a child is allergic to wheat products and cannot eat bread for sandwiches, preparing a bag lunch for school may be a difficult daily problem that only good planning can eliminate.

If a child's allergies involve pollen sensitivities, planning vacations at a time when the pollen count is lowest may make the vacation more pleasant for the family. If desensitization against a specific pollen is necessary, assist parents in planning to start desensitization so it will be effective by the time the pollen count of the offending allergen rises.

Health promotion is also important to prevent HIV/AIDS. Teaching children safer sex practices is an important part of this. All health care providers can help prevent the spread of HIV/AIDS by using standard infection precautions. The parents of children with immune deficiencies may need to be reminded periodically to take measures to keep their children free of disease, such as keeping immunizations updated and seeking help immediately for infections.

BOX 42.2 ✻ Focus on Family Teaching

Avoiding Secondary Smoke

Q. Dexter's mother says to you, "Neither my husband nor I smoke, but some of our relatives and friends do. How can we keep our child from being exposed to secondary smoke?"

A. Use the following guidelines to help avoid secondary smoke:

- Declare your home a smoke-free zone.
- If family members smoke, ask them to smoke outside.
- If at a restaurant, ask to sit in a no-smoking area, or visit only smoke-free restaurants.
- If staying at a hotel, ask for a nonsmoking room.
- Do not be reluctant to ask people around your child at a social gathering to stop smoking.
- As smoke adheres to people's clothing, suggest a person who smokes not hold a young baby.
- Encourage your friends or family members who smoke to take quit-smoking courses (for their own benefit as well as yours).

BOX 42.3 ✻ Focus on Evidence-Based Practice

Are children who live close to busy streets at higher risk for atopic diseases than others?

Long-term exposure to particulate matter such as that stirred up by traffic may serve as triggers for illnesses such as allergic rhinitis (hay fever) and asthma. To discover whether the distance a child lives from a busy street makes a difference, researchers studied 2860 children 4 years of age and 3061 children 6 years of age regarding their degree of atopic diseases and allergic sensitization. Strong positive associations were found between the distance to the nearest main road and asthmatic bronchitis, hay fever, eczema, and sensitization. The highest odds ratio that a child would have symptoms was in children living less than 50 m from busy streets. Exposure was not associated with eczema.

Suppose a family wanted to buy a new home that is close to their child's school but also close to a busy traffic area? Based on the above, would you advise the family to do so?

Source: Morgenstern, V., et al. (2008). Atopic diseases, allergic sensitization, and exposure to traffic-related air pollution in children. *American Journal of Respiratory and Critical Care Medicine, 177*(12), 1331–1337.

IMMUNODEFICIENCY DISORDERS

When any one portion of the immune system is not functioning adequately, an immunodeficiency results. The immunodeficiency disorder may be primary (congenital) or acquired (secondary to viral invasion or exposure to a toxic substance). Only a part or the entire system may fail in its goal of protecting the body from invading organisms.

Primary (Congenital) Immunodeficiency

Children with primary congenital immunodeficiencies are born without an essential immune substance or function or with inadequate amounts of immune substances. Usually these deficiencies become apparent relatively early in life. However, it may take a few months for B-lymphocyte deficiencies to produce symptoms, because a newborn is born with enough maternal IgG (which crossed the placenta during pregnancy) to supply protection for approximately the first 6 months of life.

B-Lymphocyte Deficiencies

B-lymphocyte deficiencies create abnormally low levels of immunoglobulins either selectively (as in an IgA deficiency) or totally, which is referred to as hypogammaglobulinemia or agammaglobulinemia (Liu, Stewart, & Johnston, 2008).

Hypogammaglobulinemia. Although hypogammaglobulinemia can occur as a result of chemotherapy or critical illness, it most often presents as an inherited X-linked recessive defect in the maturation of B lymphocytes that results in abnormally low levels of all immunoglobulins (Estrella, Foley, & Cunningham-Rundles, 2007). At approximately 6 months of age, when passively transferred maternal antibodies fade, male infants begin to develop frequent bacterial respiratory, digestive, or throat infections. Autoimmune diseases such as rheumatoid arthritis and systemic lupus erythematosus may occur in later life. The cellular or T-lymphocyte response remains adequate, allowing the child to resist viral, fungal, and parasitic infections.

This deficiency is treated with monthly intravenous immune globulin (IVIG) injections to supply immunoglobulins. Bone marrow transplantation may be successful in restoring immune competency. Parents and children, as they grow older, need to be taught the importance of recognizing infection early. Also help them set up a schedule for IVIG injections so these are not forgotten.

Common Variable Immunoglobulin Deficiencies. The most common disorder in this group is deficiency of IgA in surface secretions. The overall level of B lymphocytes is normal, but IgA production is reduced or absent, perhaps because of an increase of IgA suppressor cells or a defect in T-helper cells important for IgA synthesis. Without IgA, infections of surfaces exposed to the external environment and normally protected by mucus become common. Sinusitis, upper respiratory tract illness, and inflammatory bowel disease are apt to occur. There are associated atopic diseases (allergies) because without IgA on the surface mucosa, many more antigens than usual can enter the body, permitting more antigens to interact with IgE and produce allergic symptoms. Chronic irritation because of these large numbers of antigens predisposes exposed tissue to malignant transformation, so malignancy of the respiratory, gastrointestinal, and lymphoid systems occurs more readily. There is an increased risk that an antibody will cross-react with a self-antigen to cause autoimmune illness, so diseases such as systemic lupus erythematosus and rheumatoid arthritis also occur at increased rates. IgA deficiency can occur as a secondary type because of treatment with phenytoin (an anticonvulsant) and penicillamine (a copper chelating agent). IVIG contains little IgA, so therapy with IVIG does not greatly reduce symptoms. Because prevention, not treatment, is the key, parents need to be conscientious about preventing infections and perhaps administering prophylactic antibiotics to prevent respiratory infections (Liu, Stewart, & Johnston, 2008).

T-Lymphocyte Deficiencies

T-lymphocyte immunodeficiencies involve inadequate numbers or inadequate functioning of one or more types of T lymphocytes; this affects cell-mediated immunity and also, because of helper T-lymphocyte function, possibly humoral immunity as well. DiGeorge anomaly (which includes failure of the thymus to develop) and chronic mucocutaneous candidiasis are two disorders caused by T-lymphocyte deficiency or malfunction. DiGeorge syndrome is a defect of chromosome 22 or 22q11.2 (Van Aken et al., 2007).

Combined T- and B-Lymphocyte Deficiency

Severe combined immunodeficiency syndrome (SCIDS) is the most frequently seen disorder characterized by an absence or reduction of both humoral and cell-mediated immunity. SCIDS occurs as either an X-linked or autosomal recessive disorder (Liu, Stewart, & Johnston, 2008). It is caused by a developmental abnormality (sometimes but not always related to the absence of a particular enzyme), which prevents the formation of T lymphocytes (a stem cell abnormality). This, in turn, prevents the maturation of both T and B lymphocytes. Children cannot respond directly to antigen invasion and no antibodies are produced. Bone marrow (stem cell) transplantation has proven to be an effective treatment for this disorder (Waruiru et al., 2007).

Secondary (Acquired) Immunodeficiency

Secondary immunodeficiency, or loss of immune system response, can occur from factors such as severe systemic infection, cancer, renal disease, radiation therapy, severe stress, malnutrition, immunosuppressive therapy, and aging. There can be complete or partial loss of both B- and T-lymphocyte response.

Stress appears to alter the immune response by stimulating the release of corticosteroids from the adrenal gland. This suppresses the inflammatory response by inhibiting macrophage action. Immunosuppressive drugs, such as prednisone, can also suppress the inflammatory response. Radiation or chemotherapy can act to limit or destroy rapidly growing cells. Because both T and B lymphocytes are rapidly growing and dividing cells, they are killed by these drugs or radiation. Extreme infection is yet another cause for a decreased immune response because the body's continued ability to combat infection becomes exhausted.

Malnutrition can decrease immunity because rapidly growing cells need protein for synthesis; renal disease with protein loss will also deplete the amount of protein available for new lymphocyte production.

HIV Infection and AIDS

AIDS is the end stage of acquired immunodeficiency caused by infection with the RNA human immunodeficiency retrovirus HIV (McFarland, 2008). The virus has at least two divisions, HIV-1 and HIV-2, with a variety of further subtypes. The virus acts by attacking the lymphoreticular system, in particular CD4-bearing helper T lymphocytes.

The virus enters, substitutes its own RNA and DNA for the cell's DNA, and replicates in these lymphocytes, destroying them in the process.

There is no defense against the virus, so it remains in the body for life. Infection results in loss of CD4 lymphocytes and the ability to initiate an effective B-lymphocyte response. A CD4 cell count in the laboratory determines how many cells are still present and functioning. Because B-lymphocyte or humoral immune function, which initiates the production of antibodies, is affected, antibody formation will be decreased (hypogammaglobulinemia). When monocytes and macrophages become affected as well, the person with HIV infection cannot resist normal infection. When this CD4 count falls below 500 cells/mm^3 or the viral load rises above 5000 copies/mL, it is difficult for infected individuals to resist opportunistic infections such as fungal infections. The final result is that both the immune response and the ability to screen and remove malignant cells from the body are lost.

Transmission. HIV infection is spread by exposure to blood and other body secretions through sexual contact, sharing of contaminated needles for injection, transfusion of contaminated blood or blood products, perinatally from mother to fetus or newborn, and through breastfeeding. A few children have acquired the infection because of sexual abuse. Health care providers must maintain vigilance to guard against needle punctures, as these injuries are a source of blood transfer.

Pediatric AIDS accounts for only 1% to 2% of the total instances of AIDS (CDC, 2008a). Although it is decreasing in incidence, transmission of HIV from mother to child by placental spread is still the most common reason for childhood HIV infection in the United States. This transmission can occur during pregnancy, at birth, and possibly during breastfeeding. Transmission by this route has declined to less than 3% since HIV-positive women have been identified during pregnancy and prescribed antiviral therapy (Suksomboon, Poolsup, & Ket-Aim, 2007).

In the past, many children with hemophilia, because they receive so many blood product transfusions during childhood, received HIV-contaminated blood and were infected. This source of transmission now almost never occurs. The increasing rate of sexual activity and the rapidly rising incidence of sexually transmitted infections among adolescents make this group, next to newborn infants who received the virus from their mother, the most vulnerable to growing rates of HIV infection (McFarland, 2008). HIV is not transmitted by animals or through usual casual contact, such as shaking hands or kissing, or in households, day care centers, or schools.

Assessment. HIV has a long incubation period of about 10 years in adults. The disorder appears to progress more rapidly in children and infants who receive the virus through placental transmission if they do not receive treatment. These individuals are usually HIV positive by 6 months and develop clinical signs by 1 to 3 years of age. Children who receive the virus from another source usually convert to HIV positivity by 2 to 6 weeks, or at least by 6 months after exposure. During this preconversion time, a child may display preliminary symptoms such as poor resistance to infection, fever, swollen lymph nodes, respiratory tract infections, and thrush.

All infants born to infected mothers test positive for antibodies to the virus at birth because of passive antibody transmission. This persists for about 18 months. The disease is diagnosed, therefore, by recovery of the HIV antigen in children under this age and antibodies to the virus in children over this age. Tests to detect the antigen are termed PCR (polymerase chain reaction) tests; those for the antibody are termed ELISA (enzyme-linked immunosorbent assay) and Western blot confirmation. CD4 counts are used to document the disease status and predict disease progression. Normal counts vary according to age because the lymphocyte count normally varies by age. Table 42.2 shows the use of Centers for Disease Control and Prevention (CDC) guidelines and CD4 counts to determine disease progress. Severe suppression indicates a condition serious enough to cause life-threatening infections (CDC, 2008a).

The CDC classification of HIV infection in children has three categories:

- Category A, *Mildly Symptomatic*: two or more symptoms such as enlarged lymph nodes, liver, or spleen, or recurrent or persistent upper respiratory infections, sinusitis, or otitis media
- Category B, *Moderately Symptomatic*: more serious illnesses such as oropharyngeal candidiasis, bacterial meningitis, pneumonia, or sepsis, cardiomyopathy, cytomegalovirus infection, hepatitis, herpes simplex virus (HSV), bronchitis, pneumonitis, or esophagitis, herpes zoster (shingles), lymphoid interstitial pneumonia (LIP), pulmonary lymphoid hyperplasia complex, or toxoplasmosis

TABLE 42.2 ✻ CD4 Cell Counts Related to Progress of HIV/AIDS in Children

	Age of Child		
	Under 12 Months	*1–5 Years*	*6–12 Years*
No evidence of suppression	1500 cells/μL	1000 cells/μL	500 cells/μL
Evidence of moderate suppression	750–1499 cells/μL	500–999 cells/μL	200–499 cells/μL
Severe suppression	750 cells/μL	500 cells/μL	200 cells/μL

Source: Centers for Disease Control and Prevention. (2008a). *HIV/AIDS recommendations*. Washington, DC: Author.

- Category C, *Severely Symptomatic (AIDS),* serious bacterial infections such as septicemia, pneumonia, meningitis, bone or joint infection, or abscess of an internal organ or body cavity; candidiasis (esophageal or pulmonary), encephalopathy, herpes simplex lasting over 1 month, histoplasmosis, lymphoma, tuberculosis, Mycobacterium or *Pneumocystis carinii* pneumonia.

In addition to these symptoms, children may develop a malignant neoplasm, most noticeably Kaposi's sarcoma or non-Hodgkin's lymphoma (Engels et al., 2008).

Therapeutic Management. Because of the success of zidovudine administration during the pregnancy of HIV-positive women, many fewer infants are born with HIV infection today (Suksomboon, Poolsup, & Ket-Aim, 2007). Those who are born with a perinatal infection, once thought to have a short life expectancy, now have an opportunity for long-term survival. To accomplish this, therapy involves a complex regimen of nutritional supplements to prevent weight loss, vaccines to prevent infections, and highly active antiretroviral therapy (HAART) as well as antibacterial agents to combat the HIV virus and opportunistic infections (Casado et al., 2007).

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for infection related to decreased immune function

Outcome Evaluation: Child's temperature is within normal parameters; no cough or skin lesions are present.

Children with HIV infection and their families must maintain strict personal hygiene by measures such as frequent handwashing and avoid close contact between the child and anyone who has a respiratory infection to try to prevent the child from contracting dangerous opportunistic infections. It is important to assess the oral cavity of children with AIDS for herpes and thrush lesions (Gennaro, Naidoo, & Berthold, 2008). When infections do occur, antiviral and antifungal treatment should be prompt and aggressive.

Combating the infection requires specific antiretroviral medications to prevent progressive deterioration of the immune system and to provide prophylactic measures against opportunistic infections. Three classes of drugs are the mainstay of therapy: nucleoside reverse transcriptase inhibitors (NRTIs), nonnucleoside reverse transcriptase inhibitors (NNRTIs), and protease inhibitors. NRTIs are designed to block production of viral DNA, limiting the ability of the virus to infect cells; zidovudine is an example (Box 42.4). NNRTIs also inhibit the DNA synthesis of viruses but act at different sites on the viral enzyme; nevirapine and efavirenz are examples. Protease inhibitors stop the ability of the virus to produce protease, limiting metastasis; amprenavir, nelfinavir, atazanavir, and ritonavir are examples of protease inhibitors used in children (Chadwick et al., 2008). Children are prescribed a regimen involving multiple drugs, such as one protease inhibitor plus two NRTIs.

BOX 42.4 ✻ Focus on Pharmacology

Zidovudine (ZDV)

Classification: Zidovudine is a thymidine analog.

Action: Zidovudine inhibits the replication of some retroviruses, including HIV (Karch, 2009).

Pregnancy risk category: C

Dosage: 2 mg/kg every 6 hours to infants born to HIV-positive mothers, starting within 12 hours of birth to 6 wk of age. 180 mg/m^2 (720 mg/m^2/dose) orally or intravenously every 6 hours to children ages 3 mo to 12 y (dosage not to exceed 200 mg every 6 hours).

Possible adverse effects: Nausea, loss of appetite, change in taste, paresthesia, headache, fever, agranulocytopenia, and rash

Nursing Implications

- When administering the drug intravenously, infuse the drug over 60 min to avoid too rapid an infusion.
- Administer the drug around the clock for maximum effectiveness.
- Monitor blood studies frequently for changes.
- Advise child to eat frequent small meals to counteract change in taste and loss of appetite.
- If the child experiences paresthesias, institute safety precautions and instruct the child and parents in measures to prevent injury related to loss of feeling.
- Caution child and parents that ZDV does not reduce the risk of HIV transmission, except placentally. Reinforce the importance of hygiene and infection control measures.

In addition, many children are given prophylactic therapy for *P. carinii* pneumonia (trimethoprim/sulfamethoxazole [TMP-SMZ]) beginning at 6 months of age. Children with HIV infection are more susceptible to tuberculosis than other children, so they also must be safeguarded against contracting this. If a child develops tuberculosis, a combination of antituberculosis drugs, such as isoniazid or rifampin, is used. Preventing tuberculosis is becoming more difficult because strains of tuberculosis have become resistant to the usual drugs (Wells et al., 2007).

Children with HIV infection should receive routine immunizations with the killed virus vaccines, including the new pneumococcal vaccine, according to the usual schedule. Symptomatic children should not receive the varicella vaccine, and those with low CD4 counts should not receive MMR. If a child is exposed to varicella, intravenous varicella zoster immune globulin (VZIG) is prescribed in an attempt to prevent this disease. Yearly influenza vaccinations should begin at 6 months of age (CDC, 2008b).

Nursing Diagnosis: Risk for compromised family coping related to diagnosis of HIV infection in child

Outcome Evaluation: Parents state ability to continue providing child's physical care; identify outside resources for help with care and decision making.

The diagnosis of HIV infection in an infant or child can prove devastating for a family. When the infection is transmitted maternally, this diagnosis may be the first indication of the existence of HIV infection in the mother; as such, this signals tremendous stress for the whole family. If the child contracted HIV infection from a contaminated blood transfusion or organ donation (rare with current protocols for donor screening), the family can feel so betrayed and angry that they are unwilling to cooperate with health care providers who, in their minds, are responsible for their child's illness. When it occurs in an adolescent, parents may blame themselves for not supervising the child's activities more closely or providing better safer sex information. In any instance, the family's coping skills are sure to be compromised. Siblings may feel left out of the family circle because of the many health care appointments needed for the ill child. They may fear contracting the infection themselves. One of the first nursing priorities in the care of such a family should be to help the family re-establish their previous level of functioning so they can turn their attention to their child's emotional and physical care needs and to their own needs as well.

Physical care requirements for the child with HIV infection may be extensive, depending on the child's symptoms and disease progression. No matter what the child's physical needs, however, love and emotional support are essential to the child's well-being and psychological health. Parents or caregivers need extensive support, education, and anticipatory guidance from nurses and other members of the health care team. Encourage parents to seek medical care for their child at the first sign of illness or infection to prevent unnecessary hospitalization and pain.

A Pregnant Woman With HIV Infection

One fourth of the nearly one million people in the United States infected with this virus are female. The infection has become the leading cause of death in women 25 to 44 years of age. One percent to 2% of every 1000 women giving birth are HIV positive. When the disorder is discovered during pregnancy, pregnancy does not appear to accelerate the progression of the disease.

Risk factors for contracting an HIV infection in women include:

- Multiple sexual partners of the individual or sexual partner
- Bisexual partners
- Intravenous drug use by the individual or sexual partner

Assessment. Unlike other sexually transmitted infections, HIV infection rarely begins with reproductive tract irritation. Instead, early symptoms are more subtle and often difficult to differentiate from those of other diseases or even from the symptoms of early pregnancy (e.g., fatigue, anemia, diarrhea, and weight loss).

Without therapy, HIV infection may progress through the following stages:

- The initial invasion of the virus, which may be accompanied by mild, flulike symptoms
- Seroconversion, in which a woman converts from having no HIV antibodies in her blood serum (HIV serum negative) to having antibodies against HIV (HIV serum positive). Seroconversion happens 6 weeks to 1 year after exposure.
- An asymptomatic period during which a woman appears to be disease-free except for symptoms such as weight loss and fatigue (a wasting syndrome), although the virus can be replicating during this time. The length of this period varies but averages 3 to 11 years.
- A symptomatic period during which a woman develops opportunistic infections and possibly malignancies (e.g., toxoplasmosis, oral and vaginal candidiasis, gastrointestinal illness, herpes simplex, *P. carinii* pneumonia [PCP], *Candida* esophagitis, Kaposi sarcoma, and HIV-associated dementia). At this point, the CD4 count is usually below 200 cells/mm^3.

Although women are not as yet routinely screened for this infection during pregnancy (as a rule, no screening program is initiated for any disease until there is a cure for the disease), women who practice high-risk sexual behaviors should be asked if they want to be screened. A woman with HIV infection may also have contracted other STIs such as syphilis, gonorrhea, chlamydia, and hepatitis B, and so should be screened for these as well. Because HIV-positive women are at higher risk for developing toxoplasmosis and cytomegalovirus infections, the health history should include questions about cat ownership, ingestion of raw meat, and recent mild, flulike symptoms (see Chapter 12). Ordinarily, toxoplasmosis presents with few symptoms. However, in the HIV-positive woman, it may invade the cerebrospinal fluid and cause extreme neurologic involvement. Tuberculosis also occurs at a higher rate in HIV-positive people than in others and may worsen during pregnancy, so a test for tuberculosis should also be included.

If a woman is found to be HIV positive (has developed antibodies from having been exposed to the virus) through an ELISA antibody reaction or a Western blot analysis, the issues of safer sex practices, testing of sexual contacts, continuation or termination of the pregnancy, and treatment during pregnancy need to be addressed. HIV infection is associated with low birth weight and preterm birth. About 20% to 50% of infants born to untreated HIV-positive women will contract the virus and develop AIDS in the first year of life. However, if zidovudine (ZVD) is administered to the woman beginning with the 14th week of pregnancy and the newborn receives antiviral therapy beginning with birth, the risk of developing AIDS falls below 10% (Zanchetta et al., 2008).

Therapeutic Management. Women who are identified as HIV positive are usually advised not to become pregnant until more is learned about how to prevent transmission to a fetus. Often, however, the existence of HIV is discovered only after pregnancy is already present. Progression of the disease is assessed by frequent CD4 cell counts and viral load levels during the coming months.

A goal of therapy is to maintain the CD4 cell count at greater than 500 cells/mm^3 by administering (in addition to oral ZVD) one or more protease inhibitors, such as ritonavir (Norvir) or indinavir (Crixivan), in conjunction with a nucleoside reverse transcriptase inhibitor (NRTI) drug.

If *P. carinii* pneumonia develops, a woman is treated with trimethoprim with sulfamethoxazole (Bactrim), a combination drug not without consequences, as trimethoprim may be

teratogenic in early pregnancy; sulfamethoxazole (Gantanol) may lead to increased bilirubin levels in the newborn if administered late in pregnancy. Pentamidine (Pentam), the drug of choice for PCP in nonpregnant women, is yet another option.

Kaposi's sarcoma, a rare malignancy that tends to occur with AIDS, is normally treated with chemotherapy. Chemotherapy is contraindicated during early pregnancy because of the potential for fetal injury but can be used later in pregnancy to halt these malignant growths.

Thrombocytopenia (lowered platelet count) may be present as a part of the disease pathology or as a response to zidovudine therapy. This may make a woman a poor candidate for an epidural injection for anesthesia during labor or for episiotomy. She may need a platelet transfusion close to birth to restore coagulation ability. To reduce the risk of mother-to-newborn transmission, women are offered the option of cesarean birth.

Follow-up testing of newborns being treated with zidovudine for the first 6 weeks is important. If the child has two negative HIV cultures at 4 months of age, HIV infection can be reasonably excluded.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Risk for infection (opportunistic) related to dysfunction of the immune system secondary to invasion of HIV

Outcome Evaluation: CD4 counts remain above 500/mm^3; viral load less than 5000 copies/mL; no symptoms of lung, vaginal, esophageal, or central nervous system infections are present.

Pregnant women who have CD4 counts below 200/mm^3 may be prescribed drugs to help prevent opportunistic infections. Such drugs include acyclovir (Zovirax) for herpes simplex, clotrimazole troches (Mycelex) for oral thrush, pyrimethamine (Daraprim) and sulfadiazine for toxoplasmosis, and trimethoprim with sulfamethoxazole (Bactrim) for PCP. They may be immunized against pneumonia, influenza, and hepatitis B.

During pregnancy and at birth, active interventions are necessary to reduce the possibility of fetal exposure to maternal blood, often the mode of transmission to the fetus. Amniocentesis, for example, presents a risk for exposure to maternal blood and therefore is avoided if at all possible for diagnosing fetal maturity. During labor, internal fetal monitors, scalp blood sampling, forceps, and vacuum extraction are avoided to prevent the creation of a source of bleeding (that is, an open lesion on the fetal scalp). Episiotomy also is avoided to limit this as a possible blood source. Although the risk may be lower than previously believed, breast milk can transmit HIV and as breastfeeding also increases the incidence of mastitis in an immunosuppressed woman, women are advised not to breastfeed (Chasela et al., 2008). Breastfeeding could also be exhausting for a debilitated woman.

Women who are HIV positive need to be aware that they can still spread this illness to others through unprotected sexual relations or unintentional contamination by blood, even though they are being treated with antibiotics or zidovudine. Nurses can help reduce this risk by providing patient education about the mode of HIV transmission and safer sex practices.

Health care providers must use standard infection precautions (see Chapter 43) to protect against the spread of HIV. This includes the use of gloves when there is a possibility of contact with body secretions; cover gowns if clothing will be exposed to secretions; and goggles at birth, when there may be splashing of amniotic fluid. Gloves should be worn when handling the newborn until all maternal blood has been removed by a first bath. No blood sampling or injections should be completed on the neonate until after a first bath and the removal of maternal blood.

Caring for a woman who is HIV positive during pregnancy and childbirth calls for great sensitivity to respect a woman as a patient with a possibly fatal disease while at the same time encouraging her to continue with prenatal care. Because research into the cause and treatment of this disease is ongoing, recommendations constantly change. Nurses need to remain current on recommendations for therapy or prevention.

✔ Checkpoint Question 42.1

When Dexter's mother learned he had an immunologic disease, she was concerned that he had developed acquired immunodeficiency syndrome (HIV infection or AIDS). What is the transmission method by which most children acquire HIV infection?

a. Blood transfusion.
b. Shared bath towels.
c. Placental transfer.
d. Sneezing and coughing.

ALLERGY

Allergic diseases occur as a result of an abnormal antigen–antibody response. Allergic symptoms can be chronic and minor, such as those that occur with seasonal rhinitis, or acute and severe, as in an anaphylactic reaction. They can disrupt a child's life and development and the life of the family. When the cause of an allergic response is difficult to pinpoint, the child and parents often become frustrated. Even when the child has a known allergy, symptoms can vary from minor to acute without warning, ultimately disrupting family functioning (Box 42.5).

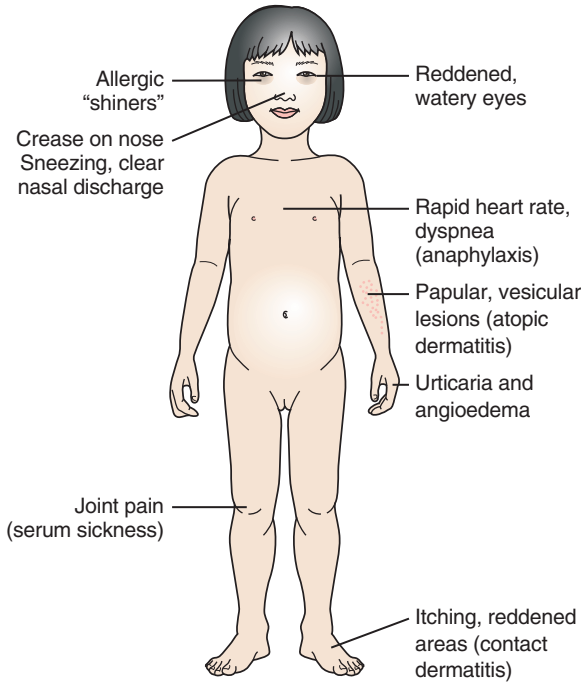
Hypersensitivity

The underlying cause of all allergic disorders appears to be an excessive antigen–antibody response when the invading organism is an allergen rather than a simple immunogen. This is termed a type I response or a **hypersensitivity response** when it happens immediately. It can also occur as a type II, III, or IV response (Table 42.3). Types I, II, and III are mediated by antibodies (humoral response), whereas type IV is mediated by the T lymphocytes (cell-mediated response).

Type I: Anaphylaxis

With a type I allergic response, IgE receptor sites attached to the surface of mast cells bind to IgE antibodies responding to

Box 42.5 Assessment
Assessing a Child With an Immune Disorder



the presence of an antigen. Mast cells are specialized cells found lining blood vessels and in connective tissue, the mucous membranes, and skin. The IgE immunoglobulin triggers mast cells to release intracellular granules. These contain histamine, leukotrienes, a slow-reacting substance of anaphylaxis (SRS-A), and chemotactic substances (substances to draw leukocytes into the area). Histamine and leukotrienes cause peripheral vasodilation and permeability of blood vessels. This leads to vascular congestion and edema. SRS-A causes extreme bronchial constriction and reduced vasodilation and permeability. **Anaphylaxis** is an acute reaction characterized by extreme vasodilation that leads to circulatory shock and extreme bronchoconstriction that decreases the airway lumens (Lane & Bolte, 2007).

Type II: Cytotoxic Response

In a **cytotoxic response,** cells are detected as foreign and immunoglobulins directly attack and destroy them without harming surrounding tissue. Foreign red blood cells that are introduced to an Rh-negative woman by an Rh-positive fetus are destroyed by this process (see Chapter 26). Tumor cells may be destroyed by this process. Why this immune response fails when malignant cells begin to proliferate is not understood. Current research is attempting to devise ways to activate the natural immune response as a method of destroying malignant cells. Care of the child with a malignancy (neoplasm) is discussed in Chapter 53.

Type III: Immune Complex

A type III response is an IgG- or IgE-mediated antigen–antibody complex reaction that involves complement and initiates the inflammatory response. Complement reactions that persist beyond the usual inhibition may serve as the basis for many of the autoimmune illnesses, such as glomerulonephritis and systemic lupus erythematosus (see Chapter 46). Serum sickness also occurs as a result of a type III response.

Type IV: Cell-Mediated Hypersensitivity

In a delayed hypersensitivity response, T lymphocytes react with antigens and release lymphokines to call macrophages into the area. An inflammatory response occurs that helps to destroy the foreign tissue. A Mantoux or purified protein derivative (PPD) tuberculin test is an example of this. Redness and induration of the site do not begin initially but only after approximately 12 hours from the injection. The reaction peaks in 24 to 72 hours (a delayed response).

Contact dermatitis is another example of a delayed hypersensitivity response. Certain substances, such as cosmetics,

TABLE 42.3 ✻ Classification of Hypersensitivity Reactions

Type	Involved Cell	Mechanism	Effect
I Anaphylaxis	IgE	IgE attached to surface of mast cell triggers release of intracellular granules from mast cells on contact with antigens	Allergies, asthma, atopic dermatitis, anaphylaxis
II Cytotoxic	IgG or IgM	Antigen–antibody reaction leading to antigen destruction; complement is activated	Hemolytic anemia, transfusion reaction, erythroblastosis fetalis
III Immune complex disease	IgG or IgE	Antigen–antibody complexes precipitate; complement is activated, leading to inflammatory response	Rheumatoid arthritis, systemic lupus erythematosus
IV Delayed	T lymphocyte	T cells combine with antigen to induce inflammatory reactions by direct cell involvement or release of lymphokines	Contact dermatitis, transplant graft reaction

household products, or cured leather, alter the protein of skin cells so that they become an antigen, or the foreign substance combines with the protein (hapten formation) to become an antigenic protein. Lymphocytes and macrophages infiltrate the area and attempt to destroy the offending protein. Redness and vesicles occur, and pruritus may be intense.

Assessment of Allergy in Children

History

Taking a health history of a child with an allergy can be time-consuming because many factors must be considered. A family history is important because there are familial tendencies with allergic diseases. Obtaining the exact symptoms of the allergy is important to help identify the allergen: rhinitis, for example, is probably because of an airborne antigen; urticaria (swelling and itching) is often caused by ingested antigens; and contact dermatitis (often a rash) must be from something that contacts the skin in that area. The time of the year that the allergy occurs also may give a clue to its cause. If the child's allergy exists all year, the antigen must be one that is present all year (house dust mites, pet dander, or a common food). If it occurs in the spring, it may be because of a tree pollen; in summer, a grass pollen; if it occurs just in August, ragweed is a prime suspect.

Children with allergic rhinitis (hay fever) develop common symptoms such as a horizontal crease across the nose (called a Dennie's line) from their habit of constantly wiping away nasal secretions. They also may develop dark patches under their eyes from back-pressure from nasal congestion.

Many symptoms of allergy are vague, described as "colds all winter," "itching," or "runny nose." Listen carefully: even though no one symptom is acute, together such symptoms can interfere with a child's comfort, school experience, and long-term health. Having the parents and the child keep a chart of when symptoms are worse and better often helps identify a specific allergen. Children with allergic rhinitis (hay fever), for example, have more symptoms on a windy day and fewer after a rainstorm (the rain washes pollen out of the air). Children are often poor reporters of when they have symptoms because they cannot remember clearly whether they had the same rhinitis and watery eye symptoms last summer as they do this summer. A record that details when symptoms start—for example, on arising, or only after the child reaches school—also can help identify an allergen.

Laboratory Testing

Few laboratory tests are helpful in establishing a diagnosis of allergy. A determination of IgE serum antibodies can be made. Most children with an allergy have an increased eosinophil count. Five percent or more of eosinophils on a differential count, or an eosinophil count of 250 or more cells per cubic millimeter, is significant. Another main cause of an increased eosinophil count is invasion by ova or parasites. This is why a stool specimen for ova and parasites is generally collected to rule out these problems as the cause of the increased eosinophil count. A radioallergosorbent test (RAST) may be ordered. This is an indirect radioimmunoassay in which the child's serum IgE is allowed to react with specific allergens impregnated in laboratory disks (Schafer et al., 2007).

Skin Testing
