Preface

Maternal-newborn and child health nursing are expanding areas as a result of the broadening scope of practice within the nursing profession and the recognized need for better preventive and restorative care in these areas. The importance of this need is reflected in the fact that many of the health goals for the nation focus on these areas of nursing.

At the same time that the information in these areas of nursing is increasing, less time is available in nursing programs for teaching it. It's difficult for students to read all of the material contained in overlapping textbooks.

Maternal and Child Health Nursing: Care of the Childbearing and Childrearing Family, Sixth Edition, is written with this challenge in mind. It views maternal-newborn and child health care not as two separate disciplines but as a continuum of knowledge. It is designed to present the content of the two disciplines comprehensively but not redundantly. It is based on a philosophy of nursing care that respects clients as individuals, yet views them as part of families and society.

The book is designed for undergraduate student use in either a combined course in maternal-newborn and child health or for a curriculum in which these courses are taught separately. It provides a comprehensive, in-depth discussion of the many facets of maternal and child health nursing, while promoting a sensitive, holistic outlook on nursing practice. As such, the book will also be useful for practicing nurses or graduate students who are interested in reviewing or expanding their knowledge in these areas.

Basic themes that are integrated into this text include the experience of wellness and illness as family-centered events, the perception of pregnancy and childbirth as periods of wellness, and the importance of knowing normal child development in the planning of nursing care. Also included are themes reflective of changes in health care delivery and the importance of meeting the needs of a culturally diverse population.

THE CHANGING HEALTH CARE SCENE

Managed care has drastically changed the health care delivery system, increasing the role of the nurse from a minor to a major player. It has made understanding multidisciplinary approaches to care more important than ever before. An increasingly multicultural population is reflected among both nurses and the clients they care for, necessitating fine-tuning of culturally sensitive care. In order that nurses can be prepared for this new level of responsibility, educational changes have to keep pace with this health care reform by emphasizing expected outcomes, a greater focus on communication, therapeutic interventions, and critical thinking.

Nursing issues that grow out of the current climate of change include:

- **An emphasis on National Health Goals:** As a way to focus care and research, National Health Goals have gained wider attention at a time when there is a greater need than ever to be wise in the choice of how dollars are spent. Students can familiarize themselves with these goals by referring to the Focus on National Health Goals displays that appear at the beginning of each chapter.
- **The importance of health teaching with families as a cornerstone of nursing responsibility:** The teaching role of the nurse has greater significance in the new health care milieu as the emphasis on preventive care and short stays in the acute care setting create the need for families to be better educated in their own care. Focus on Family Teaching displays present detailed health information for the family, emphasizing the importance of a partnership between nurses and clients in the management of health and illness.
- **The importance of individualizing care according to sociocultural uniqueness:** This is a reflection of both greater cultural sensitivity and an increasingly diverse population of caregivers and care recipients. Greater emphasis is being placed on the implications of multiple sociocultural factors in terms of how they affect responses to health and illness. Focus on Communication boxes are included in each chapter to give examples of effective and less effective communication.
- **The importance of basing nursing care on nursing process and evidence based practice:** The variety of new care settings, as well as the diversity of roles in which nurses practice, is reflected both in the proliferation of community-based nursing facilities and also in the increase in the numbers of nurse-midwives and pediatric and neonatal nurse practitioners. This new edition places emphasis on the need for nurses to practice based on solid evidence in all settings. Focus on Evidence-Based Practice boxes in each chapter supply concrete examples of research and how it could be applicable to nursing practice. Focus on Nursing Care Planning boxes detail the use of nursing process in multidisciplinary oriented care.
- **Nursing process:** Nursing process serves as the foundation for nursing practice. Nursing Process Overview boxes included in each chapter provide a strong theoretical underpinning for nursing process and ways to use the nursing process in clinical practice.

ORGANIZATION OF THE TEXT

Maternal and Child Health Nursing follows the family from the pregnancy period, through labor, delivery, and the postpartal period; it then follows the child in the family from birth through adolescence. Coverage includes ambulatory and in-patient care and focuses on primary as well as secondary and tertiary care.

The book is organized in eight units:

Unit I provides an introduction to maternal and child health nursing. A framework for practice is presented, as well as current trends and the importance of considering childbearing and childrearing within a diverse socioeconomic and family/community context.

Unit II examines the nursing role in preparing families for childbearing and childrearing, and discusses reproductive and sexual health, the role of the nurse as a genetic counselor, reproductive life planning, and the concerns of the subfertile family.

Unit III presents the nursing role in caring for a pregnant family during pregnancy, birth and the postpartal period and serving as a fetal advocate. A separate chapter details the role of the nurse in providing comfort during labor and birth.

Unit IV addresses the nursing role when a woman develops a complication of pregnancy, labor or birth, or has a complication during the postpartal period. Separate chapters address the role of the nurse when a woman has a preexisting illness, develops a complication during pregnancy or the postpartal period, has a special need, or chooses or needs a cesarean birth. A final chapter details care of the high risk newborn or a child born with a physical or developmental challenge.

Unit V discusses the nursing role in health promotion during childhood. The chapters in this unit cover principles of growth and development and care of the child from infancy through adolescence, including child health assessment and communication and health teaching with children and families.

Unit VI presents the nursing role in supporting the health of children and their families. The effects of illness on children and their families, diagnostic and therapeutic procedures, medication administration, and pain management are addressed, with respect to care of the child and family in hospital, home, and ambulatory settings.

Unit VII examines the nursing role in restoring and maintaining the health of children and families when illness occurs. Disorders are presented according to body systems so that students have a ready orientation for locating content.

Unit VIII discusses the nursing role in restoring and maintaining the mental health of children and families. Separate chapters discuss the role of the nurse when intimate partner or child abuse or mental, long-term, or fatal illness is present.

PEDAGOGIC FEATURES

Each chapter in the text is organized to provide a complete learning experience for the student. Numerous pedagogic features are included to help a student understand and increase retention. Important elements include:

- **Chapter Objectives:** Learning objectives are included at the beginning of each chapter to identify outcomes expected after the material in the chapter has been mastered.
- **Key Terms:** Terms that would be new to a student are listed at the beginning of each chapter in a ready reference list. When the terms first appear in the text, they are shown in boldface type and then defined. Definitions appear again in the Glossary.
- **Chapter-Opening Scenarios:** Short scenarios appear at the beginning of each chapter. These vignettes are designed to help students appreciate that nursing care is always individualized and provide a taste of what is to come in the chapter. At the end of the chapter, Critical Thinking questions related to the scenario bring the chapter full circle.
- **Nursing Process Overview:** Each chapter begins with a review of nursing process in which specific suggestions, such as examples of nursing diagnoses and outcome criteria helpful to modifying care in the area under discussion, are presented. These reviews are designed to improve students' preparation in clinical areas so they can focus their care planning and apply principles to practice.
- **Nursing Diagnoses and Related Interventions:** A consistent format highlights the nursing diagnoses and related interventions throughout the text. A special heading draws the students' attention to these sections where individual nursing diagnoses and outcome evaluation are detailed for the major conditions and disorders discussed.
- **Tables and Displays:** Numerous tables and displays summarize important information or provide extra detail on topics so that a student has ready references to this information.
- **Focus on National Health Goals:** To emphasize the nursing role in accomplishing the health care goals of our nation, these displays state specific ways in which maternal and child health nursing can provide better outcomes for both mother and child. They help the student to appreciate the importance of national health planning and the influence that nurses can have in creating a healthier nation.
- **Focus on Evidence-Based Practice:** These displays summarize research on topics related to maternal and child health nursing. They appear throughout the text to accentuate the use of evidence-based practice as the basis for nursing care.
- **Focus on Communication:** This feature presents case examples of less effective communication and more effective communication, illustrating for the student how an awareness of communication can improve the patient's understanding and positively impact outcomes.
- **Focus on Family Teaching:** These boxes present detailed health teaching information for the family, emphasizing the importance of a partnership between nurses and clients in the management of health and illness.
- **Focus on Pharmacology:** These boxes provide quick reference for medications that are commonly used for the health problems described in the text. They give the drug name (brand and generic, if applicable), dosage, pregnancy category, side effects, and nursing implications.
- **Focus on Nursing Procedures:** Techniques of procedures specific to maternal and child health care are boxed in an easy-to-follow two-column format, often enhanced with color figures.
- **Focus on Assessment:** These visual guides provide head-to-toe assessment information for overall health status or specific disorders or conditions.
- **Focus on Nursing Care Planning: Multidisciplinary Care Maps:** Because nurses rarely work in isolation, but rather as a member of a health care team or unit, Multidisciplinary Care Maps written for specific clients are included throughout the text to demonstrate the use of the nursing process, provide examples of critical thinking, and clarify nursing care for specific client needs. Multidisciplinary care maps not only demonstrate nursing process but also accentuate the increasingly important role of the nurse as a coordinator of client care.
- **Checkpoint Questions:** Throughout the text, multiple-choice Checkpoint Questions appear to help readers check progress and comprehension. They ask readers to use the knowledge just gained in the last few pages, helping them retain this information. Answers are supplied in the accompanying CD.

- **"What If" Questions:** "What If" (critical-thinking) questions also appear in each chapter in the text. These ask readers to apply the information just acquired in an "actual" situation. Readers must process the information and apply it to the new situation, thus maximizing learning and emphasizing critical thinking. Suggested solutions are supplied in the accompanying CD.
- **Key Points:** A review of important points is highlighted at the end of each chapter, to help students monitor their own comprehension.
- **Critical Thinking Exercises:** To involve a student in the decision-making realities of the clinical setting, several thought-provoking questions are posed at the end of each chapter. These could also serve as a basis for conference or class discussion. Suggested considerations are supplied in the accompanying CD.
- **Critical Thinking Scenarios:** An accompanying CD-ROM contains a patient care scenario detailing a full health history and examination findings pertinent to the chapter content as well as 20 related multiple-choice RN-CLEX types of questions to answer for further chapter review. These could also be used for classroom or clinical instruction.
- **References and Suggested Readings:** These provide a student with the information needed to do more in-depth reading of the sources noted in the text, as well as other relevant articles on the topics included in the chapter.
- **Appendices:** Appendices provide a quick reference to laboratory values, growth charts, vital sign parameters, nutrition pyramids, and drugs safe for use during lactation.

ANCILLARY PACKAGE

A complete learning and teaching package accompanying the text includes:

- **Free Interactive Self-Study CD-ROM:** Found on the inside front cover of each book, this free CD contains 300 **multiple-choice NCLEX-style questions** to challenge the student's comprehension and application of the material in the textbook. Feedback is provided for each answer.
- **Instructor's Resource DVD:** The perfect complement to classroom teaching strategies, this resource contains useful lecture points, discussion questions, and assignments for each chapter. Also included is a **computerized test bank,** containing more than 1000 multiple-choice NCLEX-style questions; an **image bank** containing art from the text; and **PowerPoint presentations** for every chapter.
- **Study Guide:** This companion to the text challenges the student's retention of key concepts and encourages critical thinking and application of information to actual nursing situations.
- **thePoint*:** Students and teachers can find additional resources to enhance learning at http://thePoint.lww.com/Pillitteri6e

Chapter

1 A Framework for Maternal and Child Health Nursing

KEY TERMS

- case manager
- certified nurse-midwife
- clinical nurse specialist
- client advocacy
- evidence-based practice
- fertility rate
- genetic nurse counselor
- maternal and child health nursing
- mortality rate
- neonate
- nurse practitioner
- nursing research
- puerperium
- scope of practice

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Identify the goals and philosophy of maternal and child health nursing.
2. Describe the evolution, scope, standards, and professional roles for nurses in maternal and child health nursing.
3. Describe family-centered care and ways that maternal and child health nursing could be made more family centered.
4. Define common statistical terms used in the field, such as *infant* and *maternal mortality*.
5. Identify legal and ethical issues important to maternal and child health nursing.
6. Use critical thinking to identify areas of care that could benefit from additional research or application of evidence-based practice.
7. Discuss the interplay of nursing process, evidence-based practice, and nursing theory as they relate to the future of maternal and child health nursing practice.
8. Integrate knowledge of trends in maternal and child health care with the nursing process to achieve quality maternal and child health nursing care.

Anna Chung is a premature neonate who will be transported to a regional center for care about 30 miles from the hospital where she was born. Her parents, Melissa and Robert, are worried because their tiny daughter will be cared for so many miles away from home. They're also concerned about whether they will be able to pay for her special care. Melissa, who is 37 years old, tells you that she feels too old to leave the hospital only 2 days after having a cesarean birth. She wonders how her first child, Micko, now 6 years old, will react to having an ill rather than a healthy sister.

This chapter discusses standards and philosophies of maternal and child health care and how these standards and philosophies affect care.

What are some health care issues evident in this scenario? What is the nursing role here?

GOALS AND PHILOSOPHIES OF MATERNAL AND CHILD HEALTH NURSING

Obstetrics, or the care of women during childbirth, is derived from the Greek word *obstare,* which means "to keep watch." *Pediatrics* is a word derived from the Greek word *pais,* meaning "child." The care of childbearing and childrearing families is a major focus of nursing practice, because to have healthy adults you must have healthy children. To have healthy children, it is important to promote the health of the childbearing woman and her family from the time before children are born until they reach adulthood. That makes both preconceptual and prenatal care essential contributions to the health of a woman and fetus and to a family's emotional preparation for childbearing and childrearing. As children grow, families need continued health supervision and support. As children reach maturity and plan for their own families, a new cycle begins and new support becomes necessary. The nurse's role in all these phases focuses on promoting healthy growth and development of the child and family in both health and illness (Nearns, 2009).

Although the field of nursing typically divides its concerns for families during childbearing and childrearing into two separate entities, maternity care and child health care, the full scope of nursing practice in this area is not two separate entities but rather a continuum: maternal and child health nursing (Fig. 1.1).

The primary goal of **maternal and child health nursing** care can be stated simply as the promotion and maintenance of optimal family health to ensure cycles of optimal childbearing and childrearing. Major philosophical assumptions about maternal and child health nursing are listed in Box 1.1. The goals of maternal and child health nursing care are necessarily broad because the **scope of practice** (the range of services and care that may be provided by a nurse based on state requirements) is so broad. The range of practice includes

- Preconceptual health care
- Care of women during three trimesters of pregnancy and the **puerperium** (the 6 weeks after childbirth, sometimes termed the fourth trimester of pregnancy)

BOX 1.1 ✻ Philosophy of Maternal and Child Health Nursing

- Maternal and child health nursing is family centered; assessment must include both family and individual assessment data.
- Maternal and child health nursing is community centered; the health of families depends on and influences the health of communities.
- Maternal and child health nursing is evidence based, because this is the means whereby critical knowledge increases.
- A maternal and child health nurse serves as an advocate to protect the rights of all family members, including the fetus.
- Maternal and child health nursing includes a high degree of independent nursing functions, because teaching and counseling are major interventions.
- Promoting health and disease prevention are important nursing roles because these protect the health of the next generation.
- Maternal and child health nurses serve as important resources for families during childbearing and childrearing as these can be extremely stressful times in a life cycle.
- Personal, cultural, and religious attitudes and beliefs influence the meaning and impact of childbearing and childrearing on families.
- Circumstances such as illness or pregnancy are meaningful only in the context of a total life.
- Maternal and child health nursing is a challenging role for nurses and a major factor in keeping families well and optimally functioning.

A

B

FIGURE 1.1 Maternal and child health nursing includes care of the pregnant woman, child, and family. (**A**) During a prenatal visit, a nurse assesses that a pregnant woman's uterus is expanding normally. (**B**) During a health maintenance visit, a nurse assesses a child's growth and development. (© Barbara Proud.)

- Care of infants during the perinatal period (6 weeks before conception to 6 weeks after birth)
- Care of children from birth through adolescence
- Care in settings as varied as the birthing room, the pediatric intensive care unit, and the home

In all settings and types of care, keeping the family at the center of care or considering the family as the primary unit of care is an essential goal. This is because the level of a family's functioning affects the health status of its members (Vonderheid, Norr, & Handler, 2007). If a family's level of functioning is low, the emotional, physical, and social health and potential of individuals in that family can be adversely affected. A healthy family, on the other hand, establishes an environment conducive to growth and health-promoting behaviors that sustain family members during crises. Similarly, the health of an individual and his or her ability to function strongly influence the health of family members and overall family functioning. For these reasons, a family-centered approach enables nurses to better understand individuals and their effect on others and, in turn, to provide holistic care. Box 1.2 provides a summary of key measures for the delivery of family-centered maternal and child health care.

BOX 1.2 ✻ Common Measures to Ensure Family-Centered Maternal and Child Health Care

Principles

- The family is the basic unit of society.
- Families come in many different forms and sizes and represent racial, ethnic, cultural, and socioeconomic diversity.
- Children grow both individually and as part of a family.

Nursing Interventions

- Consider the family as a whole as well as its individual members.
- Assess families for strengths as well as for specific needs or challenges.
- Respect diversity in families as a unique quality of that family.
- Share or initiate information on health planning with family members so that care is family oriented.
- Encourage family bonding through rooming-in in both maternal and child health hospital settings.
- Encourage families to give care to a newborn or ill child.
- Family members affect other members; individual members affect the total family group.
- Encourage family and sibling visits in the hospital to promote family contacts.
- Participate in early hospital discharge programs to reunite families as soon as possible.
- Include developmental stimulation in nursing care.
- Encourage families to reach out to their community so that family members are not isolated from their community or from each other.

STANDARDS OF MATERNAL AND CHILD HEALTH NURSING PRACTICE

The importance a society places on human life can best be measured by the concern it places on its most vulnerable members—its elderly, disadvantaged, and youngest citizens. To promote consistency and ensure quality nursing care and outcomes in these areas, specialty organizations have developed guidelines for care in their specific areas of nursing practice. In maternal-child health, standards have been developed by the Division of Maternal-Child Health Nursing Practice of the American Nurses Association in collaboration with the Society of Pediatric Nurses. These standards are shown in Box 1.3.

The Association of Women's Health, Obstetric, and Neonatal Nurses (AWHONN) has developed similar standards for the nursing care of women and newborns. These are summarized in Box 1.4. Notice how both these practice directives speak to family-centered care.

A FRAMEWORK FOR MATERNAL AND CHILD HEALTH NURSING CARE

Maternal and child health nursing can be visualized within a framework in which nurses, using nursing process, nursing theory, and evidence-based practice, care for families during childbearing and childrearing years through four phases of health care:

- Health promotion
- Health maintenance
- Health restoration
- Health rehabilitation

Examples of these phases of health care as they relate to maternal and child health are shown in Table 1.1.

The Nursing Process

Nursing care, at its best, is designed and implemented in a thorough manner, using an organized series of steps, to ensure quality and consistency of care (Carpenito, 2007). The nursing process, a form of problem solving based on the scientific method, serves as the basis for assessing, making a nursing diagnosis, planning, organizing, and evaluating care. That the nursing process is applicable to all health care settings, from the prenatal clinic to the pediatric intensive care unit, is proof that the method is broad enough to serve as the basis for nursing care.

Because nurses rarely work in isolation but rather as a member of a health care team or unit, multidisciplinary care maps are included throughout the text to demonstrate the use of the nursing process for selected clients, provide examples of critical thinking, and clarify nursing care for specific client needs. These also serve to accentuate the increasingly important role of the nurse as a coordinator of client care and member of a collaborative team.

Evidence-Based Practice

Evidence-based practice is the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of patients (Foxcroft & Cole, 2009). Evidence can be a combination of research, clinical expertise, and

BOX 1.3 ✻ American Nurses Association/Society of Pediatric Nurses Standards of Care and Professional Performance

Standards of Care

Comprehensive pediatric nursing care focuses on helping children and their families and communities achieve their optimum health potentials. This is best achieved within the framework of family-centered care and the nursing process, including primary, secondary, and tertiary care coordinated across health care and community settings.

Standard I: Assessment
The pediatric nurse collects patient health data.

Standard II: Diagnosis
The pediatric nurse analyzes the assessment data in determining diagnoses.

Standard III: Outcome Identification
The pediatric nurse identifies expected outcomes individualized to the child and the family.

Standard IV: Planning
The pediatric nurse develops a plan of care that prescribes interventions to obtain expected outcomes.

Standard V: Implementation
The pediatric nurse implements the interventions identified in the plan of care.

Standard VI: Evaluation
The pediatric nurse evaluates the child's and family's progress toward attainment of outcomes.

Standards of Professional Performance

Standard I: Quality of Care
The pediatric nurse systematically evaluates the quality and effectiveness of pediatric nursing practice.

Standard II: Performance Appraisal
The pediatric nurse evaluates his or her own nursing practice in relation to professional practice standards and relevant statutes and regulations.

Standard III: Education
The pediatric nurse acquires and maintains current knowledge and competency in pediatric nursing practice.

Standard IV: Collegiality
The pediatric nurse interacts with and contributes to the professional development of peers, colleagues, and other health care providers.

Standard V: Ethics
The pediatric nurse's assessment, actions, and recommendations on behalf of children and their families are determined in an ethical manner.

Standard VI: Collaboration
The pediatric nurse collaborates with the child, family, and other health care providers in providing client care.

Standard VII: Research
The pediatric nurse contributes to nursing and pediatric health care through the use of research methods and findings.

Standard VIII: Resource Utilization
The pediatric nurse considers factors related to safety, effectiveness, and cost in planning and delivering patient care.

American Nurses Association and Society of Pediatric Nurses. (2003). *Scope and standards of pediatric clinical practice.* Washington, DC: American Nurses Association Publishing House.

patient preferences when all three combine in decision making. The worth of evidence is ranked according to:

- **Level I:** Evidence obtained from at least one properly designed randomized controlled trial.
- **Level II:** Evidence obtained from well-designed controlled trials without randomization, well-designed cohort or case-control analytic studies, or multiple time series with or without an intervention. Evidence obtained from dramatic results in uncontrolled trials might also be regarded as this type of evidence.
- **Level III:** Opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert committees (U.S. Preventive Services Task Force, 2005).

Use of evidence-based practice helps to move all health care actions to a more solid, and therefore safer, scientific base. The Cochrane Database of Systematic Reviews is good source for discovering evidence-based practices as the organization consistently reviews, evaluates, and reports the strength of health-related research.

Nursing Research

Bodies of professional knowledge grow and expand to the extent that people in that profession plan and carry out research. **Nursing research,** the controlled investigation of problems that have implications for nursing practice, provides evidence for practice and justification for implementing activities for outcome achievement, ultimately resulting in improved and cost-effective patient care.

A classic example of how the results of nursing research can influence nursing practice is the application of the research carried out by Rubin (1963) on a mother's approach to her newborn. Before the publication of this study, nurses assumed that a woman who did not immediately hold and cuddle her infant at birth was a "cold" or unfeeling mother. After observing a multitude of new mothers, Rubin concluded that attachment is not a spontaneous procedure; rather, it more commonly begins with only fingertip touching. Armed with Rubin's findings and integrating these findings into practice, nurses became better able to differentiate

BOX 1.4 ✻ Association of Women's Health, Obstetric, and Neonatal Nurses Standards and Guidelines

Standards of Professional Performance

Standard I: Quality of Care
The nurse systematically evaluates the quality and effectiveness of nursing practice.

Standard II: Performance Appraisal
The nurse evaluates his/her own nursing practice in relation to professional practice standards and relevant statutes and regulations.

Standard III: Education
The nurse acquires and maintains current knowledge in nursing practice.

Standard IV: Collegiality
The nurse contributes to the professional development of peers, colleagues, and others.

Standard V: Ethics
The nurse's decisions and actions on behalf of patients are determined in an ethical manner.

Standard VI: Collaboration
The nurse collaborates with the patient, significant others, and health care providers in providing patient care.

Standard VII: Research
The nurse uses research findings in practice.

Standard VIII: Resource Utilization
The nurse considers factors related to safety, effectiveness, and cost in planning and delivering patient care.

Standard IX: Practice Environment
The nurse contributes to the environment of care delivery within the practice settings.

Standard X: Accountability
The nurse is professionally and legally accountable for his/her practice. The professional registered nurse may delegate to and supervise qualified personnel who provide patient care.

Association of Women's Health, Obstetric, and Neonatal Nurses. (1998). *Standards for the nursing care of women and newborns* (5th ed.). Washington, DC: Author.

healthy from unhealthy bonding behavior in postpartum women. Women who did not follow this step-by-step pattern of attachment were no longer categorized as unfeeling. By documenting these healthy and unhealthy parameters, nurses can identify women who do not follow a healthy pattern, and interventions can be planned and instituted to help these mothers gain a stronger attachment to their new infants. Additional nursing research in this area (discussed in Chapter 17) has provided further substantiation about the importance of this original investigation.

Evidence-based practice requires ongoing research to substantiate current actions as well as to provide guidelines for future actions. Some examples of current questions that warrant nursing investigation in the area of maternal and child health nursing include the following:

- What is the most effective stimulus to encourage women to come for prenatal care or parents to bring children for health maintenance care?
- How much self-care should young children be expected (or encouraged) to provide during an illness?
- What is the effect of market-driven health care on the quality of maternal-child nursing care?
- What active measures can nurses take to reduce the incidence of child or intimate partner abuse?

TABLE 1.1 ✻ Definitions and Examples of Phases of Health Care

Term	Definition	Examples
Health promotion	Educating clients to be aware of good health through teaching and role modeling	Teaching women the importance of rubella immunization before pregnancy; teaching children the importance of safer sex practices
Health maintenance	Intervening to maintain health when risk of illness is present	Encouraging women to come for prenatal care; teaching parents the importance of safeguarding their home by childproofing it against poisoning
Health restoration	Promptly diagnosing and treating illness using interventions that will return client to wellness most rapidly	Caring for a woman during a complication of pregnancy or a child during an acute illness
Health rehabilitation	Preventing further complications from an illness; bringing an ill client back to an optimal state of wellness or helping a client to accept inevitable death	Encouraging a woman with gestational trophoblastic disease to continue therapy or a child with a renal transplant to continue to take necessary medications

- How can nurses best help families cope with the stress of long-term illness?
- How can nurses help prevent violence such as homicide in communities and modify the effects of violence on families?
- What do maternal-child health nurses need to know about alternative therapies such as herbal remedies to keep their practices current?

The answers to these and other questions provided by research help to bolster a foundation for specific actions and activities that have the potential to improve maternal and child health care. The Focus on Evidence-Based Practice boxes included in chapters throughout the text contain summaries of current maternal and child health research studies and are designed to assist you in developing a questioning attitude regarding current nursing practice and in thinking of ways to incorporate research findings into care (Box 1.5).

BOX 1.5 ✻ Focus on Evidence-Based Practice

Do nonsmoking programs actually reduce the level of smoking?

Cigarette smoking is strongly associated with heart and respiratory disease. If interventions to stop smoking could be employed in workplace settings, potentially thousands more individuals could be reached with such programs.

To see if workplace nonsmoking intervention programs are effective, researchers analyzed the outcome of a group of programs targeting individual smokers: 10 studies of group therapy, 7 studies of individual counseling, 9 studies of self-help materials, and 5 studies of nicotine replacement therapy. Workplace interventions aimed at the workforce as a whole included 14 studies of tobacco bans, 2 studies of social support, 4 studies of environmental support, 5 studies of incentives, and 8 studies of comprehensive (multicomponent) programs. Following the analysis, the authors concluded:

1. Interventions directed toward individual smokers such as advice from health care professionals or the use of pharmacological treatments increase the likelihood of individuals quitting smoking.
2. There is limited evidence that including competition or incentives organized by an employer can increase participation in programs.
3. There is consistent evidence that workplace tobacco policies and bans can decrease cigarette consumption during the working day by smokers and exposure of nonsmoking employees to environmental tobacco smoke at work. Such bans, however, may not decrease the overall prevalence of smoking or overall consumption of tobacco by smokers.

Suppose you are interested in reducing cigarette smoking in a family you care for? Could you use these findings to help plan a program for them?

Source: Moher, M., Hey, K. & Lancaster, T. (2009). Workplace interventions for smoking cessation. *Cochrane Database of Systematic Reviews, 2009*(1), (CD003440).

Nursing Theory

One of the requirements of a profession (together with other critical determinants, such as member-set standards, monitoring of practice quality, and participation in research) is that the concentration of a discipline's knowledge flows from a base of established theory.

Nursing theorists offer helpful ways to view clients so that nursing activities can best meet client needs—for example, by seeing a pregnant woman not simply as a physical form but as a dynamic force with important psychosocial needs, or by viewing children as extensions or active members of a family as well as independent beings. Only with this broad theoretical focus can nurses appreciate the significant effect on a family of a child's illness or of the introduction of a new member.

Another issue most nursing theorists address is how nurses should be viewed or what the goals of nursing care should be. Extensive changes in the scope of maternal and child health nursing have occurred as health promotion, or keeping parents and children well, has become a greater priority.

With health promotion as a major nursing goal, teaching, counseling, supporting, and advocacy are also common roles (Vonderheid et al., 2007). Nurses care for clients who are more critically ill than ever before. Because care of women during pregnancy and of children during their developing years helps protect not only current health but also the health of the next generation, maternal-child health nurses fill these expanded roles to a unique and special degree.

✔ Checkpoint Question 1.1

Suppose Melissa Chung asks you whether maternal-child health nursing is a profession. What qualifies an activity as a profession?

a. Members supervise other people.
b. Members use a distinct body of knowledge.
c. Members enjoy good working conditions.
d. Members receive relatively high pay.

A CHANGING DISCIPLINE

At the beginning of the 20th century, the infant **mortality rate** in the United States (i.e., the number of infants per 1000 births who die during the first year of life) was greater than 100 per 1000. In response to efforts to lower this rate, health care shifted from a treatment focus to a preventive one, dramatically changing the scope of maternal and child health nursing. Research on the benefits of early prenatal care led to a major national effort to provide prenatal care to all pregnant women through prenatal nursing services (home visits) and clinics. Today, thanks to these and other community health measures (such as efforts to encourage breastfeeding, increased immunization, and injury prevention), as well as many technological advances, the U.S. infant mortality rate has fallen to 6.6 per 1000 (Eldridge & Sutton, 2009).

Medical technology has contributed to a number of important advances in maternal and child health: childhood diseases such as measles and poliomyelitis are almost eradicated through immunization; specific genes responsible for many inherited diseases have been identified; stem cell therapy may make it possible in the next few years to replace

diseased cells with new growth cells; new fertility drugs and techniques allow more couples than ever before to conceive; and the ability to delay preterm birth and improve life for premature infants has grown dramatically. In addition, a growing trend toward health care consumerism, or self-care, has made childbearing and childrearing families active participants in their own health monitoring and care. Health care consumerism has also moved care from hospitals to community sites such as retail shopping malls and from long-term hospital stays to overnight surgical and emergent care settings.

Even in light of these changes, much more still needs to be done. National health care goals are established every 10 years for the following decade to continuously stress the importance of maternal and child health to overall community health (U.S. Department of Health and Human Services [DHHS]). Although health care may be more advanced, it is still not accessible to everyone. These and other social changes and trends have expanded the roles of nurses in maternal and child health and, at the same time, have made the delivery of quality maternal and child health nursing care a continuing challenge.

National Health Goals

In 1979, the U.S. Public Health Service first formulated health care objectives. These goals are ongoing and modified every 10 years (http://www.nih.gov). Many of these objectives directly involve maternal and child health care, because improving the health of this young age group will have such long-term effects. Two overarching national goals are to (a) increase quality and years of healthy life and (b) eliminate health disparities. The 10 leading health indicators or important secondary goals are shown in Box 1.6. Ongoing goals specific for each content area are highlighted in later chapters. National health goals are intended to help citizens more easily understand the importance of health promotion and disease prevention and to encourage wide participation in improving health in the next decade. It is important for maternal and child health nurses to be familiar with these goals because nurses play such a vital role in helping the nation achieve these objectives through both practice and research. The goals also serve as the basis for grant funding and financing of evidence-based practice.

Trends in the Maternal and Child Health Nursing Population

The maternal and child population is constantly changing because of changes in social structure, variations in family lifestyle, and changing patterns of illness. Table 1.2 summarizes some of the social changes that are altering health care priorities for maternal and child health nurses. Client advocacy, participating in cost-containment measures, focusing on health education, and creating new nursing roles are ways in which nurses have adapted to these changes. **Client advocacy** is safeguarding and advancing the interests of clients and their families. The role includes knowing the health care services available in a community, establishing a relationship with families, and helping them make informed choices about what course of action or service would be best for them. Some examples of English-Spanish communication that could be helpful are included at http://thePoint.lww.com.

Measuring Maternal and Child Health

Measuring maternal and child health is not as simple as defining a client as ill or well because individual clients and health care practitioners may have different perspectives on illness and wellness. For example, some children with chronic but controllable asthma think of themselves as well; others with the same degree of involvement consider themselves ill. Although pregnancy is generally considered a well state, some women think of themselves as ill during this period. A more objective view of health is provided by using national or regional health statistics.

A number of statistical terms are commonly used to express the outcomes of pregnancies and births and to describe maternal and child health (Box 1.7). Such statistics are useful for comparisons among states and for planning of future health care needs. Statistics require accurate recording, collection, and analysis, and nurses play a major role in the accurate collection and recording of these data that allow the nation's present and future health to be described.

Birth Rate

The birth rate in the United States has gradually decreased over the past 100 years from a high of 30.2 per 1000 population in 1909 to 13.9 per 1000 population at present (Eldridge & Sutton, 2009) (Fig. 1.2). Currently, the average family in the United States has 1.2 children. Boys are born more often than are girls, at a rate of 1050 boys to every 1000 girls (Eldridge & Sutton, 2009). Births to teenaged mothers are steadily declining (presently at 40.4 per 1000 from a high of 61.8 per 1000 in 1961). Births to women older than 40 years are steadily increasing (presently at 9.4 per 1000 from a low of almost no births in this age group).

Fertility Rate

The term **fertility rate** reflects what proportion of women who could have babies are having them. Fertility rates may be low in countries troubled by famine, war, or disease. The fertility rate in the United States is currently 66.7%, a rate that reflects a healthy postindustrial country (Eldridge & Sutton, 2009).

Fetal Death Rate

Fetal death is defined as the death in utero of a child (fetus) weighing 500 g or more, roughly the weight of a fetus of 20 weeks' or more pregnancy. Fetal deaths may occur because of maternal factors such as maternal disease, premature cervical dilation, or maternal malnutrition or fetal factors such as fetal disease, chromosome abnormality, or poor placental attachment. Many fetal deaths occur for reasons that are unknown. The fetal death rate is important in evaluating the health of a nation because it reflects the overall quality of maternal health and prenatal care. The emphasis on both preconceptual and prenatal care has helped to reduce this rate from a number as high as 18% in 1950 to 6.2% at present (Eldridge & Sutton, 2009).

Neonatal Death Rate

The first 28 days of life are known as the *neonatal period*, and an infant during this time is known as a **neonate.** The neonatal death rate reflects not only the quality of care available to women during pregnancy and childbirth but also the quality of care available to infants during the first month of life.

BOX 1.6 * Focus on National Health Goals

Leading Health Indicators

Physical Activity
Regular physical activity throughout life is important for maintaining a healthy body, enhancing psychological well-being, and preventing premature death. The objectives selected to measure progress in this area are:

- Increase the proportion of adolescents who engage in vigorous physical activity that promotes cardiorespiratory fitness 3 or more days per week for 20 or more minutes per occasion.
- Increase the proportion of adults who engage regularly, preferably daily, in moderate physical activity for at least 30 minutes per day.

Overweight and Obesity
Overweight and obesity are major contributors to many preventable causes of death. The objectives selected to measure progress in this area are:

- Reduce the proportion of children and adolescents who are overweight or obese.
- Reduce the proportion of adults who are obese.

Tobacco Use
Cigarette smoking is the single most preventable cause of disease and death in the United States. Smoking results in more deaths each year in the United States than AIDS, alcohol, cocaine, heroin, homicide, suicide, motor vehicle crashes, and fires—combined. The objectives selected to measure progress in this area are:

- Reduce cigarette smoking by adolescents.
- Reduce cigarette smoking by adults.

Substance Abuse
Alcohol and illicit drug use are associated with many of this country's most serious problems, including violence, injury, and HIV infection. The objectives selected to measure progress in this area are:

- Increase the proportion of adolescents not using alcohol or any illicit drugs during the past 30 days.
- Reduce the proportion of adults using any illicit drug during the past 30 days.
- Reduce the proportion of adults or adolescents engaging in binge drinking of alcoholic beverages during the past month.

Responsible Sexual Behavior
Unintended pregnancies and sexually transmitted infections (STIs), including infection with the human immunodeficiency virus that causes AIDS, can result from unprotected sexual behavior. The objectives selected to measure progress in this area are:

- Increase the proportion of adolescents who abstain from sexual intercourse or use condoms if currently sexually active.
- Increase the proportion of sexually active adults who use condoms.

Mental Health
Approximately 20% of the U.S. population is affected by mental illness during a given year; no one is immune. Of all mental illnesses, depression is the most common disorder. More than 19 million adults in the United States suffer from depression. Major depression is the leading cause of disability and is the cause of more than two thirds of suicides each year. The objective selected to measure progress in this area is to:

- Increase the proportion of adults including postpartum depression who receive treatment.

Injury and Violence
More than 400 Americans die each day from injuries, due primarily to motor vehicle crashes, firearms, poisonings, suffocation, falls, fires, and drowning. The risk of injury is so great that most persons sustain a significant injury at some time during their lives. The objectives selected to measure progress in this area are:

- Reduce deaths caused by motor vehicle crashes.
- Reduce homicides.

Environmental Quality
An estimated 25% of preventable illnesses worldwide can be attributed to poor environmental quality. In the United States, air pollution alone is estimated to be associated with 50,000 premature deaths and an estimated $40 billion to $50 billion in health-related costs annually. The objectives selected to measure progress in this area are:

- Reduce the proportion of persons exposed to air that does not meet the U.S. Environmental Protection Agency's health-based standards for ozone.
- Reduce the proportion of nonsmokers exposed to environmental tobacco smoke.

Immunization
Vaccines are among the greatest public health achievements of the 20th century. Immunizations can prevent disability and death from infectious diseases for individuals and can help control the spread of infections within communities. The objectives selected to measure progress in this area are:

- Increase the proportion of young children who receive all vaccines that have been recommended for universal administration.
- Increase the proportion of noninstitutionalized adults who are vaccinated annually against influenza and ever vaccinated against pneumococcal disease.

Access to Health Care
Strong predictors of access to quality health care include having health insurance, a higher income level, and a regular primary care provider or other source of ongoing health care. Use of clinical preventive services, such as early prenatal care, can serve as indicators of access to quality health care services. The objectives selected to measure progress in this area are:

- Increase the proportion of persons with health insurance.
- Increase the proportion of persons who have a specific source of ongoing care.
- Increase the proportion of pregnant women who begin prenatal care in the first trimester of pregnancy.

From http://www.nih.gov.

TABLE 1.2 ✻ Trends in Maternal and Child Health Care and Implications for Nurses

Trend	Implications for Nursing
Families are not as extended so are smaller than previously.	Fewer family members are present as support people in a time of crisis. Nurses are called on to fulfill this role more than ever before.
Single parents have become the most common type of parent in the United States.	A single parent may have fewer financial resources than dual employed parents; this is more likely if the parent is a woman. Nurses can help by informing parents of care options and providing a backup opinion when needed.
Ninety percent of women work outside the home at least part-time.	Health care must be scheduled at times a working parent can come for care for herself or bring a child for care. Problems of latch-key (self-care) children and the selection of child care centers need to be addressed.
Families are more mobile than previously; there is an increase in the number of homeless women and children.	Good interviewing and health monitoring are necessary with mobile families so a health database can be established and there can be continuity of care.
Both child and intimate partner abuse is increasing in incidence.	Screening for child or intimate partner abuse should be included in all family contacts. Nurses must be aware of the legal responsibilities for reporting abuse.
Families are more health conscious than ever before.	Families are ripe for health education; providing this can be a major nursing role.
Health care must respect cost containment.	Comprehensive care is necessary in primary care settings because referral to specialists may no longer be an option. Health insurance is not available for all families.

The leading causes of infant mortality during the first 4 weeks of life are prematurity (early gestational age or low birth weight of less than 2500 g ([17%]) and congenital malformations (20%). Approximately 80% of infants who die within 48 hours after birth weigh less than 2500 g (5.5 lb). The proportion of infants born with low birth weight is about 12.5% of all births. This number rises slightly each year due to the increase in multiple births and better prenatal care that allows infants who would have died in utero (fetal death) to be born and survive (Hamilton et al., 2007).

Perinatal Death Rate

The perinatal period is the time period beginning when a fetus reaches 500 g (about week 20 of pregnancy) and ending about 4 to 6 weeks after birth. The perinatal death rate is the sum of the fetal and neonatal rates.

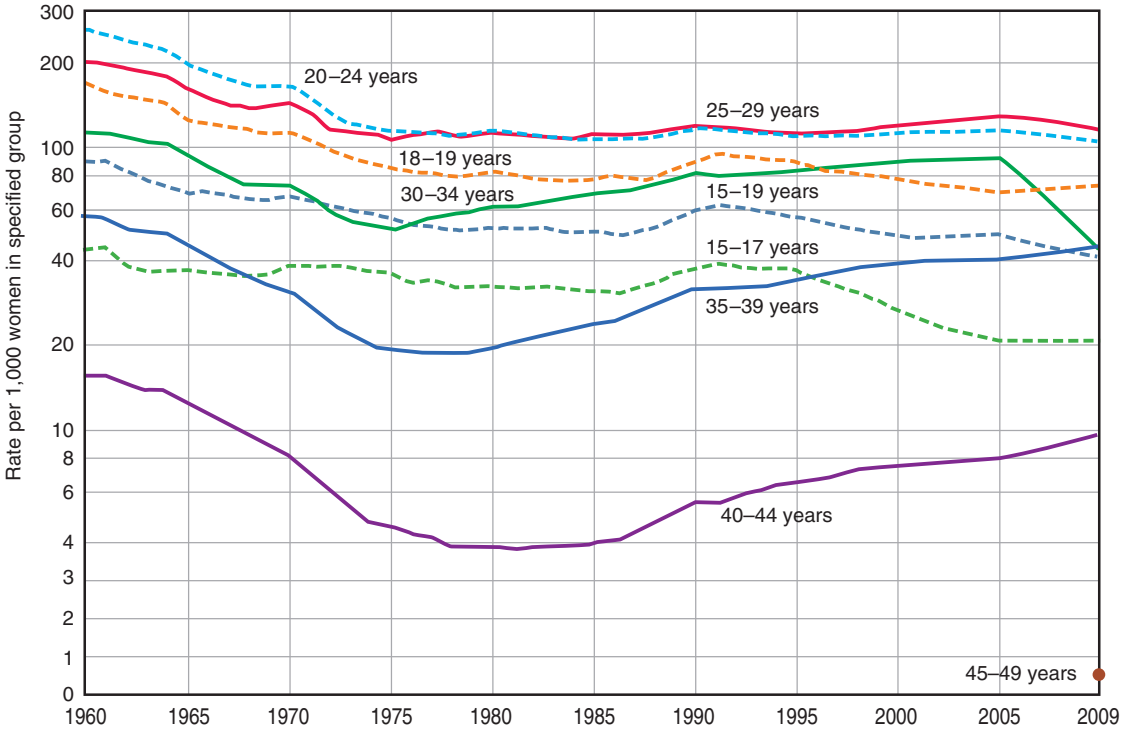
Infant Mortality Rate

The infant mortality rate of a country is an index of its general health because it measures the quality of pregnancy care, nutrition, and sanitation as well as infant health. This rate is the traditional standard used to compare the health care of a nation with that of previous years or of other countries.

Because of health care advances and improvements in child care, the infant mortality rate in the United States has been steadily declining in recent years to reach a record low of 6.6 per 1000 population (Eldridge & Sutton, 2009) (Fig. 1.3). Unfortunately, infant mortality is not equal for all people. The mortality rate for African American infants, for example, is almost 15%. This difference in infant deaths is thought to be related to the higher proportion of births to young African American mothers, unequal provision of health care, and the higher percentage of low-birth-weight babies born to African American women: 12%, compared with approximately 5% for white and Asian women (Eldridge & Sutton, 2009). Because teenage pregnancy leads to increased premature births, this can result in infants being born who are not as well prepared as others to face extrauterine life (Hamilton et al., 2007).

BOX 1.7 ✻ Statistical Terms Used to Report Maternal and Child Health

Birth rate: Number of births per 1000 population.
Fertility rate: Number of pregnancies per 1000 women of childbearing age.
Fetal death rate: Number of fetal deaths (weighing more 500 g) per 1000 live births.
Neonatal death rate: Number of deaths per 1000 live births occurring at birth or in the first 28 days of life.
Perinatal death rate: Number of deaths of fetuses weighing more than 500 g and within the first 28 days of life per 1000 live births.
Maternal mortality rate: Number of maternal deaths per 100,000 live births that occur as a direct result of the reproductive process.
Infant mortality rate: Number of deaths per 1000 live births occurring at birth or in the first 12 months of life.
Childhood mortality rate: Number of deaths per 1000 population in children, 1 to 14 years of age.



NOTE: Rates are plotted on a log scale.

FIGURE 1.2 Birth rates by age of mother: United States, 1960–2009. (From National Center for Health Statistics. [2009]. Births, marriages, divorces and deaths. *National Vital Statistics Report, 57*[1], 6.)

The infant mortality rate also varies greatly from state to state within the United States (Table 1.3). For example, in the District of Columbia, the area with the highest infant mortality, the rate is almost three times higher than that of Massachusetts, the state with the lowest rate.

Table 1.4 shows the ranking of the United States compared with other countries. One would expect that a country such as the United States, which has one of the highest gross national products in the world and is known for its technological capabilities, would have the lowest infant mortality rate. The U.S. infant mortality rate is higher, however, than that of 32 other countries (United Nations Statistics Division, 2007).

Two factors that may contribute to national differences in infant mortality are the number of infants born to adolescent mothers (38% of U.S. infants are born to women under 20 years of age) and the type of health insurance and care available. In Sweden, for example, a comprehensive health care program provides free maternal and child health care to all residents. Women who attend prenatal clinics early in pregnancy receive a monetary award, a practice that almost guarantees that women come for prenatal care. This

policy varies sharply with the availability of health care in an occupation-linked insurance system such as the U.S.

Fortunately, the proportion of pregnant women who receive prenatal care in the United States is increasing (about 83% now begin care in the first trimester). Early prenatal care is important, because it identifies potential risks and allows preventive strategies to help reduce complications of pregnancy.

The main causes of infant death in the United States are problems that occur at birth or shortly thereafter. Before antibiotics and formula sterilization practices became available, gastrointestinal disease was a leading cause of infant death. By advocating breastfeeding and teaching mothers strict adherence to good sanitary practices, health care practitioners help ensure that gastrointestinal infection does not again become a major factor in infant mortality.

Today, prematurity, low birth weight, congenital malformations, and sudden infant death syndrome (SIDS) are all major causes of mortality. SIDS is the sudden death of an infant less than 1 year of age that cannot be explained after a thorough investigation of the cause of death is conducted (Sahni, Fifer, & Myers, 2007). Although other factors that contribute to SIDS are yet to be determined, the recommendation to place infants on their back or side and to allow infants to sleep with a pacifier, made by the American Academy of Pediatrics, has led to an almost 50% decrease in its incidence (Centers for Disease Control and Prevention [CDC], 2007a). Nurses have been instrumental in reducing the number of these deaths as they are the health professionals who most often discuss newborn care with new parents (Esposito, Hegyi, & Ostfeld, 2007).

Maternal Mortality Rate

The maternal mortality rate is the number of maternal deaths that occur as a direct result of the reproductive process per 100,000 live births. Early in the 20th century, this rate in the United States reached levels as high as 600 per 100,000 live births. It is still high in developing countries such as Afghanistan (over 3500 per 100,000 births) (Eldridge & Sutton, 2009). In the United States at present, the maternal mortality rate has declined to a low of 6.5 per 100,000 live births (Fig. 1.4). This dramatic decrease can be attributed to improved preconceptual, prenatal, labor and birth, and postpartum care such as

- Increased participation of women in prenatal care
- Greater detection of disorders such as ectopic pregnancy or placenta previa and prevention of related complications through the use of ultrasound
- Increased control of complications associated with hypertension of pregnancy
- Decreased use of anesthesia with childbirth

For most of the 20th century, uterine hemorrhage and infection were the leading causes of death during pregnancy and childbirth. This has changed because of the increased ability to prevent or control hemorrhage and infection; now hypertensive disorders have become the leading causes of death in childbirth. Pregnancy-induced hypertension adds to preexisting hypertensive disorders, especially in older women. Nurses who are alert to the signs and symptoms of hypertension are invaluable guardians of the health of pregnant and postpartum women.

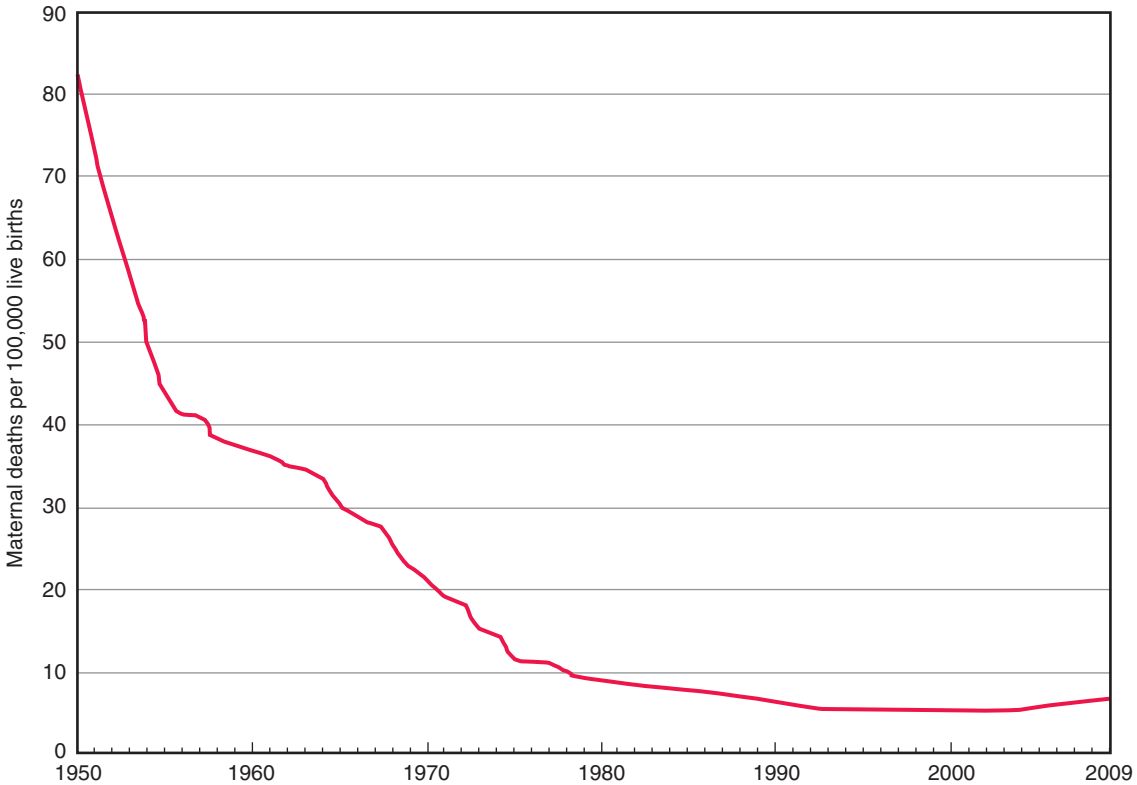

FIGURE 1.4 Maternal mortality rates. (From National Center for Health Statistics. [2009]. Births, marriages, divorces and deaths. *National Vital Statistics Report, 57*[1], 3.)

✔ Checkpoint Question 1.2

Nursing is changing because social change affects care. Which of the following is a trend that is occurring in nursing because of social change?

a. Children are treated in emergent care clinics, so nurses are hardly needed.
b. Immunizations are now available for all childhood infectious diseases.
c. The use of skilled technology has made nursing care more complex.
d. Pregnant women are so healthy today that they rarely need prenatal care.

Childhood Mortality Rate

Like the infant mortality rate, the childhood mortality rate in the United States is also declining. In 1980, for example, the mortality rate was about 6.4% for children aged 1 to 4 years and 3.1% for children aged 4 to 14 years; today, it is 2.9% and 1.4%, respectively (National Vital Statistics Service, 2009a). The risk of death in the first year of life is higher than that in any other year before age 55. Children in the prepubescent period (aged 5–14 years) have the lowest mortality rate of any child age group (Hamilton et al., 2007).

The most frequent causes of childhood death are shown in Box 1.8. Motor vehicle crashes remain the leading cause of death in children, although many of these accidents are largely preventable through education about the value of car seats and seat belt use, the dangers of drinking/drug abuse and driving, and the importance of pedestrian safety.

A particularly disturbing mortality statistic is the high incidence of homicide and suicide in the 10- to 19-year-old age group (more girls than boys attempt suicide, but boys are more often successful). Although school-aged children and adolescents may not voice feelings of depression or anger during a health care visit, such underlying feelings may actually be a primary concern (Hempstead, 2007). Nurses who are alert to cues of depression or anger can be instrumental in detecting these emotions and lowering the risk of suicide.

BOX 1.8 ✻ Major Causes of Death in Childhood

Under 1 Year
1. Congenital malformations and chromosomal abnormalities
2. Disorders related to short gestation age and low birth weight
3. Sudden infant death syndrome
4. Newborn affected by maternal complications of pregnancy
5. Unintentional injuries (accidents)

1–4 Years
1. Unintentional injuries (accidents)
2. Congenital malformations and chromosomal abnormalities
3. Malignant neoplasms
4. Assault or homicide
5. Diseases of the heart

5–14 Years
1. Unintentional injuries (accidents)
2. Malignant neoplasms
3. Assault or homicide
4. Intentional self-harm (suicide)
5. Congenital malformations and chromosomal abnormalities

15–24 Years
1. Unintentional injuries (accidents)
2. Assault or homicide
3. Intentional self-harm (suicide)
4. Malignant neoplasms
5. Diseases of the heart

National Center for Health Statistics. (2009a). *Trends in the health of Americans*. Hyattsville, MD: Author.

Childhood Morbidity Rate

Health problems commonly occurring in large proportions of children today include respiratory disorders (including asthma and tuberculosis), gastrointestinal disturbances, and consequences of injuries. Obesity has become such a health problem in some communities that more 20% of school-aged children are obese (National Vital Statistics Service, 2009b). Obesity in school-aged children can lead to cardiovascular disorders, self-esteem issues, and type 2 diabetes (Hussain et al., 2007). Nurses can be instrumental in teaching better nutrition and encouraging increased exercise to help decrease this incidence (Summerbell et al., 2009).

As more immunizations become available, fewer children in the United States are affected by common childhood communicable diseases. For instance, the incidence of poliomyelitis (once a major killer of children) is now zero because almost all children in the United States are immunized against it (National Vital Statistics Service, 2009a). Measles flared in incidence in the early 1990s but now is scheduled as a disease to be completely eradicated by 2010. It is important that this change happen, because measles encephalitis can be lethal. Continued education about the benefits of immunization against rubella (German measles) is also needed, because if a woman contracts this form of measles during pregnancy, her infant can be born with severe congenital malformations. The new vaccine against human papillomavirus (HPV) suggested for prepubertal girls should help prevent HPV infections that can have the same disastrous results (American Academy of Pediatrics, 2009).

Although the decline in the overall incidence of preventable childhood diseases is encouraging, as many as 25% of children younger than 4 years in some communities are still not fully immunized (CDC, 2009). There is a potential for the incidence of childhood infectious diseases to increase again if immunization is not maintained as a high national priority.

The advent of human immunodeficiency virus (HIV) infection has changed care considerations in all areas of nursing, but it has particular implications for maternal and child health nursing. Sexually active teenagers are at risk for becoming infected with HIV through sexual contact or

exposure to blood and blood products (Purswani et al., 2007). Infected women may transmit the virus to a fetus during pregnancy through placental exchange (Paintsil & Andiman, 2007).

Nurses play a vital role in helping prevent the spread of HIV by educating adolescents and young adults about safer sexual practices (see Chapter 5). Follow standard infection precautions in maternal and child health nursing, as in other areas of nursing practice, to safeguard yourself, other health care providers, and clients from the spread of infection.

Other infectious diseases that are increasing in incidence include syphilis; genital herpes; hepatitis A, B, and C viruses; and tuberculosis. The rise of syphilis, hepatitis C virus, and genital herpes probably stems from an increase in nonmonogamous sexual relationships and lack of safer sex practices. The increase in hepatitis B virus infection is due largely to drug abuse and the use of infected injection equipment. One reason for the increase in hepatitis A virus is shared diaper-changing facilities in day care centers. Tuberculosis, once considered close to eradication, has experienced a resurgence, occurring today at approximately the same rate as measles in young adults. One form occurs as an opportunistic disease in HIV-positive persons and is particularly resistant to the usual therapy (Fraser et al., 2009).

Trends in Health Care Environment

The settings and philosophy of maternal and child health care are both changing to better meet the needs of increasingly well-informed and vocal consumers.

Initiating Cost Containment

Cost containment refers to systems of health care delivery that focus on reducing the cost of health care by closely monitoring the cost of personnel, use and brands of supplies, length of hospital stays, number of procedures carried out, and number of referrals requested while maintaining quality care (Callens, Volbragt, & Nys, 2007).

The advent of managed care has direct implications for maternal and child health nursing because lack of financial ability to pay is a major reason why women do not obtain prenatal care or children do not receive well-child care. A woman may fear that not working during pregnancy may lead to loss of insurance coverage, thereby reducing her ability to pay for services. As a result, she may continue to work long hours or in unfit conditions during pregnancy. Nurses are challenged to help reduce costs while maintaining quality care so that prenatal care remains available.

Before the philosophy of cost containment became prominent, health care insurance companies paid separately for each procedure or piece of equipment a client received. Under managed care, the agency receives a certain sum of money for a client's care, no matter how many supplies, procedures, or personnel are used in the client's care. In a managed care environment, helping to curtail cost yet provide quality care is an important nursing function. Suggestions such as using generic-brand supplies, never breaking into kits of supplies to remove a single item, and urging the use of disposable supplies so that less personnel time will be spent on cleaning and sterilizing items are welcome, cost-effective suggestions.

Cost containment has had dramatic effects on health care, most noticeably in limiting the number of hospital days, decreasing the number of uncompensated patients accepted by agencies, and changing the roles of personnel (McKay & Meng, 2007). Before managed care, for example, women stayed in a hospital for 3 or 4 days after childbirth; today, they rarely stay longer than 48 hours. Before managed care, nurses completed all care procedures for patients, no matter how small or unskilled the task. With managed care, ancillary personnel (e.g., unlicensed assistive personnel) perform many tasks under the supervision of the nurse. This system is designed to move the registered nurse (RN) to a higher level of function, because it makes the RN accountable for a fuller range of services to patients. It accentuates point-of-service care. It also increases the accountability and responsibility of RNs to delegate tasks appropriately. As a result of managed care, the new advanced-practice role of case manager was created.

It is important to know the legal aspects of delegation, as identified in individual state nursing practice acts, because some laws address specific tasks and activities that RNs may or may not delegate in that state. Accountability for completion and quality of the task remains with the nurse, so the nurse is responsible for knowing that the condition of the patient and the skill level of the assistive person are conducive to safe delegation. Four rules to follow when delegating are to

- Delegate the right task for the situation
- Delegate to the right person to complete the task
- Use right communication concerning what is to be done
- Ask for right feedback or evaluation that the task was completed

Examples of delegation responsibility that can occur in maternal and child health are highlighted in the multidisciplinary care maps located throughout this text.

Increasing Alternative Settings and Styles for Health Care

During the past 100 years, there have been several major shifts in settings for maternity care. At the turn of the 19th century, most births took place in the home, with only the very poor or ill giving birth in "lying-in" hospitals. By 1940, about 40% of live births occurred in hospitals; today, the figure has risen to 99%. At least 10% of these births are attended by certified nurse-midwives, not physicians (National Vital Statistics Service, 2009a). Today, a less dramatic but no less important trend that is occurring is an increase in the number of families once more choosing childbirth at home or in alternative birth settings rather than hospitals. These alternative settings provide families with increased control of the birth experience and options for birth surroundings that are unavailable in hospitals. One strength of this movement is its encouragement of family involvement in birth. It also increases nursing responsibility for assessment and professional judgment and provides expanded roles for *advanced practice nurses* such as the nurse-midwife and the nurse practitioner (nurses educated at the master's or doctoral level) (Declercq, 2007).

Hospitals have responded to consumers' demand for a more natural childbirth environment by refitting labor and delivery suites as birthing rooms, often called labor-delivery-recovery (LDR) or labor-delivery-recovery-postpartum (LDRP) rooms. Partners, family members, and other support people are invited to stay with the woman in labor so they feel a part of the

FIGURE 1.5 A couple, soon to be parents, share a close moment in a birthing room.

childbirth. The room is designed as a homelike environment (Fig. 1.5). Couplet care—care for both the mother and newborn by the primary nurse—is encouraged after the births. LDRP rooms promote a holistic, family-centered approach to maternal and child health care and are appealing to many families who might otherwise have opted against a hospital birth. Hospitals are continuing to search for the best labor, birth, and postpartum options. Whether childbirth takes place at home, in a birthing center, or in a hospital, the goal is to keep it as natural as possible while ensuring the protection that experienced health care providers can provide.

Health care settings for children are also changing. Clients' homes, community centers, school-based or retail setting emergent care clinics, and group homes are examples of settings in which comprehensive health care may be administered. In these settings, a nurse may provide immunizations, screenings, health and safety education, counseling, crisis intervention for teens, parenting classes, and care of ill children and families. This form of community-based care can provide cost-effective health promotion, disease prevention, and patient care to a large number of children and families in an environment that is familiar to them.

More and more children and women who are experiencing a pregnancy complication, who might otherwise have been admitted to a hospital, are now being cared for in ambulatory clinics or at home. Separating a child from his or her family during a long hospitalization has been shown to be potentially harmful to the child's development, so any effort to reduce the incidence of separation has a positive effect (see Chapter 36). Avoiding long hospital stays for women during pregnancy is also a preferable method of care, because it helps to maintain family contact.

Ambulatory or non–hospital-based care requires intensive health teaching by the nursing staff and follow-up by home care or community health nurses. Teaching parents of an ill child or a woman with a complication of pregnancy what danger signs to watch for that will warrant immediate attention includes not only imparting the facts of self-care but also providing support and reassurance that the client or parents are capable of this level of care. Retail clinics or emergent care clinics located in shopping malls are often staffed by nurse practitioners, so nurses play a vital role in seeing that such health care settings do not limit continuity of care (Berman, 2007).

What if... Melissa Chung has to remain in the hospital after the birth of her new baby while her baby is transported to a regional center for care? How could you help her keep in touch with her new baby?

Including the Family in Health Care

Health promotion with families during pregnancy or childrearing is a family-centered event, because teaching health awareness and good health habits is accomplished chiefly by role modeling. When children must be admitted to the hospital for extended stays, open visiting hours allow parents to visit as much as possible and sleep overnight in a bed next to their child. Encourage parents in such a setting to do as much for their child as they wish, such as feeding and bathing their child or administering oral medicine. Most of a parent's time, however, should be spent simply being close by to provide a comfortable, secure influence on their child. For the same reasons, the most important role of parents on a maternity unit is to room-in and give total care to their newborn (Box 1.9).

Family-centered nursing this way increases the number of clients a nurse cares for—that is, not four children, for ex-

BOX 1.9 * Focus on Family Teaching

Tips for Selecting a Health Care Setting

Q. Melissa Chung, the patient you met at the beginning of the chapter, asks you, "With so many health care settings available, how do we know which one to choose?"

A. When selecting a health care setting, asking the following questions can help you decide what is best for your family:

- Can it be reached easily? (Going for preventive care when well or for continuing care when ill should not be a chore.)
- Will the staff provide continuity of care so you will always see the same primary care provider if possible?
- Does the physical setup of the facility provide for a sense of privacy, yet a sense that health care providers share pertinent information so you do not have to repeat your history at each visit?
- Are the cost of care and the number of referrals to specialists explained clearly?
- Are preventive care and health education stressed (keeping well is as important as recovering from illness)?
- Is health education done at your learning level?
- Do health care providers respect your opinion and ask for your input on health care decisions?
- Do health care providers show a personal interest in you?
- Will the facility still be accessible if a family member becomes disabled?

ample, but four children plus four sets of parents; not just a single newborn, but his or her two parents as well. Caring for families rather than individuals, however, has an immeasurable effect on the health of children and parents and client satisfaction (Mullen et al., 2007).

Illness in a child is automatically a family-centered event. Parents may need to adjust work schedules to allow one of them to stay with the ill child; siblings may have to sacrifice an activity such as a birthday party or having a parent watch their school play; and family finances may have to be readjusted to pay for hospital and medical bills. When a mother is pregnant, family roles or activities may have to change to safeguard her health. A family may feel drawn together by the fright and concern of an acute illness. On the other hand, if an illness becomes chronic, it may pull a family apart or destroy it.

By adopting a view of pregnancy, childbirth, or illness as a family event, nurses can be instrumental in including family members in events from which family members were once totally excluded, such as an unplanned cesarean birth. They can help child health care to be family centered by consulting with family members about a plan of care and providing clear health teaching so that family members can monitor their own care (Fig. 1.6).

The U.S. government recognizes that the care of individual family members should be viewed as a family-centered event. The Family and Medical Leave Act of 1993 is a federal law that requires employers with 50 or more employees to provide a minimum of 12 weeks of unpaid, job-protected leave to employees under four circumstances crucial to family life:

- Birth of the employee's child
- Adoption or foster placement of a child with the employee
- Need for the employee to care for a parent, spouse, or child with a serious health condition
- Inability of the employee to perform his or her functions because of a serious health condition

A *serious health condition* is defined as "an illness, injury, impairment, or physical or mental condition involving such circumstances as inpatient care or incapacity requiring 3 workdays' absence" (U.S. Department of Labor, 1995). Specifically mentioned in the law is any period of incapacity due to pregnancy or for prenatal care with or without treatment. Illness must be documented by a health care provider. Nurse practitioners and nurse-midwives are specifically listed as those who can document a health condition. Although not as generous a program as that of many other developed countries, unpaid leave helps appreciably with the care of an ill child or a woman who is ill during pregnancy.

Increasing the Number of Intensive Care Units

Over the past 20 years, care of infants and children has become extremely technical. It is generally assumed that newborns with a term birth weight (more than 2500 g or 5.5 lb) will thrive at birth. However, many infants are born each year with birth weights lower than 2500 g or who are ill at birth and do not thrive. Such infants are regularly transferred to a neonatal intensive care unit (NICU) or intensive care nursery (ICN). Children who are undergoing cardiac surgery or recovering from near-drownings or multi-injury accidents are cared for in a pediatric intensive care unit (PICU). Intensive care at this early point in life is one of the most costly types of hospitalization. Expenses of $1000 to $2000 a day, or $20,000 to $100,000 for a total hospital stay, are not unusual for care during a high-risk pregnancy or care for a high-risk infant. As the number of these settings increases, the opportunities for advanced-practice nurses also increase (Riendeau, 2007).

Regionalizing Intensive Care

To avoid duplication of care sites, communities establish centralized maternal or pediatric health services. Such planning creates one site that is properly staffed and equipped for potential problems rather than a number of less well-equipped sites. When a newborn, older child, or parent is hospitalized in a regional center, the family members who have been left behind need a great deal of support. They may feel they have "lost" their infant, child, or parent unless health care personnel keep them abreast of the ill family member's progress by means of telephone calls or snapshots and encourage the family to visit as soon as possible.

When regionalization concepts of newborn care were first introduced, transporting the ill or premature newborn to the regional care facility was the method of choice (Fig. 1.7). Today, if it is known in advance that a child may be born with a life-threatening condition, it may be safer to transport the mother to the regional center during pregnancy, because the uterus has advantages as a transport incubator that far exceed those of any commercial incubator yet designed.

An important argument against regionalization for pediatric care is that children will feel homesick in strange settings, overwhelmed by the number of sick children they see, and frightened because they are miles from home. An important argument against regionalization of maternal care is that being away from her community and support network places a great deal of stress on the pregnant woman and her family and limits her own physician's participation in her care. These are important considerations. Because nurses more than any other health care group set the tone for hospitals, they are responsible for ensuring that clients and families feel as welcome in a regional center as they would have been in a small hospital. Staffing should be adequate to allow sufficient

FIGURE 1.7 A nurse prepares an infant transport incubator to move a premature infant to a regional hospital. Helping with safe movement of pregnant women and ill newborns to regional centers is an important nursing responsibility. (© Caroline Brown, RNC, MS, DEd.)

time for nurses to comfort frightened children and prepare them for new experiences or to support the pregnant woman and her family. Documenting the importance of such actions allows them to be incorporated in critical pathways and preserves the importance of the nurse's role.

Increasing Comprehensive and Collaborative Care Settings

Comprehensive or collaborative health care is designed to meet all of a child's or woman's needs in one setting. In the past, a woman with a complication of pregnancy found herself visiting both an internist and an obstetrician for care. A child born with an illness such as myelomeningocele or cerebral palsy might have been followed by a corps of specialists such as a neurologist, a physical therapist, an occupational therapist, a psychologist for intelligence quotient testing, a speech therapist, an orthopedic surgeon, and, finally, a special education teacher. The parents might have needed to find a special dentist who accepts clients with multiple disabilities. Unfortunately, each specialist would look at only one area of the child's needs rather than the whole child's development. Without extra guidance, parents could find themselves lost in a maze of visits to different health care personnel. If they were not receiving financial support for their child's care, they may not have been able to afford all the necessary services at one time and had to make decisions as to which of their child's problems needed to be treated immediately and which could be left untreated without worsening and developing into a permanent disability. Although specialists are still important to care, a trusted primary care provider to help a family coordinate these specialized services is essential in today's managed care environment. In many settings, this primary care provider, who follows the woman or child through all phases of care, is an advanced-practice nurse such as a family nurse practitioner, pediatric nurse practitioner, or women's health nurse practitioner working in collaboration with a physician. Nurses can be helpful in seeing that both women and children become empowered to seek out a family-centered setting that will be best for their health.

Increasing Use of Alternative Treatment Modalities

There is a growing tendency for families to use alternative forms of therapy, such as acupuncture or therapeutic touch, in addition to, or instead of, traditional health care. Nurses have an increasing obligation to be aware of complementary or alternative therapies as these have the potential to either enhance or detract from the effectiveness of traditional therapy (Smith et al., 2007).

Health care providers who are unaware of the existence of some alternative forms of therapy may lose an important opportunity to capitalize on the positive features of that particular therapy. For instance, it would be important to know that an adolescent who is about to undergo a painful procedure is experienced at meditation, because asking the adolescent if she wants to meditate before the procedure could help her relax. Not only could this decrease the child's discomfort, but it could also offer her a feeling of control over a difficult situation. People are using an increasing number of herbal remedies, so asking about these at health assessment is important to prevent drug interactions. Ginger, for example, is frequently taken during pregnancy to relieve morning sickness (White, 2007).

Increasing Reliance on Home Care

Shortened hospital stays have resulted in the return home of many women and children before they are optimally ready to care for themselves. Ill children and women with complications of pregnancy may choose to remain at home for care rather than be hospitalized. This has created a "second system" of care requiring many additional care providers (Shepperd et al., 2009). Nurses are instrumental in assessing women and children on hospital discharge to help plan the best type of continuing care, devise and modify procedures for home care, and sustain clients' morale. Because home care is a unique and expanding area in maternal and child health nursing, it is discussed in Chapter 4.

Increasing Use of Technology

The use of technology is increasing in all health care settings. The field of assisted reproduction technology such as in vitro fertilization with the possibility of stem cell research is forging new pathways (Garrett & Yoder, 2007). Charting by computer, seeking information on the Internet, and monitoring fetal heart rates by Doppler ultrasound are other examples. In addition to learning these technologies, maternal and child health nurses must be able to explain their use and their advantages to clients. Otherwise, clients may find new technologies more frightening than helpful to them.

Freebirthing

Freebirthing refers to women giving birth without any health care provider supervision (Cooper & Clarke, 2008). Women may also refer to it as unassisted birth or couples birth. Using

this technique, a woman may learn pregnancy care from sources including the Internet and then arrange to have her child at home in complete privacy or may invite family or friends to share the experience with her. Women choose an unassisted birth for a number of reasons:

- A belief that birth is a normal function of the female body and so does not require medical interventions and that some medical interventions have the potential to cause more harm than good.
- A belief that women are able to sense the natural flow of birth and so can recognize the optimal position or technique for birth if they are allowed to do this in an undisturbed birth setting.
- A belief that birth is a potentially orgasmic experience that will be experienced best with privacy.
- A belief that unassisted birth will increase the ability to bond with and take responsibility for her child.
- Lack of health insurance that makes home birth without health care supervision an economic advantage.
- Lack of information about patient rights in modern maternity units.

Freebirthing is potentially dangerous because if a complication of birth should occur, the woman may not recognize that the complication is occurring until damage to her child or herself results. Even after she recognizes that a problem is occurring, there is a space of time before emergency help can arrive to assist her. Freebirthing is particularly dangerous if a woman avoids prenatal care as well or depends solely on Internet information. Educating women that not all Internet information is reliable and that supervised birth does not mean that they have no choice in their care, such as whether they want pain relief or to use a special position for birth, are effective ways to help women make safer choices about birth.

Health Care Concerns and Attitudes

Health care made great strides in the past century. As we progress through the 21st century, there are likely to be even more changes as the United States actively works toward effective health goals and improved health care for all citizens. These steps can create new concerns.

Increasing Emphasis on Preventive Care

A generally accepted theory is that it is better to keep individuals well than to restore health after they have become ill. Counseling parents on ways to keep their homes safe for children is an important form of this type of prevention. Research supporting the facts that accidents are still a major cause of death in children and that women still do not receive preconceptual or prenatal care are testaments to the need for much more anticipatory guidance in maternal and child health.

Increasing Concern for the Quality of Life

In the past, health care of women and children was focused on maintaining physical health. Today, a growing awareness that quality of life is as important as physical health has expanded the scope of health care to include the assessment of psychosocial facets of life in such areas as self-esteem and independence. Good interviewing skills are necessary to elicit this information at health care visits. Nurses not only can help obtain such information but also can plan ways to improve quality of life in the areas the client considers most important.

One way in which quality of life is being improved for children with chronic illness is the national mandate to allow them to attend regular schools, guaranteeing entrance despite pregnancy, severe illness, or use of medical equipment such as a ventilator (Public Law 99-452). Adolescents who are pregnant cannot be excluded from school. School nurses or nurses asked to be consultants to schools play important roles in making these changes possible.

Increasing Awareness of the Individuality of Clients

Maternal and child clients today do not fit easily into any set mold. Varying family structures, cultural backgrounds, socioeconomic levels, and individual circumstances lead to unique and diverse clients (Jarvis, 2007). Some women having children are younger than ever before, and an increasing number of women are experiencing their first pregnancies after the age of 35 (Hamilton et al., 2007). About 38% of babies born are born to women outside of marriage. Gay and lesbian couples are also beginning to raise families, conceiving children through artificial insemination or adoption. As a result of advances in research and therapy, women who were once unable to have children, such as those with cystic fibrosis, are now able to manage a full-term pregnancy. Individuals with cognitive and physical challenges who once would have been isolated from childbearing are now able to establish families and rear children.

Many families who have emigrated from other countries enter the U.S. health care system for the first time during a pregnancy or with a sick child. This requires sensitivity to sociocultural aspects of care on the part of health care providers as people not used to non–government-sponsored health care can be easily lost in the U.S. system. They may have different cultural beliefs about health and illness than a health care provider. As the level of violence in the world increases, more and more families are exposed to living in violent communities. All of these concerns require increased nursing attention.

Empowerment of Health Care Consumers

In part because of the influence of market-driven care and a strengthened focus on health promotion and disease prevention, individuals and families have recently begun to take increased responsibility for their own health. This begins with learning preventive measures to stay well. For most families, this means following a more nutritious diet and planning regular exercise; for some families, this means adopting an entire new lifestyle. When a family member is ill, empowerment means learning more about the illness, participating in the treatment plan, and preventing the illness from returning. Parents want to stay with their ill child in the hospital. They are eager for information about their child's health and want to contribute to the decision-making process. They may question treatments or care plans that they believe are not in their child's best interest. If health care providers do not provide answers to a client's questions or are insensitive to needs, many health care consumers are willing to take their business to another health care setting or rely totally on alternative therapies.

Nurses can promote empowerment of parents and children by respecting their views and concerns, regarding parents as important participants in their own or their child's health, and keeping them informed and helping them to

make decisions about care. Although a nurse may have seen 25 clients already in a particular day, he or she can make each client feel as important as the first by showing a warm manner and keen interest. Family Teaching displays are presented throughout this text to provide insight into ways in which nurses can help empower families.

What if... Melissa Chung demands that her 6-year-old, diagnosed with pneumonia, be hospitalized, even though it is your clinic's policy to have such children cared for at home by their parents? Would you advocate for hospitalization or not?

ADVANCED-PRACTICE ROLES FOR NURSES IN MATERNAL AND CHILD HEALTH

As trends in maternal and child health care change, so do the roles of maternal and child health nurses. In all settings, maternal and child health nurses function as caregivers, client advocates, researchers, case managers, and educators. Many nurses with a specified number of years of direct patient care, clinical expertise, and validated completion of pertinent continuing education programs are certified in a specialty. Those with advanced education function in advanced-practice roles.

Clinical Nurse Specialist

Clinical nurse specialists are nurses prepared at the master's or doctorate degree level who are capable of acting as consultants in their area of expertise, as well as serving as role models, researchers, and teachers of quality nursing care. Examples of areas of specialization are neonatal, maternal, child, and adolescent health care; genetics; childbirth education; and lactation consultation (McArthur & Flynn, 2008).

Consider the care necessary when a 4-year-old child with diabetes mellitus who has been admitted to the hospital becomes difficult to care for because he is both fearful of hospitalization and perplexed because his parents seem to be having such difficulty accepting his diagnosis. A clinical nurse specialist could be instrumental in helping a primary nurse organize care and in meeting with the parents to help them accept what is happening. Neonatal nurse specialists manage the care of infants at birth and in intensive care settings; they provide home follow-up care to ensure the newborn remains well. Childbirth educators teach families about normal birth and how to prepare for labor and birth. Lactation consultants educate women about breastfeeding and support them while they learn how to do this. **Genetic nurse counselors** consult with families about patterns of inheritance and offer support to families with a child who has inherited a genetic disorder.

Case Manager

A **case manager** is a graduate-level nurse who supervises a group of patients from the time they enter a health care setting until they are discharged from the setting or, in a seamless care system, into their homes as well, monitoring the effectiveness, cost, and satisfaction of their health care. They help prevent fragmentation of care and ensure that such important qualities as continuity of care and providing a feeling of "medical home" are included in care. Case management can be a vastly satisfying nursing role, because if the health care setting is "seamless," or one that follows people both during an illness and on their return to the community, it involves long-term contacts and lasting relationships and creates a high degree of satisfaction among clients (Hodnett, 2009).

Nurse Practitioner

Nurse practitioners are nurses educated at the master's or doctoral level. Recent advances in technology, research, and knowledge have amplified the need for longer and more in-depth education for nurse practitioners as they play pivotal roles in today's health care system. Doctor of nursing practice programs are designed to prepare nurse practitioners with the highest level of practice expertise integrated with the ability to translate scientific knowledge into complex clinical interventions. Preparing nurse practitioners at the doctor of nursing practice level has the potential to expand the scientific basis for practice as well as create leaders for organization and system management, quality improvement, health policy development, and interdisciplinary collaboration (Fain, Asselin, & McCurry, 2008).

Women's Health Nurse Practitioner

A women's health nurse practitioner has advanced study in the promotion of health and prevention of illness in women. Such a nurse plays a vital role in educating women about their bodies and sharing with them methods to prevent illness; in addition, they care for women with illnesses such as sexually transmitted infections, and offer information and counsel them about reproductive life planning. They play a large role in helping women remain well so that they can enter a pregnancy in good health and maintain their health throughout life.

Pediatric Nurse Practitioner

A pediatric nurse practitioner (PNP) is a nurse prepared with extensive skills in physical assessment, interviewing, and well-child counseling and care. In this role, a nurse interviews parents as part of an extensive health history and performs a physical assessment of the child (Fig. 1.8). If the

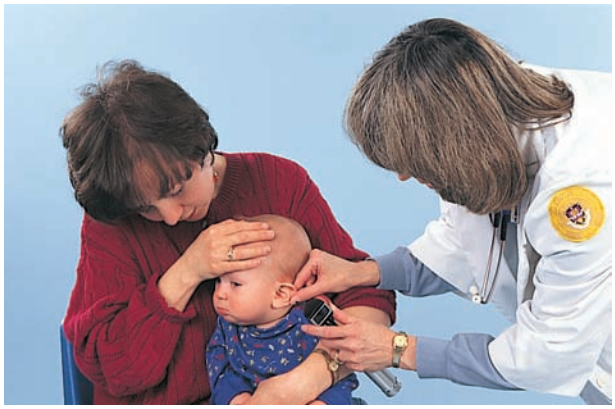

FIGURE 1.8 A pediatric nurse practitioner examines a 1-year-old child. (© Barbara Proud.)

nurse's diagnosis is that the child is well, he or she discusses with the parents any childrearing concerns mentioned in the interview, administers any immunizations needed, offers necessary anticipatory guidance (based on the plan of care), and arranges a return appointment for the next well-child checkup. The nurse has served as a primary health caregiver or as the sole health care person the parents and child see at that visit.

If the PNP determines that a child has a common illness (such as iron deficiency anemia), he or she orders the necessary laboratory tests and prescribes appropriate drugs for therapy. If the PNP determines that the child has a major illness (such as congenital subluxated hip, kidney disease, heart disease), he or she consults with an associated pediatrician; together, they decide what further care is necessary. Nurse practitioners may also work in inpatient or specialty settings such as genetics or cardiac care or emergency department settings providing continuity of care to children and adults (Percy & Sperhac, 2007). PNPs employed by schools provide care to all children in a given community or school setting.

Neonatal Nurse Practitioner

A neonatal nurse practitioner (NNP) is an advanced-practice role for nurses who are skilled in the care of newborns, both well and ill. NNPs may work in level 1, level 2, or level 3 newborn nurseries, neonatal follow-up clinics, or physician groups. The NNP's responsibilities include managing and caring for newborns in intensive care units, conducting normal newborn assessments and physical examinations, and providing high-risk follow-up discharge planning (Bowen, 2007). They also are responsible for transporting ill infants to these different care settings.

Family Nurse Practitioner

A family nurse practitioner (FNP) is an advanced-practice role that provides health care not only to women and children but also to the family as a whole. In conjunction with a physician, an FNP can provide prenatal care for a woman with an uncomplicated pregnancy. The FNP takes the health and pregnancy history, performs physical and obstetric examinations, orders appropriate diagnostic and laboratory tests, and plans continued care throughout the pregnancy and for the family afterward. FNPs then monitor the family indefinitely to promote health and optimal family functioning during health and illness.

Certified Nurse-Midwife

A **certified nurse-midwife** (CNM) is an individual educated in the two disciplines of nursing and midwifery and licensed according to the requirements of the American College of Nurse-Midwives (ACNM) who plays an important role in assisting women with pregnancy and childbearing. Either independently or in association with a physician, the nurse-midwife assumes full responsibility for the care and management of women with uncomplicated pregnancies. Nurse-midwives play a large role in making birth an unforgettable family event as well as helping to ensure a healthy outcome for both mother and child (Declercq, 2007) (Fig. 1.9).

FIGURE 1.9 A certified nurse-midwife plays an important role in ensuring a safe and satisfying birth. (© Caroline Brown, RNC, MS, DEd.)

LEGAL CONSIDERATIONS OF MATERNAL-CHILD PRACTICE

Legal concerns arise in all areas of health care. Maternal and child health nursing carries some legal concerns that extend above and beyond other areas of nursing, because care is often given to an "unseen client"—the fetus—or to clients who are not of legal age for giving consent for medical procedures. In addition, labor and birth of a neonate are considered "normal" events, so the risks for a lawsuit are greater when problems arise (O'Grady et al., 2007). Nurses are legally responsible for protecting the rights of their clients, including confidentiality, and are accountable for the quality of their individual nursing care and that of other health care team members. New regulations on patient confidentiality guarantee that patients can see their medical record if they choose but health information must be kept confidential from others (DHHS, 2007). In a society in which child abuse is of national concern, all health care providers are becoming increasingly responsible for identifying and reporting incidents of suspected abuse in children (Newton & Vandeven, 2007).

Understanding the scope of practice and standards of care can help nurses practice within appropriate legal parameters.

Documentation is essential for protecting a nurse and justifying his or her actions. This concern is long-lasting, because children who feel they were wronged by health care personnel can bring a lawsuit at the time they reach legal age. This means that a nursing note written today may need to be defended as many as 21 years into the future. Nurses need to be conscientious about obtaining informed consent for invasive procedures and determining that pregnant women are aware of any risk to the fetus associated with a procedure or test. In divorced or blended families (those in which two adults with children from previous relationships now live together), it is important to establish who has the right to give consent for health care. Adolescents who support themselves or who are pregnant are termed "emancipated minors" or "mature minors" and have the right to sign for their own health care. Personal liability insurance is strongly recommended for all nurses, so that they do not incur great financial losses during a malpractice or professional negligence suit.

The specific legal ramifications of procedures or care are discussed in later chapters that describe procedures or treatment modalities. In some states, obstetric services are facing a crisis situation as more physicians and nurse-midwives find the cost of malpractice insurance to guard against "wrongful birth" is making their practice no longer profitable. A wrongful birth is the birth of a disabled child when the parents would have chosen to end the pregnancy if they had been informed about the disability during pregnancy. "Wrongful life" is a claim that negligent prenatal testing on the part of a health care provider resulted in the birth of an unperfect child. "Wrongful conception" denotes a contraceptive measure that failed, allowing an unwanted child to be conceived and born (O'Grady et al., 2007). Because many genetic disorders can be identified prenatally, the scopes of both "wrongful birth" and "wrongful life" grow yearly.

If a nurse knows that the care provided by another practitioner was inappropriate or insufficient, he or she is legally responsible for reporting the incident. Failure to do so can lead to a charge of negligence or breach of duty.

ETHICAL CONSIDERATIONS OF PRACTICE

Some of the most difficult ethical quandaries in health care today are those that involve children and their families. Examples are

- Conception issues, especially those related to in vitro fertilization, embryo transfer, ownership of frozen oocytes or sperm, cloning, stem cell research, and surrogate mothers
- Abortion, particularly partial-birth abortions
- Fetal rights versus rights of the mother
- Use of fetal tissue for research
- Resuscitation (for how long should it be continued?)
- Number of procedures or degree of pain that a child should be asked to endure to achieve a degree of better health
- Balance between modern technology and quality of life

Legal and ethical aspects of issues are often intertwined, which makes the decision-making process complex. Because maternal and child health nursing is so strongly family centered, it is common to encounter some situations in which the interests of one family member are in conflict with those of another. Maintaining privacy while aiding problem solving can be difficult (Recupero, 2008). It is not unusual for the values of a client not to match those of a health care provider. For example, if a pregnancy causes a woman to develop a serious illness, the family must make a decision either to terminate the pregnancy and lose the child or to keep the pregnancy and work to support the mother through the crisis. If the fetus is also at risk from the illness, the decision may be easier to make; however, the circumstances usually are not clear cut, and the decisions that need to be made are difficult. These and other issues are bound to emerge during the course of practice. Nurses can help clients who are facing such difficult decisions by providing factual information and supportive listening and helping the family clarify their values.

The Pregnant Woman's Bill of Rights and the United Nations Declaration of Rights of the Child (see Appendix A) provide guidelines for determining the rights of clients in regard to health care.

✔ Checkpoint Question 1.3

What is a legal implication pertinent to maternal and child health?

a. Informed consent is rarely needed as children are unable to understand this.
b. All adolescents over age 14 are able to sign consent for their own health care.
c. Children who feel they have been wronged can sue years into the future.
d. Pregnant women are not legally mandated to protect the health of their fetus.

Key Points for Review

- Standards of maternal and child health nursing practice have been formulated by the American Nurses Association, the Society of Pediatric Nurses, and AWHONN to serve as guidelines for practice.
- Nursing research and use of evidence-based practice are methods by which maternal and child health nursing expands and improves.
- The most meaningful and important measure of maternal and child health is the infant mortality rate. It is the number of deaths among infants from birth to 1 year of age per 1000 live births. This rate is declining steadily, but in the United States it is still higher than in 32 other nations.
- Trends in maternal and child health nursing include changes in the settings of care, increased concern about health care costs, improved preventive care, and family-centered care.
- Advanced-practice roles in maternal and child health nursing include women's health, family, neonatal, and pediatric nurse practitioners; nurse-midwives; clinical nurse specialists; and case managers. All of these expanded roles contribute to make maternal and child health care an important area of nursing and health care.
- Maternal and child health care has both legal and ethical considerations and responsibilities over and above those in other areas of practice because of the role of the fetus and child.

CRITICAL THINKING EXERCISES

1. How might family-centered care help the Chung family, described in the beginning of the chapter? How can you explain recent changes in health care so that Melissa might understand why her hospital stay is so short? How can you empower the family so that they feel more in control of what is happening to them?
2. Mrs. Chung says she has trouble paying for health care. Some other countries in the world have a health care delivery system based not on profit but on provision of

care for all citizens through a tax-supported program. The infant mortality rate in many of these countries is lower than that in the United States. What are some reasons that might contribute to these lower rates?

3. The age at which women are having babies is increasing. For many women such as Melissa Chung, this age is now 35 years or older. How do you anticipate that this trend will change health care in the future? Are there special services that should be provided for such women? How will this trend influence childrearing in the future?
4. Examine the national health goals related to maternal, newborn, and child health. Most government-sponsored money for nursing research is allotted based on these goals. What would be a possible research topic to explore, pertinent to these goals, that would be applicable to the Chung family and could also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX types of questions related to trends in maternal and child health care. Confirm your answers are correct by reading the rationale for answers.

Chapter 2

Sociocultural Aspects of Maternal and Child Health Nursing

KEY TERMS

- acculturation
- assimilation
- cultural values
- culture
- discrimination
- diversity
- ethnicity
- ethnocentrism
- minority
- mores
- norms
- prejudice
- stereotyping
- taboos
- transcultural nursing

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe ways that sociocultural influences affect maternal and child health nursing.
2. Identify National Health Goals related to sociocultural considerations that nurses can help the nation achieve.
3. Use critical thinking to analyze how sociocultural aspects of care affect family functioning and health and develop ways to make nursing care more family centered.
4. Assess a family for sociocultural influences that might influence the way it responds to childbearing and childrearing.
5. Formulate nursing diagnoses related to culturally influenced aspects of nursing care.
6. Develop outcomes to assist families who have specific cultural needs to thrive in their community.
7. Plan nursing care that respects the sociocultural needs and wishes of families.
8. Implement nursing care to assist a family adapt to today's changing sociocultural environment.
9. Evaluate expected outcomes for achievement and effectiveness of care.
10. Identify areas of care related to sociocultural considerations that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate sociocultural aspects of care with nursing process to achieve quality maternal and child health nursing care.

Maria Rodriques is a 12-year-old who is hospitalized for surgical repair of a broken tibia. She has a cast on her leg and will be on bed rest for 3 days, then allowed to learn crutch walking.

In planning care for Maria, you assume that because her culture is Hispanic, her family orientation will be male-dominant, her time focus will be on the present, and her nutrition preferences will be Mexican American. Based on this, you consult with Maria's father regarding the major aspects of her care. You concentrate on talking mainly about her current problem (bed rest) rather than her return to school. You caution her to avoid milk, because lactase deficiency is present in many Mexican Americans.

You are surprised on the second day of Maria's hospital stay to hear her say that she feels "second class." No one asks her for input in her care; she'd like some milk to drink and doesn't feel bed rest is a problem but is concerned that she won't be able to play soccer by next month.

The previous chapter described the standards and philosophy of maternal and child health nursing. This chapter adds information on caring for families from diverse cultures.

What went wrong with Maria's care? What would have been a better approach for determining this child's cultural preferences?

Culture is a view of the world and a set of traditions that a specific social group uses and transmits to the next generation. **Cultural values** are preferred ways of acting based on those traditions. **Ethnicity** refers to the cultural group into which a person was born, although the term is sometimes used in a narrower context to mean only race. *Race* refers to a category of people who share a socially recognized physical characteristic. The term is rarely used today as the research on the human genome shows no basic differences in structure among people.

Assessing sociocultural status, ethnicity, and cultural beliefs of families and clients can reveal why people take the type of preventive health measures that they do or seek a particular type of care for illness, because the way people react to health care is a cultural value (Crombleholme, 2009).

Cultural values differ from nation to nation because they often arise from environmental conditions (in a country where water is scarce, daily bathing is not valued; in a country where meat is scarce, ethnic recipes use little meat). The usual values of a group are termed **mores** or **norms.** Expecting women to come for prenatal care and parents to bring children for immunizations are examples of norms in the United States, but these are not beliefs worldwide (Niederhauser & Markowitz, 2007). Actions that are not acceptable to a culture are called **taboos.** Three taboos that are universal are murder, incest, and cannibalism. Issues such as abortion, robbery, and lying are controversial because these are taboos only to some people, not to everyone.

Cultural values are formed early in life and strongly influence the manner in which people plan for childbearing and childrearing, as well as the way they respond to health and illness (Whitley & Kirmayer, 2008). In a culture in which men are the authority figures, for example, it might be the father rather than the mother who expects to answer questions about an ill child at a health care visit. If you are from a culture in which women usually provide all child care, and were not aware of this family's norms, you might direct your questions to the wrong parent during a health interview. The way people respond to pain is heavily culturally influenced. If you believe that stoic behavior is the "proper" response to pain, and were unaware that there are cultural differences, you might be impatient with a woman who has been raised to believe that expressing discomfort during childbirth is "proper." When doing research, nurses need to be mindful to include all cultural groups in research samples, so that more can be learned about cultural preferences in relation to nursing interventions and care (Abuidhail & Fleming, 2007).

Cultural differences occur not only across different ethnic backgrounds but also different lifestyle behaviors such as drinking alcohol or smoking cigarettes (Angstman et al., 2007). Adolescents, urban youth, the hearing-challenged, and gay or lesbian couples have separate cultures from the mainstream, and respecting these cultures is just as important as respecting ethnic differences. A parent who has been deaf since birth, for example, expects her deaf culture to be respected by having health care professionals locate a sign language interpreter for her while she is in labor. A mother who is lesbian at a well-child visit would appreciate being asked, "Is your partner here?" rather than, "Is your husband here?"

Differing cultural values can be a major source of conflict between parents and children as children see opposing values in friends and school peers. Nurses can be instrumental in helping relieve this type of conflict by always including a cultural assessment at a health care visit (Gound et al., 2007).

FIGURE 2.1 Various cultural preferences are evident in childrearing. In some cultures, extended family members such as grandparents are the primary caregivers. (© Kathy Sloane.)

Diversity means there is a mixture or variety of lifestyles and beliefs in a population (Fig. 2.1). The United States is a country of such varied cultural groups and socioeconomic conditions that you are likely to see a wide range of behaviors exhibited in any health care setting. National Health Goals in reference to cultural influences are shown in Box 2.1.

BOX 2.1 * Focus on National Health Goals

Several National Health Goals are concerned with health practices that may be influenced by cultural factors:

- Increase the proportion of pregnant women who receive early and adequate prenatal care from a baseline of 74% to a target of 90%.
- Increase the proportion of mothers who breastfeed their babies in the early postpartum period from a baseline of 64% to a target of 75%, and increase the number to at least 60% (from a baseline of 43%) the proportion of mothers who breastfeed exclusively through 3 months.
- Increase the proportion of healthy full-term infants who are put down to sleep on their backs from a baseline of 35% to a target of 70%.
- Increase the proportion of young children who receive all vaccines that have been recommended for universal administration from a baseline of 73% to a target of 80% (http://www.nih.gov).

Nurses can help the nation achieve these goals by helping design prenatal and child care services that take into account cultural diversity and by promoting the nutritional and immunologic advantages of breastfeeding in a culturally sensitive manner. Additional nursing research is needed on ways to make prenatal care and child health services more appealing to culturally diverse populations and on the educational methods that best reach people who may not be proficient in English.

Nursing care that is guided by cultural aspects and respects individual differences is termed **transcultural nursing** (Leininger, 2007).

Nursing Process Overview

For Respecting Sociocultural Aspects of Care

Assessment

Assessment of sociocultural factors is important to be certain that care is planned based not on predetermined assumptions but on the actual preferences of a family. To do this, assess each client individually, not as one of a group. Note particularly any cultural characteristics that differ from the usual expectations of the setting in which care is being provided so that potential conflicts can be acknowledged and culturally competent care can be planned. Learn as much as you can about different cultures by reading about or talking to members of as many different ethnic groups as possible. Specific areas to assess, along with important findings in these areas, are shown in Table 2.1.

Assessing the culture of a community is as important as assessing individual families because families are intrinsically joined to their community. An important area to assess is whether the family matches the dominant culture in their community. This can be important because the type of foods stocked in supermarkets, the type of entertainment events that are available, and the values and history that are stressed in schools and work settings are all influenced by the dominant culture.

Communities age, the same as families. When homes are first built, many families tend to be young adults with children. Over the years, these families "settle in" to middle age and later the homes are filled with families at retirement. Older adults may find it difficult to relate if they move into a "young" community. A family who moves into a retirement-age community with young children may feel equally out of place. In all instances, a family that is of a culture other than the dominant one may have strong ties within the family but may have difficulty making strong, effective relationships in the community; this causes it to be more isolated than it would like to be. The importance of community assessment is further discussed in Chapter 4.

Nursing Diagnosis

Several nursing diagnoses speak to the consequences of ignoring cultural preferences in care:

- Powerlessness related to expectations of care not being respected
- Powerlessness related to sociocultural isolation
- Impaired verbal communication related to limited English proficiency
- Nutrition, less than body requirements, related to unmet cultural food preferences
- Anxiety related to a cultural preference for not bathing while ill
- Fear related to possible discrimination related to ethnicity

Outcome Identification and Planning

Planning needs to be very specific for individual families because sociocultural preferences tend to be very personal. Care may begin with in-service education for health care providers who are unfamiliar with a particular cultural practice and its importance to the specific family involved. The plan of care may include arranging for variations in policy, such as the length of family visiting hours, types of food served, or type of child care provided. Such planning is beneficial not only because it can make health care more acceptable to a child or family but also because it can motivate providers to examine policies, question the rationale

TABLE 2.1 ✻ Assessing for Cultural Values

Area of Assessment	Questions to Ask or Observations to Make
Ethnicity	What is the family's cultural preference?
Communication	What is the main language used in the home?
Touch	Do the family members typically touch each other? Do they use intimate or conversational space?
Time	Is being on time important? Is planning for the future important?
Occupation	Is work important to the family? Do they plan leisure time or leave it unstructured?
Pain	Does the family express pain or remain stoic when faced with it? What do they believe relieves pain best?
Family structure	Is the family nuclear? Extended? Single-parent? Are family roles clear? Can an individual name a family member he or she would call on for support in a crisis?
Male and female roles	Is the family male or female dominant?
Religion	What is the family's religion? Do they actively practice their religion?
Health beliefs	What does the family believe about health? What do they believe causes illness? Makes illness better? Do they use alternative therapies or traditional medical practices?
Nutrition	Does the family eat mainly ethnic foods? Are the foods they enjoy available in their community?
Community	Is the predominant culture in the community the same as the family's? Can they name a neighbor they could call on in a crisis?

behind them, and initiate more diverse care. Reputable websites to use for additional information on the importance of diversity are the National Association of Hispanic Nurses (http://www.the hispanicnurses.org), the National Black Nurses Association (http://www.nbna.org), and the Transcultural Nursing Society (http://www.tcns.org).

Implementation

Appreciate that cultural values are usually unchangeable. An example of implementing care might be to make arrangements for a new Native American mother to take home the placenta after birth of her child if that is important to her or planning home care for a Chinese American child whose family believes in herbal medicine. It might be to establish a network of health care agency personnel or personnel from a nearby university or importing firm to serve as interpreters. It might be to educate a child, family, or community about the reason for a hospital practice. There may be situations in which the health care provider or agency is unable to adapt to the particular cultural situation. This may call for both sides to adjust (cultural negotiation).

Outcome Evaluation

Assessing whether expected outcomes have been met should reveal that a family's sociocultural preferences were considered and respected during care. If this was not achieved, procedures may need to be modified until this can be realized. Examples of expected outcomes that might be established include:

- Parents list three ways they are attempting to preserve cultural traditions in their children.
- Child states she no longer feels socially isolated because of cultural differences.
- Family members state they have learned to substitute easily purchased foods for traditional foods unavailable in local stores to obtain adequate nutrition.
- Child with severe hearing impairment writes that he feels communication with ambulatory care staff has been adequate.

SOCIOCULTURAL DIFFERENCES AND IMPLICATIONS FOR DIVERSITY IN MATERNAL AND CHILD HEALTH NURSING

Given the cultural mix in the world today, almost any behavior can be considered appropriate for some individuals at some time and place. **Stereotyping** means expecting a person to act in a characteristic way without regard to his or her individual traits. It is generally derogatory in nature. Statements such as, "Men never diaper babies well" or "Japanese women are never assertive," are examples of stereotyping. Stereotyping occurs largely because of lack of exposure to enough people in a particular group and, consequently, a lack of understanding of the wide range of differences among people. In these examples, the first statement, having seen one man change diapers poorly, assumes that this represents the entire male population. The second example demonstrates lack of knowledge of a changing culture. Stereotyping can interfere with effective care because it can prevent you from planning care that is accurate, individualized, and valued (Box 2.2).

On the other hand, it is important not to ignore cultural characteristics in an attempt to not stereotype, because most people take pride in their cultural heritage. It is possible to acknowledge and celebrate a client's culture without stereotyping by admiring the way in which he or she expresses cultural characteristics, such as appreciating the ways a woman cooks an ethnic meal once a week to remind her family of their ethnic roots.

Women are often called the "keepers of the culture" or the people most influential in passing on cultural traditions from one generation to another. Respecting sociocultural values in this way is particularly important in maternal and child health care, because childbearing and childrearing are times in life that are surrounded by many cultural traditions (Andrews & Boyle, 2007).

In the past, the United States was viewed as a giant cultural "melting pot," where all new arrivals gave up their native country's traditions and values and became "Americans." **Acculturation** refers to the loss of ethnic traditions in this

BOX 2.2 ✻ Focus on Evidence-Based Practice

Do children's stereotypes about obesity differ across cultures?

Stereotyping behavior can be evident in children as early as 3 years of age. Because children in mainland China see less obvious obesity than do children in the United States, it follows that U.S. children might show more bias or stereotyping of obese children than those living in China.

To investigate this question, researchers recruited 60 Caucasian children 7 years or 10 years of age from Virginia or Colorado and 61 children of the same ages from Guilin, China. Children were shown eight bottles of supposedly new drinks and asked to sample them for taste. Each bottle actually held identical fluid but the color of the fluid and the labels on the bottles were each different. The labels included a child's photograph and an explanation that the child pictured had created that flavor of drink. When asked afterward which drink tasted worst or was most apt to make them ill, both Chinese and American children most often chose the bottle of drink with an obese child pictured on the label. Chinese children reported consistent findings between age groups; the older group of Caucasian children were even more opposed to the drink created by the obese child than the younger group, or their bias against obese children increased with age.

Would the results of this study influence the way you plan care for obese children?

Source: Klaczynski, P. A. (2008). There's something about obesity: culture, contagion, rationality, and children's responses to drinks "created" by obese children. *Journal of Experimental Child Psychology, 99*(1), 58–74.

way. Cultural **assimilation** means that people have adopted the values of the dominant culture.

In the past, many Americans were intolerant of any behavior that was not like that of middle-class Americans, because they believed that the American way (which actually was the northern European way) was the "best" way. This belief that one's own culture is superior to all others is referred to as **ethnocentrism.**

Ethnocentrism can lead to **prejudice** (believing that some people are less than others based on their physical or cultural traits) because the feelings and ways of other cultures cannot be understood or appreciated without the philosophy that the world is large enough to accommodate a diversity of ideas and behaviors and that there is probably no "best" way to accomplish anything. **Discrimination** is the act of treating people differently based on their physical or cultural traits. Traditionally, people whose culture differs most drastically from the dominant culture suffer the greatest amount of rejection, because they are least able to assimilate. Over years of familiarity, mutual cultural assimilation does occur. As an example, when many Italians moved into American communities in the early 1900s, the average Italian family learned to speak English and the average American family learned to cook spaghetti with Italian sauce.

Today, many people question the idea that America ever was a melting pot; instead, the preferred concept is that of a "salad bowl," in which cultural traditions and values are tossed together but with all their crispness and flavor retained to make a perfect mix. Retaining ethnic traditions strengthens and enriches family life. It provides security to younger family members to realize that they are one of a continuing line of people who have a past and will have a future (Fig. 2.2, Box 2.3).

Cultural competence, or respecting cultural differences, allows you to plan culturally competent care and the integration of cultural elements into care, a goal worth achieving (Schim et al., 2007). Numerous levels of cultural intolerance or acceptance continue to persist, however, because many people continue to hold different beliefs along a cultural competence continuum (Fig. 2.3).

As a nurse, you will have the opportunity to meet many people who hold cultural values different from your own. When planning nursing care, try to not only respect people's cultural differences but also help people share their cultural beliefs with health care providers so that their beliefs can be considered and respected.

FIGURE 2.2 Cultural traditions offer a sense of security to children. (© Caroline Brown, RNC, MS, DEd.)

BOX 2.3 ✻ Focus on Family Teaching

Preserving Cultural Heritage

Q. Mrs. Rodriques says, "I'm proud of my family's ethnic traditions. How can I help my family preserve these?"

A. Preserving your individual heritage when living in another culture calls for creative planning. Some common suggestions for doing this are as follows:

- Plan an "ethnic night" once a week when only ethnic food is served. Encourage children to invite friends for the meal and discuss the traditions behind the various foods.
- If a foreign language is part of your traditions, reserve one night a week when family members speak only the native language so they will value two languages.
- Choose books for children that are written by authors from your culture or that advantageously describe your culture. Read them together as a family.
- Monitor television for programs that focus positively on your culture. Watch them with your children.
- As bedtime stories or "talk time," talk to your children about your childhood and traditions and values so they can appreciate how long these values have been revered by your family.
- Celebrate holidays in your traditional manner. Including cultural influences in holiday celebrations adds a rich ingredient and feeling of security to these occasions.

✔ Checkpoint Question 2.1

While she is in the hospital, Maria Rodriques makes the following statements. Which is the best example of stereotyping?

a. My doctor is funny; he tells jokes and makes me laugh.
b. I'm glad I'm Mexican because all Mexicans are smart.
c. I'm sure my leg will heal quickly; I'm always healthy.
d. I like Mexican food, although not if it tastes too spicy.

Sociocultural Assessment

Almost all nations have a set of people who are its dominant or advantaged group. They hold the greater share of wealth in the nation and hold the majority of political offices. Almost all nations also have **minority** or disadvantaged groups—groups not necessarily fewer in number but who

CULTURAL DESTRUCTIVENESS	CULTURAL BLINDNESS	CULTURAL AWARENESS	CULTURAL SENSITIVITY	CULTURAL COMPETENCE
Making everyone fit the same cultural pattern, and excluding of those who don't fit—forced assimilation. Emphasis on differences and using differences as barriers.	Do not see or believe there are cultural differences among people. Everyone is the same.	Being aware that we all live and function within a culture of our own and that our identity is shaped by it.	Understanding and accepting different cultural values, attitudes, and behaviors.	The capacity to work effectively and with people, integrating elements of their culture—vocabulary, values, attitudes, rules, and norms. Translation of knowledge into action.

FIGURE 2.3 Cultural competence continuum. (Courtesy of the National Council of La Raza.)

hold less power and wealth. When assessing families regarding whether there are socioeconomic or cultural influences that will make special considerations of care necessary, several categories of information related to the structure (composition) and function (roles and actions) of a family can be examined.

Communication Patterns

Communication patterns (not only what people say but also how they say it) are culturally determined. People whose primary language is not English can have great difficulty detailing a health history in English to a health care provider. Language barriers can be particularly significant for people who must give health histories when they or their child is ill, because their ability to cope and express themselves in any language when they are stressed may be at a low point (Darby, 2007). Even if people are able to converse well in English in social situations, they may not be able to give a health history as well as they would like because they cannot recall the English words for symptoms such as nausea or dizziness, words not commonly taught in English as a second language class. Unless you appear receptive, this person might omit mentioning a symptom rather than try to pantomime it or describe it in a different way. Listening to English instructions and translating them into another language can also cause confusion. The statement, "I need you to wait," for example, is easy to translate as "I need your weight." The word "hallmark" translates as "mark on the hall," or graffiti.

Children who are embarrassed or bashful about speaking another language may simply not talk, so their needs may go unmet. As a general rule, it is unfair to ask children to interpret for their parents. If a child is frequently asked to interpret for his or her parents, the child may be forced to miss days of school. Translating also can place a child in situations that require adult judgment and knowledge. In some cultures, it might be unacceptable for a younger person to serve as an interpreter for an older person, because this shifts authority.

The terms "Hispanic" and "Latina" or "Latino" refer to people who identify with a Spanish culture. There are about 18 million documented persons of Mexican, Puerto Rican, Cuban, or other Spanish-speaking origin in the United States. When added to the number of Spanish-speaking people who are undocumented or living illegally in the country, this group numbers close to 44 million, or about 14.8% of the total U.S. population (U.S. Census Bureau, 2009). Health care providers and Hispanic communities are encouraged to work together to bridge communication gaps by helping both community members who are not English proficient to learn more English and health care providers who are not Spanish proficient to learn to communicate better in Spanish. The type of health care provider that people choose is yet another trait that is not uniform across cultures. For some Hispanics, turning to a *yerbero* or *curandero* is preferable to professional health care because these people may not charge a fee but accept a donation or an exchange of goods or services. Also, relating health problems to them is not difficult because there is no language problem. Box 2.4 explains these terms.

Communication problems arise not only from foreign languages but also from dialects within a country. Something as simple as a New Englander adding an "r" sound to the end of words (saying "idear" instead of "idea") may make an explanation difficult to follow. The slow cadence of a person

BOX 2.4 ✻ English–Spanish Communication

Common Terms to Describe Hispanic Health Care Providers

brujo: Person who can not only revoke evil spells but also turn them around onto others

curandero: Person who heals by the use of herbs or diet

el que sabe ("the one who knows"): Trusted family member to whom family members turn to first for consultation and approval to seek therapy

espiritualisto: Person who can treat supernaturally caused illnesses

el enfermero or *la enfermera:* Nurse

médico or *médica:* Doctor

partera: Midwife who cares for women during pregnancy and birth

yerbero (herbalist): Person outside the family structure who grows herbs and instructs people in the use of herbs or cures

from the South may seem strange to someone who is used to the rapid speech pattern of residents of New York City. Inner-city residents often speak a dialect unique to them. To care for such clients, learn their dialect's cadence and common words but do not attempt to use them yourself, unless that is your dialect. Trying to speak in a dialect not your own could be misinterpreted as mockery.

Touch, such as with a kiss or hug to greet another person, is a form of communication and is also culturally determined. Some people do not like to be hugged. Some prefer to bow in contrast to shaking hands. Some Asian Americans feel that rumpling the hair or palpating fontanelles is an intrusive gesture because they believe the head is the seat of the body's spirit and should not be touched (Giger & Davidhizar, 2008).

Whether people look at one another when talking is also culturally determined. Chinese Americans, for example, may not make eye contact during a conversation. This social custom shows respect for the position of the health care professional and is a compliment, not an avoidance issue.

Cultural variations such as these should be respected in written as well as oral communications. In many instances, written communication is even more problematic than oral communication: many people can speak a second language but cannot write or read it. Using short, easy sentences and being certain not to use words with double meanings are important techniques (Boxes 2.5 and 2.6).

BOX 2.5 ✻ Focus on Communication

Anna Rodriques brings her 4-year-old son, Pedro, to your pediatric clinic because she thinks he has an ear infection. She has brought a neighbor as an interpreter.

Less Effective Communication

Nurse: What's the reason you're here today?
Neighbor: She thinks her son has an ear infection.
Nurse: Is he pulling or tugging at it?
Neighbor: Not that I've seen.
Nurse: Does he have any pain?
Neighbor: She hasn't said anything about that.
Nurse: Well, I'll take his temperature, but I doubt it's an infection.

More Effective Communication

Nurse: What's the reason you're here today?
Neighbor: She thinks her son has an ear infection.
Nurse: Ask if he has been pulling or tugging at it.
Neighbor: I haven't seen him doing that.
Nurse: Would you ask if his mother has?

[The neighbor addresses Anna and then reports back.]

Neighbor: She says he's been pulling at it all morning.
Nurse: Ask Pedro if he has any pain.

[The neighbor addresses the child and then reports back.]

Neighbor: He says yes.
Nurse: Those are symptoms of an ear infection, all right.

Effectively using an interpreter adds additional responsibility to history taking. The nurse in the first scenario asked her first question of the mother but then directed all other questions to the interpreter. This means she secured a secondary history. When using an interpreter, be certain that the interpreter is "interpreting," not giving the history.

BOX 2.6 ✻ Improving Health Care When Clients Have Limited English Proficiency

1. Many people can speak a second language better than they can read it. Assess each client's reading level and rewrite information at an easier reading level if necessary.
2. Ask an interpreter to translate material into the family's primary language.
3. Be certain that rooms in your health care agency, such as bathrooms, are labeled with international symbols.
4. Learn a few phrases, such as "Good morning" or "This won't hurt," from other languages, and use them in interactions with clients.
5. Use hand gestures or draw a figure, if need be, to communicate better. Imparting health information is what is important for safe care, not worrying how you look.
6. When using an interpreter, do not ignore the person seeking health care in preference to the interpreter. Observe their facial expressions for confirmation that they understand instructions. Use short sentences; avoid slang words that do not interpret cleanly.

Use of Conversational Space

People of different cultures use the space around them differently. In the Western world, physical examinations are conducted in a very tight (intimate) space, because palpation is a part of the examination. Conversation, on the other hand, is usually held at a distance of between 18 inches and 4 feet. Business is most often conducted at a 4-foot distance, as that allows room for a desk between parties. Any space beyond that, such as shouting across a parking lot, is public space. Use of the Internet or telephone can vary from private space ("I have a secret to tell you") to public space (conversation in a chat room). Everyone has had the uncomfortable experience of speaking to someone who moves closer to them than they expected or invades their intimate space while talking to them. Likewise, everyone has had someone shout something they wanted to be kept confidential (violation of public space). Being aware that use of space is culturally determined and can vary from person to person helps you to respect the use of space for clients.

Respect for modesty is a way to respect close space. Be aware that women from Middle Eastern cultures adhere to a level of modesty exceeding what you may be used to.

Time Orientation

The cultural pattern in the United States is geared toward punctuality regarding appointments. "Time is money" is an

often-quoted axiom. Other cultures, however, may not have this concern for time. They may have, instead, a concept that time is to be enjoyed. For such a person, there is no such thing as wasted time. In some South Asian cultures, being late for appointments is a sign of respect (giving the person you are meeting time to organize and be prepared for your arrival). Women who do not have a strict time orientation may view the hospital's practice of feeding infants at designated times such as 10 AM or 2 PM as strange. People who are not accustomed to adhering to schedules in this way may have difficulty following a strict medical regimen. If they are told, for example, to give a child a medication at 8 AM, noon, and 6 PM daily and to return for another appointment at 2 PM in a week's time, you may have to stress that the medication should be taken three times a day, not necessarily at the specific times. Also stating that returning for a checkup at a set time is important because their physician is only in the health care facility at that time is also helpful.

Another way that time orientation differs is in whether a culture concentrates on the past, the present, or the future. The dominant U.S. culture is oriented to the present and future. People are expected not only to take care of themselves at the present moment but also to make plans and save money for the future. Other cultures are oriented toward the past: they carefully preserve traditions, allowing only the slightest changes or variations in practices. Still others are oriented toward the present; saving money for college (a future-oriented action) may not be a high priority in these cultures. If a family's orientation is for the present or the past, members may have difficulty accepting a long-term rehabilitation plan (e.g., by 6 months after an accident a boy will be walking with crutches, but it will be a full year before he will be fully ambulatory again). They may need to be motivated by present indications of progress (e.g., this afternoon the child will be allowed to sit up for the first time; this evening he can begin to have periods of time without oxygen).

The Amish are an example of a past-oriented culture: they adhere to time-honored traditions that do not include technologic advances such as immunizations. Some Native Americans also hold a past orientation. People from lower socioeconomic groups tend to be more present oriented than those in middle or higher socioeconomic groups because of the struggle just to get through each day. They may make different health care decisions because of this (Horodynski et al., 2007). People with strong religious convictions may be future oriented (looking forward to a future existence better than their present one). Knowledge of these different time orientations helps to plan effective care.

Work and School Orientation

The predominant culture in the United States stresses that everyone should be employed productively (called the Protestant work ethic) and that work should be a pleasure and valued in itself (as important as the product of the work). Other cultures do not value work in itself but see it as only a means to an end (you work to get money or food, not satisfaction). Suppose that a pregnant woman you care for has been told that she must be at home on bed rest for the remainder of her pregnancy. It is easy to think that she will be most concerned because this will not allow her to continue her job as a grade school teacher. A woman with a different work orientation might be more distressed to learn that she cannot continue her hobby (going to baseball games). This could be misconstrued as being unproductive when it is actually a cultural difference.

Because people in the United States are expected to work, they also are expected to finish school so they can learn an occupation and support themselves in their adult life. Work orientation has come to include using leisure time effectively, such as exercising or learning a new skill rather than just passively watching television. Because cultural influences dictate leisure time activity this way, and values differ, assessment will reveal differences in what people prefer to do during their leisure time and also the effect this can have on their overall health if sufficient exercise is not included (Brandes, 2007).

Family Orientation

Family structure and the roles of family members are other lifestyles that are culturally determined. In most cultures, the nuclear family (mother, father, and children) is most common. In other cultures, extended families (nuclear family plus grandparents, aunts, uncles, and cousins) and single-parent families (one parent and child) may be more common. Some cultures stress that information about a family should be carefully guarded (as a way of keeping the family intact and unique and perhaps also as a reflection of mistrust for health care providers). Other cultures willingly share the same information. When caring for children, be certain to identify a child's primary caregiver before giving health care instructions because who cares for children in a family can vary by culture. Identifying the family decision-maker can also be important, because this role can vary greatly among families.

Male and Female Roles

In most cultures, the man is the dominant figure. In such a culture, if approval for hospital admission or therapy is needed, the man is the one to give this approval. In a culture in which men are very dominant and women are extremely passive, a woman may be unable to offer an opinion of her own health or be embarrassed to submit to a physical examination, especially from a male physician or nurse practitioner, unless a female nurse is also present. The incidence of intimate partner violence may be higher in male-dominant cultures. In an extremely male-dominated family, a woman's pregnancy may have resulted not from a mutual decision but from sexual relations she felt she could not refuse.

In contrast, in some cultures, the woman may be the dominant person in the family. The oldest woman in the home would be the one to give consent for treatment or hospital admission.

It is important to evaluate male and female roles in this way, because knowing the identity of the dominant person in the household also helps you to understand the impact of the illness on a family. If a woman is the family's dominant person and can no longer make her usual decisions because she is ill during pregnancy, the entire family may be thrown into confusion. If the woman is a nondominant member, you may have to act as an advocate for her rights with a more dominant person.

In most health care settings today, a father is expected to play an active role during labor, as well as during a child's hospital stay. However, a man who sees his role as a passive

one may be uncomfortable participating in labor or visiting a hospital to play with an ill child. Awareness that male and female roles differ from country to country in this way can help you find a middle ground for a parent's participation in pregnancy and child care.

What if... Mr. Rodriques says he does not wish to participate in labor when his wife has her new baby? Would you encourage him to time contractions (a typical role for fathers) or allow him to sit quietly in a corner of the room, as he prefers?

Religion

There are wide variations in religious practices, and many of these are culturally determined. Because religion guides a person's overall life philosophy, it influences how people feel about health and illness, what foods they eat, and their preferences about birth and death rituals (Miklancie, 2007). Knowing what religion a family practices helps you locate a religiously important support person when needed. It helps you in planning care because many nutritional practices, such as whether the family eats meat, can be dictated by religious beliefs. It also can have important implications for decision making during a difficult pregnancy or for childhood terminal care.

Health Beliefs

Health beliefs are not universal. For example, most people are familiar with the current controversy about whether male circumcision is necessary. More surprising to many people is a belief that female circumcision (amputation of the clitoris and perhaps a portion of the vulva) is thought to be necessary in some cultures (Braddy & Files, 2007).

It is generally assumed in developed countries that illness is caused by documented factors such as bacteria, viruses, or trauma. In other cultures, however, illness may be viewed primarily as a punishment from God or an evil spirit, or as the work of a person who wishes harm to the sick person. An example of this is a belief among some Hispanics that an "evil eye" (*mal ojo*) can cause illness. People who believe that their own sins caused an illness may not be highly motivated to take medication or other measures to get well again as they do not believe that a spoonful of penicillin will cure them. People with such beliefs may receive more comfort from a spiritualist or counselor than from their physician or nurse practitioner. They may believe it is necessary to suffer pain to be rid of the illness and so may be reluctant to ask for pain medication. Understanding different beliefs of this kind allows you to understand differing attitudes toward procedures and to work out mutual goals, even when the patient's views are not those you would choose for yourself or for a member of your family (see Focus on Nursing Care Planning Box 2.7).

As another example, women's concept of whether pregnancy is a time of wellness or illness and whether breastfeeding is advocated or not differs in various cultures (Oetzel et al., 2007). Most American women visit health care facilities early in pregnancy, follow prenatal directives, and, at birth, allow a health care provider to supervise the birth. In other cultures, pregnancy and childbearing are considered such natural processes that a health care provider is unnecessary. The woman knows the special rules and taboos she must follow to ensure a safe birth and a healthy child and depends on other women rather than on health care providers to guide her safely through labor and birth. She may plan to breastfeed until the next child is born, or for as long as 5 years. Unless differences such as these are respected, it is difficult to plan prenatal care that meets individual women's needs.

The type of therapy people choose to restore health is also dependent on culture. When one person wakes up with an upper respiratory infection, for example, he or she may immediately call a health care provider for a formal prescription. Another person with the same symptoms would not call at all but depend on an herbal or "natural" self-help method. Be aware when taking health histories that many people today from all cultures rely on complementary or alternative therapies. Ask if people use these to be certain that a prescribed medication will not counteract or be synergistic with these or if they want some advice on what would work better for them (Smith et al., 2009).

What if... The Rodriques family tells you that they believe the accident that caused Maria's broken leg was "God's will," not Maria's fault? Would it be appropriate to educate Maria about street safety, or would doing so interfere with the family's cultural beliefs?

Nutrition Practices

Foods and their methods of preparation are strongly culturally related. In many instances, people cannot find any food on a hospital menu that appeals to them because of cultural preferences. A Japanese diet, for example, includes many vegetables such as bean sprouts, broccoli, mushrooms, water chestnuts, and alfalfa. Children with this preference tire quickly of the macaroni and cheese common to a middle-class American childhood diet. Fortunately, in most instances, a child's family can provide food that is appealing culturally and is still within prescribed dietary limitations (Fig. 2.4).

When counseling a woman about nutrition during pregnancy, remember that respect for culturally preferred foods is

FIGURE 2.4 Families differ regarding what food selections they prefer because of sociocultural preferences. (© Photo Researchers/Jeffrey Greenberg.)

BOX 2.7 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Child Needing Sociocultural Care

Maria Rodriques is a 12-year-old child who is hospitalized following surgical repair of a broken tibia that was broken when she rode her bicycle into a busy street. She has a cast on her right leg and will be on bed rest for 3 days and then allowed to learn crutch walking.

Family Assessment ✻ Maria lives with her mother, Anna, her father, Carlos, and a 4-year-old brother, Pedro. She attends a local grade school and enjoys playing video games and reading Harry Potter books. Her mother is 4 months pregnant.

Client Assessment ✻ Temperature, 99.4° F; pulse, 86 beats/min; respirations, 24/min. Observed lying on side, gritting teeth as if in pain. Hands clenched and eyes tearing. When asked if she has pain, she quietly stated, "No. I'm okay." Father was overheard saying to her, "We're proud you're so brave." Cast on right leg dry and intact. Toes warm to touch. Intravenous fluid infusing without difficulty. Oral intake primarily tea and soup. Client's mother states, "She needs 'hot' foods to get better. Don't you have anything hotter?"

Nursing Diagnosis ✻ Pain related to tissue trauma of surgery, with cultural belief to not voice pain.

Outcome Criteria ✻ Client accepts pain medication when offered; nonverbal expressions of pain are minimal to absent. Client begins to eat and manage self-care.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Self-Care Activities		
Nurse/ physical therapist	Assess what self-care activities child feels ready to begin.	Plan a program of self-care that is possible within constraints of limited ambulation.	Ability to complete self-care can add to self-esteem and supply physiologic benefits.	Client feeds self, is out of bed in 3 days, and completes hygiene measures at 12-year-old level.
		Consultations		
Nurse	Assess pain level on a 1-to-10 scale. Determine what child feels would relieve pain best.	Consult with pain management team to establish a total pain relief plan for client.	Optimal health care is often a collaborative practice.	Child states that pain management plan is acceptable to her. Rates her pain level as below 2 on a 1-to-10 scale.
		Procedures/Medications		
Nurse	Assess for both verbal and nonverbal indicators of pain.	Offer pain medication as prescribed before pain becomes acute.	Offering medications relieves the client of the need to ask for relief when her belief is that she should not express pain. It also allows the child to have some choice and control in her care.	Child's chart documents that pain medication was offered every 4 hours during waking hours throughout hospital stay.
		Nutrition		
Nurse/ nutritionist	Assess whether the child has food preferences that are not being met by hospital service.	Encourage the family to bring in foods from home that meet their cultural preferences.	Allowing the family to bring in foods demonstrates respect for their culture and increases the child's sense of security and being cared for.	Client increases nutrient intake by including foods brought from home.

(continued)

BOX 2.7 ✻ Focus on Nursing Care Planning (continued)

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Patient/Family Education		
Nurse	Assess the child's knowledge of broken bones and of why trauma leads to pain.	Explain the physiology of pain to family members as a way of explaining why the client is experiencing it.	Explanations help a child of this age understand what is happening so minimize fear.	Client describes what pain is and acknowledges that she will have some until healing is complete and that asking for something to relieve it is expected and acceptable.
		Spiritual/Psychosocial/Emotional Needs		
Nurse	Assess whether child has unmet needs other than pain relief.	Explain to child that you want to help but that she needs to verbally express her needs to enable you to do so.	Children may imagine that health care providers are all-knowing.	Child agrees to participate in expressing the presence of other factors, such as loneliness or fear.
		Discharge Planning		
Nurse	Assess with child what modifications she will need to make in her daily routine to adjust to cast.	Discuss with parents that their child may need modifications in daily routine to return to school.	Well-informed parents and children are able to make informed decisions.	Child attends school daily because of modifications in usual lifestyle.

important. People from some cultures, for example, tend to eat much less meat than do those from other cultures. Adequate protein can be ingested, however, by mixing sources of incomplete protein such as beans and rice. Some women may omit various foods during pregnancy because they believe a particular food will mark a baby (e.g., strawberries cause birthmarks, raisins cause brown spots), or they believe that it is necessary to eat "hot" or "cold" foods to ensure fetal growth. Pregnancy is usually considered a "hot" condition, so it may be difficult for a woman who is trying to eat only "cold" foods to agree to increase her intake of meat, usually considered a "hot" food. Asian women may believe in a similar pattern of required balances (yin and yang).

Before beginning nutrition counseling, become aware of what is the dominant type of food available in your health care agency's local food stores. Women who cannot buy the foods you recommend in their own neighborhood may not eat well because of the inconvenience involved in shopping elsewhere.

A trait present in many people that is ethnically determined is lactose intolerance. This is the absence of lactase, the enzyme that breaks down the sugar (lactose) in milk so milk can be used by the body. People with lactose intolerance (including many Asians and blacks) develop diarrhea and stomach cramps if they drink milk because of lactase deficiency (Bauchner, 2007). Be certain when counseling during pregnancy that you do not advise a woman who is lactose intolerant to drink milk. She can obtain adequate calcium through supplements or other foods high in calcium such as dark green vegetables. Adding a lactase additive to milk is yet another suggestion.

Pain Responses

A person's response to pain is a final category that is both individually and culturally determined (Jacob et al., 2008). Although all people may have the same threshold sensation (the amount of stimulus that results in pain), their pain threshold (the point at which the individual reports that a stimulus is painful) and pain tolerance (the point at which an individual withdraws from a stimulus) vary greatly.

Caring for a person having pain can be problematic when the caregiver's concept of "proper" responses to pain differs from the patient's concept. One woman in labor might report labor contractions as "agonizing" each time she feels one, whereas a woman in the room next to her, experiencing the same degree of pain, might report her pain as tolerable and barely change her facial expression with contractions because of her different cultural attitude toward expressing pain. Because there are so many possible responses to pain, it is important to assess each person individually.

Strategies to help recognize cultural influences on pain perception are to (a) appreciate that the meaning of pain varies among cultures, (b) appreciate that not all people communicate or express their level of pain in the same way, (c) recognize that communication of pain may not even be acceptable within a culture, (d) develop an awareness of your

personal values and beliefs and that they may affect how you respond to people in pain, and (e) use an assessment tool, such as a 1-to-10 scale, to assist in measuring pain so you are certain that you are being as objective as possible (Giger & Davidhizar, 2008). Further assessment of pain and its meaning to people is discussed in Chapters 16 and 39.

✔ Checkpoint Question 2.2

Maria Rodriques is the 12-year-old student you met at the beginning of the chapter. Which statement by her is the best example of ethnocentrism?

a. My school, Stevens Park, is the best in the city.
b. Many schools in my city have good soccer teams.
c. Children from many cultures attend my school.
d. I want to go to a public, not a private, college.

Key Points for Review

- Culture is an organized structure that guides behavior into acceptable ways for that group. Usual customs are termed "mores" or "norms." Actions that are not acceptable to a culture are "taboos."
- Stereotyping is expecting a person to act in a characteristic way without regard to his or her individual traits. Prejudice is thinking that people are different in some way, or is an *intellectual* act. Discrimination is treating people differently based on their physical or cultural traits, or is a *doing* act.
- Each culture differs to some degree from every other. Most people are proud of these differences or cultural traits.
- Cultural practices arise from environmental conditions and are transmitted by both formal and informal ways from generation to generation.
- Although cultural concepts adapt from time to time, they tend to remain constant.
- There is wide variation within a culture concerning values and actions, because individuals make up the group and individually express their cultural heritage.
- People bring cultural values and beliefs to nursing interactions, and these affect nursing and health care.
- Cultural aspects that are important to assess are communication patterns; use of conversational space; response to pain; time, work, and family orientation; and social organization including nutrition, family roles, and health beliefs.

CRITICAL THINKING EXERCISES

1. Maria Rodriques is the 12-year-old child you met at the beginning of the chapter. *What could the nurse have done differently in the plan of care for this child?* What would have been a better approach for determining this family's cultural preferences? Supposing Maria is present oriented: how would you approach discussions of a long-term rehabilitation program with her?
2. When you talk to Mrs. Rodriques, you realize that she is pregnant but has not gone for prenatal care. She states that before coming to the clinic she wants to visit a *yerbero,* who will both predict her child's sex and guarantee a safe birth. Would recommending that she have a sonogram (which also could predict the fetal sex) likely be as satisfying for her?
3. Although you know Maria is being raised as a vegetarian for religious reasons, suppose at lunch time you notice a hamburger on her meal tray. What would be your best action? Would you ask her to eat it because she needs protein for healing? Or ask for another food choice for her?
4. Examine the National Health Goals related to sociocultural aspects of health care. Most government-sponsored money for nursing research is allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to the Rodriques family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter; then answer the questions to further sharpen your skills and grow more familiar with NCLEX types of questions related to cultural influences. Confirm your answers are correct by reading the rationales.

Chapter 3

The Childbearing and Childrearing Family

KEY TERMS

- ecomap
- family
- family nursing
- family of orientation
- family of procreation
- family theory
- genogram
- polygamy
- polygyny

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe family structure, function, and roles, and ways that these are changing.
2. Identify National Health Goals related to the family and specific ways that nurses can help the nation achieve these goals.
3. Use critical thinking to analyze additional ways that nursing care can be more family centered or that family members can be better integrated into maternal-child health care.
4. Assess a family for structure and healthy function.
5. Formulate nursing diagnoses related to family health.
6. Develop expected outcomes to help a family achieve optimal health.
7. Plan health teaching strategies, such as helping a family modify its lifestyle to adjust to a pregnancy, accommodate an ill child, or face a major life event such as loss of a job.
8. Implement nursing care, such as teaching a family more effective wellness behaviors.
9. Evaluate outcome criteria for achievement and effectiveness of nursing care to be certain that expected outcomes have been achieved.
10. Identify areas of care related to family nursing that could benefit from additional nursing research or the application of evidence-based practice.
11. Integrate knowledge of family nursing with nursing process to promote quality maternal and child health nursing care.

Marlo Hanovan is a 32-year-old who has a 10-year-old child, Carey, from a first marriage. Carey has been sick since birth with cystic fibrosis. He attends the local grade school although he needs daily respiratory therapy. Stone, Marlo's present husband, has a 2-year-old son, Brian, from his first marriage who is also part of the family. Stone is currently unemployed because of an accident at work a year ago. He has some income from selling woodworking products at craft shows. Mrs. Hanovan, a freelance writer, is pregnant now with a second child. She states that on many weeks she is forced to choose between health care and groceries.

The previous chapters discussed the philosophy of maternal and child health nursing and how cultural mores affect care. This chapter adds information about families and how nurses can help ensure healthy outcomes for families. Inadequate family support, which can occur in a dysfunctional family, can contribute to poor pregnancy outcome or poor childrearing practices.

Is the Hanovan family a well family? Is their structure typical of other American families?

Humans have always lived in families, but the types of families formed and family goals established have changed as the rest of the world has changed. For example, when the largest number of families lived on farms, families were extended or had a wealth of relatives close by for both physical and psychological support. As more people moved into cities, families became typically nuclear with only two parents and children present. Less support was available to families. Today, the most frequent type of family seen in the United States is a single-parent family (National Center for Health Statistics [NCHS], 2009). This has important implications for nurses as parents in this type of family may not even have one other adult to give them support. This makes families look more to health care providers for guidance when a problem with pregnancy or childrearing occurs (Crombleholme, 2009).

Families are important to a country as no other social group has the potential to provide the same level of support and long-lasting emotional ties as a person's own family. What people learn in their family determines how they relate to people, what moral values they learn, and their perspective on both the present and the future (Clay et al., 2007).

Maintaining healthy family life is so important to the health and welfare of the nation that several National Health Goals speak directly to maintaining healthy family and community life (Box 3.1). Because the family has such an influence on the individual, nursing care that considers the family, not the individual **(family nursing)**—is a focus of modern nursing practice. **Family theory** details a set of perspectives from the family's point of view that can help nurses address the important health issues of childbearing and childrearing families.

BOX 3.1 * Focus on National Health Goals

Several National Health Goals focus on ways to improve the quality of family or community life. Representative of these are:

- Lower the current baseline of 25.2 per 1000 children younger than age 18 who are maltreated.
- Reduce physical abuse directed at women by male partners to no more than 27 per 1000 couples from a current baseline of 30 per 1000 couples.
- Eliminate the prevalence of blood lead levels exceeding 10 μg/dL in children aged 1 month to 6 years from a baseline of 4.4% (http://www.nih.gov).

Nurses can help to see that goals such as these for healthier family living are met by assessing families and their environment to identify families at risk, assisting with counseling, and maintaining contact with families to ensure that as a family grows its changing needs can be recognized and met. Intimate partner and child abuse are further discussed in Chapter 55; lead poisoning from excessive lead in the environment is discussed in Chapter 52.

For a family to adjust to a new family member, the family must have structure and roles that are flexible enough to adjust to the changes that pregnancy and a newborn will bring. An ill family member or one who is going through a difficult developmental period, such as adolescence, can put a tremendous strain on a family as well. The roles individuals assume in the family and their ability to adjust to new roles can influence a family's perception of the child's illness, as well as the family's ability to adjust to new situations and work through difficult times to a positive family outcome. Because families do not live in isolation, the family's ability to thrive in a community and gain strength from the community is equally important. For this reason, the modern concept of maternal and child health nursing is not limited to assessing individuals or individual circumstances but rather examines them first from a family and community standpoint (Shields, et al., 2009).

Family-centered maternal and child health nursing considers the strengths, vulnerabilities, and patterns of families to support families during childbirth and childrearing and to encourage healthy coping mechanisms in families facing a crisis. Health assessment and intervention planning is best when it includes considerations of the family's social, emotional, spiritual, and financial resources, as well as the physical and emotional condition of the home and the community.

Nursing Process Overview

For Promotion of Family Health

Assessment

Assessment of the structure, function, strengths, and challenges of families provides information on the ability of a family to remain well during both calm and stressful times. It can reveal the meaning of a current health situation as well as the emotional support an individual family member can expect from other members or the community. This can be vital to understanding what a pregnancy or childhood illness will mean to different family members, especially if not all members appear to be in agreement.

Nursing Diagnosis

Nursing diagnoses formulated for families generally relate to a family's ability to handle stress and to provide a positive environment for growth and development of members. Examples are:

- Parental role conflict related to prolonged separation from child during long hospital stay
- Interrupted family processes related to emergency hospital admission of oldest child
- Impaired parenting related to unplanned pregnancy
- Ineffective family coping related to inability to adjust to mother's illness during pregnancy
- Readiness for enhanced family coping related to improved perceptions of child's capabilities
- Health-seeking behaviors related to birth of first child

"Impaired parenting" and "parental role conflict" are diagnoses that suggest parents need additional help with parenting. The first family coping diagnosis ("ineffective

family coping") indicates that a family is not functioning at an optimal level; the second ("readiness for enhanced family coping") suggests a family that is ready for new growth because of a specific event, such as sudden illness in a child or discovery of an unplanned pregnancy. "Readiness for enhanced parenting" and "health-seeking behaviors" are diagnoses that apply to families who are investigating more effective ways to manage their present situation and improve family/community functioning.

Outcome Identification and Planning

Planning for nursing care is most effective if it includes a design that is family centered and so is both appropriate and desired by the majority of family members; otherwise, opposing family members may have difficulty following the plan. Be certain that plans also consider the community. For example, it is not helpful to suggest that a family take regular walks together to encourage shared decision making and improve family communication if walking in their neighborhood park is unsafe; participation in a family aerobics class at a local YMCA might be a more practical suggestion. To help women balance family and work, an interesting website to visit is The National Partnership for Women & Families (http://www.nationalpartnership.org).

Implementation

Implementations to improve family health should flow smoothly if family members have agreed on a plan of action out of support for one another. It may be necessary in some instances, however, to encourage family members to agree on a plan or to abide by a chosen plan. Otherwise, they can expend needless energy carrying out an activity that is counterproductive or in direct opposition to their major goal.

Outcome Evaluation

Evaluation should reveal not only that a goal was achieved but also that the family feels more cohesive after working together toward the goal. If evaluation does not reveal these two factors, reassess the goal as necessary to determine whether further interventions are required. Examples of expected outcomes that might be established are:

- Family members state they are adapting well to the presence of a newborn.
- Mother states she feels prepared to manage home care of her ill child.
- Father states he has arranged the family finances to accommodate new health care expenses for his family.
- Grandmother states she will omit trans-fatty acids from cooking to better safeguard the health of her family.

THE FAMILY

How well a family works together and how well it can organize itself against potential threats depend on its structure (who its members are) and its function (the activities or roles family members carry out). Recognizing different family structures can help you focus on family-centered care or provide a family-friendly environment for health care (Crea, Barth, & Chintapalli, 2007).

Defining the Concept of Family

A **family** is defined by the U.S. Census Bureau (2009) as "a group of people related by blood, marriage, or adoption living together." This definition is workable for gathering comparative statistics but is limited when assessing a family for its health concerns or the support people available, because some families are made up of unrelated couples, and at certain points in life not all family members may live together. Allender and Spradley (2008) define the family in a much broader context as "two or more people who live in the same household (usually), share a common emotional bond, and perform certain interrelated social tasks." This is a better working definition for health care providers because it addresses the broad range of types of families that could be encountered in any health care setting.

Family Types

Many types or structures of families exist, and family structures change over time as they are affected by birth, work, death, divorce, and the growth of family members. For the purposes of assessing families in maternal and child health nursing, two basic family types can be described:

- **Family of orientation** (the family one is born into; or oneself, mother, father, and siblings, if any)
- **Family of procreation** (a family one establishes; or oneself, spouse or significant other, and children)

Almost all families, regardless of type, share common activities (Cherlin, 2008). They influence the health and activities of their members (Chen, Shiao, & Gau, 2007). Specific descriptions of family types vary greatly depending on family roles, generational issues, means of family support, and sociocultural influences.

The Dyad Family

A dyad family consists of two people living together, usually a woman and a man, without children. Newly married couples, as an example, are dyad families. This category also refers to single young same sex adults who live together as a dyad in shared apartments, dormitories, or homes for companionship and financial security while completing school or beginning their careers. Dyad families are generally viewed as temporary arrangements, but if the couple chooses childfree living, this can also be a lifetime arrangement.

The Cohabitation Family

Cohabitation families are composed of heterosexual couples, and perhaps children, who live together but remain unmarried. Although such a relationship may be temporary, it may also be as long-lasting and as meaningful as a more traditional alliance. Many couples choose cohabitation as a way of getting to know a potential life partner better before marriage as it seems as if this might make their eventual marriage stronger. Statistically, however, couples who cohabit before marriage have a higher divorce rate than those who do not (Cherlin, 2008). This may occur because cohabitation couples enter the union without a real commitment. That is a contrast to married couples who enter a union with a "until death do I part" philosophy. The feeling that a union can be

easily broken may influence a couple not to work at a marriage but merely walk away from that as well.

When in place, an effective cohabitation arrangement offers psychological comfort and financial security similar to marriage. Long-term cohabitation unions of this type are growing in number. The increasing numbers to adhere to a monogamous relationship through cohabitation could help contribute to decreasing sexually transmitted infections and decrease the financial burdens on the cohabiters. Because cohabitation unions simulate dyads, they offer the same companionship and security as dyad families.

The Nuclear Family

The traditional nuclear family structure is composed of a husband, wife, and children. In the past, it was the most common structure seen worldwide. Today, however, in the United States, the number of nuclear families has declined to about 49% of families. This is because of the increase in divorce, acceptance of single parenthood, and the greater acceptance of alternative lifestyles (NCHS, 2009). An advantage of a nuclear family is its ability to provide support to family members, because, with its small size, people know each other well and can feel genuine affection for each other. In a time of crisis, this same characteristic may become a challenge to a family as there are few family members to share the burden and offer support. Helping nuclear families locate and reach out to support people during a crisis can be an important nursing responsibility.

The Polygamous Family

Although **polygamy** (a marriage with multiple wives) has been illegal in the United States since 1978 and so is rarely seen today, such marriages are not that unusual an arrangement worldwide. New immigrants, particularly those from the Middle East, may have been raised in this type of family (Elbedour, Bart, & Hektner, 2007).

Polygyny (a marriage with one man and several wives) tends to occur in nations where women have low social status or are not valued for their individual talents. It can be attractive for men as it allows for sexual variety. It can serve as the mark of a wealthy man as wives cost money. With more than one wife having children, it also increases the chance that the marriage will produce a male heir. Advantages to women are that women in polygyny marriages are able to have fewer children than if they were a lone wife so it lowers their chance of dying in childbirth, a concern for women in nations where prenatal care is not a high national priority. If differences in wealth are great, women may prefer polygyny to being the wife of a poor man. Problems that can arise are jealousy and rivalry between wives because of perceived favoritism (Gibson & Mace, 2007).

The Extended (Multigenerational) Family

An extended family includes not only the nuclear family but also other family members such as grandmothers, grandfathers, aunts, uncles, cousins, and grandchildren. An advantage of such a family is that it contains more people to serve as resources during crises and provides more role models for behavior or values. A possible disadvantage of an extended family is that family resources, both financial and psychological, must be stretched to accommodate all members. In a typical extended family, although many members are present, there is usually only one main income provider and that can strain the family's resources. When assessing such families, remember that because many members are present, a parent's strongest support person may not be a spouse or intimate partner, and a child's primary caregiver may not be his or her own mother or father. The grandmother or an aunt or another sibling, for example, may provide the largest amount of support or child care, even though spouses and the child's parents are also present every day.

The Single-Parent Family

The incidence of single-headed families has increased from 10% of all families in 1960 to almost 51% today. Of these families, 17% have a man as the single parent (NCHS, 2009). A health problem in a single-parent family is almost always compounded. If the parent is ill, there is no back-up person for child care. If a child is ill, there is no close support person to give reassurance or a second opinion on whether the child's health is worsening or improving.

Low income is often an additional problem encountered by single-parent families, because the parent is most often a woman. Traditionally, women's incomes are lower than men's by about 33% (Cherlin, 2008). Single parents also may have difficulty with role modeling or clearly identifying their role in the family (i.e., they must provide duplicate roles, or financial support as well as child care). Trying to fulfill several central roles in this way is not only time-consuming but also mentally and physically exhausting and, in many instances, not rewarded. Such a parent may develop low self-esteem if things are not going well, especially if a spouse left them for another or if the other parent refuses to help with child support. Single-parent fathers may have difficulty with home management or child care if they had little experience with these roles before the separation. Such feelings have the potential to interfere with decision making and impede daily functioning.

Single-parent families have a special strength in that such a family can offer the child a special parent–child relationship and increased opportunities for self-reliance and independence. If there has been a divorce, one parent may have been given legal custody of the children or both parents may have joint custody. Either way, both parents often participate in decision making. At a time of illness, both may stay with the ill child in the hospital and be eager to receive reports of the child's progress. Identifying who is the custodial parent is especially important when consent forms for care are signed.

The Blended Family

In a blended family, or a remarriage or reconstituted family, a divorced or widowed person with children marries someone who also has children. Advantages of blended families include increased security and resources for the new family. Another benefit is that the children of blended families are exposed to different customs or culture and may become more adaptable to new situations.

Childrearing problems may arise in this type of family from rivalry among the children for the attention of a parent. In addition, each spouse may encounter difficulties in helping rear the other's children. Often stepparents believe they have been thrust into a limited or challenged role of authority. Children may not welcome a stepparent because they

have not yet resolved their feelings about the separation of their biologic parents (through either divorce or death); the stepparent may differ from the biologic parent, particularly in terms of discipline and caregiving; or they may believe that the stepparent threatens their relationship with their biologic parent. They also may have heard so many stories about evil stepparents that they come to the new family prejudiced against their new parent. They may become extremely distressed at seeing their other biologic parent move into another home and become a stepparent to other children.

Although blended families usually lessen financial difficulties, finances can be severely limited, especially if one or both parents are obligated to pay child support for children from a previous marriage while supporting the children of the current marriage. If there is economic disparity between the biologic parents, conflicts and distorted expectations can occur. Nurses can be instrumental in offering emotional support to members of a remarriage family until the adjustments for mutual living can be made.

The Communal Family

Communes are formed by groups of people who choose to live together as an extended family. Their relationship to each other is motivated by social or religious values rather than kinship (Cherlin, 2008). The values of commune members may be more oriented toward freedom and free choice than those of a traditional family. Some communes are described as cults or composed of a group of people who follow a charismatic leader. Adolescents, because they are in the process of determining what values to adopt for their future life, may find this type of commune particularly appealing.

People living in a commune may have difficulty following traditional health care regimens, preferring instead to use complementary or alternative therapies (health care may be seen as an established system that they are rejecting). On the other hand, people who reject traditional values may be the most creative people in a community, the most interested in participating in their own care, and ripe for health teaching and learning.

The Gay or Lesbian Family

In homosexual unions, individuals of the same sex live together as partners for companionship, financial security, and sexual fulfillment. Such a relationship offers support in times of crisis comparable to that offered by a nuclear or cohabitation family. Some lesbian and gay families include children from previous heterosexual marriages or through the use of artificial insemination, adoption, or surrogate motherhood. Laws governing homosexual partners can affect health care if they limit health insurance coverage. Lack of understanding by health care providers of the strength and richness of these unions can further impede health care (Short, 2007).

✔ Checkpoint Question 3.1

The Hanovan family was a single-parent family before Mrs. Hanovan remarried. What is a common concern of single-parent families?

a. Reading disorders are common.
b. Finances are inadequate.
c. Children miss many days of school.
d. Children do not know any other family like theirs.

The Foster Family

Children whose parents can no longer care for them may be placed in a foster or substitute home by a child protection agency (Risley-Curtiss & Stites, 2007). Foster parents may or may not have children of their own. They receive remuneration for their care of the foster child. Foster home placement is theoretically temporary until children can be returned to their own parents. If return is impossible or is not imminent, children, unfortunately, may be raised to adulthood in foster care. Such children can experience almost constant insecurity, concerned that soon they will have to move again. In addition, they may have some emotional difficulties related to the reason they were removed from their original home (Rubin et al., 2007).

Most foster parents are as concerned with health care as the biologic parents. They can be entrusted to follow health care instructions as needed. When caring for children from foster homes, be certain to determine who has legal responsibility to sign for health care for the child (many times the child protection agency is the one with legal responsibility).

The Adoptive Family

Many types of families (nuclear, extended, cohabitation, single-parent, gay and lesbian) adopt children today. No matter what the family structure, adopting brings several challenges to the adopting parents and the child, as well as to any other children in the family (Fontenot, 2007).

Methods of Adoption

Agency Adoption. In traditional agency adoption, a couple usually contacts an agency by first attending an informational meeting. If the couple decides to apply to the agency, they are then put on a waiting list for processing that will include extensive interviewing and a home visit by an agency social worker to determine whether the couple can be relied on to provide a safe and nurturing environment for an adopted child. Once approved by the agency, the couple is placed on a second waiting list until a child is available. Depending on the area of the country and the couple's particular requests, this second waiting period may extend from a few months to 5 or 6 years. There are children in every state waiting for adoption and who can be placed immediately into adopting homes, but most of these children are older, have special care needs, or are of a different ethnic or cultural background from the prospective adoptive parents. They often have lived with many foster families or have gone back and forth between the homes of their birth parents and foster care many times to reach this point in life. Although adopting special needs children is not an option that is appealing for every couple, adoption of such children can be extremely rewarding for the right couple and can achieve an immediate family for them. Counsel parents to obtain a clear health history of any child they adopt so they can be aware of potential health problems and better prepared to help with health care decisions about their child.

Historically, there was little or no communication between a woman placing her baby for adoption and an adopting couple. This was seen as an advantage because the birth mother could then not interfere in the new couple's lives. Today, the disadvantage of this arrangement for the child is being realized: should a child want to learn his or her birth family's

name or medical history or location, this information is not available. This has led to "open adoption" procedures, in which the identity of neither the birth mother nor the adoptive parents is kept secret, allowing as much interaction as desired between the two sets of parents (Wolfgram, 2008).

International Adoption. As many as 20,000 children are adopted to the United States from other countries yearly (Hellerstedt et al., 2008). International adoption can often provide a baby in less time than a traditional agency adoption but may create unanswered questions about prenatal health care or the birth parent's background. In addition, countries that are willing to permit abandoned or orphaned children to be adopted internationally are often economically disadvantaged or war torn, meaning the child's health or development may have suffered. War conditions may allow children to be released from the country one day but not the next. This means that couples who are waiting for an international adoption must be ready at a moment's notice to travel to the foreign country or to a neutral location to pick up their child or to give up the adoption because political reforms have stopped the release of children.

A home visit from a local agency and a significant amount of paperwork and communication with the international agency are usually required before a family can be approved for this type of adoption. Typically, the adoption is final before the child enters the country or shortly afterward. Encourage parents to examine their feelings ahead of time about having a child from a different culture. Help them explore ways to respect the child's natural heritage and deal with possible prejudice toward the child by neighbors and family who are not as culturally accepting as they are. Local support groups consisting of other families who have successfully adopted internationally can be helpful to couples considering this option. In addition, many of the international adoption agencies provide follow-up support. It may be difficult for internationally adopted children to learn about or locate their natural parents in years to come, because records of their birth may have been destroyed or changed in their native countries. In some countries, the birth certificate is deliberately changed to reflect the adoptive couple as the birth parents.

Private Adoption. For families who have exhausted other options or who cannot wait for the traditional agency adoption process, private adoption is another alternative. With private adoption, the adopting parents usually agree to pay a certain amount of money to a birth mother, part of which presumably goes toward the birth mother's prenatal and medical expenses. Sometimes, strict anonymity is maintained between the two parties; in other instances, the adopting couple and birth mother come to know each other well. Some pregnant women prefer to place their child for adoption directly with a couple this way rather than through an agency, so they can approve of the couple and maintain contact with the child afterward. The adopting parents might even attend the child's birth if the birth mother wishes.

The Internet has become a source where women wanting to place a baby for adoption can contact couples who want to adopt. Usually, a lawyer serves as the go-between to make certain all the legal ramifications of adoption have been considered by each party. It is important to caution adopting parents that Internet sites may not be reliable. They need to be certain to obtain a reliable health history on the child and discuss what will be their legal responsibility if the child is born with a health problem or dies at birth.

In some instances, close familiarity between the two parties creates difficulties later on: some couples may want to have the birth mother or father play a continued role in their lives, but others do not. If not, the birth mother may find it difficult to lose contact not only with the baby she has carried for 9 months but also with her new friends, who may have been extremely supportive of her during her pregnancy. These issues need to be worked out legally well in advance of the birth, because it is possible for a birth mother to change her mind about giving up her baby before the adoption is finalized. There is little that an adopting couple can do in this circumstance, because court decisions tend to favor the rights of the birth mother. Parents who adopt by this route may live in fear for years that the birth mother will change her mind. Although many states have laws that place a time limit on the period during which the birth mother can change her mind, many courts have ruled in favor of returning an adopted child to the birth mother no matter what period of time has elapsed.

Caring for Adoptive Families

Regardless of the type of adoption, new parents should visit a health care facility shortly after a child is placed in their home so that a baseline of health information on the child can be obtained, potential problems can be discussed, and solutions can be explored. If the birth mother of an adopted child ate inadequately or received little prenatal care, for example, the adopted child is at a higher risk for abnormal neurologic development than he or she would normally be. Children from countries that are war torn or poverty stricken have a greater risk of having illnesses such as hepatitis B, intestinal parasites, and growth restriction. They may lack immunizations (Bramlett, Radel, & Blumberg, 2007).

When assessing a family with a newly adopted child, determine the stage of parenting the parents have reached. The average parents have 9 months to prepare physically and emotionally for a coming baby. Although adoptive parents may have been planning on a baby for much longer than 9 months, the actual appearance of a child can occur suddenly. In a few days' time, the adoptive parents are asked to make the mental steps toward parenthood that biologic parents make over 9 months. There may be a great need at health care visits to explore their feelings about this change in their lives and their feelings about being parents so suddenly. If they have low self-esteem because they were unable to conceive or married a partner who was unable to conceive, they may need reassurance at health care visits that they are functioning well as parents. With the increase in foreign adoptions, parents often express a conflict between trying to preserve the child's native culture and socializing the child into the community and appreciate having this problem addressed.

Also be sure to assess siblings' responses to the adopted child. Biologic children (whether born before or after the adoption) may feel inferior to the adopted child because they were "just born," not "chosen." On the other hand, they may feel superior because they are the "real" children of the parents. These feelings can interfere with their relationship with the adopted child as well as their parents.

It is generally accepted that adopted children should be told as early as they can understand that they are adopted.

Knowing this from early childhood is not nearly as stressful as accidentally stumbling onto the information when they are school-aged or adolescents. By 3 years old, children are able to understand the story of their adoption. It is important for parents not to criticize the birth mother as part of the explanation to help build the child's self-esteem.

When children are first told they are adopted, they may exhibit "honeymoon behavior" or may try to behave perfectly for fear of being given away again. After this honeymoon period, children may deliberately test their parents to see whether, despite bad behavior such as disobeying or even shoplifting, the parents will still keep them. It helps parents to put this behavior in perspective if they are aware that it may happen and that nonadoptive children may use the same testing strategies on some occasions.

Counseling an adopted child or forming a relationship with one as a health care provider carries additional responsibility by making certain that the relationship is not ended abruptly or without closure. When ending a relationship, try to introduce the person who will continue health supervision for the child so the child does not feel abandoned. When hospitalized, all preschoolers worry about being abandoned and left in the hospital. Preschoolers who have just been told they are adopted, that they were chosen by their adoptive parents "from all the babies in the hospital nursery," may be terribly afraid that they are now being returned to the hospital to be given back. Parents of an adopted child may need additional help in preparing the child for the hospital experience and to be encouraged to stay with the child in the hospital as much as possible to reduce these types of postadoption fears.

As adopted children enter puberty and begin to think about having children of their own, they may begin to worry whether they will make good parents. Some children of this age have difficulty establishing a sense of identity because they do not know who their birth parents were. It is common for them to spend time tracing records and trying to locate their birth parents. Counsel adopting parents that this is not a rejection of them but a normal consequence of being adopted. Children seek their birth parents not because they do not love their adoptive parents but because they need that information to know where they fit into the eternal scheme of life.

FAMILY FUNCTIONS AND ROLES

A family is a small community group, and, as a group, it works best if it can designate certain people to complete certain tasks. Otherwise, it is easy for work to be duplicated or never completed. The family roles that people view as appropriate are usually the ones they saw their own parents fulfilling. As each new generation takes on the values of the previous generation, family traditions and culture pass to the next generation.

Because family roles are more flexible and often not as well defined as in the past, an important part of family assessment is to identify the roles of family members. Most families, for example, can identify an individual who serves as the wage earner or who supplies the bulk of the income for the family. In the past, this was the father, but today, it may just as easily be the mother. Also identified can be a financial manager (the person who pays the bills), a problem-solver, a decision-maker, a nurturer, a health manager, an environmentalist, a culture bearer, and a gatekeeper or the person who allows information into and out of the family. Knowing who fulfills these roles in a family helps you to work most effectively with the family.

If a hospitalized child will need continued care after he or she returns home, for example, it would be important to identify and contact the nurturing member of the family, because this person is probably the one who will supervise or give the needed care at home. Be careful not to make assumptions about role fulfillment based on gender or stereotyping, because every family operates differently. Although nurturing has typically been thought of as a female characteristic, many men fill this role today.

✔ Checkpoint Question 3.2

Mrs. Hanovan serves many roles in her family. If, when you talk to Carey, her 10-year-old son, she interrupts to say, "Don't tell our family secrets," she is fulfilling what family role?

a. Decision-maker
b. Gatekeeper
c. Problem-solver
d. Safety officer

Family Tasks

Duvall and Miller (1990) identified eight tasks that are essential for a family to perform to survive as a healthy unit. These tasks differ in degree from family to family and depend on the growth stage of the family, but they are usually present to some extent in all families. Wellness behaviors such as these may decrease during periods of heightened stress. Therefore, assessing families for these characteristics is helpful in establishing the extent of stress on a family and empowering the family to move toward healthier behaviors.

- *Physical maintenance:* A healthy family provides food, shelter, clothing, and health care for its members. Being certain that a family has enough resources to provide for a new or ill member is an important assessment.
- *Socialization of family members:* This task involves preparing children to live in the community and to interact with people outside the family. It means the family has an open communication system among family members and outward to the community. A family that lives in a community with a culture or values different from its own may find this a difficult task.
- *Allocation of resources:* Determining which family needs will be met and their order of priority is allocation of resources. In healthy families, there is justification, consistency, and fairness in the distribution. Resources include not only material goods but also affection and space. In some families, resources are limited, so, for example, no one has new shoes. A danger sign would be a family in which one child is barefoot while the others wear $100 sneakers.
- *Maintenance of order:* This task includes establishing family values, establishing rules about expected family responsibilities and roles, and enforcing common regulations for family members such as using "time out" for toddlers. Determining the place of a new infant and what rules will pertain to him or her may be an important task for a developing family. In healthy families, members know the family rules and respect and follow them.

- *Division of labor:* Healthy families evenly divide the work load among members and are flexible enough that they can change work loads as needed. Pregnancy or the illness of a child may change this arrangement and cause the family to have to rethink family tasks.
- *Reproduction, recruitment, and release of family members:* Often not a great deal of thought is given to this task; who lives in a family often happens more by changing circumstances than by true choice. Having to accept a new infant into an already crowded household may make a pregnancy a less-than-welcome event or cause reworking of this task.
- *Placement of members into the larger society:* Healthy families realize that they do not have to operate alone but can reach out to other families or their community for help when needed. Because they have the ability to be sensitive to the needs of individual family members they are able to select community activities, such as schools, religious affiliation, or a political group, that correlate with the family's beliefs and values. Selecting a birth setting, a special school setting, or choosing a hospital or hospice setting is part of this task.
- *Maintenance of motivation and morale:* Healthy families are able to maintain a sense of unity and pride in the family. When this is created, a sense of pride helps members defend the family against threats as well as serve as support people for each other during crises. It means that parents are growing with and through the experience of their children the same as children are growing through contact with the parents. Assessing whether this feeling is present tells you a lot about the overall health of a family.

Family Life Cycles

Families, like individuals, pass through predictable developmental stages (Duvall & Miller, 1990). To assess whether a family is using stage-appropriate health promotion activities, it is helpful to first determine a family's developmental stage. The age of the oldest child marks the stage. Because families are delaying the age at which they have a first child and parents are living longer, the lengths of stages 1, 7, and 8 are growing.

Stage 1: Marriage

Although Duvall referred to this stage as marriage, what occurs during it is also applicable to couples forming cohabitation, lesbian/gay, or single alliances. During this first stage of family development, members work to:

- Establish a mutually satisfying relationship
- Learn to relate well to their families of orientation
- If applicable, engage in reproductive life planning

Establishing a mutually satisfying relationship includes merging the values that the couple brings into the relationship from their families of orientation. This includes not only adjusting to each other in terms of routines (e.g., sleeping, eating, housecleaning) but also sexual and economic aspects. This first stage of family development is a tenuous one, as evidenced by the high rate of divorce or separation of partners at this stage. The illness of a family member or an unplanned pregnancy at this stage may be enough to destroy the still lightly formed bonds if the partners do not receive support from their former family members or health care providers do not recognize a problem exists.

Stage 2: The Early Childbearing Family

The birth or adoption of a first baby is usually both an exciting and a stressful event because it requires both economic and social role changes. An important nursing role during this period is health education about well-child care and how to integrate a new member into a family. It is a further developmental step for a family to change from being able to care for a well baby to being able to care for an ill one. One way of determining whether a parent has made this change is to ask what the new parent has tried to do to solve a child-rearing or health problem. Even if what the person answers is not therapeutic or the best solution to the problem, as long as it is sensible (not "I don't do anything when the baby's sick; just take her right to my mother" but instead, "I've been trying to give her a little water and keep her temperature down"), it probably means the parent has mastered this developmental step. Parents who have difficulty with this step need a great deal of support and counseling from health care providers to be able to care for an ill child at home or to manage a difficult pregnancy.

Stage 3: The Family With a Preschool Child

A family with preschool children is a busy family because children at this age demand a great deal of time. Their imagination is at such a peak that safety considerations such as avoiding unintentional injuries (accidents) become a major health concern. If a child is hospitalized because of an accident, parents may have difficulty giving care because they feel they should have done more to prevent the child's injury. It may be difficult for parents to room in at the hospital because they have other young children at home who need care. If the child returns home for further care, a family in this stage may need continued support and help from a community health nurse to provide necessary health care for the ill child.

Stage 4: The Family With a School-Age Child

Parents of school-age children have the important responsibility of preparing their children to function in a complex world while at the same time maintaining their own satisfying marriage relationship. That makes this a trying time for many families. Family support systems seem strong but also can be deceptive: family members may be physically present but provide little or no emotional support if internal tension exists. Illness imposed at this stage adds to the burdens already present and may be enough to dissolve a family. Many families during this period need to turn to a tertiary level of support, such as friends, a religious affiliation, or counseling, for adequate support.

Important nursing concerns during this family stage are monitoring children's health in terms of immunization, dental care, and health care assessments; monitoring child safety related to home or automobile accidents; and encouraging a meaningful school experience that will make learning a lifetime concern, not one of merely 12 years.

Stage 5: The Family With an Adolescent

The primary goal for a family with a teenager differs considerably from the goal of the family in previous stages, which was to strengthen family ties and maintain family unity.

Now the family must loosen family ties to allow adolescents more freedom and prepare them for life on their own. As technology advances at a rapid rate, the gap between generations increases. Life when the parents were young was very different from what it is for their teenagers. This can make stage 5 a trying stage for both children and adults.

Violence—accidents, homicide, and suicide—is the major cause of death in adolescents (NCHS, 2009). As adolescents become sexually active, they risk contracting sexually transmitted infections such as human immunodeficiency virus (HIV) and gonorrhea. A nurse working with families at this stage needs to spend time counseling members on safety (driving defensively and not under the influence of alcohol; safer sex practices; proper care and respect for firearms) and the dangers of chemical abuse. If there is a "generation gap" between the parents and an adolescent, the adolescent may not be able to talk to the parents about these problems, particularly those of a controversial nature such as sexual responsibility. A nurse can be a neutral person to assist families at this stage when communication can be difficult while maintaining confidentiality between the family members.

Stage 6: The Launching Stage Family: The Family With a Young Adult

For many families, the stage at which children leave to establish their own households is the most difficult stage because it appears to represent the breaking up of the family. Parental roles change from those of mother or father to once-removed support people or guideposts. The stage may represent a loss of self-esteem for parents, who feel themselves being replaced by other people in their children's lives. They may feel old for the first time and less able to cope with responsibilities. Illness imposed on a family at this stage can be detrimental to the family structure, breaking up an already disorganized and noncohesive group.

Many young adults return home to live with their family after college until they can afford their own apartment or get married. They are termed a "boomerang" generation. As a general rule, this arrangement works best if there are no young children in the home and if the young adult has a job to supply some income. Males tend to remain home longer than females and females are generally asked to do more work around the house and are chaperoned more closely by parents.

A nurse can serve as an important counselor to such a family. He or she can help the parents see that what their children are doing is what they have spent a long time preparing them to do, or that leaving home is a positive, not a negative, step in family growth.

Stage 7: The Family of Middle Years

When a family returns to a two-partner unit, as it was before childbearing, the partners may view this stage either as the prime time of their lives (an opportunity to travel, economic independence, and time to spend on hobbies) or as a period of gradual decline (lacking the constant activity and stimulation of children in the home, finding life boring without them, or experiencing an "empty nest" syndrome). They may realize that they have grown in such different ways that they have very little in common any more. Women tend to experience less "empty nest" feelings than previously because few women in developed countries measure their worth by only their ability to care for children (Cherlin, 2008).

Because the family has returned to a two-partner union, support people may not be as plentiful as they were. Having children return home to live after college or a failed relationship can create a "sandwich family," or parents who are squeezed into taking care of both their aging parents and these returning young adults.

Stage 8: The Family in Retirement or Older Age

Families of retirement age account for approximately 15% to 20% of the population (NCHS, 2009). Although families at this stage are not having children, they remain important in maternal and child health because they can offer a great deal of support and advice to young adults who are just beginning their families. Many grandparents care for their grandchildren while the parents are at work. This can be a strain on older adults as they struggle to meet young children's needs in relation to both energy level and finances needed.

✔Checkpoint Question 3.3

The Hanovan family consists of two parents plus Carey, age 10, and Brian, 2. Mrs. Hanovan is 5 months pregnant. Which of Duvall's family life stages is the family currently experiencing?

a. Pregnancy stage
b. Preschool stage
c. School-age stage
d. Launching stage

Changing Patterns of Family Life

Family life has changed significantly in the United States during the past 50 years because of many complex and interrelated factors, such as the increased mobility of families, an increase in the number of families in which both parents work outside the home (dual-earner families), an increase in the number of single-parent families, and an increase in shared childrearing responsibilities. Many couples delay marriage and childrearing until they are completely finished with school and established in their careers. This delay has implications for fertility and the need for assisted reproduction strategies. Some parents, believing they were finished with childrearing, are surprised to find their grown children returning home after college to live with them again. Others find themselves playing duel rules by caring for both children and aging parents. Understanding the impact these changes have on family structure and family life can help you create care plans that are realistic and meet the needs of today's families.

Increasing Mobility Patterns

Population movement has an important influence on the quality of family life. During the 20th century, vast numbers of rural families moved to urban communities, and many urban families moved to the suburbs. Today, families are moving back to inner cities to fill remodeled buildings that once held factories or served as warehouses (gentrification). This pattern of mobility is expected to continue into the future. This can mean that an area with many maternal and child health care facilities may find itself with few women and children to use them in the future; conversely, areas with

many women and children may find few nearby facilities. This can cause a problem as parents will travel a great distance to obtain health care for an ill child or during a pregnancy with complications, but they are less likely to do so for health maintenance or health promotion; therefore, prenatal care or routine immunizations may be neglected. When assessing families, always ask if a family has ready accessibility to health care (Box 3.2).

Families of immigrants or migrant farm workers can have difficulty finding consistent health care because of their seasonal movement (Connor et al., 2007). Children from these families may also be at high risk for intestinal parasites, low socioeconomic status, and lack of immunizations. New immigrants have special problems in that they must adjust not only to a new country but also to a differently structured health care system than they have become accustomed to in their home country. If they entered the country illegally, their ability to even locate health care can be further compromised. Nurses can be instrumental in seeing that health care organizations consider these issues and institute innovative measures, such as providing transportation to facilities, changing locales or services so facilities and needs remain balanced, or setting up outreach and translator programs so families who are not proficient in English can receive adequate health care.

BOX 3.2 ✻ Focus on Communication

The Hanovan family consists of Mr. and Mrs. Hanovan and two children, Carey, age 10, and Brian, 2. You are concerned because Brian has missed so many health maintenance visits that he is underimmunized.

Less Effective Communication

Nurse: It's good to see you in clinic today, Ms. Hanovan. I know money is a problem, but you've got to start coming more often until your child gets caught up with immunizations.
Ms. Hanovan: It's hard with a 2-year-old—
Nurse: Babies, you know, have almost no natural immunity. That's why they need immunizations.
Ms. Hanovan: It's hard—
Nurse: It's hard to understand any reason important enough not to get him immunized.
Ms. Hanovan: I'll do better. I promise.

More Effective Communication

Nurse: It's good to see you in clinic today, Ms. Hanovan. I know money is a problem, but you've got to start coming more often until Brian gets caught up with his immunizations.
Ms. Hanovan: It's hard with a 2-year-old—
Nurse: Is there something I could do to make coming to the clinic easier?
Ms. Hanovan: I should never come. Brian's outgrown his car seat and it's illegal for me to drive him here.
Nurse: Let me give you the number of an agency to call to borrow a seat, not only so you can come to the clinic but so you can take him out safely at other times.

In our zeal to educate people about good health practices, it is easy to rush in and teach without first assessing a family's most important needs. Unless these needs are met, people may agree to comply with a better health regimen but then be unable to do so because their original need was not met.

Changing Cultural Patterns

Although families are more mobile today than formerly, cultural values and characteristics remain constant. Knowing some of the basic norms and taboos of different cultural groups is important as it allows you to understand and accept different practices of families. It helps you understand the family's value system and the degree of support family members are apt to have available.

Poverty tends to be a problem for nondominant (minority) ethnic groups. Characteristic responses that are sometimes described as cultural limitations are actually the consequences of poverty—for example, a mother seeking medical care for her child late in the course of an illness or late in pregnancy for herself is just as apt to be a financial influence as a cultural one. Solving this type of problem may be a question of locating financial resources rather than overcoming cultural influences.

Increasing Poverty

Although the United States is a large and wealthy country, extreme poverty also exists, and in some areas, the incidence is growing. As many as 20% of families with children have incomes that fall below the poverty line. This places children and families at risk for a variety of health problems (Kilanowski & Ryan-Wenger, 2007). A pregnant woman living in poverty, for example, is less likely to receive prenatal care or be able to afford important prenatal vitamins.

Each year the government determines the poverty level by computing the cost of food for a family of four. An average family spends about one-third of their income on food. A family that earns less than triple that defined price of food, therefore, earns significantly less than optimally or is said to be below the poverty line.

A family that must choose between buying groceries and paying for a child's immunizations will obviously buy groceries; the child's immunizations must wait until another time. If a family is forced to make this same choice week after week, the child could reach adulthood without protection against a number of potentially lethal diseases such as measles. Poverty allows acute illness to become chronic, forces families to live in dangerous neighborhoods, and, because of the high stress level always present, may increase the incidence of intimate partner abuse (Joly, 2007).

Reducing Government Aid Programs

Current legislation aimed at reducing the duration of government assistance to families and encouraging people receiving such assistance to begin or return to work was designed to stimulate parental productivity. Although some families who ordinarily would not qualify for Medicaid funding qualify for aid if the mother is pregnant, these laws reduce the number of people eligible for aid and so create child care problems and possibly increase poverty for individual families (Kaushal & Kaestner, 2007).

Health care providers can help families secure benefits such as food stamps or funding from the Women, Infants, and Children Special Supplemental Food Program (WIC) and free or scaled-payment health care programs to obtain health care despite their limited financial resources. Encouraging families to secure more education so they can better increase their earning capability and no longer need government assistance can also be helpful (Cricco-Lizza, 2008).

Increasing Numbers of Homeless Families

More than 3.5 million people in the United States today are homeless (NCHS, 2009). Although there is diversity in homeless families, as in all others, many homeless families are headed by a woman, and an increasing number are headed by pregnant and parenting adolescents (Tischler, Rademeyer, & Vostanis, 2007). The frequency of drug and alcohol abuse and severe psychiatric problems is greater among homeless families. Many mothers of homeless families were physically abused as children and have been battered by an intimate partner (Joly, 2007). Such families may not use health care providers or community agencies as effectively as other families because of their inexperience with bureaucracies or lack of transportation and money.

At least half of homeless children are younger than 5 years. Because of decreased environmental stimulation and lack of exposure to normal play activities, such children tend to not perform as well as others on standard developmental screening tests such as the Denver II. They tend to have more physical illnesses, such as anemia, pneumonia, dental problems, and restricted growth.

When caring for homeless families, remember that every day represents a struggle for such families. They often lack support people, so they may need a health care provider to serve in this capacity to help them achieve a healthier lifestyle or to give them active support during times of stress such as illness.

Increasing Divorce Rate

Divorce is rarely easy for anyone involved. Because parents are so emotionally entangled and their perceptions of their roles are changing so drastically, they may be unable to give their children the support they need during a divorce. This can leave marked long-term, negative effects on children or make the loss of a parent through divorce little different from the loss of a parent through death. Severing ties with grandparents or other relatives can also be difficult (Ahrons, 2007).

Children react in different ways to divorce depending on their developmental age and the explanations that parents give them. Divorce, as a rule, has three separate phases, and children's responses follow a course similar to grief. The first phase of divorce for parents is an antagonistic phase when parents realize they are no longer compatible; this is a time of quarreling, hurt feelings, and often whispered conversations. This can be an upsetting period for children because they do not understand what is happening. They may react with denial or anger and may believe that the impending divorce is their fault.

The second phase of divorce is the actual separation stage. Everyone in the family is asked to take on an unfamiliar role and perhaps a new home and a marked difference in financial arrangements. It is a time for grieving for the missing parent. Although it is comforting to be free from a house filled with tension and arguing, children may also wish they had their old life back (similar to the bargaining stage of grieving).

The third phase of divorce involves reshaping. Parents may remarry; financial arrangements stabilize. Children realize that their lives are permanently changed and they cannot go back to the time before the divorce (similar to the acceptance stage of grieving).

Boys may have emotional turmoil if the mother has custody and they lose their gender role model. All children may manifest their grief with physical symptoms such as nausea or fatigue. Their school performance may suffer. Most children report that when the noncustody parent remarries, it is one of the hardest moments for them because at that point they have to accept the divorce is final (Ahrons, 2007).

Although divorce is a stressful time for children, a redeeming feature may be that the period following a divorce may actually be less stressful to children than living in a home where there is a high level of conflict between parents. Children need an explanation of why the divorce has occurred and assurance that it was not their fault. If they do not receive this, they may have difficulty in the future thinking of themselves as good people; they may feel a loss of self-esteem if they believe one of their parents is a "bad person." The parent who will now be raising them may need help in avoiding saying any derogatory comments about the former partner. You can help by showing the parent that, although the former spouse was not a good marriage partner, he or she may have been a good parent and may be well loved and missed by the children.

Decreasing Family Size

The birth rate in the United States has declined steadily from 1900 to the present, putting the United States at a rate of almost zero population growth or with fewer births each year than deaths. The average number of children in families has decreased to 2.1 children (NCHS, 2009). Although small families mean fewer child care requirements for parents, this also limits the parents' experience in childrearing, so the amount of childrearing counseling time per parent may increase. As children have fewer older role models, they may need more counseling in behaviors such as how to manage stress or survive a failure at school.

Increasing Dual-Parent Employment

As many as 60% of women of childbearing age work at a full-time job outside the home today, and as many as 90% work at least part-time (Cherlin, 2008). The implication of this trend for health care providers is that health care facilities need to schedule appointments at times when parents are free to come (parents are willing to miss work if their child is sick, but not necessarily for a health maintenance or a routine prenatal visit). Instructions about how to take medications must take into account a child's schedule. For instance, help parents tailor administration of medicine to the times that they will be with the child to supervise the administration (e.g., before breakfast, following after-school child care, and at bedtime) rather than just "three times a day."

Dual-parent employment has increased the number of children attending day care centers or after-school programs (Trost, Rosenkranz, & Dzewaltowski, 2008). This

may have an impact on health care, because children attending day care centers have an increased incidence of illnesses. Help parents choose a quality day care center or after-school program that takes the necessary precautions against infection (see Chapter 31). School-age children often return home from school before their parents return from work. Helping parents prevent loneliness in these "latchkey" or "self-care" children as well as helping children make good use of their time alone is another nursing responsibility (see Chapter 32).

What if... Mrs. Hanovan, who works outside her home from 9 AM to 5 PM, needs to supervise Carey taking a medication four times a day. At what times would you suggest he take the medication?

Increasing Family Responsibility for Health Monitoring

In the past, parents relied on health care providers to monitor their children's health, and they accepted advice about health care without asking many questions or expressing opinions. Today, most parents take (and should be encouraged to take) an active role in monitoring their children's and their own health and participating in planning and goal setting. Changes in health care such as short hospital stays and an increased focus on health promotion and maintenance add to the increased responsibility for families to be knowledgeable health care consumers.

Because of this new consumer awareness, be sure to include parents and children in health care decisions. Using the nursing process for planning helps to accomplish this because the goal-setting step encourages patient participation. Health teaching, such as reducing smoking in the home, increasing the fiber content in meals, and omitting trans-fatty acids from cooking, becomes more effective if the learners are interested in improving their health.

Increasing Technology

Family life today is loaded with technological innovations such as television, computers, cellular phones, and iPods. Such technology has opened up a world to children that they were never exposed to in years past—a world that brings encyclopedias of knowledge to their fingertips but also can bring the danger of predators (Wolak, Mitchell, & Finkelhor, 2007). On a typical day, as many as 75% of children watch television; 32% watch videos/DVDs for approximately 1 hour 20 minutes. Twenty-seven percent of 5- to 6-year-olds use a computer for about 50 minutes on a typical day. Many young children (one fifth of 0- to 2-year-olds and more than one third of 3- to 6-year-olds) have a television in their bedroom (Vandewater et al., 2007). So much time spent in sedentary activities such as television watching is one reason that obesity in children is at epidemic proportions (Gable, Chang, & Krull, 2007).

It is important for children to learn to live in a fast-paced world, but parents need to be certain they are monitoring how fast the world is being presented to their children. News of world events travels so fast today that information about an event is flashed across a television screen only minutes after the event has occurred. News is then reported over and over. That type of repetition can frighten children as it may seem as if 100 planes have gone down instead of one being reported over and over.

It can be difficult for parents to limit the amount of news their children are exposed to as news alerts often interrupt children's programs. Discussing the importance of blocking inappropriate television programs and limiting and monitoring viewing time are important to reduce the level of stress from television to which children are exposed to daily.

An additional danger of too much technology is that it can interfere with communication in a family. Everyone has seen a family strolling through a mall, but instead of talking to each other, everyone is listening to music or text messaging. At the end of the afternoon, although the family has spent the entire afternoon together, they have really communicated very little with each other. Technology has the potential to enrich children's lives, but it also may limit their ability to interact with others, a skill they need to thrive in a school or work setting. Discussing the role of technology in homes can help parents evaluate whether they need to limit technology times and encourage more time in activities, discussing the day's events or participating in an activity where all family members are brought together (Box 3.3).

BOX 3.3 ✻ Focus on Family Teaching

Tips to Improve Family Communication

Q. Suppose Mrs. Hanovan tells you, "My family doesn't communicate well. How can I improve this?"

A. Traditionally, families gathered for an evening meal, and this practice allowed a set period each day for interaction, problem solving, and conflict resolution while problems were still small. If family meals are not possible because of busy work or school schedules, suggestions for better communication might include:

- Plan a time (even 15 minutes) daily when all family members "touch base" with each other.
- Use a telephone answering tape to leave daily messages.
- Set up a bulletin board or a chalk board that family members check each day for messages.
- Have all members check in daily by e-mail or a text message.
- Plan an earlier wake-up time two or three mornings a week so all family members can have breakfast together.
- Reserve one night a week as "family night," when the family plans a special activity to do together such as play a board game or watch a favorite movie.
- Agree that the night is off limits to cell phones, television, CDs, computers, iPods, etc., so family members are not distracted by outside sources.
- Plan special activities for holidays or weekends that involve the whole family.
- Participate in each other's activities (e.g., if one is playing in a ball game, all come and watch).

Increasing Obesity, Reduced Exercise, and Fast Foods

The level of exercise of families today is greatly reduced compared with what families enjoyed in the past. Children are often bused or given rides to school. They spend their time after school playing computer games instead of playing active games such as tag or sandlot baseball. After-school programs are structured around desk work rather than exercise (Box 3.4). Because families are busy and fast food is so available, families fix fast food lunches and dinners. Although this type of food solves problems of time management, it causes families to ingest more fat daily than may be good for them. The combined lack of exercise and consumption of fatty foods has led to a national epidemic of obesity in both adults and children (Biagioli et al., 2007). This has led to disorders such as morbid obesity and diabetes mellitus type 2 occurring in what otherwise would be problem-free pregnancies. Counseling families about their exercise program and nutrition should be on the agenda for all well-child and prenatal health care visits.

Increasing Abuse in Families

An alarming statistic in today's families is that the incidence and reports of domestic abuse (both child and intimate partner) are increasing yearly (Barlow et al., 2007). Detecting abuse begins with the awareness that it does occur. Both intimate partner and child abuse are discussed in Chapter 55.

BOX 3.4 ✻ Focus on Evidence-Based Practice

What environmental factors would best encourage urban teenagers to increase their level of physical exercise?

More children today are obese than ever before. An important component to reducing this obesity epidemic is encouraging adolescents to participate more in physical exercise. To discover what were deterrents to physical exercise among inner city youth, researchers presented 397 children between the 9th and 12th grade in two inner-city magnet high schools with 77 items that might interfere with physical activity and asked them to rate the items regarding their importance.

When selecting items that encouraged physical activity, both boys and girls rated highest the following items: places for activities, friends with whom you can be physically active, physical activity or sports programs outside of school, open fields or free space in the neighborhood, and siblings encouraging you to be active. Items that were most apt to deter physical activity for boys were concrete items such as unsafe facilities and no lights on basketball courts. Girls, in contrast, rated more communitywide deterrents such as crime, violence, sexual offenders, drugs and drug dealers, gangs, and dark outside when you get home from school.

Suppose you join a committee assigned to design a new inner-city recreation center. Would the results of this study be a help in planning?

Source: Ries, A. V., et al. (2008). Adolescents' perceptions of environmental influences on physical activity. *American Journal of Health Behavior, 32*(1), 26–39.

ASSESSMENT OF FAMILY STRUCTURE AND FUNCTION

Family characteristics can be assessed on a variety of levels and in varying degrees of detail. The type of family data collected and the method of collection should match the way in which the assessment data will be used.

General characteristics of family type and functioning can be assessed using observation and general history questions (Table 3.1). If more detailed information about family environment and roles is required, using an assessment tool specifically developed for that purpose is most effective.

The Well Family

Assessment of psychosocial family wellness requires measurement of how the family relates and interacts as a unit, including communication patterns, bonding, roles and role relationships, division of tasks and activities, governance, decision making, problem solving, and leadership within the family unit. Assessment also looks at how the family relates to the outside community.

The **genogram,** a diagram that details family structure, provides information about the family's history and the roles of various family members over time, usually through several generations. It can provide a basis for discussion and analysis of family interaction (Fig. 3.1).

The Family APGAR (Smilkstein, 1978) is a screening tool of the family environment (Fig. 3.2). A Family APGAR form is administered to each family member, and their scores are then compared. The tool is easy to use and can complement a family history.

Another aspect of family assessment is to document the "fit" of a family in their community. This is done by means of an **ecomap,** a diagram of family and community relationships (Fig. 3.3). To construct such a map, first draw a circle in the center to represent the family. Around the outside draw circles that represent the family's community contacts such as church, school, neighbors, or other organizations. Families that "fit" well into their community usually have many outside circles or community contacts. A mark of abusive families is that they have few community contacts as they deliberately keep outside people remote from them. Constructing such a map helps you assess the emotional support available to a family from the community. A family whom you assess as having few connecting lines between its members and the community may need increased nursing contact and support to remain a well family (see Focus on Nursing Care Planning Box 3.5).

Although family assessment is best done when a family is managing well, assessment of a family often first occurs when a family is in crisis. The way families react to a crisis depends largely on the particular crisis, their past experiences with problem solving, their perception of the event (whether they can clearly see what is the problem), and the resources available to them to help solve the problem. McCubbin and

(text continues on page 56)

TABLE 3.1 ✻ Family Assessment

Area of Assessment	Questions to Ask
Type of family	Who lives in the home? Is the family nuclear, extended, or other?
Family finances	Are finances adequate? Is money divided evenly among family members?
Safety	Is the home safe from fire or unintentional injuries (are smoke alarms present and police and fire telephone numbers posted?)
Health	Does the family eat a nutritious diet? Do they receive adequate sleep? Are immunizations current? Is there a balance between work and recreation? Can they cope with problems adequately?
Emotional support	
Within family	Do members eat together or spend an equal amount of time with each other daily? Do they band together to defend each other from outsiders?
Outside family	Is the family active in community organizations or activities? Do they visit (or are they visited by) friends and relatives? Can the family name one outside person they can always rely on for help in a time of crisis?
Family roles	
Nurturer	Who is the primary caregiver to children or any physically or cognitively challenged member?
Provider	Who brings in the bulk of the family's income?
Decision-maker	Who makes decisions, particularly in the area of lifestyle and leisure time?
Financial manager	Who supervises the family finances (pays the bills, provides for future savings)?
Problem-solver	On whom does the family depend to provide the solution to problems?
Health manager	Who ensures that family members keep health appointments, immunizations are kept current, and preventive care such as a mammogram for the mother is scheduled?
Culture bearer	Who maintains family and community customs to give children a sense of where they belong in history?
Environmentalist	Who is responsible for recycling, for not wasting electricity or water?
Gatekeeper	Who determines what information will be released from the family or what new information can be introduced?

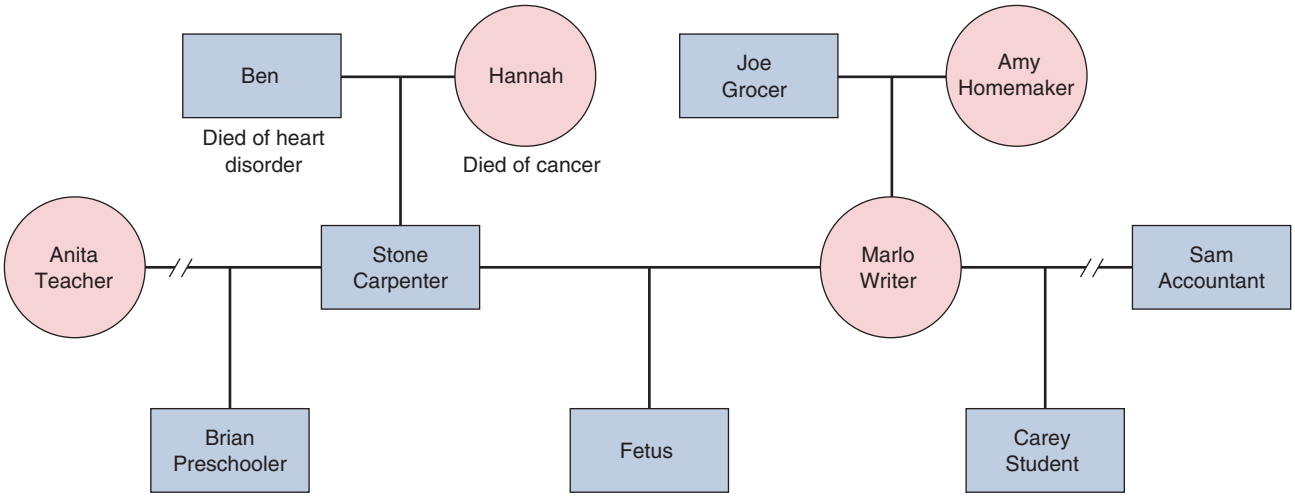

FIGURE 3.1 A Hanovan family genogram showing three generations. Males are shown by squares, and females by circles.

The Family APGAR Questionnaire

	Almost always	Some of the time	Hardly ever
I am satisfied with the help that I receive from my family* when something is troubling me.	_____	_____	_____
I am satisfied with the way my family discusses items of common interest and shares problem solving with me.	_____	_____	_____
I find that my family accepts my wishes to take on new activities or make changes in my lifestyle.	_____	_____	_____
I am satisfied with the way my family expresses affection and responds to my feelings such as anger, sorrow and love.	_____	_____	_____
I am satisfied with the way my family and I spend time together.	_____	_____	_____

SCORING

Scoring: The patient checks one of three choices, which are scored as follows: 2 points for "Almost always," 1 point for "Some of the time" and 0 for "Hardly ever." The scores for each of the five questions are then totaled. A score of 7 to 10 suggests a highly functional family. A score of 4 to 6 suggests a moderately dysfunctional family. A score of 0 to 3 suggests a severely dysfunctional family.

WHAT IS MEASURED

Adaptation	How resources are shared, or the member's satisfaction with the assistance received when family resources are needed.
Partnership	How decisions are shared, or the member's satisfaction with mutuality in family communication and problem solving.
Growth	How nurturing is shared, or the member's satisfaction with the freedom available within the family to change roles and attain physical and emotional growth or maturation.
Affection	How emotional experiences are shared, or the member's satisfaction with the intimacy and emotional interaction within the family.
Resolve	How time* is shared, or the member's satisfaction with the time commitment that has been made to the family by its members.

*Besides sharing time, family members usually have a commitment to share space and money. Because of its primacy, time was the only item included in the Family APGAR; however, the nurse who is concerned with family function will enlarge understanding of the family's resolve by inquiring about family member's satisfaction with shared space and money.

FIGURE 3.2 The Family APGAR Questionnaire. (From Smilkstein, G. [1978]. The family APGAR: a proposal for a family function test and its use by physicians. *Journal of Family Practice, 6*(6), 1231–1239.)

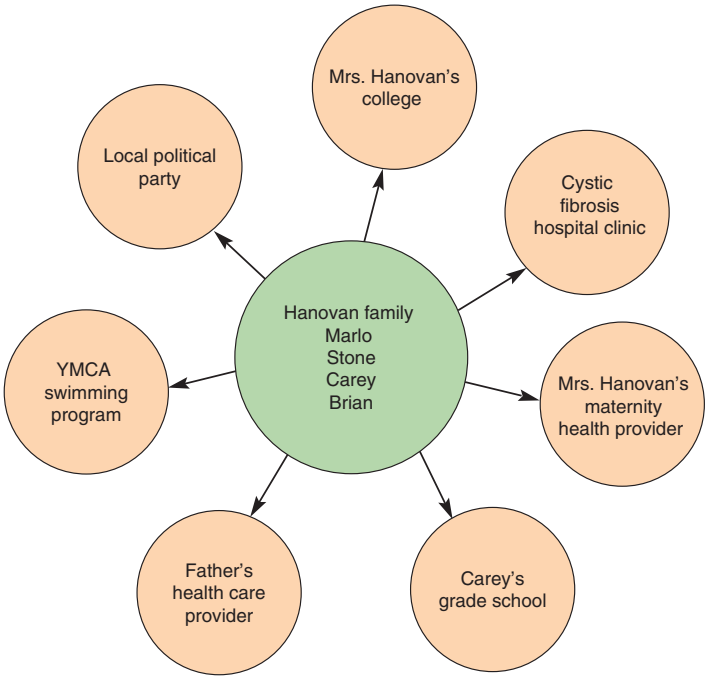

FIGURE 3.3 An ecomap of the Hanovan family's relationship to its community. The family members are shown in the center circle; the outer circles show community contacts.

BOX 3.5 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Family With an Ill Child

Carey Hanovan is a 10-year-old child with cystic fibrosis. His mother tells you, "He's been acting out in school for the last month and doesn't always eat like he should, take his medicines, or do his treatments. He refuses to help around the house." Carey states, "Everybody's so busy, nobody has time for me. And I'm not like other kids. I'm always sick. Things will get even worse when the new baby comes."

Family Assessment ✻ Blended middle-class family that lives in an older three-bedroom home in the central city. Father is disabled from on-the-job accident; does not participate in community activities. Mother attends community college full-time with financial aid; is 5 months pregnant and active in local political party. Client is oldest child with one stepbrother, age 2 years. Mother swims weekly at the local YMCA; client refuses to go with her. Client is responsible for homework and cleaning kitchen after school while he is home alone. Client has few close friends. Two neighbors are available in case of emergency during his alone time.

Client Assessment ✻ Client's respiratory rate: 26 breaths per minute. Appears thin and pale. Productive cough with tenacious sputum. Medications last taken this morning. Lungs with fine bilateral rales.
Nursing Diagnosis ✻ Interrupted family processes related to effect of child's illness and situational stressors
Outcome Criteria ✻ Family demonstrates greater participation in family activities and positive methods of communication by 3 months' time. Client says he feels more family attachment and personal self-esteem by 3 months' time.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Interview family regarding family structure and family roles.	Complete a family APGAR and genogram. Prioritize needs for each family member.	Family APGAR provides information about how families relate and interact. A genogram details family structure and roles. Priority setting promotes more focused, directed care for outcome achievement.	Family and health care providers complete a family APGAR and genogram with needs of family prioritized by next health-care visit.

Nurse	Help family explore and decide on a common activity enjoyed by all members.	Encourage participation in this activity, initially once a month, then twice a month, then weekly.	Participation in a group activity fosters bonding. Gradually increasing the frequency of the activity promotes integration into the family routine.	Client maintains a schedule documenting his participation at least once a week in a family activity.
		Consultations		
Nurse	Assess the number of contacts the family has in the community.	Draw and evaluate family's ecomap.	Ecomapping helps to assess the community support available to the family.	Ecomap reveals possible sources of community contacts that could serve as emotional support.
Social worker/ nurse	Assess what community agencies are available in the Hanovan family's community that could serve as additional sources of support.	Contact local community organizations with client and set up a visit. Possibly enlist the aid of the school nurse and guidance counselor in providing contacts.	Contacting the organization with the client offers support and helps reduce his possible anxiety with new situations. School personnel provide additional support and reassurance.	Client visits local or school agencies that provide community contacts.
		Procedures/Medications		
Nurse	Assess and list all of child's required exercises and medications.	Demonstrate exercise and medication procedures, if necessary, and have client return demonstration. Help client incorporate regimens into usual routine.	Review and redemonstration helps to reinforce measures and ensure client is doing them correctly. Incorporating them into client's routine helps to promote positive adjustment and decrease feelings of being different.	Client is able to redemonstrate procedures with 90% accuracy. Combines at least one exercise or medication with usual routine.
Nurse in conjunction with physical therapist	Help family assess which family member could serve as backup support for child's exercise and medication regimens.	Meet with family and plan a schedule that will allow a backup family member to supervise and participate in child's exercise and medication regimens.	Family involvement divides the responsibility and minimizes the risk of added stress on the family system.	Family members state that they cooperate with and encourage client to follow treatment regimen. Client says that he is adhering to treatment regimen 90% of time.
		Nutrition		
Nurse/ nutritionist	Assess nutrition needs based on medical prescriptions.	Review special diet needed by client with client and father (food preparer).	The food preparer needs to be as well informed about a special diet as the client.	Both client and father state that they understand that a special diet is necessary and describe a typical breakfast, lunch, and dinner for diet.
Nurse/ nutritionist	Assess family's eating habits.	Encourage family to eat together as a family unit at least two times a week.	Eating together should not only help client to comply with nutrition plan but provide a time for family sharing and communication.	Family reports they eat together at least twice a week or, if not possible, arrange for a substitute "sharing time."

(continued)

BOX 3.5 ✻ Focus on Nursing Care Planning (continued)

		Patient/Family Education		
Nurse	Assess client's present knowledge of his illness.	Review with client and parents an explanation of illness based on their present knowledge base.	Building on a client's knowledge base facilitates teaching and learning and minimizes repetition.	Client and family state that they understand the underlying cause of illness and rationale for treatments.
Nurse	Assess with client what a typical day consists of.	Brainstorm with client ways that he can "fit" into school routine better.	A feeling of "being different" can be detrimental to high self-esteem.	Client states that he has made at least one new friend by 2 months' time.
		Psychosocial/Spiritual/Emotional Needs		
Nurse	Help each family member identify the area of his or her greatest stress.	Help family members reduce stress by teaching better problem-solving techniques.	Identifying problems is the first step in effective problem solving.	Family members identify the greatest stressors in their family life and potential means to decrease stress.
Nurse	Assess stress-reducing measures currently being used.	Help family members develop strategies such as better time management to assist each other in meeting priority needs.	Use of therapeutic measures assists in clarifying family needs and expectations and also helps reduce stress.	Family members state that they are using strategies such as time management to better meet priorities.
		Discharge Planning		
Nurse	Meet with family to identify areas of needed support. Encourage family members to verbalize needs and feelings.	Help family identify a common activity enjoyed by all members that can be used to encourage family bonding. Encourage weekly participation in this activity.	Working together on a common task can foster group interaction, communication, trust, and bonding.	Family members state that they all participate in at least one enjoyable home activity by 2 months' time.
Nurse/case manager	Assess home rules and delegation of responsibilities.	Encourage joint cooperation in household tasks so client does not feel so isolated when home alone.	Joint ownership of household tasks encourages a sense of family.	Family members demonstrate they have a family schedule that evens out tasks and involves all members.
Nurse/case manager	Assess what resources are available in the Hanovans' community, such as the Cystic Fibrosis Foundation, that could be used as support resources.	Meet with family to see if members are interested in using any identified community organizations as resources.	Community resources provide additional support in areas of need.	Family members state that they have attended at least one Parents of Cystic Fibrosis Children meeting by 3 months' time.

colleagues (2000) suggest that assessing these factors is vital to predicting the probable extent of the crisis for the family. As a crisis can change a family's perceptions and the resources available to them, renewed assessment is necessary at the end of the crisis to see how the family has weathered the impact (a double ABCX model of assessment; Fig. 3.4).

To use this model, first assess what is the stressor (the event or transition that has the potential to influence the family's dynamics) and, then, how it is affecting the family. A house fire or illness of a family member is an example of a crisis situation. After identifying the stressor, assess the family's perception of the event. If the family states, for example,

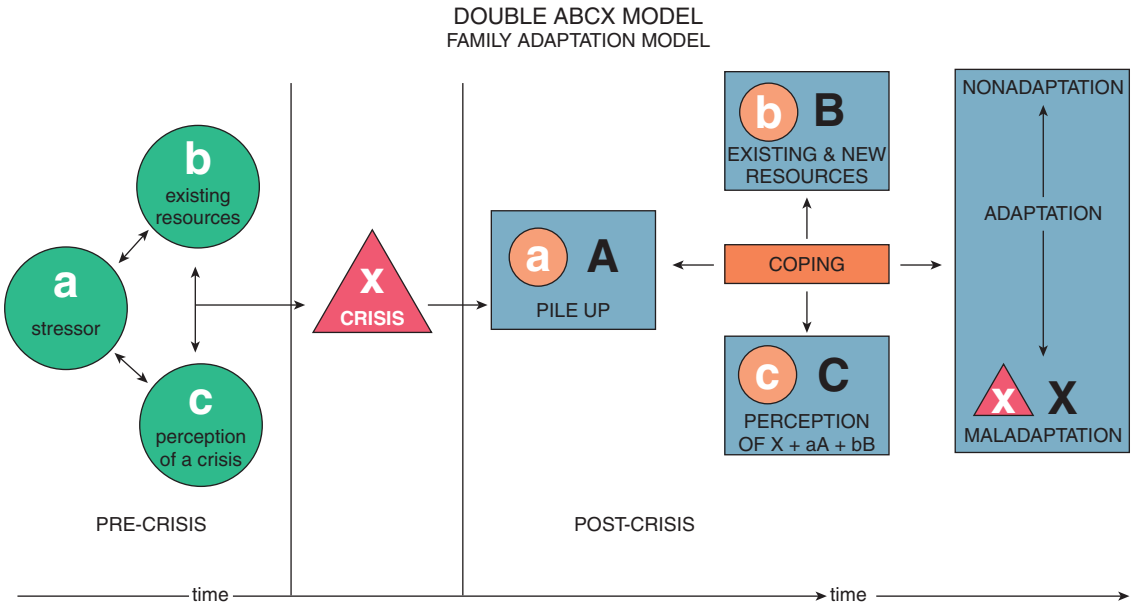

FIGURE 3.4 The ABCX System for Family Assessment. (From McCubbin, H. I., Thompson, E. A., Thompson, A. L., et al. [2000]. *The dynamics of resilient families.* Thousand Oaks, CA: Sage Publications.)

that they have adequate home or health insurance so the expense of replacing the house or a long hospitalization will be minimal, the stressor may have little effect. On the other hand, if they feel overwhelmed by the loss of their home and possessions or the strain of caring for someone so ill, the stressor is causing a major effect. The third step is to evaluate the resources available to the family, both internal and external. What are their challenges? What is the family type? What are their strengths? Do they have friends who can give them support? Do they belong to a church or temple that will help? Every family makes some kind of adjustment to a problem. What type of adjustment did they make? This adjustment and the resulting changed perception of the event reveal whether the family has weathered this event and may actually have become stronger or whether they need further assessment and guidance about steps to take.

This model is a useful one for family assessment, because it does not assume that just because a stressor happens, an automatic outcome will occur. It respects the individuality of families, an important factor to remember in family assessment.

Listing a family's strengths and coping abilities as well as its possible challenges actually strengthens a family as it brings out insights and better prepares family members to cope with their current level of stress and the difficult decisions that may be ahead. Box 3.6 provides practical suggestions to help families endure periods of stress.

What if... Your assessment of one child who is ready for hospital discharge shows that his family has multiple connections with the community, but the assessment of Carey and the Hanovan family shows only the hospital as a connection? Which family might need more discharge planning?

Key Points for Review

- A family is a group of people who share a common emotional bond and perform certain interrelated social tasks.
- Because families work as a unit, the unmet needs of any member can spread to become the unmet needs of all family members.
- Common types of families include nuclear, extended, single-parent, blended, cohabitation, single alliance, gay and lesbian, foster, and adopted families.
- Common family tasks are physical maintenance, socialization of family members, allocation of resources, maintenance of order, division of labor, reproduction, recruitment and release of members, placement of members into the larger society, and maintenance of motivation and morale.
- Common life stages of families are marriage; early childbearing; families with preschool, school-age, and adolescent children; launching stage; middle-years families; and the family in retirement.
- Changes in patterns of family life that are occurring are increased mobility, dual-parent employment, increased divorce, social problems such as abuse and poverty, reduced family size, and the addition of technology.
- Considering a family as a unit (a single client) helps in planning nursing care that meets the family's total needs.
- Families exist within communities; assessment of the community and the family's place in the community yields further information on family functioning and abilities.
- Families do not always function at their highest level during periods of crisis; reassessing them during a period of

BOX 3.6 ✻ Focus on Family Teaching

Tips for Reducing Family Stress

Q. Suppose Mr. Hanovan tells you he is worried because the tension level in his family is growing. He asks you, "How can my family better manage stress?"

A. Managing stress calls for interventions specific to each family, but some general suggestions are:

1. Recognize that stress levels differ from person to person. Because one person is not upset by some condition does not mean that another person will not be. On the other hand, if a situation does not annoy a person, that person should not feel that he or she has to react to it just because someone else does.
2. Anticipate life events and plan for them to the extent possible. Anticipatory guidance will not totally prepare you for a coming event but will at least serve notice that distress over the situation is normal.
3. Face a situation as honestly as possible. As a rule, knowing the exact nature of a threat is less stressful than a "something-is-out-there" feeling. On the other hand, do not feel compelled to face intense threats, such as a serious complication of pregnancy or a fatal illness in a child, until you have had time to mobilize your defenses, or you can feel overwhelmed.
4. Learn to change those things you cannot accept and accept those things you cannot change. Trial and error is often required to determine the difference.
5. Often a total change is unnecessary; a simple modification in one thing will be enough to make a difference.
6. Try to describe why you feel so stressed. Almost nothing limits the extent of a threat more than being able to describe it accurately. Detailing a problem is the beginning of problem solving.
7. Reach out for support. When you are under stress, it is easy to be so involved in the problem that you do not realize that people around you want to help. Sometimes people closest to you are under the same threat and so are no longer able to offer support. When this happens, you might have to call on second- or third-level support people (family or community) for help.
8. Reach out to give support when others are being threatened. Survival is a collaborative function of social groups; a favor offered now can be called in when you are in need at a later date.
9. Try to reduce the number of stressors that are coming at you by turning off television, dimming the lights, and spending time with just your inner self. Praying can also offer comfort.
10. Ask yourself if you really need to accomplish all the tasks that are piling up around you. Do you need to be room mother this month? Does the garage need to be cleaned this week?
11. Remember that unintentional injuries increase when people are under stress. A person worrying about a complication of pregnancy, for example, is more apt to have an automobile accident than a person who is stress free. Children are more apt to poison themselves when the family is under stress because parents are more apt to leave pills on counters during this time.
12. Action feels good during stress because doing something brings a sense of control over feelings of helplessness and disorganization. Action often is so satisfying that people do things such as write threatening letters or shout harmful remarks that they later regret. Channel your energy into therapeutic action (such as going for a long walk and quietly reflecting) instead.
13. Do not rush decisions or make final adaptive outcomes to a stressful situation. As a rule, major decisions should be delayed at least 6 weeks after an event; 6 months is even better.

stability may reveal a stronger family than appeared on first assessment.

CRITICAL THINKING EXERCISES

1. You met the Hanovan family at the beginning of the chapter. Why is this a particularly unfortunate time for the Hanovans to have to choose between health care and groceries? Would their needs change if they were an extended family? A single-parent family? A cohabitation family?
2. The Hanovan family is a family under stress because of a poor financial base, a serious family illness, and limited family communication stemming from busy life roles. What other health care providers would it be helpful to include in a team approach for problem solving with this family?
3. As communities change, a family may find that it is the only family with children on a street or the only family who does not work at the local factory. What if you discovered the Hanovan family was "out of sync" with its community this way? How could you help such a family?
4. Examine the National Health Goals designed to improve the health of families. Most government-sponsored money for nursing research is allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would advance evidence-based practice in relation to the Hanovan family?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter; then answer the questions to further sharpen your skills and grow more familiar with NCLEX types of questions related to family health. Confirm your answers are correct by reading the rationales.

Chapter 4

The Childbearing and Childrearing Family in the Community

KEY TERMS

- community
- direct care
- home care
- hospice care
- indirect care
- perinatal home care
- skilled home nursing care

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe a healthy community and usual nursing and client concerns when home care is required during pregnancy or childhood.
2. Identify National Health Goals related to home care during pregnancy or childhood that nurses can help the nation achieve.
3. Use critical thinking to analyze how home care influences family functioning, and develop ways to make home nursing care more family centered.
4. Assess a pregnant woman or child and their community for likely success for home care.
5. Formulate nursing diagnoses related to care of a child or pregnant client at home.
6. Identify expected outcomes for a family requiring home care.
7. Plan nursing care appropriate to meet the needs of a home care client such as suggesting ways to keep in contact with significant others.
8. Implement nursing care to meet the needs of a pregnant woman or child on home care such as teaching techniques of intravenous therapy.
9. Evaluate expected outcomes for effectiveness and achievement of care.
10. Identify areas of home care nursing that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of home care with nursing process to achieve quality maternal and child health nursing care.

Lee Puente, a 16-year-old who is 20 weeks pregnant, lives with her parents. She was admitted to the hospital for 3 days at 14 weeks of her pregnancy and placed on a program of total parenteral nutrition because she has been vomiting at least four times daily since the beginning of pregnancy. She managed well on parenteral nutrition until last week, when her blood pressure rose to 160/90 mm Hg and she was diagnosed with hypertension of pregnancy. Bed rest with fetal and uterine surveillance at home was added to her care. She tells you it's impossible for her to rest at home: she's bored and wants to be back in school with her friends. She has missed three doses of her hypotensive agent because she forgot to take them. She wants to be hospitalized again for care.

Previous chapters discussed common types of families and how cultural traditions affect families. This chapter adds information about families and their community as they prepare to care for an ill family member at home.

Is Lee a good candidate for home care? What additional interventions does she need to help make home care more successful?

Home care is care of persons in their own home, provided by or supervised through a certified home health care or community health care agency. In recent years, as hospital stays have decreased in length, the need for home rehabilitation periods of this type has grown substantially.

Acute care or postsurgical clients often need follow-up home visits. Pregnant women with conditions that require monitoring and bed rest but not critical care can also be cared for at home. Children with chronic conditions such as bronchial pulmonary dysphasia, cystic fibrosis, and childhood cancer are cared for at home rather than in hospital settings when at all possible so they are not separated from their family. Many children in terminal stages of disease are also cared for at home (**hospice care**).

There is a strong economic incentive to provide care in the home (it is less costly for health care plans). Several factors have contributed to the success of the home as a health care setting. Technological advances have made it possible for potentially complicated procedures, such as the administration of total parenteral nutrition and ventilation therapy, to be performed safely at home. Perhaps the greatest benefit of home care for women and children is the opportunity it brings to include the entire family in health care planning and the ability to focus not only on a specific health problem but also on promoting healthy behaviors for the entire family (Pignone & Salazar, 2009).

BOX 4.1 * Focus on National Health Goals

National Health Goals are concerned with eliminating common infectious diseases of childhood and reducing complications of pregnancy both by encouraging better adherence to immunization programs for children and by better monitoring and preventing complications during pregnancy.

Both prevention of common childhood infectious illnesses and pregnancy complications would reduce the hours spent in home care. Examples of National Health Goals that speak to this area of concern are:

- Increase to at least 90% the proportion of all pregnant women who receive early and adequate prenatal care, from a baseline of 74%.
- Reduce the rate of preterm births, from a baseline of 11% to a target of 7.6%.
- Reduce or eliminate indigenous cases of vaccine-preventable diseases such as mumps, poliomyelitis, and diphtheria (http://www.nih.gov).

Nurses can help the nation achieve these goals by helping women better accept and adhere to home care if it is advised during pregnancy. They can remind parents that routine immunizations for children are important. Nursing research topics to address in this area are: What are the most effective ways to relieve a woman's anxiety about home care? What is the ideal frequency for home visits? When nursing care time is included in costs, is home care cost-effective? What is a good reminder system to help parents schedule immunization visits on time?

Whether home care is successful can be influenced by cultural expectations, especially male–female roles. In a family in which men and women share responsibility, for example, care tasks as well as time away from the stress of home care can be distributed equally. In contrast, in cultures in which the male is dominant and child care is strictly delegated to the woman, women can become exhausted from trying to keep house, prepare meals, care for other children, and also care for themselves or a medically fragile child.

Evaluating families individually is important to see what the family's usual childrearing practices are as well as how care is given during illness.

It is well documented that women who receive prenatal care have better pregnancy outcomes than those who do not (Bernstein & Weinstein, 2007). Because home care can be a means of increasing prenatal care, especially in the areas of additional health teaching and monitoring, National Health Goals that speak to prenatal and child care also apply to home care (Box 4.1).

Nursing Process Overview

For the Pregnant Woman or Child on Home Care

Assessment

Being able to assess communities becomes more and more important as, because of personal preferences or short hospital stays, more children spend time at home recuperating from illnesses than ever before. Fewer pregnant women with a complication of pregnancy are hospitalized and are also using home care. Most women and children who will be scheduled for home care are first seen in an ambulatory health care setting or an acute care facility for initial diagnosis and then discharged from that facility with a referral to a home care program.

Home care is not a level of care adequate for everyone or every situation, so evaluating whether a family is a good candidate for home care is the first assessment needed. Figure 4.1 shows a typical assessment tool used to qualify women for home care. Using this tool, women or children can be divided into three levels of care based on the identification of factors, both physical and psychosocial, that may affect care and final outcome. Those categorized as low risk (level I) probably need only weekly visits; those at intermediate risk (level II), one to three visits per week; and those at high risk (level III), as many as four to seven visits per week. Both women and children need to be reevaluated about every 30 days to see if their risk level, and therefore the number of home visits needed, has changed.

Assessment for home care begins with an interview to identify ways a family thinks the illness and care at home will change their lives. This could include a wide range of situations such as increased expenses, the need for one parent to take a leave from work to care for an ill child or spouse at home, the need to schedule frequent ambulatory visits, consultation to handle body image changes, and the need to arrange for child care for other children. Because these needs change as the course of an illness changes, assessment must be ongoing.

A first home visit usually includes a thorough health history and physical examination to document a woman's

or child's current status and an environmental, community, and social assessment. Other assessments focus on likely adherence to medical, preventive, or medication regimens; whether the family will be able to continue to monitor the client's health at home; and what other services or resources the family needs such as the services of a home health care assistant or further nursing visits to ensure that home care is optimal. Future visits focus on continuing assessment and evaluation of patient progress and readiness to move to another level of health care.

The term "resources" refers not only to material objects (e.g., hospital bed, oxygen, fetal home monitor) but also to whether a family can deal with the chronic stress of home care. Women often have to quit work to become home care patients. One parent of an ill child usually has to do the same. This can reduce a family's income dramatically and cause financial problems. Environmental considerations also can add to the stress of the situation. Assess if the home's physical surroundings are adequate for home care. Is there enough floor space for a hospital bed? Is there space for a fetal heart monitor or oxygen equipment? Is there a telephone that can be reached by the pregnant woman or child? Is there adequate heat or air conditioning so an ill person can be comfortable?

Typically, women receiving care are taught how to self-assess various health parameters such as blood pressure, temperature, pulse, perhaps urine for protein or glucose, fundal height, fetal movement, fetal heart rate, and uterine contractions in preparation for home care. Parents or other family members of an ill child need to assess vital signs, comfort level, and side effects of medications. When teaching these assessments, spend enough time with the woman or family to assess the learning capabilities of the family so you know they thoroughly understand both the reason for the assessment and the priority procedures necessary for care. Assess at home care visits not only the results of the measurements but whether they are being done correctly and consistently.

Because the structure of families is culturally determined, home care is easier for some families than for others. If the family is extended, for example, a mother may be so involved in the care of other family members, such as an older adult, that she is unable to rest adequately at home or add enough time to care for an ill child to her other responsibilities. On the other hand, in such a family, there may be many people to offer care and support, so home care will be ideal.

In male-dominant cultures, the thought of the man giving care to his wife or an ill child contradicts a usual pattern. If a woman is the dominant member of the household, becoming a passive, cared-for partner may be extremely difficult for her.

Some cultures stress that women must be active during pregnancy to help ensure a small baby and therefore an easier birth. That makes bed rest difficult for a family to enforce. The culture of a particular community might oppose the use of technology, so a family living there might not like having a van come to supply needed oxygen or intravenous equipment. Assess each family individually to determine how home care may affect that particular family.

Nursing Diagnosis

Nursing diagnoses for home care may address the physiologic reason for supervised home care or the effect of the experience on the family, such as:

- Deficient knowledge related to complication of pregnancy and necessary procedures and treatments
- Interrupted family processes related to need for home care
- Ineffective role performance related to bed rest at home
- Social isolation related to need for home care
- Anxiety related to complication of pregnancy requiring home care

Home care of a child can place a heavy burden on a family. The stress of being responsible for an ill child's daily health status can have a negative impact on a parent's self-esteem or a couple's marriage, or it can prevent parents from spending time with their other children. Examples of possible nursing diagnoses that arise out of these factors are:

- Readiness for enhanced family coping related to increased time together because of home care
- Health-seeking behaviors related to skills needed to continue home care
- Risk for delayed growth and development related to lack of usual childhood activities
- Interrupted family processes related to dependence of ill child
- Disabled family coping related to changes in family routine brought about by home care needs of ill child

Outcome Identification and Planning

Outcome identification and planning for home care require close collaboration between a health care agency and health care providers supervising care at home. Typically, the initial referral from the health care agency provides the foundation from which the home care or community health nurse develops a plan of care. A major portion of this planning involves reviewing with a family exactly what their needs are, what will be expected of them, and what they can expect of the nurse and developing outcomes that address these needs and expectations such as extending the length of the pregnancy or increasing the comfort of a child on home care. If this is not carefully done, some families will assume that not going outside the home is all that is required by home care, when what is actually required is complete bed rest. "Walking through a day" helps a family determine at what points during the day they will need additional assistance so the pregnant woman or ill child can remain in bed at home. For example, a woman on bed rest may need assistance with meal preparation or hygiene while her partner is at work. In this situation, a referral for a home health assistant would probably be appropriate. She also may need help with transporting her children to school or activities. Discussing these issues with her helps her call on resources such as other family members, neighbors, or community volunteer groups.

Children need to continue with school if at all possible so they maintain contact with friends, do not fall behind a grade level, and have the stimulation of learning. This means parents must either make some sort of arrangement for this through their local school district (many

schools are able to establish a telecommunication setup for children ill at home) or investigate their ability to home school the child.

Determining family roles (see Chapter 3), such as who is the wage earner, the decision maker, the nurturer, or the problem solver, is important for planning. Home care is most successful when these family roles are not disrupted but strengthened to support whatever new activities or concerns need to be addressed. Good Internet referral sites for families regarding come care are The International Association for Hospice & Palliative Care (http://www.hospicecare.com) and The National Association of Home Care and Hospice (http://www.nahc.org).

Implementation

Women and children receiving home care have the advantage over those hospitalized of being in their own environment with their families. Because home care provides only intermittent visits, however, there is the possible disadvantage of not being constantly supervised by health care personnel. Reassure women and children after assessment that their condition has not changed and it is safe for them to remain at home on the present program, assuming that is true. If changes have occurred, introduce new interventions and evaluate their effectiveness.

Interventions performed for a client at home are little different from those performed in an acute care facility. They range from teaching and counseling to hands-on care. To do this, home care nurses need to have the same background and level of expertise as acute care nurses. In addition, they may need to be more flexible and adaptable because each home visit may be very different from the one just before or after.

Nursing interventions for home care often involve teaching family members how to give care. This may include encouraging members to voice the frustration they feel at being constantly confined at home or what they perceive to be a lack of progress in their child's or partner's condition. If a child has a terminal illness, parents may need support to express their grief. They can grow discouraged because the work they are accomplishing is making the child comfortable but not preventing death.

Outcome Evaluation

Because a home setting is less structured than a health care facility, evaluation will show that some goals for care are more difficult to accomplish in the home. For the same reason, because there is more room for innovation at home, some goals will be more easily accomplished. Evaluation may reveal that circumstances have changed such as the client's condition requiring more monitoring than originally believed, the demands are greater than the family is willing to undertake, or family composition changes, making a responsible caregiver no longer available.

Outcome evaluation for the pregnant woman receiving home care includes determining whether a woman and fetus are remaining well at home and whether a woman feels comfortable and secure with the arrangement. For many women, successful home care can mean the difference between too early a birth and a successful term pregnancy.

Examples of outcome criteria for pregnant women could include:

- Client demonstrates adequate skill at performing home monitoring procedures.
- Client verbalizes changes in condition she will need to report to her health care provider.
- Client participates as a member of the family within limitations imposed by pregnancy complication.
- Family members state they have adjusted to home care of mother.
- Client states she is able to maintain contact with friends and family despite complete bed rest at home.

Examples of outcome criteria for an ill child might include:

- Parents state they have been able to make adjustments to accommodate care of ill child at home.
- Child states he or she enjoys respite care in hospice setting one weekend a month.
- Parents state they are actively trying to supply adequate growth experiences for siblings in light of home care of oldest child.

THE FAMILY AS PART OF A COMMUNITY

Families rarely live alone on islands, so they have to interact with a surrounding community to get food, use transportation, and receive wages for work (Monsen & Finley, 2007). A **community** can be defined in many ways, but it is generally accepted to refer to a limited geographic area in which the residents relate to and interact among themselves (Allender & Spradley, 2008). When asked what community they are from, people may mention an entire city, a school district, a geographic district ("the East Side"), a street name ("Pine Street area"), or a natural marking ("the Lower Creek area").

Because the health of individuals is influenced by the health of their community, it is important to become acquainted with the community in which you practice. Community assessment can reveal if there are aspects about a community that contributed to an illness (and therefore need to be corrected) and determine whether the person will be able to return to the community without extra help and counseling after recovering from an illness.

Knowing the individual aspects of families or a community can help you understand why some people reach the illness level they do before they come for health care (e.g., a woman has no transportation available to her until her husband comes home from work so this prevents her from coming for daytime prenatal care; a 5-year-old child develops measles because there are no free immunization services in the community).

Community assessment consists of examining the various systems that are present in almost all communities to see whether they are functioning adequately as well as features that are unique to a client's community (Conway, McClune, & Nosel, 2007). It is easier for you to prepare a woman or child for return to a community after childbirth or a hospital stay if, for example, you know the specific features of their community (Does the Pine Street area have well or city water? How many flights of stairs does someone from the

TABLE 4.1 ✻ Community Assessment

Area of Assessment	Questions to Ask
Age span	Is the family within the usual age span of the community and thereby assured of support people? Is the community a "young," a "settled-in," or a "retired" one? Is it at the same stage as the family?
Education	If the family has school-age children, are there schools nearby? Is there a public library for self-education? Is there easy access to such places if the person becomes physically challenged? If a special program such as diet counseling is needed, does it exist?
Environment	Are environmental risks present, such as air pollution? Busy highways? Train yards? Pools of water where drowning could occur? Could hypothermia be a problem?
Financial status	Is there a high rate of unemployment in the community? What is the average occupation? Will this family have adequate finances to manage comfortably in this neighborhood? Are supplemental aid programs available?
Health care	Is there a health care agency the family can use for comprehensive care? Is it convenient, in terms of finances and time?
Housing	Are houses primarily privately owned or apartments? Are homes close enough together to afford easy contact? Are they in good repair? Will new construction or deteriorated housing be a safety problem?
Political	Is the community active politically? Can adults reach a local polling place to vote, or do they know how to apply for absentee ballots?
Recreational	Are recreational activities of interest available? Are they economically feasible?
Religion	Is there a facility where the family can worship as they choose? Is there easy transportation to it?
Safety	Is there adequate protection so family members can feel safe to leave home or remain home alone? Do they know about available hotlines and local police and fire department numbers? Are there smoke alarms in the bedrooms and near the kitchen?
Sociocultural	What is the dominant culture in the community? Does the family fit into this environment? Are foods that are culturally significant available?
Transportation	Is there public transportation? Will family members have access to it if they become physically challenged?

Stevens Plaza area have to walk to reach an apartment? Is there public transportation so the mother can take her toddler for emergent care?). Table 4.1 summarizes areas to examine in community assessment. Drawing an ecomap or a diagram of a family's relationship to their community (see Chapter 3, Fig. 3.3) can help identify what community contacts are available for a family. Different communities may or may not have resources for families with special needs such as home physical therapists or occupational therapists to assist children whose growth or development is delayed.

HOME CARE

Home care providers work out of agencies that can be either freestanding or allied with a health care facility. Specialized services such as providing supplies for total parenteral nutrition, fetal monitoring, or laboratory analysis may be furnished by special service companies. Voluntary agencies often provide services such as transportation to and from health care agency assessments or respite care so parents can have time free from continual care (Yantzi, Rosenberg, & McKeever, 2007).

In some settings, telephone contacts and e-mail and chat room contacts are used to link health care providers with families during home care. In many instances, nurses need to be assertive enough to help a family secure adequate funding and resources for home care.

Perinatal home care is care of pregnant women in their homes. Many public health departments have maternal–newborn projects that provide home care this way during pregnancy, allowing women to maintain contact with their families rather than being hospitalized for long periods and provide psychological and social support as well as aspects of medical care (Roman et al., 2007).

Care at home may include **direct care,** in which a nurse remains in continual attendance or visits frequently and actually administers care, or **indirect care,** in which a nurse plans and supervises care given by others, such as home care assistants.

Nursing care is considered **skilled home nursing care** if it includes physician-prescribed procedures such as dressing changes, administration of medication, health teaching, or observation of a woman or child's progress or status through such activities as monitoring vital signs or fetal heart rate. Whether nursing care is categorized as skilled or

not can determine whether it will be paid for by third-party reimbursement.

Home care is most successful if there are effective support people from the family or community to offer help. Otherwise, both women and children can experience such loneliness and low self-esteem that it interferes with their ability to remain on continuous bed rest or continue with a medical regimen.

It works best when a family is strongly committed to home care and well prepared to cooperate with health care providers. Pregnant women with complications such as preterm labor that has been halted, hyperemesis gravidarum (excessive nausea and vomiting of pregnancy), and hypertension of pregnancy are examples of pregnant women usually able to remain at home with supervision and periodic visits by a community or home care nurse. Frequent home visits are also helpful to monitor the health of newborns who were born with low birthweights or who arrived prematurely (Donovan et al., 2007). Although it is not well documented that bed rest prolongs such pregnancies, women with multiple pregnancies may be another example (Crowther, 2009).

Low birthweight occurs in newborns when preterm labor begins early and cannot be halted. In other women, labor can be halted but the woman needs careful monitoring for the rest of her pregnancy to be certain that the fetus is doing well in utero and labor is not beginning again. Nurses can be instrumental in seeing that women who are candidates for monitoring at home receive enough orientation and support that they are able to remain on home care and possibly prevent low birthweight. They can also be influential in seeing that time spent during home care is not wasted time but a time of preparation for birth and childrearing.

There may be an advantage of placing women with premature ruptured membranes on home care rather than hospital care because of the decreased exposure to infection in their own homes compared to hospitals. Children with chronic illnesses who need monitoring but not critical care are equally good candidates. It is possible that having a caring person such as a community health nurse visit frequently and take an interest in a family could have long-term effects, such as lowering the incidence of child abuse and child injury (Barlow et al., 2007).

Among the advantages of home care for a family are:

- It prevents extensive disruption of the family unit. For children who are acutely but not terminally ill, this extra emotional support may not be as immediately important as physical care. For those who are chronically ill or dying, being close to their family and friends may be the most important aspect of their care. For these children, home care is ideal (Tuffrey, Finlay, & Lewis, 2007).
- It can increase a woman's or child's self-confidence because it allows for more self-care and often more control of circumstances.
- Families can be better assessed in their own environment than in an agency, because family interactions, values, and priorities are more obvious than in a health care setting.
- Home visits provide a private, one-on-one opportunity for health teaching.
- Home care can reduce the cost of care when monitoring is the main type of care necessary.

In most instances, it is less costly to the health care delivery system to care for pregnant women or children at home rather than in a hospital setting because the number of health care personnel needed is so reduced. Cost containment, however, has to be weighed against the safety and quality of care. Not all home settings are safe for care and not all families have the commitment necessary, so it is not an alternative for all families. In addition, although home care is cost-effective for health care agencies, it may not be cost-effective for the family. Costs that health insurance would have paid for, such as dressings and medications, for example, had the client been hospitalized may no longer be covered once the person is transferred to home care.

Disadvantages of home care can be:

- It can actually increase the cost for an individual family if the family's insurance does not cover the cost of nursing visits or necessary supplies.
- It can cause increased anxiety and concern because pregnant women or family members are asked to assume a much greater responsibility for monitoring their own or a child's condition.
- The physical care required (e.g., tracheal suctioning or a complicated medication regimen) can be overwhelming for family caregivers.
- The financial strain of at least one parent or a spouse having to quit work and, therefore, not earning an income can cause a great financial strain on a family.
- Bed rest at home can cause social isolation and the disruption of normal family life.

Orienting families to home care, making home visits, supervising and coordinating home health personnel, providing health teaching in relation to pregnancy and childrearing, and evaluating whether home care remains appropriate are all important nursing responsibilities.

BEGINNING HOME CARE

Discharge planners in acute care settings can be instrumental in setting the stage for home care by discussing the need for continued health supervision with families and helping them begin establishing personal goals for home care. Several steps are then necessary for the actual home visit to be successful. These steps can be divided into previsit, visit, and postvisit phases.

Preparing for a Home Visit

Typically, a first home visit is made within 24 hours of discharge from an acute care facility or after notice from the ambulatory care facility. Be certain to obtain a copy of the client's referral form to familiarize yourself with the treatment course and plan of care. Obtain any supplies that may be needed for the visit. Keep in mind that you are going to be a guest in the client's home, so respect for the client's and family's privacy, beliefs, lifestyles, routines, culture, and requests is crucial.

As a part of individualizing care, make a telephone call to a client or family in advance to arrange a time for a visit so it will be convenient for the client and the fam-

BOX 4.2 ✻ Safety Tips for Home Health Care Travel and Visits

- Plan your trip in advance using a reliable map of the area so you do not become lost in a strange neighborhood.
- Let someone know where you are going and when you expect to return.
- Keep your automobile in good repair and filled with gasoline so you can avoid having to make stops at unfamiliar service stations.
- Park your car in a well-lighted, busy area. Lock the car door.
- Do not leave valuable objects such as an expensive CD player in your car, so it is not a target for car thieves.
- Lock any valuables in the trunk of your car *before* you leave the health care agency, not after you park in front of a home to visit, so no one sees you do this.
- Learn the location of public telephones in the area, or keep a cellular phone with you.
- If you suspect that someone is following you in your car, drive to the nearest police or fire station.
- If you suspect that someone is following you while you are walking, walk into a business establishment.
- Do not carry a purse or backpack that suggests you are carrying a large sum of money or drugs or valuables.
- Carry only minimal supplies so your hands are free to defend yourself.
- Drive or walk on main or busy streets; avoid shortcuts through alleys or unoccupied areas.
- Avoid approaching homes by a dark back alley; use the front door or a busy hallway.
- Use special caution in stairwells and elevators. Leave a stairwell or elevator if a potentially threatening person enters, with an excuse such as, "I've forgotten my red pen."
- Walk determinedly, as if you have a purpose and are in charge of your environment and situation.
- When you first enter a home, assess it for personal safety. Ask who is at home. If there are animals in the house, ask if they are friendly.
- If there are animals, take precautions to avoid getting flea bites (sit on a kitchen chair, not an upholstered chair).
- Be cautious about accepting food or drink if you are not certain about the hygiene of the dishes or food. Decline it gracefully with an excuse such as, "I'm trying to cut down on the amount of coffee I drink," or "It's against my agency's rules."
- Have your car keys in your hand when you leave the house so you can unlock and enter your car quickly.
- Look under your car when approaching it and in the back seat before entering it to be certain no one is there. Relock your car door immediately once inside.
- Leave a home immediately if you feel threatened or unsafe.
- If both you and the client are in personal danger, call the community emergency number, such as 911, for help.

ily. Obtain necessary instructions to reach the home. To avoid disrupting family routines, try not to visit at mealtime unless observing what a client is eating for a typical meal is necessary for assessment. Keep in mind that the ethical and legal aspects of nursing care, such as confidentiality, informed consent, decision making, and client rights, commonly associated with acute care nursing are also applicable to home care. Remember this especially when transporting a chart or notes or when discussing the visit with others.

Ensuring Personal Safety

Because home care visits are often made alone, take measures to ensure your personal safety on the way to a client's home, during a visit, and afterward. Safety tips for traveling in an unfamiliar community are shown in Box 4.2.

✔ Checkpoint Question 4.1

You need to schedule a first home visit for Lee Puente following a hospital stay. When is a first home-care visit typically made?

a. Within 1 hour after discharge
b. Within 24 hours after discharge
c. Within 4 days after discharge
d. Within 1 week of discharge

Making the Visit

Depending on the location of a client's home, the facilities and resources available may vary. The setting also varies from a house, apartment, mobile home, or shelter. On arrival at a client's home, knock or ring the bell and wait for someone to let you in. Greet the client and any other family members present. Greet family pets if they come to greet you (but do not pet strange dogs). Dogs typically serve a guard function, and you want them to view you as a friendly, not a threatening, visitor. Sometimes special advance arrangements, such as having a neighbor let you in, may be necessary if a woman lives alone and cannot walk down a stairway or a long hallway to answer the door.

As in any health care setting, wash your hands before touching a client for assessment, and follow standard infection precautions while giving care. Many home care nurses carry liquid soap and paper towels or disposable wipes with them for handwashing if the facilities in a home are inconvenient or unavailable.

What if... Lee Puente's family lives in a trailer park? Their nearest neighbor stops you every time you visit to ask you how Lee is doing. How would you answer her?

Assessing the Client

Typically, on a first home visit, a thorough health assessment is necessary, including a health history and physical

examination, as well as evaluation of the social environment, medications, nutrition, safety, and adherence to treatment this far. In addition, a consent for treatment and release of information form may need to be signed (Fig. 4.2).

Provide privacy and confidentiality when obtaining the health history and performing a physical examination. At all times, despite the informality of the setting, good interviewing and physical assessment skills are important (Box 4.3). Some homes may be too cool early in the morning for physical assessment because the heat has been turned down during the night. Arranging for a visit later in the day alleviates this problem. If a home has few rooms, finding a private location can be difficult. Be certain to include assessment not only of physical aspects but of mental or psychosocial ones as well to detect depression, which can occur out of worry or loneliness (Secco et al., 2007). Families receiving home care are usually anxious to have a nurse confirm that they are well and that the self-assessments they have been making have been accurate. Throughout the assessment, evaluate the client's needs and provide instructions and reinforcement about any specific areas that are necessary.

If bed rest is required, ask how women or children occupy their time. A woman is not really resting if she is concerned about her family or finances, is caring for older children, or is bored. Children are not really resting if they are sitting up playing active video games.

Before leaving, be certain to evaluate the family's understanding of the illness and what danger signs to report immediately if they should occur. Be certain that the family has a means of obtaining refills on prescriptions and knows what measures to take if the woman's or child's condition should worsen, such as calling 911, the hospital, or a primary care provider. Many clients or families feel more comfortable calling the home care agency rather than the primary care provider's office if the agency has nurses on call around the clock. The nurse on call can then help the client determine what action would be best to take.

As a final check, be certain that families know what their responsibilities will be, when home care personnel will visit again, any modifications of their home that need to be made, the dates and times of return visits to a health care facility, and whether they have transportation for these visits.

Client Name: _____

Address: _____

City: _____ State: _____ Zip: _____ Phone: ( )_____

Insurance Company:_____ Insurance I.D.#

I, the _____ (of the patient), intending to be legally bound, hereby:

1. Consent to such care and treatment by , and its employees and agents (collectively, the "Agency"), as prescribed by the client's physician or dictated by the client's condition.
2. Authorize the Agency to release any medical records in its possession concerning the client as may be required by law or to pay benefits on the client's behalf. I authorize the client's physicians, insurers, and hospitals to release such medical records to the Agency at the Agency's request.
3. Authorize my insurer to disclose to the Agency the terms and extent of my coverage, and the amount of payments made to me for services provided by the Agency.
4. Assign, transfer, and set over to the Agency all of my or the client's rights to insurance proceeds or other funds to which I am or the patient is or will become entitled as a result of the services rendered by the Agency.
5. Consent to and authorize payment, which would otherwise be payable to me or the client, to be made directly to the Agency. The Agency may issue a receipt for such payment which shall discharge the insurance company of its obligations under the policy to the extent of such payment.
6. Agree that I remain individually responsible to pay the Agency for all charges not paid for any reason by the insurer or other third-party payer. I understand that payment in full is due upon receipt of my bill. If payment for the Agency's service is made directly to me by my insurer, I agree to endorse the check to and forward it to the Agency within three days of receipt.

A photocopy of this document, if executed, shall be considered as effective and valid as the original.

The effect of this form and the Client's Rights and Responsibilities on the back of this form have been explained to me by the Agency and I understand its content and significance.

Date: _____ Signature: _____

Name: _____

BOX 4.3 ✻ Focus on Communication

Lee Puente is receiving home care because of hyperemesis of pregnancy and elevated blood pressure. She lost 15 pounds at the beginning of pregnancy but now, at 20 weeks, has gained back the lost pounds, plus 2 extra pounds, since beginning supplemental enteral feedings every day. A home health care assistant visits her three times a week to supervise her nutrition. She always seems pleased to be visited by a home care nurse once a week.

Less Effective Communication

Nurse: Hello, Lee. Is everything going all right?
Lee: Great.
Nurse: Are you eating everything you're supposed to?
Lee: Sure.
Nurse: Not throwing up any more, are you?
Lee: No.
Nurse: Good. I'm glad you're doing so well.

More Effective Communication

Nurse: Hello, Lee. How is everything?
Lee: Great.
Nurse: Are you eating everything you're supposed to?
Lee: Sure.
Nurse: What did you eat for breakfast this morning?
Lee: A slice of toast.
Nurse: What happened afterward?
Lee: I threw it up. I do that about once—maybe twice—a day.
Nurse: I need to do a more thorough assessment.

Because home settings are more informal than those of health care agencies, it is easy to forget that a home is a health care setting and to let a relationship become more relaxed than therapeutic. In the first scenario, the nurse lapsed into using leading questions rather than structured ones for a health interview. Lee responded to the leading questions by supplying answers she thought the nurse wanted to hear, not necessarily the true answers.

Assessing the Environment

During a visit, observe whether the house is safe for home care. This means there is adequate water, electricity, heat, and refrigeration. Are there smoke detectors in the home? Are they in working order? Are there drafts or broken windows? Are there rodents or insects or lead-based paint in the house that make the environment unsafe?

Evaluate how far the bathroom is from the client's bed. A bedside commode may be necessary to avoid a long walk. Check that there is a telephone nearby so the client has a means of calling someone, both to prevent loneliness and to secure emergency help. If a client needs assistance with personal hygiene, evaluate the floor plan of the bathroom or evaluate the need for a referral for a home health assistant.

Be sure that medical equipment brought into the home can be accommodated (Fig. 4.3). Hospital beds can be rented from medical supply companies. If a family cannot afford one, they can elevate a house bed on wooden or concrete blocks. Many home mattresses are not firm; a piece of plywood slid under the mattress improves firmness. A cardboard box or additional pillows can be placed under the mattress to elevate the head of a regular bed to a gatch position. Bed trays can be purchased at any department store or made from a heavy cardboard box.

If the client will use a wheelchair to ambulate, family members need to consider what adaptations of their home will be necessary. A local carpenter can build a ramp across the house steps to allow wheelchair access. Unless the person will be using a motorized wheelchair, the ramp should have a railing that can be grasped to pull the chair upward or to stop the wheelchair from moving downward too fast. Wheelchair lifts or elevators can be purchased and mounted alongside house steps, but they are usually more expensive.

Because it is difficult to move a wheelchair across a high-pile carpet, covering the carpet with plastic is helpful. Throw rugs usually have to be removed because they become tangled in wheelchair wheels. Placing furniture along the walls allows increased safe turning space for a wheelchair.

It is often impossible to reach high shelves from a wheelchair. A pair of tongs can be helpful to do this. Family members may have to move supplies that are used often, such as boxes of cereal, to a lower cabinet so the wheelchair challenged family member can reach them. If a kitchen counter is too high to prepare foods, placing a board across the wheelchair arms provides a workspace. If a stove has controls at the back, it is difficult for a person in a wheelchair to turn it on or off. Caution parents that if a child attempts to reach across a hot burner to reach the controls, he or she could be badly burned. A microwave oven placed on a low table can be a solution that allows a person to warm up meals and prepare snacks independently. Installing a safety rail by the toilet in the bathroom helps a person

FIGURE 4.3 Procedures at home need to be modified to adjust to the setting. Here a young boy uses a backpack to carry an ambulatory bag for his gastrostomy tube feeding. (John Meyer/Custom Medical Stock Photograph.)

transfer from wheelchair to toilet. A chair placed in the bathtub alongside safety rails allows the person to transfer to the bathtub.

Federal law mandates that all public buildings provide easy access for people in wheelchairs or using walkers. In some towns, buildings may not be equipped this way because no one has ever asked for the service before. Urge the family to contact their city council if a problem exists. Serve as an advocate if the family's approach is met with less-than-prompt action so that everyone who uses a wheelchair will have access to facilities such as the public library, zoo, museums, and shopping malls.

Home Care Assistants

Effective home care requires a team of health care providers, including the supervising physician, home care nurses, health equipment suppliers, and home care assistants. Home health assistants are an invaluable help in providing home health care because they can supply the bulk of personal care services, such as assisting with or providing hygiene, assisting with ambulation, and providing adequate nutrition. Home care assistants have varied levels of education depending on the home health care or community health care agency policies and the level of care they are being asked to provide.

When working with unlicensed assistive personnel:

- Be sure you are familiar with their level of ability and education so you do not assign a task to them that is above their ability or one that prevents them from using their full potential.
- When making assignments, be certain they understand that making an assessment (e.g., recording a blood pressure) is not the same as evaluating the meaning of the assessment. That requires professional expertise.
- When they are in a client's house, remind them that they are a guest in the house and need to respect the values and patterns of that household.
- When a client no longer needs home care and the time comes to terminate the relationship, they may need your help with ending the relationship and saying good-bye because, often, their services have been of such a personal nature.

What if... When you're visiting Lee Puente, you discover large mouse holes in the bedroom that will be used by her new baby? What would you do?

Postvisit Planning

Postvisit planning consists of documenting all information gained from the visit in relation to a client's condition, completing agency forms so billing for supplies and nursing time can be accurate, and evaluating a client's current status and future needs. It may include communicating a change in status to the primary health care provider, asking for a renewal of orders, or updating and revising the plan of care. Although the forms may vary, the rules for accurate documentation in home care are the same as for any health care facility and just as essential.

Follow-up Visits

Subsequent home visits are planned depending on a client's circumstances and the amount of health education and supervision needed. A second visit could be scheduled as often as the next day or as infrequently as once a month. Frequent assessments accomplished at subsequent visits include vital signs, nutrition assessment, medication adherence, and nursing care actions such as health education.

✔ Checkpoint Question 4.2

In the middle of a visit to Lee Puente's home, her former boyfriend arrives and threatens you and Lee. What would be your best action?

a. Tell him that threatening someone is not mature behavior and he should stop.
b. Suggest that Lee change all of her home locks so this man cannot visit again.
c. Leave the home and notify your agency that you were in unsafe circumstances.
d. Call 911 and report that you and a client are being threatened.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Interrupted family process related to stress of caring for ill family member at home

Outcome Evaluation: Family members state they feel able to manage home care; family meets weekly to discuss problems and share accomplishments.

Nursing responsibilities for women and children receiving home care vary greatly because the reason for home care and the actions needed to be taken vary greatly. Typical interventions carried out in homes are concerned with promoting a healthy environment and healthy family function.

Ensure Bed Rest

Women and children on bed rest react in several ways, but many report feeling "tied down," "like a prisoner," and "as if I'm missing out." One solution to help them cope with the stress of the experience is for them to keep busy or use their time to learn a new skill. Most women can name activities they would like to do but have never had time to begin to do. For example, if a woman likes to read but does not always have the time, bed rest at home may provide an ideal time for her to catch up on her reading (Fig. 4.4). If she has other children, she can spend part of her time reading to them. She could also use the time to take a home-study course, learn a new hobby, write a short story, or study for a certifying examination related to her work. In any event, helping her plan meaningful activities such as these can help her view home care not as wasted time but as time invested in her family or career (Box 4.4).

Children need to involve themselves in school work or play, perhaps learning a new game or Sudoku or crossword puzzles. Otherwise, they may spend their time simply watching television or napping. Although play is a universal activity

FIGURE 4.4 Bed rest can be stressful. Helping a woman who is on bed rest identify enjoyable and productive activities to pass the time can help ease stress.

of children, not all parents realize how important it is to children. Children's play activities vary greatly depending on cultural and socioeconomic circumstances. When a child is not proficient in English and that is the language of health care providers, games such as stacking blocks or building with Tinker Toys can be played despite communication difficulty. Playing CDs or tapes of well-loved children's songs can also be effective, because the child does not need to be able to understand the words to enjoy the music or clap with the rhythm.

Identify a Child's Primary Caregiver

Although traditionally the primary caregiver for an ill child is the mother, in today's families, if a father works more flexible hours, he may be the parent best able to give the bulk of care. In some homes, a grandparent or an older sibling will be the person primarily responsible for care. Arrange to include this person in planning and problem solving because this person knows best what strategy of care will be most effective with the child, as well as what strategy will be most appropriate in light of the physical layout of the home and the family's financial ability and lifestyle.

Determine Knowledge Level of Family

Before anyone can be cared for at home, teaching may be required so the family understands the illness and principles of care. Include in the Nursing Care Plan both the things to be learned immediately and additional care measures that will need to be taught as the client's condition changes (Box 4.5).

Identify Available Resources

The term "resources" refers not only to material objects (e.g., hospital bed, portable oxygen, or glucometer) but also to whether family members are able to deal with the chronic stress of fatiguing or around-the-clock nursing care. Assess physical surroundings: Is there adequate floor space for a hospital bed, oxygen equipment, and so forth? Is a fire company nearby, able to respond in case cardiopulmonary resuscitation (CPR) is needed? Is a backup resource available to power needed equipment if a blackout should occur? Does the family have a telephone? Could the patient be evacuated easily in case of a fire? Does the family have transportation to a health care facility for follow-up care? Table 4.2 lists additional important assessments to make, depending on the age of a child.

BOX 4.4 ✻ Focus on Family Teaching

Suggestions for Best Use of Time While on Bed Rest

Q. Lee Puente tells you, "I feel like I'm wasting my time just being home this way. What can I do to keep busy?"

A. Try these suggestions:

- Concentrate on school work; make this a time to really delve into a subject.
- Ask your teacher if there is a special project you could work on from home while on bed rest.
- Renew an old hobby or begin a new one.
- Ask someone to bring you books on newborn care from the library so you can pass the time reading.
- Telephone your friends. Rest next to a telephone so friends know they will not be disturbing you when they return calls.
- Catch up on your correspondence. Friends and family will be surprised and delighted to hear from you.
- Investigate whether there is a local community project (e.g., making telephone calls for a political campaign, urging neighbors to write letters of support for a new playground) you could work on while on bed rest.
- If you have Internet access, spend time online looking for information about pregnancy, childbirth, or childrearing or just chatting with friends or others (if you have a dial-up connection, be conscious of the telephone bill that might result).
- Learn a second language; many books are available on this.
- Take a mail-order course on something you want to learn more about (e.g., creative writing; learning to be a paralegal).
- Ask your home care nurse about preparation-for-childbirth information. By conscientiously practicing breathing exercises while on bed rest, you can become well prepared for labor and birth.

Promote Healthy Family Functioning

A family that is supportive of all family members and provides an environment conducive to each member's continued growth and development is more likely to be able to manage home care than is a family with a history of ineffective or destructive coping strategies—that is, a family in which parents have unrealistic expectations of family members, one with a history of abusive relationships, or one that is coping ineffectively with other stressors in their lives. Even a family that appears to be functioning well, however, may be so adversely affected by the stress of home care that its members' ability to be successful with home care can be limited. For example, the loss of employment income, resentment over missed promotions, or cramped living space could put a family at risk for ineffective coping. Remember that every family operates differently and handles stress in different ways. Events that may seem overwhelming for a visiting health care provider may actually be easy for the family to handle. Conversely,

BOX 4.5 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Pregnant Adolescent at Home on Bed Rest

Lee Puente, a 16-year-old, who is 20 weeks pregnant, lives with her parents. She was admitted to the hospital for 3 days at 14 weeks of her pregnancy and placed on a program of total parenteral nutrition because she has been vomiting at least four times daily since the beginning of pregnancy. She managed well on parenteral nutrition until last week, when her blood pressure rose to 160/90 mm Hg and she was diagnosed with hypertension of pregnancy. Bed rest with fetal and uterine surveillance at home was added to her care. She tells you it is impossible for her to rest at home: she is bored and wants to be back in school with her friends. She has missed three doses of her hypotensive agent because she forgot to take them. She wants to be hospitalized again for care.

Family Assessment ✻ Child lives with parents in a two-story home. Child's bedroom is on second floor with bathroom located approximately 20 feet from child's bed. Child's mother is primary wage earner in the family; works full-time as a travel agent. Father is full-time doctoral student receiving only a student stipend. He stays home until noon daily.

Client Assessment ✻ Vital signs: Temperature 98.4° F; pulse 76; respirations 22; blood pressure 144/94; FHR 148. Mild facial edema; +1 protein in urine; 2-pound weight gain in 1 week.

Nursing Diagnosis ✻ Anxiety related to need for bed rest secondary to nausea and hypertension of pregnancy

Outcome Criteria ✻ Client identifies methods to continue in school while maintaining bed rest; expresses increased satisfaction with imposed bed rest; maintains bed rest until fetal maturity. Blood pressure remains 140/80 or less; FHR within acceptable parameters; urine for protein remains +1 or less; weight gain limited to 1 lb/week; edema limited and without increase for the duration of pregnancy.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Assess vital signs, including heart rate, BP, and FHR at every visit.	Instruct client how to take own vital signs. Instruct how to do a "count-to-ten" assessment daily to document fetal activity.	Assessment of vital signs, especially BP and fetal activity, provides a baseline for future comparison and evidence of the client's and fetus's status.	Client demonstrates she is able to accurately obtain own pulse, BP, and fetal activity. Findings compare with nurse's weekly findings.
		Consultations		
Physician/nurse	Assess what services will be most appropriate for client.	Arrange for home care visiting by hospital home care team. Care assistant: daily; RN 1× week.	Home care functions best when it is part of a "seamless" service.	Client agrees to services of hospital home care team.
		Procedures/Medications		
Nurse	Assess random urine specimen for protein at each home visit. Assess what client interprets home bed rest to mean.	Instruct client to assess urine specimen and weigh herself every day. Review concept of complete bed rest. Arrange for a bedside commode if necessary.	Proteinuria +3 indicates severe edema. Increasing weight suggests tissue fluid retention. Varying degrees of bed rest may be necessary to reduce symptoms of hypertension of pregnancy.	Client voices an understanding of need for bed rest and adheres to restrictions. Demonstrates ability to carry out procedures accurately.

		Nutrition		
Nutritionist/ nurse	Obtain a 24-hour recall pattern to determine nutritional intake.	Encourage a diet high in protein and adequate fluid intake.	Protein may affect the degree of hypertension of pregnancy.	Client lists a 24-hour intake that is adequate for pregnancy.
		Patient/Family Education		
Social worker/ nurse	Assess what client feels are her chief needs to allow her to remain on bed rest at home.	Assist client with planning effective bed rest; discuss possible sources of help from friends and family in addition to daily health care assistant.	Planning concrete methods to make bed rest more tolerable alleviates stress.	Client demonstrates ways she has adapted to bed rest restrictions. Voices plan for creative uses of her time
		Urge parents to arrange for telephone jack or wireless connection so client can arrange computer connection to continue school activities.	Helping establish a means of communication provides stimulation and a better possibility of continuing in school.	Client demonstrates how she will use telephone, computer, and fax machine to continue to participate in school.
		Psychosocial/Spiritual/Emotional Needs		
Nurse	Discuss with client areas of concern.	Encourage the client to plan frequent periods of quiet time for herself. Suggest activities such as reading and listening to music.	Discussion provides baseline information to identify client's needs, beliefs, and responsibilities.	Client describes any areas of concern that could interfere with bed rest. Client lists at least three restful activities that she can use to occupy her day.
		Discharge Planning		
Nurse	Assess for readiness to participate in home monitoring.	Instruct client and family members in signs and symptoms of increased hypertension, such as increased edema, increased protein in urine, headache, dizziness, blurred vision, increased weight gain, or decreased urine output. Advise client to call the home care agency or primary health care provider if these occur.	Knowledge of danger signs and symptoms allows for early identification and prompt intervention to prevent threats to the mother and fetus.	Client lists signs and symptoms of elevated blood pressure and telephone number she will call if pressure is over 140/80.

problems that seem minor could be disruptive enough to affect the family's ability to provide adequate care at home.

Many women fulfill multiple roles in their family, such as financial manager, peacemaker, problem solver, nurturer, and decision maker. Even when a woman is on bed rest, help her to continue in these roles to ensure the family's usual functioning, because support people often have great difficulty assuming these roles in her place. In some families, older children fill these roles so need to be encouraged to continue in these roles if they are the ill family member being cared for at home.

As a rule, support people can only be supportive if they understand the need for the home care program and the importance of their role. Arranging for a homemaker service to help care for children or an aging parent or to help with light housework may be necessary to prevent support people from feeling stretched so thin they cannot function. Often support people are not present at the time of a home visit for a

TABLE 4.2 ✻ Assessment Criteria for Home Care by Age Group

Age	Points to Assess
All age groups	Are there adequate three-pronged plugs needed for the care equipment available? If oxygen will be used, is there a sign to omit smoking in the room? Is the oxygen away from a fireplace, gas space heater, or stove? Does the family know not to light candles near oxygen in a power failure or for a birthday? Is there adequate space for supplies? Is there a smoke detector in the patient's room? If a special diet is necessary, does the person who will cook have adequate knowledge of food preparation? Do caregivers know the emergency call system procedure in their community? How to reorder supplies? Has the power company been notified if an electrical appliance is necessary for life support? What would be the caregiver's actions in a power failure? What emergency steps should the caregiver take if the patient is suddenly worse?
Infant	Is there a suitable sleeping place? Do side rails of a crib lock securely? Can the infant be heard from the parents' room at night? Is there a functioning refrigerator if formula will be used? Is there protection from mosquitoes? Is the home free of rodents that might attack a small infant?
Toddler and preschooler	Is there a safe area for play free from stairs and poisoning possibilities? Are there screens or locks on windows to prevent a child from crawling onto a ledge? Is there provision for stimulation and learning activities?
School-age child and adolescent	What is the provision for schooling (possibly an intercom with a regular classroom or home tutor)? Is peer interaction possible? If adolescent is self-medicating, will reminder sheets or some other reminder system be necessary?

pregnant woman because they work during the day. Ask a woman at home visits how her support people are coping and if there are ways this experience could be made easier for them as well as for her. The ability to make decisions about her own care such as this can make a significant difference in whether a woman thinks her home care experience is satisfactory.

Provide Health Teaching

A home care visit can provide many more opportunities for one-on-one health teaching than a health care agency setting. An important aspect of teaching for a pregnant woman might be providing childbirth education, because a woman on bed rest will not be able to attend formal classes. For a child, it could be teaching the whole family about the child's illness and why the current therapy is needed.

Provide for Safe Medicine Administration

Most people receiving home care are prescribed some type of medicine, such as a tocolytic for pregnant women to halt preterm labor or an antibiotic for a child to cure an infection. Review the rules of safe medication administration with the family to minimize mistakes such as taking the medicine more frequently than prescribed or forgetting to take it (Box 4.6).

Manage Pain

Children who are on home care post surgery or those with a chronic or terminal illness may need efficient pain management while they are cared for at home. Be certain that parents understand the principles of pain management such as giving medication before pain becomes acute (Box 4.7). Other aspects of pain management are discussed in Chapter 39.

Provide for Adequate Nutrition and Hydration

A woman who is on home care often needs help maintaining adequate nutrition. If ordinarily she is the person who plans menus, shops for food, and cooks for the family, with her on bed rest, other family members must assume these roles. If other family members are inexperienced at cooking, the entire family, including the pregnant woman, may not be eating enough healthy foods.

BOX 4.6 ✻ Safety Tips for Safely Taking Medicine at Home

- Keep drugs in a safe place. In most homes, this is in a locked medicine cabinet or drawer above the height a child could reach.
- Remind parents that most childhood poisonings occur when a family is under stress; during these times, the family can forget usual procedures such as locking away a drug. Reinforce the need to take special precautions to lock away medications at these times.
- Never take medicine in front of children (children can imitate this action with the parent's medication).
- Do not pour or prepare medicine in the dark. Because almost all medicine bottles dispensed from local pharmacies look and feel the same, it is easy to pour the wrong liquid, extract the wrong pills, or read the bottle instructions incorrectly without adequate light.
- Make out a reminder sheet and hang it in a prominent place. Cross off each time the medication is taken.
- Purchase a medicine box with an individual compartment for each day of the week. Fill it at the beginning of the week. Such boxes help to eliminate confusion over whether medicine was taken or not.

BOX 4.7 ✻ Focus on Evidence-Based Practice

Do parents adequately manage pain in children who are on home care after a tonsillectomy?

Tonsillectomy is one of the most common surgical procedures performed on children. It is done routinely on an ambulatory or day-surgery basis so most children spend only 3 to 4 hours in the ambulatory center. This puts the major responsibility for postoperative care including adequate pain management on the parents after the child returns home.

To investigate whether children usually receive adequate pain management while at home, nurse researchers asked 76 children ranging in age from 7 to 12, who were undergoing tonsillectomy to record their pain level, the type and timing of analgesics they received, and whether they received pain relief from the medicine while they were at home.

The children's diaries revealed that most children rated their pain level as "moderate." Ninety-six percent of the 25 children who were prescribed hydrocodone/acetaminophen (Vicodin), an opioid analgesic, were given by parents a dose below the recommended standard. Only 69% of the 22 children who were prescribed codeine and acetaminophen (Tylenol) received the recommended dose; 6.3% received less than the recommended dose, and 25% received more than the recommended dose. Drinking fluid can help relieve edema and therefore also reduce pain. Only 11% of children met the recommended amount of fluid intake in the first 24 hours after surgery.

The authors conclude that parents may need more information on hospital discharge regarding how to administer pain medication. A telephone call from the surgery setting in the first 24 hours might be helpful to assist parents with adequate pain management.

How would you use the above study findings if you were visiting a child in his home after surgery?

Source: Huth, M. M., & Broome, M. E. (2007). A snapshot of children's postoperative tonsillectomy outcomes at home. *Journal for Specialists in Pediatric Nursing, 12*(3), 186–195.

As ill children do not get as much activity as usual, they may not be hungry at mealtime. You may need to make suggestions for healthy snacks so a child's total daily intake is adequate even if not a lot of food is eaten at formal meals.

All women during pregnancy should drink six to eight full glasses of fluid a day to obtain adequate fluid for effective kidney function and placental exchange (Rojas, Wood, & Blakemore, 2007). Be certain women on bed rest have a supply of fluid close to their bed so they can do this easily.

Intravenous Administration

Many women and children on home care receive intravenous therapy as a route of medication administration (Balaguer & Gonzales de Dios, 2009). Women with hyperemesis gravidarum (uncontrolled vomiting during pregnancy) receive it as a means of hydration (Lamondy, 2007). Women and children with blood dyscrasias may receive blood transfusions in the home.

Intravenous medication and fluid administration can be accomplished by either a peripheral or central insertion site. Because peripheral intravenous lines frequently become dislodged, in the home setting, intravenous fluid is often administered by a central line or a peripherally inserted catheter threaded to a central blood vessel (a PICC line). Specially pressurized fluid containers allow for fast and easy administration of special solutions. To be certain that fluid infuses slowly and accurately, an intravenous infusion pump is strongly recommended. Many drugs, especially antibiotics, are given through bagged "piggyback" infusions that are kept frozen until the time of administration. Be certain a woman or a family member knows how to monitor intravenous insertion sites for inflammation and infiltration, how to protect the site from becoming infected (e.g., cover it with plastic rather than letting it get wet), and how to monitor the amount and kind of fluid or medication infused.

Home Enteral Nutrition

Chronically ill children and women who have hyperemesis gravidarum may receive nutrition by a nasogastric tube. The supplies necessary for enteral feedings, such as feeding tubes and enteral pumps, are available for rent or purchase through pharmacies or medical supply houses or the home care agency. Such tubes are usually changed every 2 to 4 weeks. The home care nurse will most likely be the person responsible for changing the tube, but this depends on the home care agency's policies. In addition to assessing the amount of formula infused by this route, be sure that a woman or family member is familiar with all aspects of care for the tube, equipment, and administration of the feeding. Caution the family to monitor the amount of formula for the feedings on hand so they do not run out, especially over weekends. Clients on enteral feedings probably will need to weigh themselves periodically and record the weight. Be certain they use the same scale, wear consistent clothing, and know when to call for advice if they are having difficulty or are unsure if their weight is remaining adequate.

Total Parenteral Nutrition

Total parenteral nutrition (TPN) is yet another way to supply complete nutrition and fluid to clients on home care. Usually the home care agency or a separate private vendor will furnish and deliver the formula, tubing, clean dressings, and an infusion pump. The formula, which consists of amino acids, hypertonic glucose, vitamins, and minerals in solution, needs to be stored in the client's refrigerator until 1 to 2 hours before use; it is then removed from the refrigerator and allowed to warm to room temperature. Women and children requiring this type of intravenous nutritional therapy usually have a central venous access device such as a central venous catheter or PICC line inserted. The home care nurse plays a key role in teaching family members about the therapy and also in assessing the woman or child's response to therapy.

Throughout therapy, be sure the client or a family member monitors the infusion of the solution and the patency of the tube, knows how to change dressings, observes the insertion site, and assesses body temperature for signs of possible infection. They also must be aware of any restrictions

that should be adhered to (e.g., no baths if the water level will rise above the catheter insertion site) and the interval at which blood should be drawn for monitoring. Because TPN solutions are hypertonic, the woman or a family member needs to obtain fingerstick blood glucose levels as necessary, about every 6 hours, and keep a record of these. Be sure the family knows what findings should be reported immediately to a health care provider.

Promote Elimination

Promoting elimination in anyone receiving home care can call for advance planning. Assess if the place where the person is going to rest is close by a bathroom so the person can reach this easily. If strict bed rest is required, a bedside commode may be necessary.

Constipation occurs at a high rate during pregnancy and can occur in children on bed rest from lack of exercise. Encourage a diet high in fiber and fluid daily to minimize this problem.

Teach Monitoring of Vital Signs

Monitoring vital signs in the home does not differ from monitoring them in a health care agency except mercury thermometers may be used in place of electronic ones. If the family will be using a mercury/glass thermometer, caution them that mercury is a toxic contaminant if the thermometer breaks and that this type of thermometer takes a full 3 minutes to register rather than the more convenient few seconds needed by electronic thermometers. To avoid risk of mercury ingestion, they should not be used with children under 5 years of age.

Blood pressure is best measured if the person is in the same position (lying down or sitting up) and the pressure is taken on the same arm each time. Using an automated cuff simplifies taking blood pressure. These can be purchased at pharmacies or from home care agencies.

Teach Self-Monitoring of Uterine Height, Contractions, and Fetal Heart Rate

Uterine (fundal) height during pregnancy is measured by using a paper tape measure according to McDonald's rule (see Chapter 11). If a woman is asked to record serial fundal height measurements, demonstrate the correct technique and have her give a return demonstration, as this measurement varies greatly depending on where the tape measure is placed. Be sure a woman is measuring the height in the same location each time. It may be necessary to mark the points to measure with a permanent ink pen to ensure consistent and accurate measurements.

Many women conduct count-to-10 assessments daily (count the number of fetal movements they feel in a designated time period; see Chapter 21) to help assess fetal well-being (Chang & Blakemore, 2007). Fetal heart rate (FHR) is usually recorded by the home care nurse at each home visit. In addition, a client may be taught how to obtain this herself. FHR can be recorded by listening with a Doppler, a fetoscope, a regular stethoscope (although FHR may be very difficult to hear), or an electronic monitoring device supplied as part of her home care program.

The client can self-monitor uterine contractions using a uterine monitor, the same as in a health care facility, or by palpation (see Chapter 9). A rhythm strip or nonstress test can be conducted using a portable monitor approximately the size of an MP3 player or cell phone. A woman straps this device to her abdomen for 20 to 30 minutes at a set time every day, or at any time she feels contractions or is concerned about the lack of fetal movement (Fig. 4.5). The monitor records both uterine contractions and FHR. At the conclusion of the monitoring period, the monitor is held next to a telephone and the tracing is transmitted to a central facility for evaluation.

FIGURE 4.5 Fetal heart rate and uterine contractions can be recorded successfully by women at home. (Photograph by Melissa Olson, with permission of Healthy Home Coming, Inc., Bensalem, PA.)

Teach Self-Monitoring by Serum or Urine Testing

Women who develop diabetes mellitus during pregnancy are required to monitor their serum glucose levels using a test strip and glucometer at least once daily (Hampton, 2007). Children with diabetes need to do the same (Hill, 2007). Most people are reluctant to learn this procedure because they do not like the thought of having to pierce the skin of a finger to draw blood. Automated lancet devices are available to help with this.

Provide Long-term Home Care

Although many families are good candidates for home care, they continue to need advice to adapt constructively to the crisis of illness and home management, as the stress and problems that can occur from being responsible for an ill family member can lower people's self-esteem. The time involved can harm a marital relationship or prevent parents from spending time with other children. Physical care requirements can disrupt the normal family routines and shift the focus of attention onto the ill child and away from other children in the family (Fig. 4.6).

Help families maintain healthy functioning by promoting communication and encouraging family members to identify and share their feelings about the new situation at home. Encourage members to voice the frustration they feel at being constantly confined at home or what they perceive to be a lack of progress in the ill person's condition. If a child has a terminal illness, support parents to express their grief and not

FIGURE 4.6 Home care of a child is family care. Here a brother helps his sister settle into her wheelchair.

grow discouraged, because the work they are accomplishing is making the child comfortable before death. Continued successful coping will require the family to acknowledge and take seriously the impact of home care on each family member and work together to solve identified problems. They may need to renegotiate roles and responsibilities within the family or seek outside help.

When a family is not functioning well at the beginning of home care or does not adjust to home care, nursing measures to support family functioning become even more important. A family whose coping strategies are maladaptive and ineffective may not be able to care for a sick family member at home for long.

✔ Checkpoint Question 4.3

Lee Puente is developing constipation from being on bed rest. What measure would you suggest she take to help prevent this?

a. Drink more milk, as increased calcium prevents constipation.
b. Walk for at least half an hour daily to stimulate peristalsis.
c. Drink eight full glasses of a fluid such as water daily.
d. Eat more frequent small meals instead of three large ones daily.

Key Points for Review

- Families exist within communities; assessment of the community and the family's place in the community yields further information on family functioning and abilities.
- Home care is increasing as a way of providing care to chronically ill children and women with complications of pregnancy. It has the advantages of being cost-effective and providing meaningful comfort and support.
- Disadvantages of home care are that families can become fatigued, the loss of a job for the primary caregiver can cause financial hardship, and social isolation and disruption of normal home life may occur.
- Home care requires careful planning and a combined effort between a home care agency and a health care provider to ensure collaboration and continuity.
- Not all homes are ideal for home care. Assess that a primary care provider is present; the family is knowledgeable about the care necessary; necessary resources are available; and safety features such as a smoke detector, a safe area for oxygen storage, and a safe refrigerator for food or medicine are present.
- Home care can be exhausting for families. Be certain a family devises a schedule of care that allows them enough rest. Advocate for medicine or treatment schedules that allow for administering medications during the day rather than a schedule that requires medication administration at night.
- Parents may need respite care to continue to be effective care providers for children the same as professionals need time off. Help parents to take turns giving care so that each has some free time during the week.

CRITICAL THINKING EXERCISES

1. Lee Puente is the adolescent you met at the beginning of the chapter. Was she a good candidate for home care? What additional interventions would she need to make home care more successful for her? Her mother is concerned that she will become exhausted because of the need for Lee's round-the-clock care. What suggestions could you offer to make care easier?
2. When you are visiting Lee in her home, do standard precautions to prevent the spread of infection apply? Explain your answer.
3. Lee Puente's father stays home from work until noon. A school friend visits every afternoon. Her mother stays with her in the evening. What would be the best time of the day to schedule a home visit?
4. Examine the National Health Goals related to home care. Most government-sponsored money for nursing research is allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to the Puente family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter; then answer the questions to further sharpen your skills and grow more familiar with NCLEX types of questions related to community assessment and home care. Confirm your answers are correct by reading the rationales.

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe anatomy and physiology pertinent to reproductive and sexual health.
2. Identify National Health Goals related to reproductive health and sexuality that nurses can help the nation achieve.
3. Use critical thinking to analyze ways in which clients' reproductive and sexual health can be improved for healthier childbearing and adult health within a family-centered framework.
4. Assess a couple for anatomic and physiologic health, biologic gender, gender role, gender identity, and readiness for childbearing.
5. Formulate nursing diagnoses related to reproductive and sexual health.
6. Identify appropriate outcomes for reproductive and sexual health education.
7. Plan nursing care related to anatomic and physiologic readiness for childbearing or sexual health, such as helping adolescents discuss concerns in these areas.
8. Implement nursing care related to reproductive and sexual health, such as educating middle school children about menstruation.
9. Evaluate expected outcomes for achievement and effectiveness of care.
10. Identify areas of care in relation to reproductive and sexual health that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of reproductive health and sexuality with nursing process to achieve quality maternal and child health nursing care.

Suzanne and Kevin Matthews, a young adult couple, 12 weeks' pregnant, come to your antepartal clinic for a sixth-month visit. Suzanne, in tears, states, "My husband isn't interested in me anymore. We haven't had sex since I became pregnant." Kevin states, "I'm afraid I'll hurt the baby." Previous chapters presented the scope of maternal and child health and how the structure, function, and culture of families can have an impact on health. This chapter adds information about how to educate children, women, and their partners about anatomy, physiology, and sexuality to better prepare them for childbearing and childrearing.

How would you counsel Suzanne and Kevin Matthews?

Regardless of whether someone is planning on childbearing, everyone is wiser by being familiar with reproductive anatomy and physiology and his or her own body's reproductive and sexual health. Women and their partners who are planning on childbearing may be especially curious about reproductive physiology and the changes a pregnant woman will undergo during pregnancy, so this is an opportune time to educate both partners about reproductive and gynecologic health (Allen & Fountain, 2007).

Although the general public is becoming increasingly sophisticated about their bodies, misunderstandings about sexuality, conception (preventing or promoting), and childbearing still abound. Sexuality is a major area of concern for school-age children and adolescents. When caring for children of these ages, they may ask you a variety of detailed questions about sexuality or reproductive health. For instance, many young adults want to know what is considered a "normal" sexual response or the "normal" expected frequency for sexual relations. A general rule in answering this question is that normal sexual behavior includes any act mutually satisfying to both sexual partners. Actual frequency and type of sexual activity vary widely (MacKay, 2009).

One of the greatest contributions nurses can make is to encourage clients to ask questions about sexual and reproductive functioning. With this attitude, problems of sexuality and reproduction are brought out into the open and made as resolvable as other health concerns or problems. If this is an area that you were raised to not discuss freely, learning to be comfortable with the topic and your own sexuality can be the first step needed.

Nurses who can clearly explain the physical and emotional changes of puberty to the adolescent, the physiologic changes of pregnancy to a young adult couple, or the expected changes of menopause to a middle-aged woman provide much-needed health teaching information. Several National Health Goals that speak directly to improving reproductive or sexual health are shown in Box 5.1.

BOX 5.1 * Focus on National Health Goals

Several National Health Goals speak directly to reproductive and sexual health:

- Reduce the proportion of adolescents who, by age 15, have engaged in sexual intercourse to no more than 15%, from a baseline rate of 27% of girls and 33% of boys.
- Increase to at least 50% the proportion of sexually active, unmarried people who used a condom at last sexual intercourse, from a baseline rate of 19%.
- Reduce deaths from cancer of the uterine cervix to no more than 1.3 per 100,000 women, from a baseline rate of 2.8 per 100,000.
- Reduce breast cancer deaths to no more than 20.6 per 100,000 women, from a baseline rate of 23 per 100,000 (http://www.nih.gov).

Nurses can help the nation achieve these goals by educating adolescents about abstinence and refusal skills, safer sex practices, and the advantage of obtaining a vaccine against the human papillomavirus (HPV), the virus associated with cervical cancer. Women need to participate in screening activities such as breast mammography and vulvar self-examination.

Nursing Process Overview

For Promotion of Reproductive and Sexual Health

Assessment

Problems of sexuality or reproductive health may not be evident on first meeting a client, because it may be difficult for a person to bring up the topic until he or she feels more secure. This makes good follow-through and planning important, because a person may find the courage to discuss a problem once but then be unable to do so again. If the problem is ignored or forgotten through a change in caregivers, it may never be addressed again.

Any change in physical appearance (such as occurs with puberty or with pregnancy) can intensify or create a sexual or reproductive concern. The person with a sexually transmitted infection (STI), excessive weight loss or gain, a disfiguring scar from surgery or an accident, hair loss such as occurs with chemotherapy, surgery or inflammation or infection of reproductive organs, chronic fatigue or pain, spinal cord injury, or the presence of a retention catheter needs to be assessed for problems regarding his or her sexual role as well as other important areas of reproductive functioning.

Assessing sexuality may not be appropriate as a routine part of every health assessment. However, it should be included when appropriate, such as when discussing adolescent development or before providing reproductive life planning information, during pregnancy, and after childbirth. At other times, it is wise to listen for verbal or nonverbal clues that suggest a person wants to discuss a sexual or reproductive concern. These clues are often subtle: "I guess marriage isn't for everyone"; "I'm not the woman I used to be"; "Are there ever funny effects from this medicine I'm taking?" Telling a seemingly inappropriate sexual joke may be yet another clue. Nonverbal clues may include extreme modesty or obvious embarrassment in response to a question about voiding or perineal pain or stitches.

Assessment in the area of reproductive health begins with interviewing to determine what a client knows about the reproductive process and STIs. Any concerns they might have about their own reproductive functioning or safer sex practices should be explored. This area of health interviewing takes practice and the conviction that exploring sexual health is as important as exploring less emotionally involved areas of health, such as dietary intake or activity level. The 14-year-old girl who is not yet menstruating, for instance, may be anxious about that fact but may be reluctant to say so unless asked directly. A statement such as the following invites discussion: "Although many of your friends at school may be menstruating, it's not at all uncommon for some girls not to begin their periods until age 15 or 16. How do you feel about not yet having your period?" This combination of providing information and questioning may encourage an

adolescent to discuss not only her possible concern about delayed **menarche** (the beginning of menstruation) but also other areas that will show her knowledge or lack of knowledge about reproductive health. Specific questions to include in a sexual history are shown in Box 5.2.

It is important to include in a physical examination observation for normal distribution of body hair such as triangle-shaped pubic hair in women and diamond-shaped pubic hair in men, for normal genital and breast development, and for signs and symptoms of STIs. Many STIs are asymptomatic, so it is important to assess whether the client is at risk for contracting an STI (see Chapters 33 and 47 for documentation of stages of sexual development and signs of STIs).

Nursing Diagnosis

Common nursing diagnoses used in regard to reproductive health include:

- Health-seeking behaviors related to reproductive functioning
- Anxiety related to inability to conceive after 6 months without birth control
- Pain related to uterine cramping from menstruation
- Disturbance in body image related to early development of secondary sex characteristics

Diagnoses relevant to sexuality could include:

- Sexual dysfunction related to as-yet-unknown cause
- Altered sexuality patterns related to chronic illness
- Self-esteem disturbance related to recent reproductive tract surgery
- Altered sexuality patterns related to fear of harming the fetus
- Anxiety related to fear of contracting an STI
- Health-seeking behavior related to learning responsible sexual practices

Outcome Identification and Planning

A major part of nursing care in this area is to empower clients to feel control over their bodies. Plan health teaching to provide clients with knowledge about their reproductive system and specific information about ways to alleviate discomfort or prevent reproductive disease. It may also be important to plan interventions to strengthen the person's gender identity or role behavior. It is essential to design care that demonstrates acceptance of all gender-related lifestyles equally. A helpful referral organization for clients is the Children of Lesbians and Gays Everywhere group (http://www.colage.org) or http://www.sexualityandu.ca, a site with helpful tips on both sexuality and reproductive life planning.

Implementation

A primary nursing role concerning reproductive anatomy and physiology is education. This is a major role, because both female and male clients may feel more comfortable asking questions of nurses than of other health care providers. To help clients understand reproductive functioning and sexual health throughout their life, specific teaching might include:

- Encouraging women over 40 to have mammograms
- Explaining to a school-age boy that nocturnal emissions are normal
- Teaching an early adolescent what is normal and abnormal in relation to menstrual function
- Teaching a young adolescent safer sex practices
- Explaining reproductive physiology to a couple who wish to become pregnant

Teaching is often enhanced by the use of illustrations from books or journals, clips from videos or compact disks, or models of internal and external reproductive organs. Nursing interventions in this area, however, include much more than just distributing educational materials. For example, empathy for a woman's concern about increased tension before menstruation may help validate her concern that she has premenstrual dysphoric syndrome. Serving as a role model for gender roles can also be a valuable intervention, particularly for young clients. Discussing the subject of reproduction in a matter-of-fact way, or treating menstruation as a positive sign of growth in a woman rather than as a burden, may help clients assume a positive attitude about these subjects.

Interventions that strengthen an individual's sense of maleness or femaleness may improve a client's gender identity or gender role. A woman who believes that part of a female role is to be assertive needs opportunities in her care plan for making decisions and self-care; a hospitalized adolescent who views a man's role as being a person who watches Monday night football needs time structured for this activity at the same priority level as other activities. Unless such activities are structured, they can be easily omitted by busy health care providers.

BOX 5.2 ✻ Specific Questions to Include in a Sexual History

- Are you sexually active?
- Is your sexual partner of the same or different gender?
- How many sexual partners have you had in the past 6 months?
- Are you satisfied with your sex life? If not, why not?
- Do you have any concerns about your sex life? If so, what would you change?
- Do you practice "safer sex"?
- Have you ever contracted a sexually transmitted infection or are you worried that you have one now?
- Have you ever experienced a problem such as erectile dysfunction, failure to achieve orgasm, or pain during intercourse?
- Are you using a method to prevent pregnancy or sexually transmitted diseases?
- Are you satisfied with your current reproductive planning method, or do you have any questions about it?
- (For girls), Have you had a vaccine against human papillomavirus (HPV)?

Men who have sex with men (MWM) or women who have sex with women (WWW) or others with alternative lifestyles usually reveal their sexual orientation to health care providers because they want help dealing with friends or family who are having difficulty accepting their gender identity. In addition to support, provide health education that addresses potential concerns of clients with all lifestyles. For example, include a discussion about anal or oral-genital sex practices when presenting information on safer sex.

Outcome Evaluation

Evaluation in the area of reproductive health must be ongoing, because health education needs change with circumstances and increased maturity. For example, the needs of a woman at the beginning of a pregnancy may be totally different from her needs at the end.

How people feel about themselves sexually may have a great deal to do with how quickly they recover from an illness, how quickly they are ready to begin self-care after childbirth, or even how well motivated they are as adolescents to accomplish activities in other life phases that depend on being sure of sexuality or gender role.

Examples of expected outcomes are:

- Client states he is taking precautions to prevent contracting an STI.
- Client states she is better able to manage symptoms of premenstrual dysphoric syndrome.
- Couple states they have achieved a mutually satisfying sexual relationship.
- Client states he is ready to tell family about MWM gender identity.

REPRODUCTIVE DEVELOPMENT

Reproductive development and change begin at the moment of conception and continue throughout life.

Intrauterine Development

The sex of an individual is determined at the moment of conception by the chromosome information supplied by the particular ovum and sperm that joined to create the new life. A **gonad** is a body organ that produces the cells necessary for reproduction (the ovary in females, the testis in males). At approximately week 5 of intrauterine life, primitive gonadal tissue is already formed. In both sexes, two undifferentiated ducts, the mesonephric (wolffian) and paramesonephric (müllerian) ducts, are present. By week 7 or 8, in chromosomal males, this early gonadal tissue differentiates into primitive testes and begins formation of testosterone. Under the influence of testosterone, the mesonephric duct begins to develop into the male reproductive organs, and the paramesonephric duct regresses. If testosterone is not present by week 10, the gonadal tissue differentiates into ovaries, and the paramesonephric duct develops into female reproductive organs. All of the **oocytes** (cells that will develop into eggs throughout the woman's mature years) are already formed in ovaries at this stage (MacKay, 2009).

At about week 12, the external genitals develop. In males, under the influence of testosterone, penile tissue elongates and the urogenital fold on the ventral surface of the penis closes to form the urethra; in females, with no testosterone present, the urogenital fold remains open to form the labia minora; what would be formed as scrotal tissue in the male becomes the labia majora in the female. If, for some reason, testosterone secretion is halted in utero, a chromosomal male could be born with female-appearing genitalia. If a woman should be prescribed a form of testosterone during pregnancy or if the woman, because of a metabolic abnormality, produces a high level of testosterone, a chromosomal female could be born with male-appearing genitalia (Torresani & Biason-Lauber, 2007).

Pubertal Development

Puberty is the stage of life at which secondary sex changes begin. These changes are stimulated when the hypothalamus synthesizes and releases gonadotropin-releasing hormone (GnRH), which in turn triggers the anterior pituitary to begin the release of follicle-stimulating hormone (FSH) and luteinizing hormone (LH). FSH and LH initiate the production of androgen and estrogen, which in turn initiate secondary sex characteristics, the visible signs of maturity. Girls are beginning dramatic development and maturation of reproductive organs at earlier ages than ever before (9 to 12 years) (McDowell, Brody, & Hughes, 2007). Although the mechanism that initiates this dramatic change in appearance is not well understood, the hypothalamus, under the direction of the central nervous system, may serve as a gonadostat or regulation mechanism set to "turn on" gonad functioning at this age. Although it is not proved, the theory is that a girl must reach a critical weight of approximately 95 lb (43 kg) or develop a critical mass of body fat before the hypothalamus is triggered to send initial stimulation to the anterior pituitary gland to begin the formation of gonadotropic hormones. Studies of female athletes and girls with anorexia nervosa reveal that a lack of fat can delay or halt menstruation. The phenomenon of why puberty occurs is even less well understood in boys.

Role of Androgen

Androgenic hormones are the hormones responsible for muscular development, physical growth, and the increase in sebaceous gland secretions that causes typical acne in both boys and girls. In males, androgenic hormones are produced by the adrenal cortex and the testes; in females, by the adrenal cortex and the ovaries.

The level of the primary androgenic hormone, testosterone, is low in males until puberty (approximately age 12 to 14 years). At that time, testosterone levels rise to influence the further development of the testes, scrotum, penis, prostate, and seminal vesicles; the appearance of male pubic, axillary, and facial hair; laryngeal enlargement and its accompanying voice change; maturation of spermatozoa; and closure of growth in long bones.

In girls, testosterone influences enlargement of the labia majora and clitoris and formation of axillary and pubic hair. This development of pubic and axillary hair because of androgen stimulation is termed **adrenarche.**

Role of Estrogen

When triggered at puberty by FSH, ovarian follicles in females begin to excrete a high level of the hormone estrogen. This hormone is actually not one substance but three compounds (estrone [E1], estradiol [E2], and estriol [E3]).

It can be considered a single substance, however, in terms of action.

The increase in estrogen levels in the female at puberty influences the development of the uterus, fallopian tubes, and vagina; typical female fat distribution and hair patterns; breast development; and an end to growth because it closes the epiphyses of long bones. The beginning of breast development is termed **thelarche.**

Secondary Sex Characteristics

Adolescent sexual development is categorized into stages (Tanner, 1990). There is wide variation in the time required for adolescents to move through these developmental stages; however, the sequential order is fairly constant. In girls, pubertal changes typically are manifest as:

1. Growth spurt
2. Increase in the transverse diameter of the pelvis
3. Breast development
4. Growth of pubic hair
5. Onset of menstruation
6. Growth of axillary hair
7. Vaginal secretions

The average age at which menarche (the first menstrual period) occurs is 12.4 years (McDowell et al., 2007). It may occur as early as age 9 or as late as age 17, however, and still be within a normal age range. Irregular menstrual periods are the rule rather than the exception for the first year. Menstrual periods do not become regular until ovulation consistently occurs with them (menstruation is not dependent on ovulation), and this does not tend to happen until 1 to 2 years after menarche. This is one reason why estrogen-based oral contraceptives are not commonly recommended until a girl's menstrual periods have become stabilized or are ovulatory (to prevent administering a compound to halt ovulation before it is firmly established).

In boys, production of spermatozoa does not begin in intrauterine life as does the production of ova, nor are spermatozoa produced in a cyclic pattern as are ova; rather, they are produced in a continuous process. The production of ova stops at menopause (the end of the fertile period in females). In contrast, sperm production continues from puberty throughout the male's life.

Secondary sex characteristics of boys usually occur in the order of:

1. Increase in weight
2. Growth of testes
3. Growth of face, axillary, and pubic hair
4. Voice changes
5. Penile growth
6. Increase in height
7. Spermatogenesis (production of sperm)

✔ Checkpoint Question 5.1

Suzanne Matthews tells you she used to worry because her breasts developed at puberty later than those of most of her friends. Breast development is termed:

a. Adrenarche
b. Mamarche
c. Thelarche
d. Menarche

ANATOMY AND PHYSIOLOGY OF THE REPRODUCTIVE SYSTEM

Although the structures of the female and male reproductive systems differ greatly in both appearance and function, they are homologues—that is, they arise from the same or matched embryonic origin (Fig. 5.1). The study of the female reproductive organs is called **gynecology. Andrology** is the study of the male reproductive organs.

Male Reproductive System

The male reproductive system consists of both external and internal divisions (Fig. 5.2).

Male External Structures

External genital organs of the male include the testes (which are encased in the scrotal sac) and the penis.

Scrotum. The scrotum is a rugated, skin-covered, muscular pouch suspended from the perineum. Its functions are to support the testes and to help regulate the temperature of sperm. In very cold weather, the scrotal muscle contracts to bring the testes closer to the body; in very hot weather, or in the presence of fever, the muscle relaxes, allowing the testes to fall away from the body. In this way, the temperature of the testes can remain as even as possible to promote the production and viability of sperm.

Testes. The testes are two ovoid glands, 2 to 3 cm wide, that lie in the scrotum. Each testis is encased by a protective white fibrous capsule and is composed of several lobules, with each lobule containing interstitial cells (Leydig's cells) and a seminiferous tubule. Seminiferous tubules produce spermatozoa. Leydig's cells are responsible for the production of testosterone.

Testes in a fetus first form in the pelvic cavity. They descend, late in intrauterine life (about the 34th to 38th week), into the scrotal sac. Because this descent occurs so late in pregnancy, many male preterm infants are born with undescended testes. These infants need to be monitored closely to see that the testes do descend when the infant reaches what would have been the 34th to 38th week of gestational age, because testicular descent does not occur as readily in extrauterine life as it does in utero. Testes that remain in the pelvic cavity may not produce viable sperm and are associated with a 4 to 7 times higher incidence of testicular cancer (Ellsworth, 2009).

Although spermatozoa are produced in the testes, they reach maturity, surrounded by semen, in the external structures through a complex sequence of regulatory events. First, the hypothalamus releases GnRH, which in turn influences the anterior pituitary gland to release FSH and LH. FSH is then responsible for the release of androgen-binding protein (ABP). LH is responsible for the release of testosterone. ABP binding of testosterone promotes sperm formation. As the amount of testosterone increases, a feedback effect on the hypothalamus and anterior pituitary gland is created that slows the production of FSH and LH and ultimately decreases or regulates sperm production.

In most males, one testis is slightly larger than the other and is suspended slightly lower in the scrotum than the other (usually the left one). Because of this, testes tend to slide past

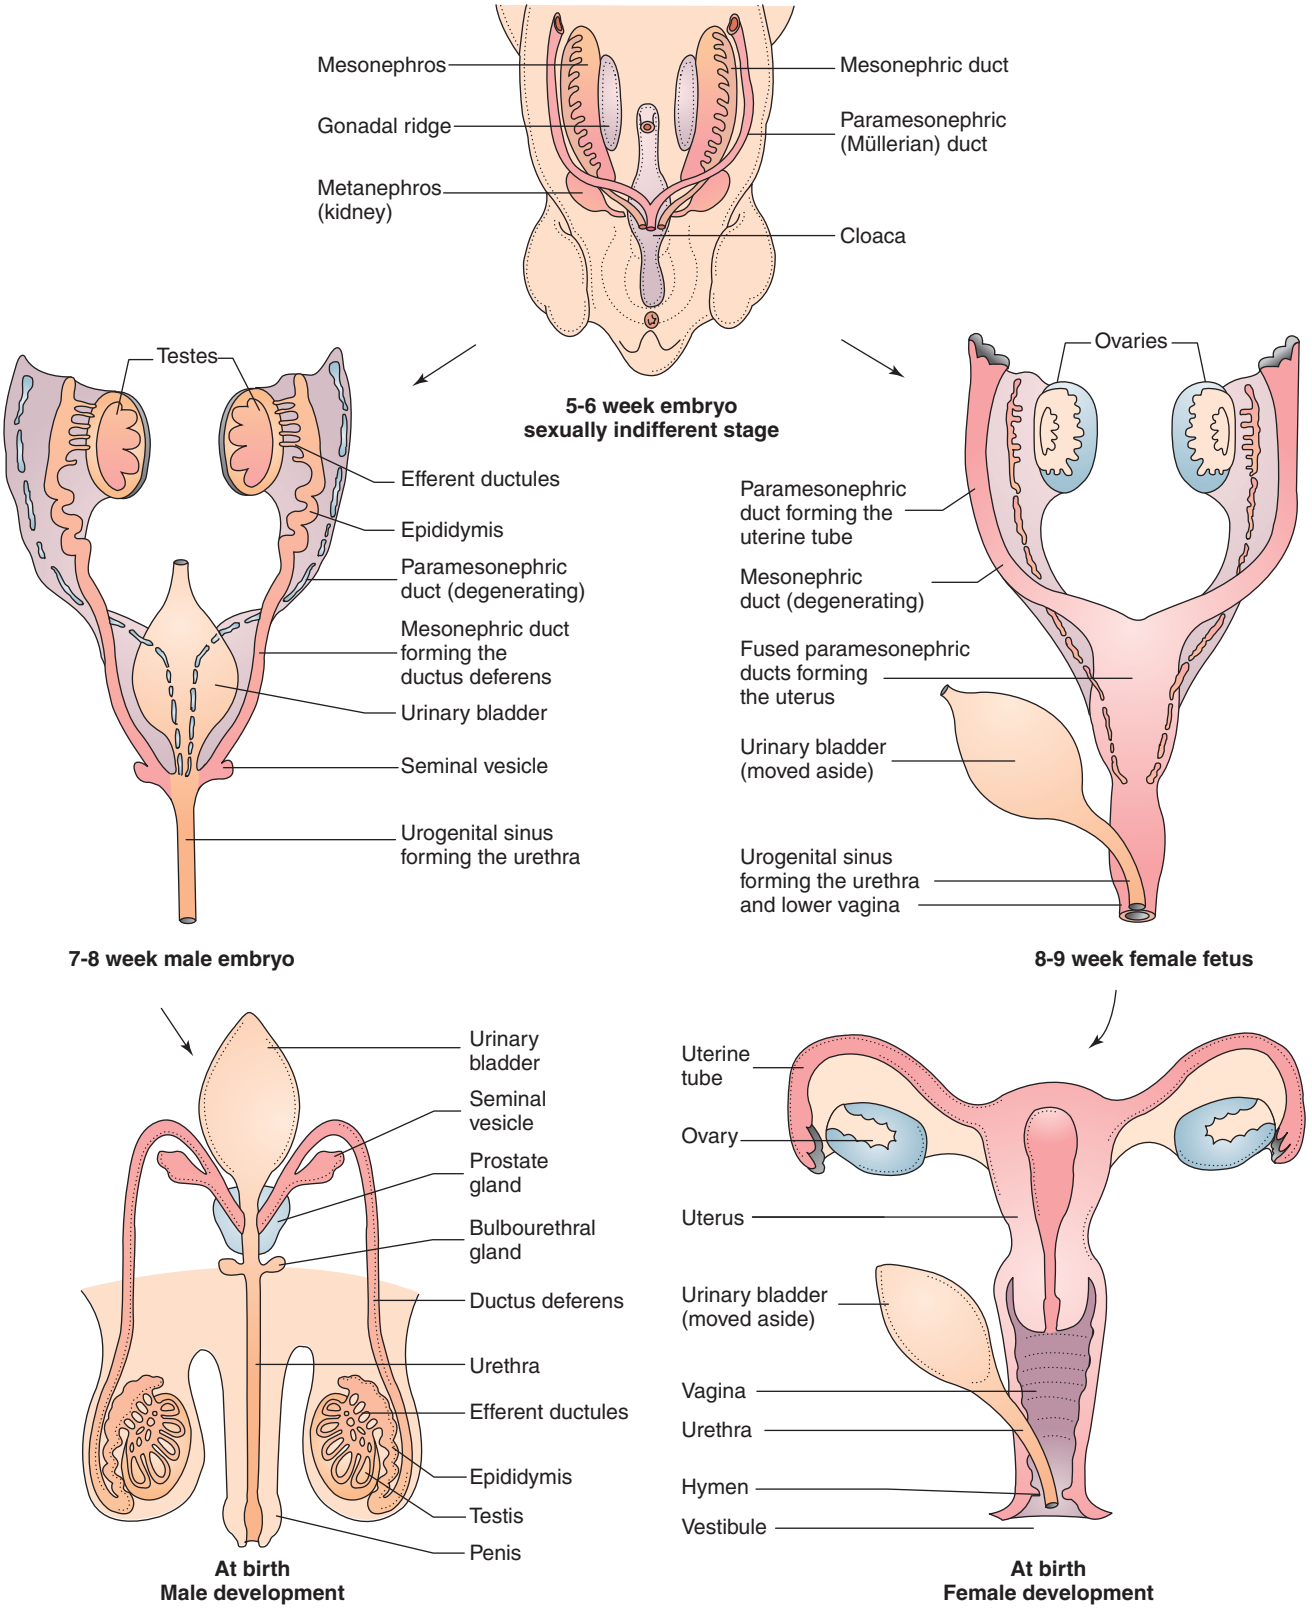

FIGURE 5.1 Development of the internal and external reproductive organs.

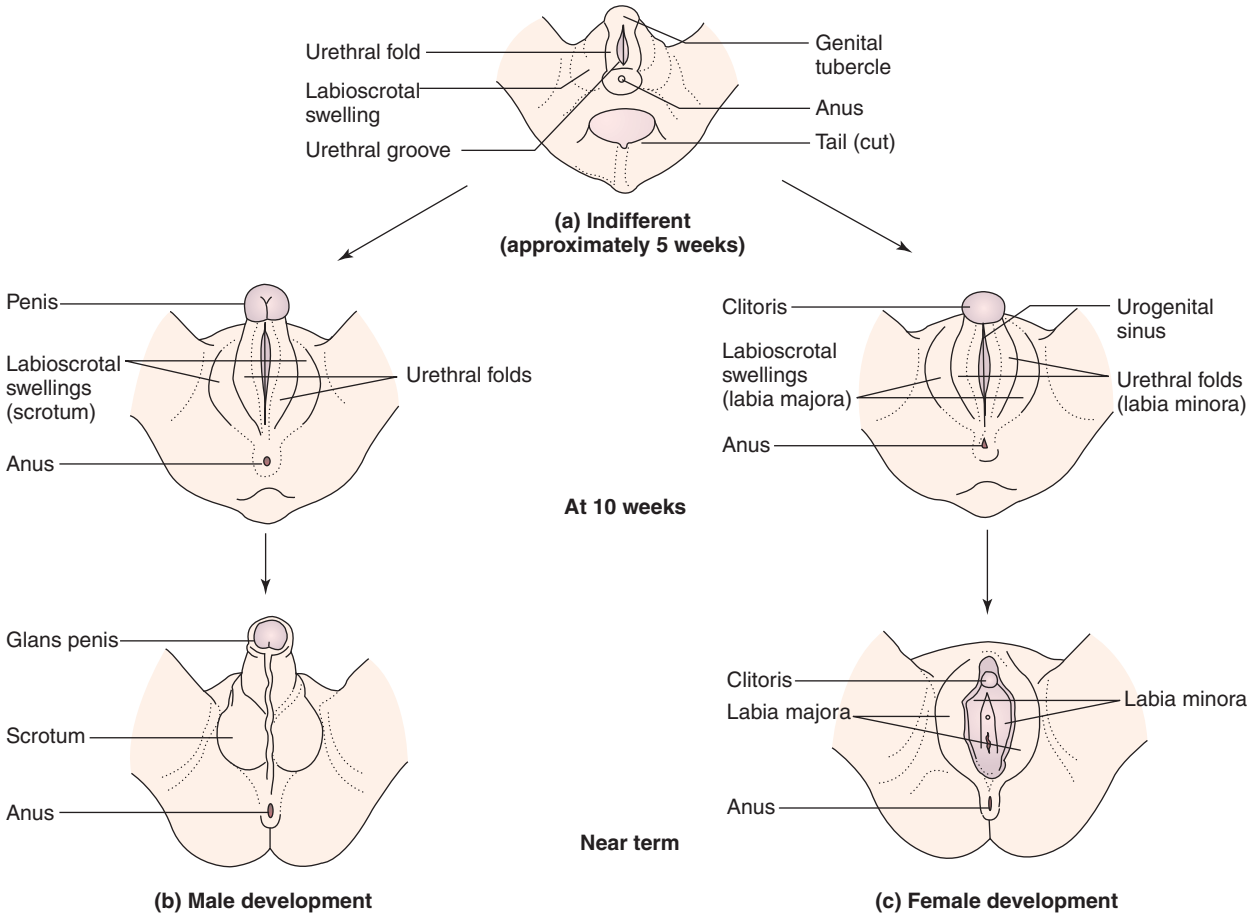

FIGURE 5.1 *(continued)*

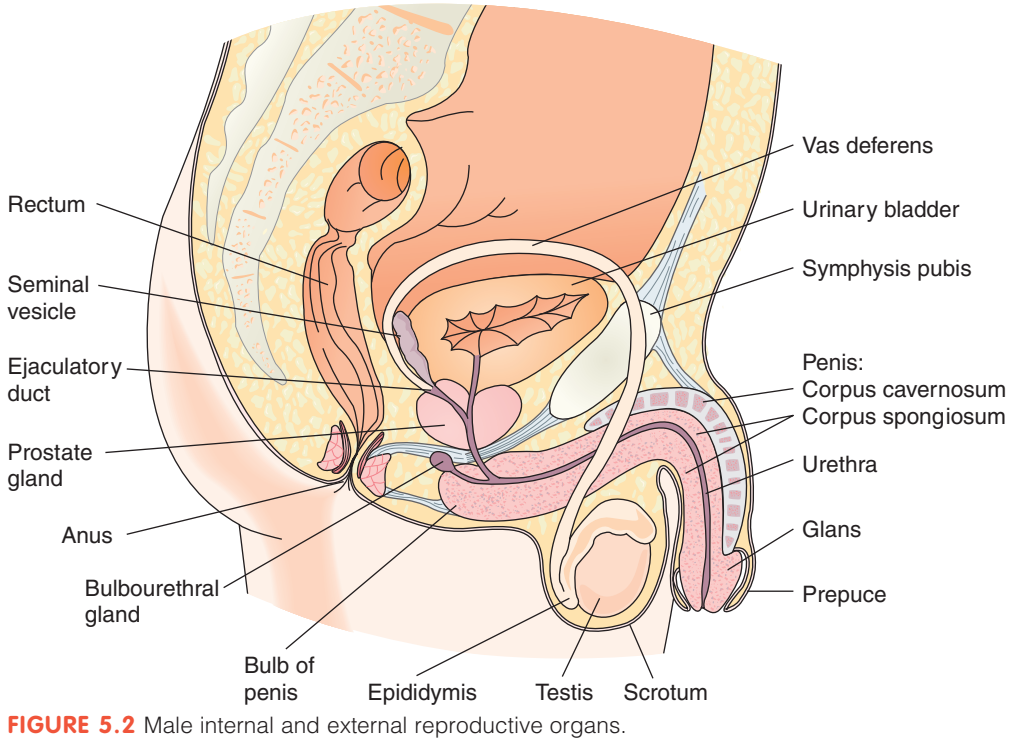

FIGURE 5.2 Male internal and external reproductive organs.

each other more readily on sitting or muscular activity, and there is less possibility of trauma to them. Most body structures of importance are more protected than are the testes (for example, the heart, kidneys, and lungs are surrounded by ribs of hard bone). Spermatozoa do not survive at a temperature as high as that of the body, however, so the location of the testes outside the body, where the temperature is approximately 1° F lower than body temperature, provides protection for sperm survival (McCance & Huether, 2007).

Beginning in early adolescence, boys need to learn testicular self-examination so that they can detect tenderness or any abnormal growth in the testes (see Chapter 34). Normal testes feel firm, smooth, and egg shaped. The epididymis (the tube that carries sperm away from the testes) can be palpated as a firm swelling on the superior aspect of the testes. Caution boys not to mistake this structure for an abnormal growth.

Penis. The penis is composed of three cylindrical masses of erectile tissue in the penis shaft: two termed the corpus cavernosa, and a third termed the corpus spongiosum. The urethra passes through these layers of erectile tissue, making the penis serve as the outlet for both the urinary and the reproductive tracts in men. With sexual excitement, nitric oxide is released from the endothelium of blood vessels. This results in dilation of blood vessels and an increase in blood flow to the arteries of the penis (engorgement). The ischiocavernosus muscle at the base of the penis then contracts, trapping both venous and arterial blood in the three sections of erectile tissue and leading to distention and erection of the penis. The penile artery, a branch of the pudendal artery, provides the blood supply for the penis. Penile erection is stimulated by parasympathetic nerve innervation.

At the distal end of the organ is a bulging, sensitive ridge of tissue, the glans. A retractable casing of skin, the prepuce, protects the nerve-sensitive glans at birth. Many infants in the United States have the prepuce tissue removed surgically (circumcision) shortly after birth (Fig. 5.3).

Male Internal Structures

The male internal reproductive organs are the epididymis, the vas deferens, the seminal vesicles, the ejaculatory ducts, the prostate gland, the urethra, and the bulbourethral glands (see Fig. 5.2).

Epididymis. The seminiferous tubule of each testis leads to a tightly coiled tube, the epididymis, which is responsible for conducting sperm from the tubule to the vas deferens, the next step in the passage to the outside. Because each epididymis is so tightly coiled, its length is extremely deceptive: it is actually over 20 ft long. Some sperm are stored in the epididymis, and a portion of the alkaline fluid that will surround sperm at maturity (semen, or seminal fluid that contains a basic sugar and mucin, a form of protein) is produced by the cells lining the epididymis. Because the epididymis is so narrow along its entire length, infection of the epididymis can easily lead to scarring of the lumen that then prohibits passage of sperm beyond the scarred point.

Sperm are immobile and incapable of fertilization as they pass or are stored at the epididymis level. It takes at least 12 to 20 days for them to travel the length of the epididymis and a total of 64 days for them to reach maturity. This is one reason that **aspermia** (absence of sperm) and oligospermia (<20 million sperm/mL) are problems that do not appear to respond immediately to therapy but rather only after 2 months.

Vas Deferens (Ductus Deferens). The vas deferens is an additional hollow tube surrounded by arteries and veins and protected by a thick fibrous coating. It carries sperm from the epididymis through the inguinal canal into the abdominal cavity, where it ends at the seminal vesicles and the ejaculatory ducts. Sperm mature as they pass through the vas deferens. They are still not mobile at this point, however, probably because of the fairly acidic medium of the semen produced at this level. The blood vessels and vas deferens together are referred to as the spermatic cord. A varicocele, or a varicosity of the internal spermatic vein, was once thought to contribute to male subfertility by causing congestion with increased warmth in the testes but this appears to actually make little difference (Evers & Collins, 2009). Vasectomy (severing of the vas deferens to prevent passage of sperm) is a popular means of male birth control (Cook et al., 2009).

Seminal Vesicles. The seminal vesicles are two convoluted pouches that lie along the lower portion of the posterior surface of the bladder and empty into the urethra by way of the ejaculatory ducts. These glands secrete a viscous alkaline liquid that has a high sugar, protein, and prostaglandin content. Sperm become increasingly motile with this added fluid, because it surrounds them with nutrients and a more favorable pH.

Ejaculatory Ducts. The two ejaculatory ducts pass through the prostate gland and join the seminal vesicles to the urethra.

Prostate Gland. The prostate is a chestnut-sized gland that lies just below the bladder. The urethra passes through the center of it, like the hole in a doughnut. The prostate gland secretes a thin, alkaline fluid. When added to the secretion from the seminal vesicles and the accompanying sperm from the epididymis, this alkaline fluid further protects sperm from being immobilized by the naturally low pH level of the urethra. In middle life, many men develop benign hypertrophy of the prostate. This swelling interferes with both fertility and urination. A benign condition, it can be relieved by medical therapy or surgery but needs to be differentiated from prostate cancer (Parsons, 2007).

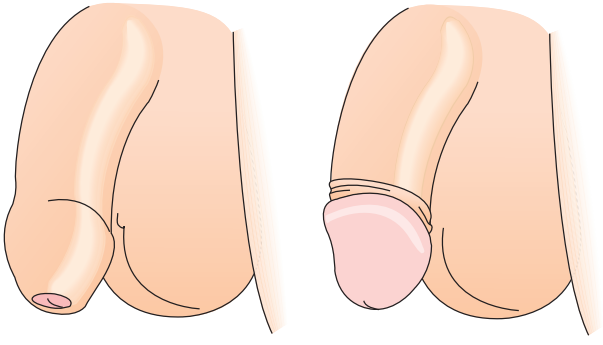

FIGURE 5.3 Uncircumcised and circumcised penis.

Bulbourethral Glands. Two bulbourethral or Cowper's glands lie beside the prostate gland and empty via short ducts into the urethra. Like the prostate gland and seminal vesicles, they secrete an alkaline fluid that helps counteract the acid secretion of the urethra and ensure the safe passage of spermatozoa. Semen, therefore, is derived from the prostate gland (60%), the seminal vesicles (30%), the epididymis (5%), and the bulbourethral glands (5%).

Urethra. The urethra is a hollow tube leading from the base of the bladder, which, after passing through the prostate gland, continues to the outside through the shaft and glans of the penis. It is approximately 8 in (18 to 20 cm) long. Like other urinary tract structures, it is lined with mucous membrane.

✔ Checkpoint Question 5.2

Suppose Kevin Matthews tells you that he is considering a vasectomy after the birth of his new child. Vasectomy is incision of which organ?

a. The testes
b. The vas deferens
c. The epididymis
d. The scrotum

Female Reproductive System

The female reproductive system, like the male system, has both external and internal components (Anderson & Genadry, 2007).

Female External Structures

The structures that form the female external genitalia are termed the vulva (from the Latin word for "covering") and are illustrated in Figure 5.4.

Mons Veneris. The mons veneris is a pad of adipose tissue located over the symphysis pubis, the pubic bone joint. It is covered by a triangle of coarse, curly hairs. The purpose of the mons veneris is to protect the junction of the pubic bone from trauma.

Labia Minora. Just posterior to the mons veneris spread two hairless folds of connective tissue, the labia minora. Before menarche, these folds are fairly small; by childbearing age, they are firm and full; after menopause, they atrophy and again become much smaller. Normally the folds of the labia minora are pink; the internal surface is covered with mucous membrane, and the external surface with skin. The area is abundant with sebaceous glands, so localized sebaceous cysts may occur here. Women who perform monthly vulvar examinations are able to detect infection or other abnormalities of the vulva such as sebaceous cysts.

Labia Majora. The labia majora are two folds of adipose tissue covered by loose connective tissue and epithelium that are positioned lateral to the labia minora. Covered by pubic hair, the labia majora serve as protection for the external genitalia and the distal urethra and vagina. They are fused anteriorly but separated posteriorly. Trauma to the area, such as occurs from childbirth or rape, can lead to extensive edema formation because of the looseness of the connective tissue base.

Other External Organs. The vestibule is the flattened, smooth surface inside the labia. The openings to the bladder (the urethra) and the uterus (the vagina) both arise from the vestibule. The clitoris is a small (approximately 1 to 2 cm), rounded organ of erectile tissue at the forward junction of the labia minora. It is covered by a fold of skin, the prepuce. The clitoris is sensitive to touch and temperature and is the center of sexual arousal and orgasm in a woman. Arterial blood supply for the clitoris is plentiful. When the ischio-

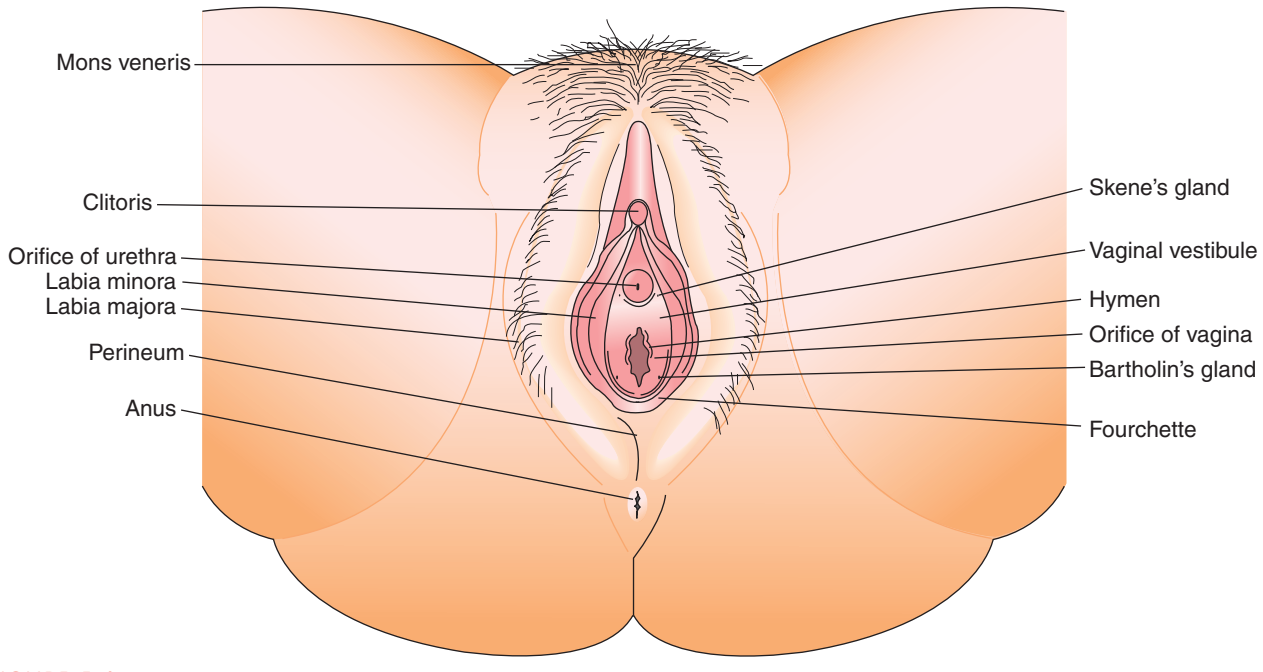

FIGURE 5.4 Female external genitalia.

cavernosus muscle surrounding it contracts with sexual arousal, the venous outflow for the clitoris is blocked, leading to clitoral erection.

Two Skene's glands (paraurethral glands) are located just lateral to the urinary meatus, one on each side. Their ducts open into the urethra. Bartholin's glands (vulvovaginal glands) are located just lateral to the vaginal opening on both sides. Their ducts open into the distal vagina. Secretions from both of these glands help to lubricate the external genitalia during coitus. The alkaline pH of their secretions helps to improve sperm survival in the vagina. Both Skene's glands and Bartholin's glands may become infected and produce a discharge and local pain.

The fourchette is the ridge of tissue formed by the posterior joining of the two labia minora and the labia majora. This is the structure that is sometimes cut (episiotomy) during childbirth to enlarge the vaginal opening.

Posterior to the fourchette is the perineal muscle or the perineal body. Because this is a muscular area, it is easily stretched during childbirth to allow for enlargement of the vagina and passage of the fetal head. Many exercises suggested for pregnancy (such as Kegel's, squatting, and tailor-sitting) are aimed at making the perineal muscle more flexible to allow easier expansion during birth without tearing of this tissue.

The hymen is a tough but elastic semicircle of tissue that covers the opening to the vagina in childhood. It is often torn during the time of first sexual intercourse. However, because of the use of tampons and active sports participation, many girls who have not had sexual relations do not have intact hymens at the time of their first pelvic examination. Occasionally, a girl has an imperforate hymen, or a hymen so complete that it does not allow for passage of menstrual blood from the vagina or for sexual relations until it is surgically incised (Dane et al., 2007).

Vulvar Blood Supply. The blood supply of the external genitalia is mainly from the pudendal artery and a portion of the inferior rectus artery. Venous return is through the pudendal vein. Pressure on this vein by the fetal head can cause extensive back-pressure and development of varicosities (distended veins) in the labia majora. Because of the rich blood supply, trauma to the area, such as occurs from pressure during childbirth, can cause large hematomas. This ready blood supply also contributes to the rapid healing of any tears in the area after childbirth (McCance & Huether, 2007).

Vulvar Nerve Supply. The anterior portion of the vulva derives its nerve supply from the ilioinguinal and genitofemoral nerves (L1 level). The posterior portions of the vulva and vagina are supplied by the pudendal nerve (S3 level). Such a rich nerve supply makes the area extremely sensitive to touch, pressure, pain, and temperature. Normal stretching of the perineum with childbirth causes temporary loss of sensation in the area. Anesthesia for childbirth may be administered locally to block the pudendal nerve, further eliminating pain sensation at the perineum during birth.

Female Internal Structures

Female internal reproductive organs (Fig. 5.5) are the ovaries, the fallopian tubes, the uterus, and the vagina.

Ovaries. The ovaries are approximately 4 cm long by 2 cm in diameter and approximately 1.5 cm thick, or the size and shape of almonds. They are grayish white and appear pitted, or with minute indentations on the surface. An unruptured, glistening, clear, fluid-filled graafian follicle (an ovum about to be discharged) or a miniature yellow corpus luteum (the structure left behind after the ovum has

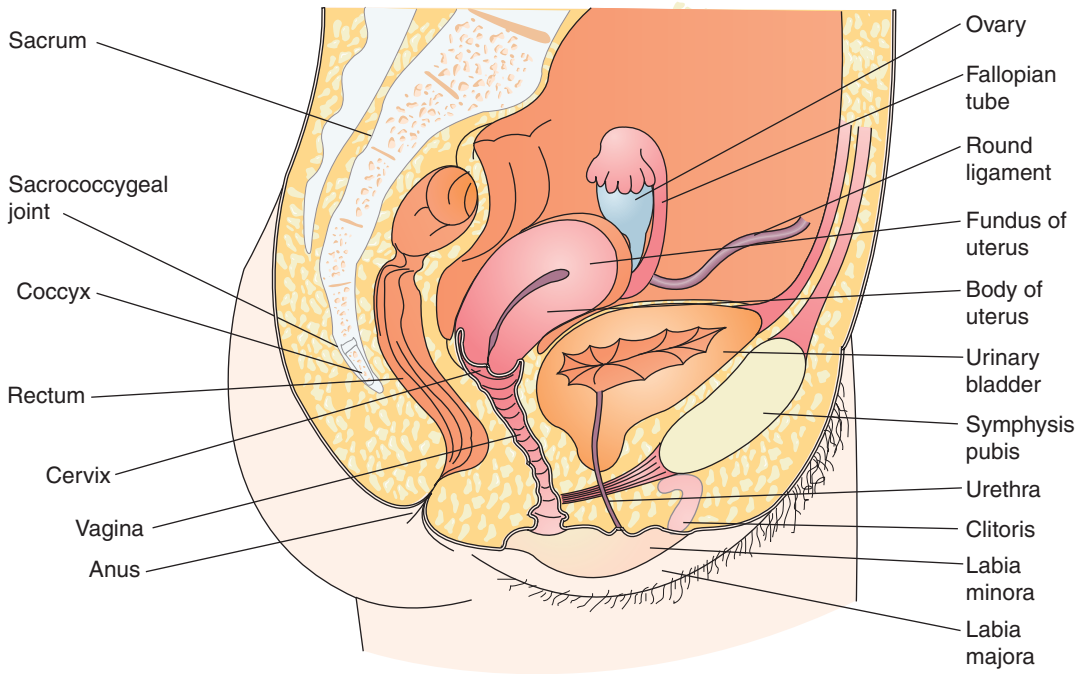

FIGURE 5.5 Female internal reproductive organs.

been discharged) often can be observed on the surface of an ovary.

Ovaries are located close to and on both sides of the uterus in the lower abdomen. It is difficult to locate them by abdominal palpation because they are situated so low in the abdomen. If an abnormality is present, such as an enlarging ovarian cyst, the resulting tenderness may be evident on lower-left or lower-right abdominal palpation.

The function of the two ovaries (the female gonads) is to produce, mature, and discharge ova (the egg cells). In the process, the ovaries produce estrogen and progesterone and initiate and regulate menstrual cycles. If the ovaries are removed before puberty (or are nonfunctional), the resulting absence of estrogen prevents breasts from maturing at puberty; in addition, pubic hair distribution assumes a more male pattern than normal. After menopause, or cessation of ovarian function, the uterus, breasts, and ovaries all undergo atrophy or a reduction in size because of a lack of estrogen. Ovarian function, therefore, is necessary for maturation and maintenance of secondary sex characteristics in females. The estrogen secreted by ovaries is also important to prevent osteoporosis, or weakness of bones, because of withdrawal of calcium from bones. This frequently occurs in women after menopause, making women prone to serious spinal, hip, and wrist fractures. Because cholesterol is incorporated into estrogen, the production of estrogen is thought to also keep cholesterol levels reduced, thus limiting the effects of atherosclerosis (artery disease) in women. Estrogen used to be prescribed for women at menopause to help prevent osteoporosis and cardiovascular disease. However, this type of long-term estrogen supplementation may contribute to breast cancer and cerebrovascular accidents, so it is no longer routinely recommended (Kulp & Zacur, 2007).

The ovaries are held suspended and in close contact with the ends of the fallopian tubes by three strong supporting ligaments attached to the uterus or the pelvic wall. They are unique among pelvic structures in that they are not covered by a layer of peritoneum. Because they are not encased in this way, ova can escape from them and enter the uterus by way of the fallopian tubes. Because they are suspended in position rather than being firmly fixed in place, an abnormal tumor or cyst growing on them can enlarge to a size easily twice that of the organ before pressure on surrounding organs or the ovarian blood supply leads to symptoms of compression. This is the reason that ovarian cancer continues to be one of the leading causes of death from cancer in women (i.e., the tumor grows without symptoms for an extended period) (Neves-E-Castro, 2007).

Ovaries have three principal divisions:

1. Protective layer of surface epithelium
2. Cortex, where the immature (primordial) oocytes mature into ova and large amounts of estrogen and progesterone are produced
3. Central medulla, which contains the nerves, blood vessels, lymphatic tissue, and some smooth muscle tissue

Division of Reproductive Cells (Gametes). At birth, each ovary contains approximately 2 million immature ova (oocytes), which were formed during the first 5 months of intrauterine life. Although these cells have the unique ability to produce a new individual, they basically contain the usual components of cells: a cell membrane, an area of clear cytoplasm, and a nucleus containing chromosomes.

The oocytes, like sperm, differ from all other body cells in the number of chromosomes they contain in the nucleus. The nucleus of all other human body cells contains 46 chromosomes, consisting of 22 pairs of autosomes (paired matching chromosomes) and 1 pair of sex chromosomes (two X sex chromosomes in the female, an X and a Y sex chromosome pair in the male). Reproductive cells (both ova and spermatozoa) have only half the usual number of chromosomes, so that, when they combine (fertilization), the new individual formed from them will have the normal number of 46 chromosomes. If both the ova and the spermatozoa carried the full complement of chromosomes, a new individual formed from them would have twice the normal number. There is a difference in the way reproductive cells divide that causes this change in chromosome number.

Cells in the body, such as skin cells, undergo cell division by mitosis, or daughter cell division. In this type of division, all the chromosomes are duplicated in each cell just before cell division, giving every new cell the same number of chromosomes as the original parent cell. Oocytes divide in intrauterine life by one mitotic division. Division activity then appears to halt until at least puberty, when a second type of cell division, meiosis (cell reduction division), occurs. In the male, this reduction division occurs just before the spermatozoa mature. In the female, it occurs just before ovulation. After this reduction division, an ovum has 22 autosomes and an X sex chromosome, whereas a spermatozoon has 22 autosomes and either an X or a Y sex chromosome. A new individual formed from the union of an ovum and an X-carrying spermatozoon will be female (an XX chromosome pattern); an individual formed from the union of an ovum and a Y-carrying spermatozoon will be male (an XY chromosome pattern).

Maturation of Oocytes. Each oocyte lies in the ovary surrounded by a protective sac, or thin layer of cells, called a primordial follicle. Between 5 and 7 million ova form in utero. The majority never develop beyond the primitive state and actually atrophy, so that by birth only 2 million are present. By age 7 years, only approximately 500,000 are present in each ovary; by 22 years, there are approximately 300,000; and by menopause, none are left (all have either matured or atrophied). "The point at which no functioning oocytes remain in the ovaries" is one definition of menopause.

Fallopian Tubes. The fallopian tubes arise from each upper corner of the uterine body and extend outward and backward until each opens at its distal end, next to an ovary. Fallopian tubes are approximately 10 cm long in a mature woman. Their function is to convey the ovum from the ovaries to the uterus and to provide a place for fertilization of the ovum by sperm.

Although a fallopian tube is a smooth, hollow tunnel, it is anatomically divided into four separate parts (Fig. 5.6). The most proximal division, the interstitial portion, is that part of the tube that lies within the uterine wall. This portion is only about 1 cm in length; the lumen of the tube is only 1 mm in diameter at this point. The isthmus is the next distal portion. It is approximately 2 cm in length and like the interstitial tube, is extremely narrow. This is the portion of the tube that is cut or sealed in a tubal ligation, or tubal sterilization

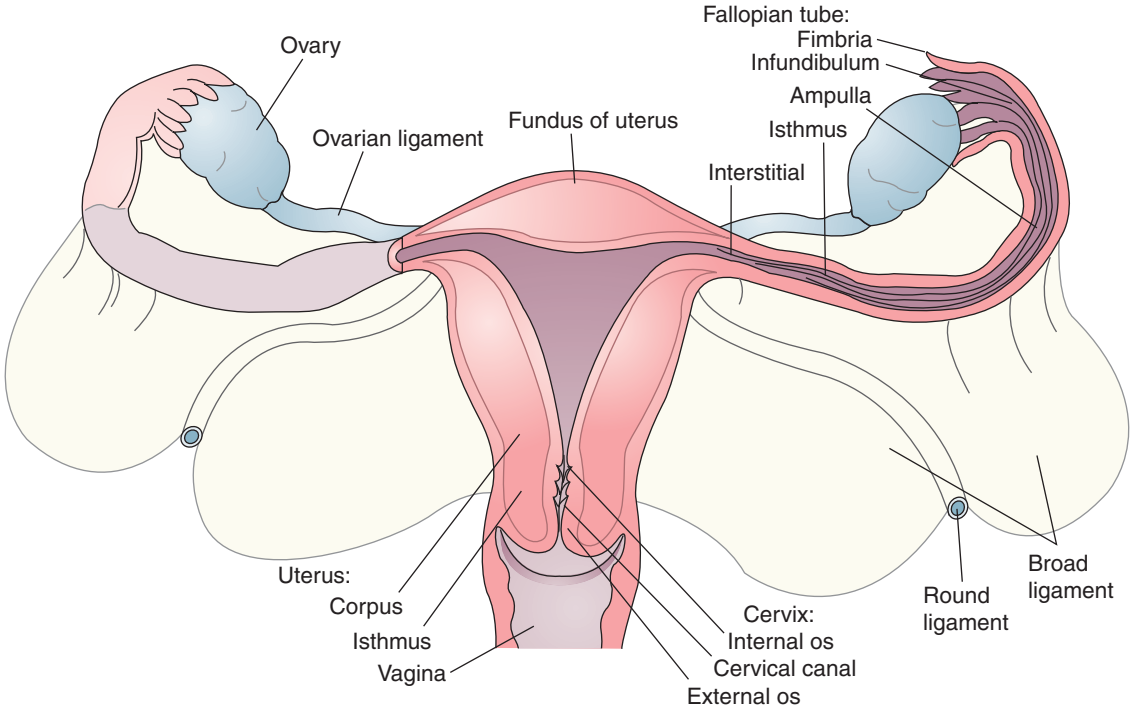

FIGURE 5.6 Anterior view of female reproductive organs showing relationship of fallopian tubes and body of the uterus.

procedure. The ampulla is the third and also the longest portion of the tube. It is approximately 5 cm in length. It is in this portion that fertilization of an ovum usually occurs. The infundibular portion is the most distal segment of the tube. It is approximately 2 cm long and is funnel shaped. The rim of the funnel is covered by fimbria (small hairs) that help to guide the ovum into the fallopian tube.

The lining of the entire fallopian tube is composed of mucous membrane, which contains both mucus-secreting and ciliated (hair-covered) cells. Beneath the mucous lining is connective tissue and a circular muscle layer. The muscle layer of the tube produces peristaltic motions that help conduct the ovum the length of the tube. Migration of the ovum is also aided by the action of the ciliated lining and the mucus, which acts as a lubricant. The mucus produced may also act as a source of nourishment for the fertilized egg, because it contains protein, water, and salts.

Because the fallopian tubes are open at their distal ends, a direct pathway exists from the external organs, through the vagina to the uterus and tubes, to the peritoneum. This pathway makes conception possible. It can also lead to infection of the peritoneum (peritonitis) if disease spreads from the perineum through the tubes to the pelvic cavity. For this reason, careful, clean technique must be used during pelvic examinations or treatment. Vaginal examinations during labor and birth are done with sterile technique to ensure that no organisms can enter.

Uterus. The uterus is a hollow, muscular, pear-shaped organ located in the lower pelvis, posterior to the bladder and anterior to the rectum. During childhood, it is approximately the size of an olive, and its proportions are reversed from what they are later (i.e., the cervix is the largest portion of the organ; the uterine body is the smallest). When a girl reaches approximately 8 years of age, an increase in the size of the uterus begins. An adolescent is closer to 17 years old before the uterus reaches its adult size. This may be a contributing factor to the low-birth-weight babies typically born to adolescents younger than this age.

With maturity, a uterus is approximately 5 to 7 cm long, 5 cm wide, and, in its widest upper part, 2.5 cm deep. In a nonpregnant state, it weighs approximately 60 g. The function of the uterus is to receive the ovum from the fallopian tube; provide a place for implantation and nourishment; furnish protection to a growing fetus; and, at maturity of the fetus, expel it from a woman's body.

After a pregnancy, the uterus never returns to its nonpregnant size but remains approximately 9 cm long, 6 cm wide, 3 cm thick, and 80 g in weight.

Anatomically, the uterus consists of three divisions: the body or corpus, the isthmus, and the cervix. The body of the uterus is the uppermost part and forms the bulk of the organ. The lining of the cavity is continuous with that of the fallopian tubes, which enter at its upper aspects (the cornua). During pregnancy, the body of the uterus is the portion of the structure that expands to contain the growing fetus. The portion of the uterus between the points of attachment of the fallopian tubes is termed the fundus. The fundus is also the portion that can be palpated abdominally to determine the amount of uterine growth occurring during pregnancy, to measure the force of uterine contractions during labor, and to assess that the uterus is returning to its nonpregnant state after childbirth.

The isthmus of the uterus is a short segment between the body and the cervix. In the nonpregnant uterus, it is only 1 to 2 mm in length. During pregnancy, this portion also

enlarges greatly to aid in accommodating the growing fetus. It is the portion of the uterus that is most commonly cut when a fetus is born by a cesarean birth.

The cervix is the lowest portion of the uterus. It represents approximately one third of the total uterus size and is approximately 2 to 5 cm long. Approximately half of it lies above the vagina and half extends into the vagina. Its central cavity is termed the cervical canal. The opening of the canal at the junction of the cervix and isthmus is the internal cervical os; the distal opening to the vagina is the external cervical os. The level of the external os is at the level of the ischial spines (an important relationship in estimating the level of the fetus in the birth canal).

Uterine and Cervical Coats. The uterine wall consists of three separate coats or layers of tissue: an inner one of mucous membrane (the endometrium), a middle one of muscle fibers (the myometrium), and an outer one of connective tissue (the perimetrium).

The endometrium layer of the uterus is the one that is important for menstrual function. It is formed by two layers of cells. The layer closest to the uterine wall, the basal layer, remains stable, uninfluenced by hormones. In contrast, the inner glandular layer is greatly influenced by both estrogen and progesterone. It grows and becomes so thick and responsive each month under the influence of estrogen and progesterone that it is capable of supporting a pregnancy. If pregnancy does not occur, this is the layer that is shed as the menstrual flow.

The mucous membrane lining the cervix is termed the endocervix. The endocervix, continuous with the endometrium, is also affected by hormones, but changes are manifested in a more subtle way. The cells of the cervical lining secrete mucus to provide a lubricated surface so that spermatozoa can readily pass through the cervix; the efficiency of this lubrication increases or wanes depending on hormone stimulation. At the point in the menstrual cycle when estrogen production is at its peak, as much as 700 mL of mucus per day is produced; at the point that estrogen is very low, only a few milliliters are produced. Because mucus is alkaline, it helps to decrease the acidity of the upper vagina, aiding in sperm survival. During pregnancy, the endocervix becomes plugged with mucus, forming a seal to keep out ascending infections (the operculum).

The lower surface of the cervix and the lower third of the cervical canal are lined not with mucous membrane but with stratified squamous epithelium, similar to that lining the vagina. Locating the point at which this tissue changes from epithelium to mucous membrane is important when obtaining a Papanicolaou smear (a test for cervical cancer), because this tissue interface is most often the origin of cervical cancer.

The myometrium, or muscle layer of the uterus, is composed of three interwoven layers of smooth muscle, the fibers of which are arranged in longitudinal, transverse, and oblique directions. This network offers extreme strength to the organ. The myometrium serves the important function of constricting the tubal junctions and preventing regurgitation of menstrual blood into the tubes. It also holds the internal cervical os closed during pregnancy to prevent a preterm birth. When the uterus contracts at the end of pregnancy to expel the fetus, equal pressure is exerted at all points throughout the cavity because of its unique arrangement of muscle fibers. After childbirth, this interlacing network of fibers is able to constrict the blood vessels coursing through the layers, thereby limiting the loss of blood in the woman. Myomas, or benign fibroid (leiomyoma) tumors, arise from the myometrium (McCance & Heuther, 2007).

The perimetrium, or the outermost layer of the uterus, serves the purpose of adding strength and support to the structure.

Uterine Blood Supply. The large descending abdominal aorta divides to form two iliac arteries; main divisions of the iliac arteries are the hypogastric arteries (Fig. 5.7). These further divide to form the uterine arteries and supply the uterus. Because the uterine blood supply is not far removed from the aorta, it is copious and adequate to supply the growing needs of a fetus. As an additional safeguard, after supplying the ovary with blood, the ovarian artery (a direct subdivision of the aorta) joins the uterine artery as a fail-safe system to ensure that the uterus will have an adequate blood supply. The blood vessels that supply the cells and lining of the uterus are tortuous against the sides of the uterine body in nonpregnant women. As a uterus enlarges with pregnancy, the vessels "unwind" and so can stretch to maintain an adequate blood supply as the organ enlarges. The uterine veins follow the same twisting course as the arteries; they empty into the internal iliac veins.

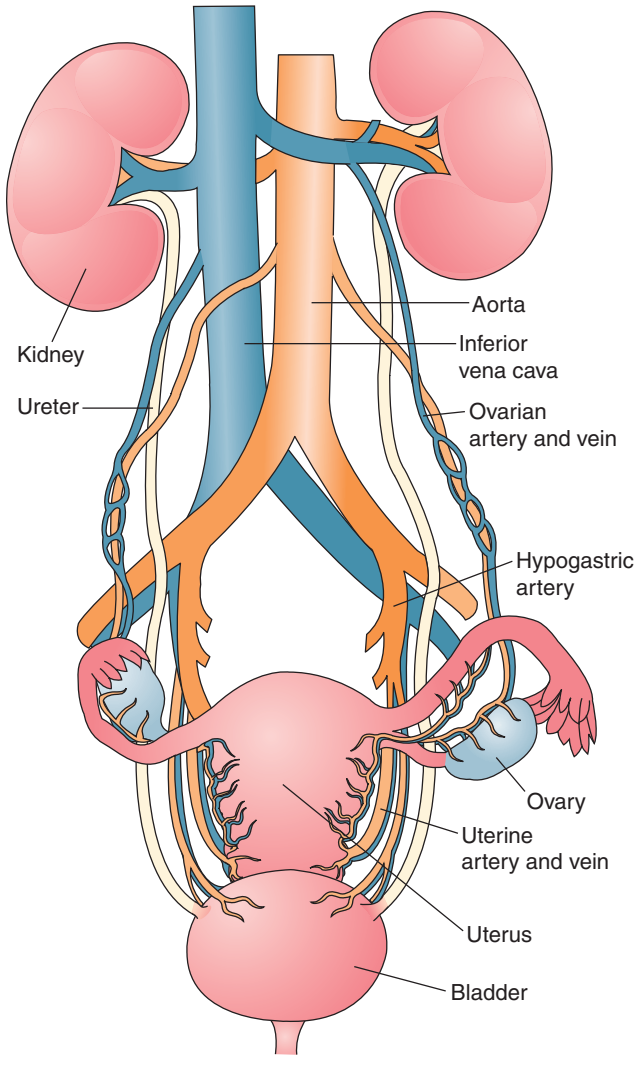

FIGURE 5.7 Blood supply to the uterus.

An important organ relationship to be aware of is the association of uterine vessels and the ureters. The ureters from the kidneys pass directly in back of the ovarian vessels, near the fallopian tubes. As shown in Figure 5.7, they cross just beneath the uterine vessels before they enter the bladder. This close anatomic relationship has implications in procedures such as tubal ligation, cesarean birth, and hysterectomy (removal of the uterus), because a ureter may be injured by a clamp if bleeding is controlled by clamping of the uterine or ovarian vessels.

Uterine Nerve Supply. The uterus is supplied by both efferent (motor) and afferent (sensory) nerves. The efferent nerves arise from the T5 through T10 spinal ganglia. The afferent nerves join the hypogastric plexus and enter the spinal column at T11 and T12. The fact that sensory innervation from the uterus registers lower in the spinal column than does motor control has implications in controlling pain in labor. An anesthetic solution can be injected near the spinal column to stop the pain of uterine contractions at the T11 and T12 levels without stopping motor control or contractions (registered higher, at the T5 to T10 level). This is the principle of epidural and spinal anesthesia (see Chapter 16).

Uterine Supports. The uterus is suspended in the pelvic cavity by several ligaments that also help support the bladder and is further supported by a combination of fascia and muscle. Because it is not fixed, the uterus is free to enlarge without discomfort during pregnancy. If its ligaments become overstretched during pregnancy, they may not support the bladder well afterward, and the bladder can then herniate into the anterior vagina (a **cystocele**). If the rectum pouches into the vaginal wall, a **rectocele** (Fig. 5.8) develops (American College of Obstetricians and Gynecologists [ACOG], 2007).

A fold of peritoneum behind the uterus forms the posterior ligament. This creates a pouch (Douglas' cul-de-sac) between the rectum and uterus. Because this is the lowest point of the pelvis, any fluid such as blood that accumulates from a condition such as a ruptured tubal (ectopic) pregnancy tends to collect in this space. The space can be examined for the presence of fluid or blood to help in diagnosis by inserting a culdoscope through the posterior vaginal wall (**culdoscopy**) or a laparoscope through the abdominal wall (**laparoscopy**).

The broad ligaments are two folds of peritoneum that cover the uterus front and back and extend to the pelvic sides to help steady the uterus. The round ligaments are two fibrous, muscular cords that pass from the body of the uterus near the attachments of the fallopian tubes, through the broad ligaments and into the inguinal canal, inserting into the fascia of the vulva. The round ligaments act as additional "stays" to further steady the uterus. If a pregnant woman moves quickly, she may pull one of these ligaments. This causes a quick, sharp pain of frightening intensity in one of her lower abdominal quadrants that can be mistaken for labor pain.

What if... Suzanne Matthews decides to have a tubal ligation (clamping of the fallopian tubes) after the birth of her baby? Why is observing women for urine output after uterine or fallopian tube surgery of this kind always a critical assessment?

Uterine Deviations. Several uterine deviations (shape and position) may interfere with fertility or pregnancy. In the fetus, the uterus first forms with a septum or a fibrous division, longitudinally separating it into two portions. As the fetus matures, this septum dissolves, so that typically at birth no remnant of the division remains. In some women, the septum never atrophies, and so the uterus remains as two separate compartments. In others, half of the septum is still present. Still other women have oddly shaped "horns" at the junction of the fallopian tubes, termed a **bicornuate uterus.** Any of these malformations may decrease the ability to conceive or to carry a pregnancy to term (Krantz, 2007). Some variations of uterine formation are shown in Figure 5.9. The specific effects of these deviations on fertility and pregnancy are discussed in later chapters.

Ordinarily, the body of the uterus is tipped slightly forward. Positional deviations of the uterus commonly seen are:

- **Anteversion,** a condition in which the entire uterus is tipped far forward
- **Retroversion,** a condition in which the entire uterus is tipped backward

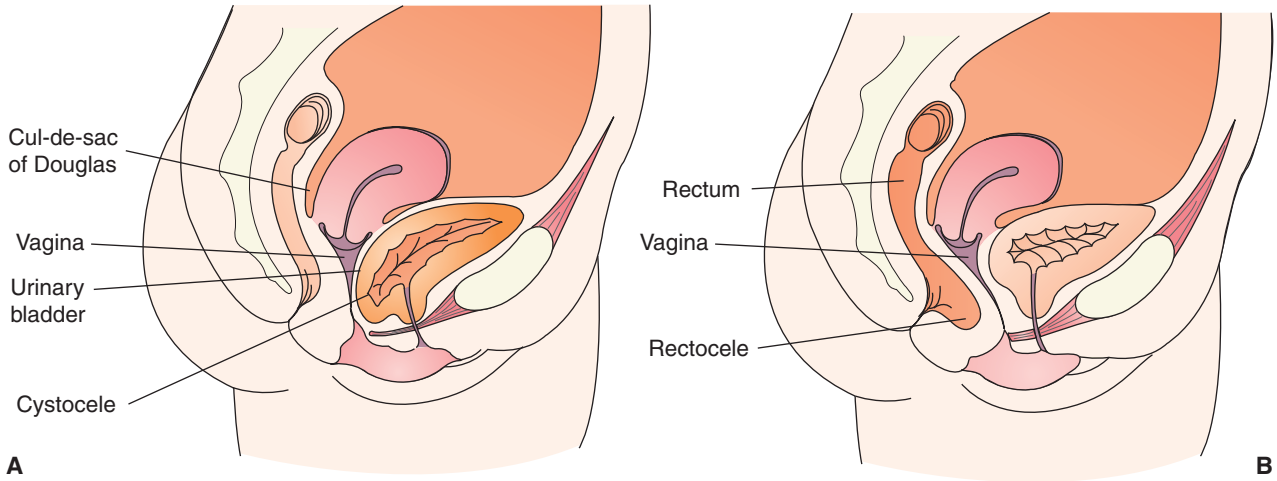

FIGURE 5.8 (**A**) Cystocele. The bladder has herniated into the anterior wall of the vagina. (**B**) Rectocele. The rectum has herniated into the posterior vaginal wall.

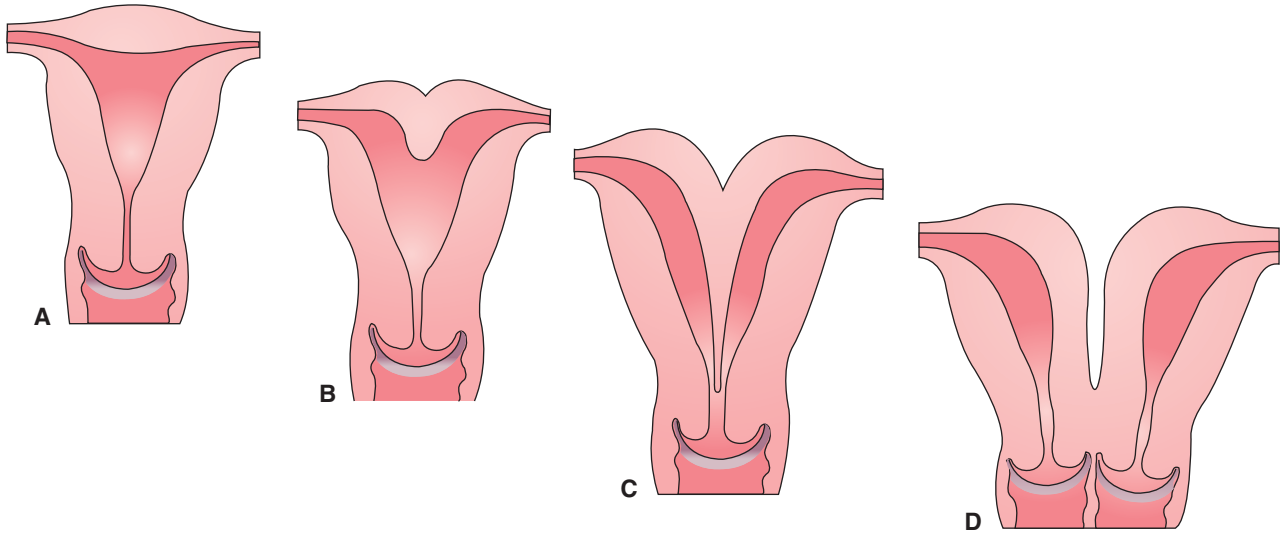

FIGURE 5.9 (**A**) Normal uterus. (**B**) Bicornuate uterus. (**C**) Septum dividing uterus. (**D**) Double uterus. Abnormal shapes of uterus allow less placenta implantation space.

- **Anteflexion,** a condition in which the body of the uterus is bent sharply forward at the junction with the cervix
- **Retroflexion,** a condition in which the body is bent sharply back just above the cervix

Minor variations of these positions do not cause reproductive problems. Extreme abnormal flexion or version positions may interfere with fertility, because they can block the deposition or migration of sperm. Examples of these abnormal uterine positions are shown in Figure 5.10.

Vagina. The vagina is a hollow, musculomembranous canal located posterior to the bladder and anterior to the rectum.

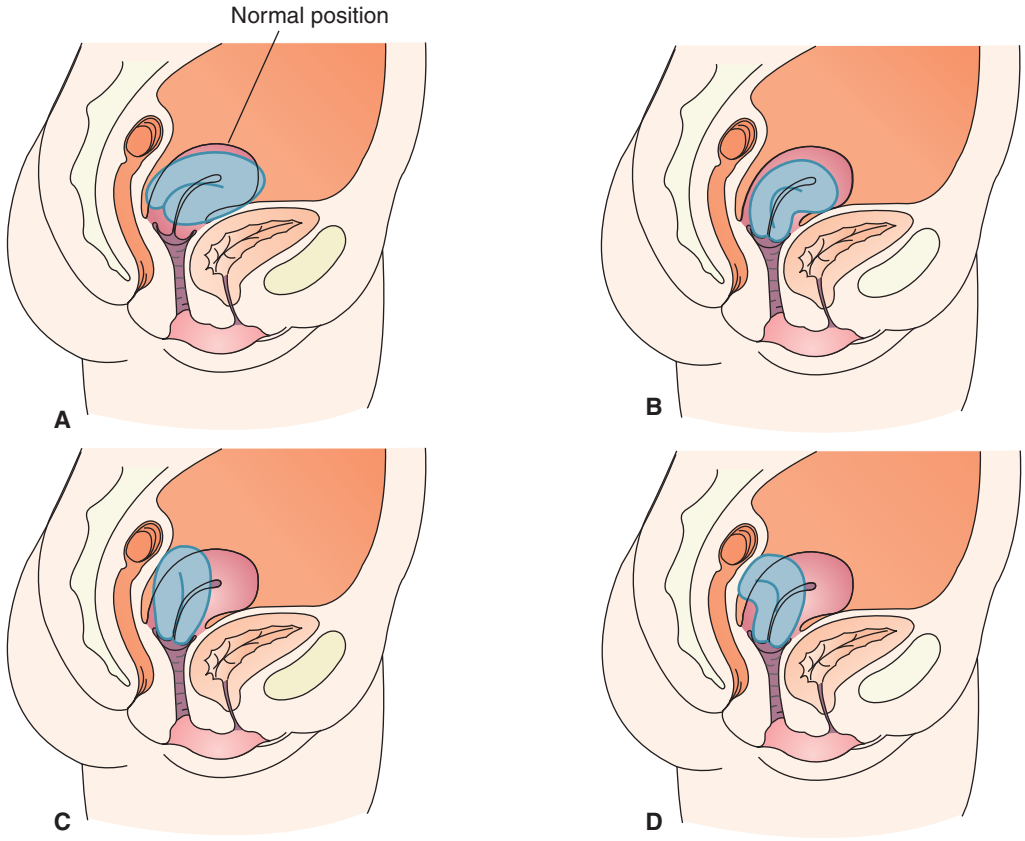

FIGURE 5.10 Uterine flexion and version. (**A**) Anteversion. (**B**) Anteflexion. (**C**) Retroversion. (**D**) Retroflexion.

It extends from the cervix of the uterus to the external vulva. Its function is to act as the organ of intercourse and to convey sperm to the cervix so that sperm can meet with the ovum in the fallopian tube. With childbirth, it expands to serve as the birth canal.

When a woman is lying on her back, as she does for a pelvic examination, the course of the vagina is inward and downward. Because of this downward slant and the angle of the uterine cervix, the length of the anterior wall of the vagina is approximately 6 to 7 cm; the posterior wall is 8 to 9 cm. At the cervical end of the structure, there are recesses on all sides of the cervix, termed fornices. Behind the cervix is the posterior fornix; at the front, the anterior fornix; and at the sides, the lateral fornices. The posterior fornix serves as a place for the pooling of semen after coitus; this allows a large number of sperm to remain close to the cervix and encourages sperm migration into the cervix.

The vaginal wall is so thin at the fornices that the bladder can be palpated through the anterior fornix, the ovaries through the lateral fornices, and the rectum through the posterior fornix. The vagina is lined with stratified squamous epithelium similar to that covering the cervix. It has a middle connective tissue layer and a strong muscular wall. Normally, the walls contain many folds or rugae that lie in close approximation to each other. These folds make the vagina very elastic and able to expand at the end of pregnancy to allow a full-term baby to pass through without tearing. A circular muscle, the bulbocavernosus, at the external opening of the vagina acts as a voluntary sphincter. Relaxing and tensing this external vaginal sphincter muscle a set number of times each day makes it more supple for birth and helps maintain tone after birth (Kegel's exercises).

The blood supply to the vagina is furnished by the vaginal artery, a branch of the internal iliac artery. Vaginal tears at childbirth tend to bleed profusely because of this rich blood supply. The same rich blood supply is also the reason that any vaginal trauma at birth heals rapidly.

The vagina has both sympathetic and parasympathetic nerve innervations originating at the S1 to S3 levels. The vagina is not an extremely sensitive organ, however. Sexual excitement, often attributed to vaginal stimulation, is influenced mainly by clitoral stimulation.

The mucus produced by the vaginal lining has a rich glycogen content. When this glycogen is broken down by the lactose-fermenting bacteria that frequent the vagina (Döderlein's bacillus), lactic acid is formed. This makes the usual pH of the vagina acid, a condition detrimental to the growth of pathologic bacteria, so that even though the vagina connects directly to the external surface, infection does not readily occur. Instruct women not to use vaginal douches or sprays as a daily hygiene measure because they may clean away this natural acid medium of the vagina, inviting vaginal infections. After menopause, the pH of the vagina becomes closer to 7.5 or slightly alkaline, a reason that vulvovaginitis infections occur more frequently in women in this age group (Selby, 2007).

✔ Checkpoint Question 5.3

On physical examination, Suzanne Matthews is found to have a cystocele. A cystocele is:

a. A sebaceous cyst arising from a vulvar fold.
b. Protrusion of the intestine into the vagina.
c. Prolapse of the uterus and cervix into the vagina.
d. Herniation of the bladder into the vaginal wall.

Breasts

The mammary glands, or breasts, form from ectodermic tissue early in utero. They then remain in a halted stage of development until a rise in estrogen at puberty produces a marked increase in their size. The size increase occurs mainly because of an increase of connective tissue plus deposition of fat. The glandular tissue of the breasts, necessary for successful breastfeeding, remains undeveloped until a first pregnancy begins. Boys may notice a temporary increase in breast size at puberty, termed **gynecomastia.** If boys are not prepared that this is a normal change of puberty, they may be concerned that they are developing abnormally. The change is most evident in obese boys (Ma & Geffner, 2008).

Breasts are located anterior to the pectoral muscle (Fig. 5.11), and in many women breast tissue extends well into the

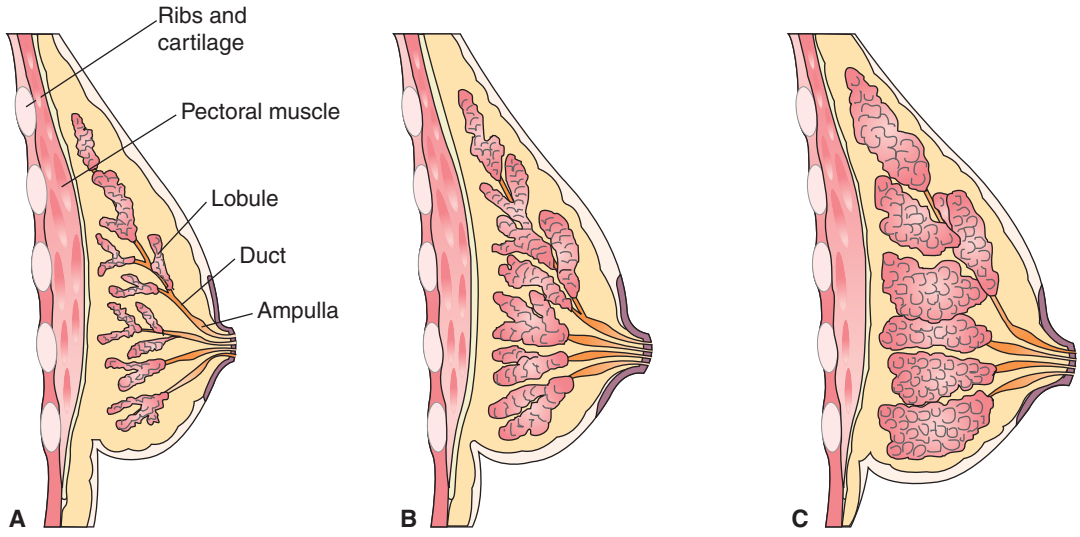

FIGURE 5.11 Anatomy of the breast. (**A**) Nonpregnant. (**B**) Pregnant. (**C**) During lactation.

TABLE 5.1 ✻ Characteristics of Normal Menstrual Cycles

Characteristic	Description
Beginning (menarche)	Average age at onset, 12.4 years; average range, 9–17 years
Interval between cycles	Average, 28 days; cycles of 23–35 days not unusual
Duration of menstrual flow	Average flow, 2–7 days; ranges of 1–9 days not abnormal
Amount of menstrual flow	Difficult to estimate; average 30–80 mL per menstrual period; saturating pad or tampon in less than an hour is heavy bleeding
Color of menstrual flow	Dark red; a combination of blood, mucus, and endometrial cells
Odor	Similar to that of marigolds

axilla. Breast self-examinations are not as effective in detecting early breast lesions as once believed and so are no longer routinely recommended (Kosters & Gotzsche, 2007). Women should have a yearly breast examination done by a health care professional, however, as this can detect breast disease. When palpating for breast health this way, always include the axillary region in the examination, or some breast tissue can be missed.

Milk glands of the breasts are divided by connective tissue partitions into approximately 20 lobes. All of the glands in each lobe produce milk by acinar cells and deliver it to the nipple via a lactiferous duct. The nipple has approximately 20 small openings through which milk is secreted. An ampulla portion of the duct, located just posterior to the nipple, serves as a reservoir for milk before breastfeeding.

A nipple is composed of smooth muscle that is capable of erection on manual or sucking stimulation. On stimulation, it transmits sensations to the posterior pituitary gland to release oxytocin. Oxytocin acts to constrict milk gland cells and push milk forward into the ducts that lead to the nipple. The skin surrounding the nipples is darkly pigmented out to approximately 4 cm and is termed the areola. The area appears rough on the surface because it contains many sebaceous glands, called Montgomery's tubercles.

The blood supply to the breasts is profuse because it is supplied by thoracic branches of the axillary, internal mammary, and intercostal arteries. This effective blood supply is important in bringing nutrients to the milk glands and makes possible a plentiful supply of milk for breastfeeding. However, it also aids in the metastasis of breast cancer if this is not discovered early with breast examination or mammography (McCance & Huether, 2007).

MENSTRUATION

A menstrual cycle (a female reproductive cycle) is episodic uterine bleeding in response to cyclic hormonal changes. The purpose of a menstrual cycle is to bring an ovum to maturity and renew a uterine tissue bed that will be responsible for the ova's growth should it be fertilized. It is the process that allows for conception and implantation of a new life. Because menarche may occur as early as 9 years of age, it is good to include health teaching information on menstruation to both school age children and their parents as early as fourth grade as part of routine care. It is a poor introduction to sexuality and womanhood for a girl to begin menstruation unwarned and unprepared for the important internal function it represents.

The length of menstrual cycles differs from woman to woman, but the average length is 28 days (from the beginning of one menstrual flow to the beginning of the next). It is not unusual for cycles to be as short as 23 days or as long as 35 days. The length of the average menstrual flow (termed menses) is 4 to 6 days, although women may have periods as short as 2 days or as long as 7 days (MacKay, 2009).

Because there is such variation in length, frequency, and amount of menstrual flow and such variation in the onset of menarche, many women have questions about what is considered normal. Contact with health care personnel during a yearly health examination or prenatal visit may be their first opportunity to ask questions they have had for some time. Table 5.1 summarizes the normal characteristics of menstruation for quick reference.

Physiology of Menstruation

Four body structures are involved in the physiology of the menstrual cycle: the hypothalamus, the pituitary gland, the ovaries, and the uterus. For a menstrual cycle to be complete, all four structures must contribute their part; inactivity of any part results in an incomplete or ineffective cycle (Fig. 5.12).

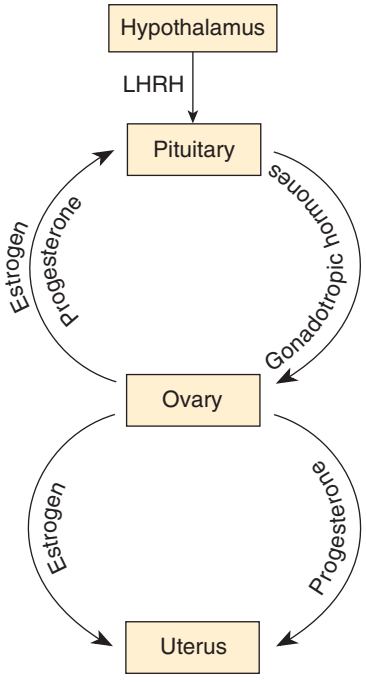

FIGURE 5.12 The interaction of pituitary-uterine-ovarian functions in a menstrual cycle.

Hypothalamus

The release of GnRH (also called luteinizing hormone–releasing hormone, or LHRH) by the hypothalamus initiates the menstrual cycle. When the level of estrogen (produced by the ovaries) rises, release of the hormone is repressed, and menstrual cycles do not occur (the principle that birth control pills use to eliminate menstrual flow). During childhood, the hypothalamus is apparently so sensitive to the small amount of estrogen produced by the adrenal glands that release of the hormone is suppressed. Beginning with puberty, the hypothalamus becomes less sensitive to estrogen feedback; this results in the initiation every month in females of the hormone GnRH. GnRH is transmitted from the hypothalamus to the anterior pituitary gland and signals the gland to begin producing the gonadotropic hormones FSH and LH. Because production of GnRH is cyclic, menstrual periods also cycle.

Diseases of the hypothalamus that cause deficiency of this releasing factor can result in delayed puberty. Likewise, a disease that causes early activation of GnRH can lead to abnormally early sexual development or precocious puberty (Kaplowitz, 2007) (see Chapter 47). In addition to the inhibitory feedback mechanism of estrogen and progesterone that halts production of the releasing factor for the remainder of each month, high levels of pituitary-based hormones such as prolactin, FSH, or LH can also inhibit the production of GnRH.

Pituitary Gland

Under the influence of GnRH, the anterior lobe of the pituitary gland (the adenohypophysis) produces two hormones that act on the ovaries to further influence the menstrual cycle: (a) FSH, a hormone that is active early in the cycle and is responsible for maturation of the ovum, and (b) LH, a hormone that becomes most active at the midpoint of the cycle and is responsible for ovulation, or release of the mature egg cell from the ovary, and growth of the uterine lining during the second half of the menstrual cycle.

Ovary

FSH and LH are called gonadotropic hormones because they cause growth (trophy) in the gonads (ovaries). Every month during the fertile period of a woman's life (from menarche to menopause), one of the ovary's primordial follicles is activated by FSH to begin to grow and mature. As it grows, its cells produce a clear fluid (follicular fluid) that contains a high degree of estrogen (mainly estradiol) and some progesterone. As the follicle reaches its maximum size, it is propelled toward the surface of the ovary. At full maturity, it is visible on the surface of the ovary as a clear water blister approximately 0.25 to 0.5 inches across. At this stage of maturation, the small ovum (barely visible to the naked eye, approximately the size of a printed period), with its surrounding follicle membrane and fluid, is termed a graafian follicle.

By day 14 before the end of a menstrual cycle (the midpoint of a typical 28-day cycle), the ovum has divided by mitotic division into two separate bodies: a primary oocyte, which contains the bulk of the cytoplasm, and a secondary oocyte, which contains so little cytoplasm that it is not functional. The structure also has accomplished its meiotic division, reducing its number of chromosomes to the haploid (having only one member of a pair) number of 23.

After an upsurge of LH from the pituitary, prostaglandins are released and the graafian follicle ruptures. The ovum is set free from the surface of the ovary, a process termed ovulation. It is swept into the open end of a fallopian tube. Teach women that ovulation occurs on approximately the 14th day before the onset of the next cycle, not necessarily at a cycle's midpoint. Because periods are typically 28 days, making the 14th day the middle of the cycle, many women believe incorrectly that the midpoint of their cycle is their day of ovulation. If their cycle is only 20 days long, however, their day of ovulation would be day 6 (14 days from the end of the cycle). If a cycle is 44 days long, ovulation would occur on day 30, not day 22.

After the ovum and the follicular fluid have been discharged from the ovary, the cells of the follicle remain in the form of a hollow, empty pit. The FSH has done its work at this point and now decreases in amount. The second pituitary hormone, LH, continues to rise in amount and acts on the follicle cells of the ovary. It influences the follicle cells to produce lutein, a bright-yellow fluid. Lutein is high in progesterone and contains some estrogen, whereas the follicular fluid was high in estrogen with some progesterone. This yellow fluid fills the empty follicle, which is then termed a corpus luteum (yellow body).

The basal body temperature of a woman drops slightly (by 0.5° to 1° F) just before the day of ovulation, because of the extremely low level of progesterone that is present at that time. It rises by 1° F on the day after ovulation, because of the concentration of progesterone (which is thermogenic) that is present at that time. The woman's temperature remains at this level until approximately day 24 of the menstrual cycle, when the progesterone level again decreases (McCance & Huether, 2007).

If conception (fertilization by a spermatozoon) occurs as the ovum proceeds down a fallopian tube and the fertilized ovum implants on the endometrium of the uterus, the corpus luteum remains throughout the major portion of the pregnancy (approximately 16 to 20 weeks). If conception does not occur, the unfertilized ovum atrophies after 4 or 5 days, and the corpus luteum (called a "false" corpus luteum) remains for only 8 to 10 days. As the corpus luteum regresses, it is gradually replaced by white fibrous tissue, and the resulting structure is termed a corpus albicans (white body). Figure 5.13 shows the times when ovarian hormones are secreted at peak levels during a typical 28-day menstrual cycle.

Uterus

Figure 5.13 also illustrates uterine changes that occur monthly as a result of stimulation from the hormones produced by the ovaries.

First Phase of Menstrual Cycle (Proliferative). Immediately after a menstrual flow (which occurs during the first 4 or 5 days of a cycle), the endometrium, or lining of the uterus, is very thin, approximately one cell layer in depth. As the ovary begins to produce estrogen (in the follicular fluid, under the direction of the pituitary FSH), the endometrium begins to proliferate. This growth is very rapid and increases the thickness of the endometrium approximately eightfold. This increase continues for the first half of the menstrual cycle (from approximately day 5 to day

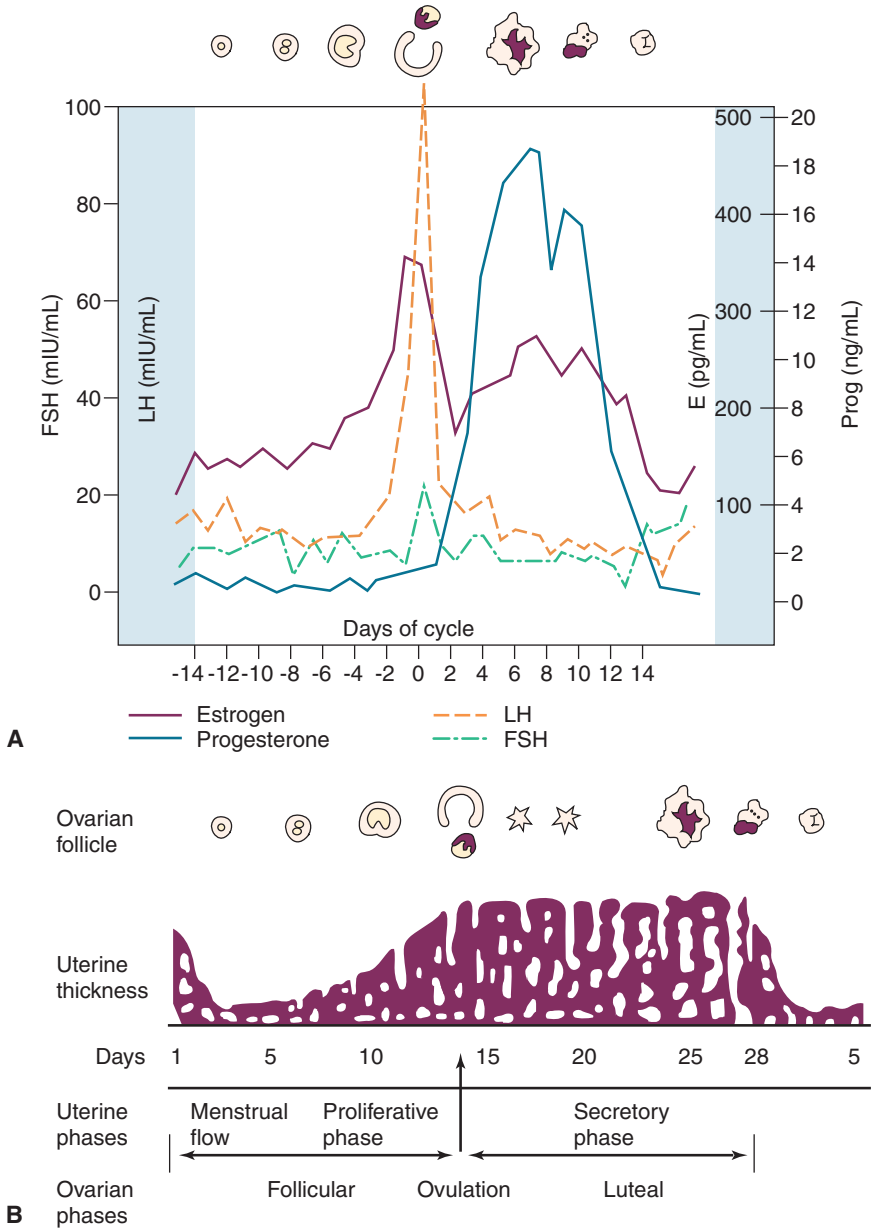

FIGURE 5.13 (**A**) Plasma hormone concentrations in the normal female reproductive cycle. (**B**) Ovarian events and uterine changes during the menstrual cycle.

14). This half of a menstrual cycle is termed interchangeably the proliferative, estrogenic, follicular, or postmenstrual phase.

Second Phase of Menstrual Cycle (Secretory). After ovulation, the formation of progesterone in the corpus luteum (under the direction of LH) causes the glands of the uterine endometrium to become corkscrew or twisted in appearance and dilated with quantities of glycogen (an elementary sugar) and mucin (a protein). The capillaries of the endometrium increase in amount until the lining takes on the appearance of rich, spongy velvet. This second phase of the menstrual cycle is termed the progestational, luteal, premenstrual, or secretory phase.

Third Phase of Menstrual Cycle (Ischemic). If fertilization does not occur, the corpus luteum in the ovary begins to regress after 8 to 10 days. As it regresses, the production of progesterone and estrogen decreases. With the withdrawal of progesterone stimulation, the endometrium of the uterus begins to degenerate (at approximately day 24 or day 25 of the cycle). The capillaries rupture, with minute hemorrhages, and the endometrium sloughs off.

Fourth Phase of a Menstrual Cycle (Menses). Menses, or the menstrual flow, is composed of:

- Blood from the ruptured capillaries
- Mucin from the glands
- Fragments of endometrial tissue
- The microscopic, atrophied, and unfertilized ovum

Menses is actually the end of an arbitrarily defined menstrual cycle. Because it is the only external marker of the cycle, however, the first day of menstrual flow is used to mark the beginning day of a new menstrual cycle.

Contrary to common belief, a menstrual flow contains only approximately 30 to 80 mL of blood; if it seems like more, it is because of the accompanying mucus and endometrial shreds. The iron loss in a typical menstrual flow is approximately 11 mg. This is enough loss that many women need to take a daily iron supplement to prevent iron depletion during their menstruating years.

In women who are beginning menopause, menses may typically consist of a few days of spotting before a heavy flow, or a heavy flow followed by a few days of spotting, because progesterone withdrawal is more sluggish or tends to "staircase" rather than withdraw smoothly.

✔ Checkpoint Question 5.4

Suzanne Matthews typically has a menstrual cycle of 34 days. She tells you she had sexual intercourse on days 8, 10, 15, and 20 of her last cycle. Which is the day on which she most likely conceived?

a. Day 8
b. Day 10
c. Day 15
d. Day 20

Cervix

The mucus of the uterine cervix, as well as the uterine body, changes each month during the menstrual cycle. During the first half of the cycle, when hormone secretion from the ovary is low, cervical mucus is thick and scant. Sperm survival in this type of mucus is poor. At the time of ovulation, when the estrogen level is high, cervical mucus becomes thin and copious. Sperm penetration and survival at the time of ovulation in this thin mucus are excellent. As progesterone becomes the major influencing hormone during the second half of the cycle, cervical mucus again becomes thick and sperm survival is again poor.

Women can analyze cervical mucus changes to help plan coitus to coincide with ovulation if they want to increase their chance of becoming pregnant or plan to avoid coitus at the time of ovulation to prevent pregnancy (see Chapter 6).

Fern Test. When high levels of estrogen are present in the body, as they are just before ovulation, the cervical mucus forms fernlike patterns caused by the crystallization of sodium chloride on mucus fibers when it is placed on a glass slide and allowed to dry. This pattern is known as arborization or ferning (Fig. 5.14). When progesterone is the dominant hormone, as it is just after ovulation, when the luteal phase of the menstrual cycle is beginning, a fern pattern is no longer discernible. Cervical mucus can be examined at midcycle to detect whether ferning, which suggests a high estrogen surge, is present. Women who do not ovulate continue to show the fern pattern throughout the menstrual cycle (i.e., progesterone levels never become dominant), or they never demonstrate it because their estrogen levels never rise.

Spinnbarkeit Test. At the height of estrogen secretion, cervical mucus not only becomes thin and watery but also can be stretched into long strands. This stretchability is in contrast to its thick, viscous state when progesterone is the dominant hormone. Performing this test, known as spinnbarkeit, at the midpoint of a menstrual cycle is another way to demonstrate that high levels of estrogen are being produced and, by implication, that ovulation is about to occur. A woman can do this herself by stretching a mucus sample between thumb and finger, or it can be tested in an examining room by smearing a cervical mucus specimen on a slide and stretching the mucus between the slide and coverslip (Fig. 5.15).

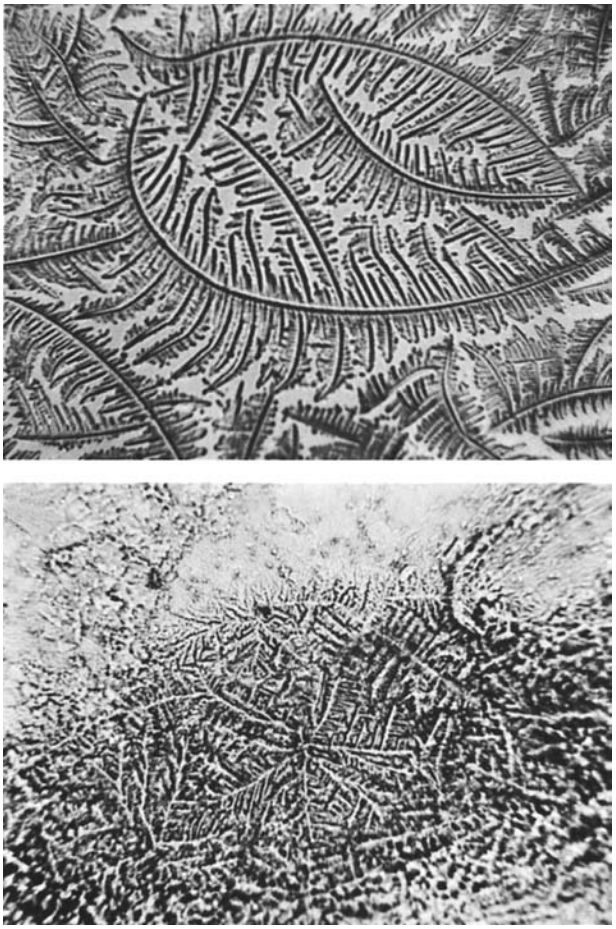

FIGURE 5.14 (**A**) A ferning pattern of cervical mucus occurs with high estrogen levels. (**B**) Incomplete ferning during secretory phase of cycle. (From Scott, J. R. [1990]. *Danforth's obstetrics and gynecology* [6th ed.]. Philadelphia: JB Lippincott.)

Education for Menstruation

Education about menstruation is an important component of comprehensive sexuality education. Many myths about menstruation still exist, such as that women should not get a hair permanent during menses, that they should not plant vegetables because the vegetables will die, or that they should not eat sour foods because this will cause cramping. Early preparation for menstruation to dispel these myths is important to a girl's concept of herself as a woman, because it teaches her to trust her body or to think of menstruation as a mark of pride or growing up rather than a burden. Education regarding menstruation is equally important for boys so they can appreciate the cyclic process that a woman's reproductive system activates and can be active participants in helping plan or prevent the conception of children.

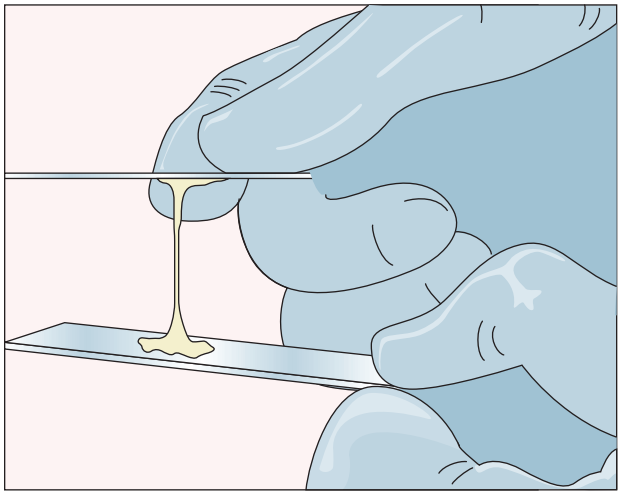

FIGURE 5.15 Spinnbarkeit is the property of cervical mucus to stretch a distance before breaking.

Girls who are well prepared for menstruation and view it as a positive happening are more likely to cope with any menstrual discomfort effectively, which results in fewer missed school days than those who view menstruation as an ill time. Important teaching points for girls at menarche regarding menstruation are summarized in Table 5.2. Menstrual disorders, including dysmenorrhea (painful menstruation), **menorrhagia** (abnormally heavy menstrual flows), **metrorrhagia** (bleeding between menstrual periods), menstrual migraines, and premenstrual dysphoric syndrome, are discussed in Chapter 47 with other reproductive system disorders.

Menopause

Menopause is the cessation of menstrual cycles. *Perimenopausal* is a term used to denote the period during which menopausal changes occur. *Postmenopausal* describes the time of life following the final menses. The age range at which menopause occurs is wide, between approximately 40 and 55 years of age with a mean age of 51.3.

The age at which menopause symptoms begin appears to be genetically influenced or at least is not associated with age of menarche. Women who smoke tend to have earlier menopause (Baram & Basson, 2007).

An older term to describe menopause was "change of life," because it marks the end of a woman's ability to bear children and the beginning of a new phase of life. Such a role change can produce psychological stress, although, through health teaching, nurses can help a woman appreciate that her role in life is greater than just bearing children; loss of uterine function may make almost no change in her life; and, for a woman with dysmenorrhea (painful menstruation) or with no desire for more children, menopause can be a welcome change. Menopause can cause physiologic stress as ovaries are a woman's chief source of estrogen. When ovaries begin to atrophy, reducing estrogen production, "hot flashes," vaginal dryness, or osteoporosis (lack of bone mineral density [BMD]) occurs. Urinary incontinence from lack of bladder support can also occur (Freeman et al., 2007).

Hot flashes can be accompanied by heart palpitations and can occur up to 20 to 30 episodes a day; episodes commonly last for 3 to 5 minutes at a time. An immediate aid in reducing this sudden overheated feeling is to sip at a cold drink or use a hand fan.

At one time, hormone replacement therapy (HR) was prescribed extensively to decrease menopause symptoms because it was believed that this therapy reduced cardiovascular complications such as atherosclerosis or heart attacks as well. HR is no longer prescribed routinely as such therapy does not appear to reduce cardiac risk or prevent osteoporosis and may be associated with endometrial cancer, cerebrovascular accidents (strokes), and perhaps breast cancer (Gabriel-Sanchez, et al., 2009).

HR may be prescribed on a short-term basis (1 to 2 years) if a woman has symptoms so severe that they interfere with her life plans but women should not receive estrogen replacement therapy indefinitely because of the possible adverse effects.

Women who notice excessive vaginal dryness can be advised to use a lubricating jelly such as KY Jelly prior to sexual

TABLE 5.2 ✻ Teaching About Menstrual Health

Area of Concern	Teaching Points
Exercise	Moderate exercise during menses promotes a general sense of well-being. Sustained excessive exercise, such as professional athletes maintain, can cause amenorrhea.
Sexual relations	Not contraindicated during menses although the male should wear a condom to prevent exposure to body fluid. Heightened or decreased sexual arousal may be noticed during this time. Orgasm may increase the amount of menstrual flow. It is improbable but not impossible for conception to occur from coitus during menses.
Activities of daily life	Nothing is contraindicated (many people believe incorrectly that activities such as washing the hair or bathing are harmful).
Pain relief	Prostaglandin inhibitors such as ibuprofen (Motrin) are most effective for menstrual pain. Applying local heat may also be helpful. If a migraine headache occurs, specific drugs for this are now available, such as sumatriptan (Imitrex). Adolescents under age 18 should not take aspirin because of the association between this and Reye's syndrome.
Rest	More rest may be helpful if dysmenorrhea interferes with sleep at night.
Nutrition	Many women need iron supplementation to replace iron lost in menses. Eating pickles or cold food does not cause dysmenorrhea.

relations. Other possibilities are application of estrogen cream or insertion of a vaginal ring that dispenses low-dose estrogen. Low-dose estrogen or testosterone can also be prescribed to increase sexual libido. Practicing Kegel's exercises (see Chapter 12) can help strengthen bladder supports and reduce urinary incontinence.

Osteoporosis occurs in as many as 13% to 18% of women over age 50. It is seen most frequently in women who are Asian, have a low body weight, have a positive family history, participate in few weight-bearing exercises, have a low intake of calcium, are cigarette smokers, have an early surgical menopause, or take certain anticonvulsant medications or corticosteroids. As calcium is withdrawn from bones, women notice a decrease in height and back pain from shortening of the vertebral column. If they fall, they are more prone to fractures than are younger women (Bessette et al., 2008).

BMD scans are helpful in diagnosis. To help prevent osteoporosis, women should be sure to ingest 1200 mg calcium daily along with 400 to 800 IU of vitamin D, in addition to beginning a program of weight-bearing exercises such as walking or low-impact aerobics. Calcitonin, a thyroid hormone that regulates body calcium, may be prescribed as a nasal spray. Other drugs commonly prescribed are selective estrogen receptor modulators (SERMS) such as Evista and bisphosphonates such as Fosamax that regulate calcium by aiding bone reabsorption.

If a woman lives to be 80, she will spend a third of her life postmenopausal. Women appreciate learning the normal parameters of menopause so they understand what will happen to them as changes occur and to be able to continue to monitor their health during this time.

SEXUALITY AND SEXUAL IDENTITY

Sexuality is a multidimensional phenomenon that includes feelings, attitudes, and actions. It has both biologic and cultural components. It encompasses and gives direction to a person's physical, emotional, social, and intellectual responses throughout life.

Biologic gender is the term used to denote a person's chromosomal sex: male (XY) or female (XX). **Gender identity** or sexual identity is the inner sense a person has of being male or female, which may be the same as or different from biologic gender. **Gender role** is the male or female behavior a person exhibits, which, again, may or may not be the same as biologic gender or gender identity (Box 5.3).

Development of Gender Identity

Several theories exist regarding whether gender identity arises from primarily a biologic or a psychosocial focus. The amount of testosterone secreted in utero (a process termed *sex typing*) may affect how gender develops. How appealing parents or other adult role models portray their gender roles may also influence how a child envisions himself or herself. For example, both sons and daughters may relate better to whichever parent is kinder and more caring. This could result in a son's assuming characteristics often regarded as feminine or a daughter's developing interests typically regarded as masculine.

Gender role is also culturally influenced. In Western society, women have in the past been viewed as having intrinsic nurturing qualities with sole responsibility for childrearing and homemaking. Men were viewed as financial providers. Gender roles today are more interchangeable: women pursue all types of jobs and careers without loss of femininity, and men participate in childrearing and household duties without loss of masculinity.

An individual's sense of gender identity develops throughout an entire life span, but the stage is set by expectations even before a child is born. Although parents usually respond to the question, "Do you want a boy or a girl?" with the answer, "It doesn't matter as long as it's healthy," many parents actually do have strong preferences for a male or female child. Although some parents may be disappointed if the child is not the gender they hoped for, most adapt quickly and will say later that they always wanted a child of that sex. Children who suspect that their parents wanted a child of the opposite sex are more likely to adopt roles of the opposite sex than if they are confident their parents are pleased with them as they are.

Infancy

From the day of birth, female and male babies are treated differently by their parents. People generally bring girls dainty rattles and dresses with ruffles; on the whole, they are treated more gently by parents and held and rocked more than male babies. People tend to buy boys bigger rattles and sports-related jogging suits. Admonitions given babies can be different. A girl might be told, "Don't cry. You don't look pretty when you cry." A boy might be told, "You've got to learn to be tougher than that if you're going to make it in this world." By the end of the first year, differences in play are usually strongly evident. Boys demonstrate more innate aggression, even at this early stage, than do girls. For more about the infant period, see Chapter 29.

BOX 5.3 * Focus on Family Teaching

Gender Identity Concerns

Q. Suzanne Matthews asks you, "Is it all right to call body parts by nicknames, such as 'peter' for penis, when we talk to children? Or should we use the anatomic name?"

A. Although this decision is strictly up to parents, using anatomic names is usually advised. This prevents children from thinking of one part of the body as so different from others (and perhaps dirty or suspect) that it cannot be called by its real name.

Q. Kevin Matthews asks you, "Will it be important to give our child unisex toys? Can't girls play with dolls and boys play with trucks anymore?"

A. Developing a sense of gender involves more than the toys that children use for play. If parents are concerned with instituting unisex roles in children, they need to begin by monitoring their own perspective on what they believe are female and male roles. Once they project a feeling that roles are interchangeable, such as both genders participating in sports and doing the same household chores, the general home milieu becomes more important than any one action in teaching this principle to children in their family.

Preschool Period

Children can distinguish between males and females as early as 2 years of age. By age 3 or 4 years, they can say what sex they are, and they have absorbed cultural expectations of that sex role. Often, boys will play rough-and-tumble games with other boys, and girls will play more quietly, although the two frequently mix at this age.

Sex role modeling is reinforced through behavior toward and expectations of the child, as well as from such things as the color and décor of the child's room and the child's clothing. Social contacts between the child and significant adults contribute to sexual identification and should be encouraged in this developmental period. A positive self-concept grows from parental love, effective relationships with others, success in play activities, and gaining skills and self-control.

Most American parents are not too rigid about what clothing or colors are appropriate for boys and girls. They strive to teach both sons and daughters about expressing feelings, performing household tasks, and engaging in the same play activities. However, some parents have fixed role identifications. Comments such as, "What kind of mommy are you going to be, treating a doll that way?" or "Is that the way a lady sits?" from parents and well-meaning friends help to govern girls' choice of actions. Common sayings such as "all boy" or "boys will be boys" represent the differences expected between the two sexes. The suggestions in Box 5.3 can help parents promote a positive and more unisex gender identity in their child.

Although the development of an Oedipus complex (the strong emotional attachment of a preschool boy for his mother or a preschool girl for her father) may have been overstated by Freud as a result of sexual bias, many children exhibit behavior that suggests such a phenomenon does occur during this time. The preschool boy shows signs of competing with his father for his mother's love and attention; the preschool girl competes with her mother for her father's attention and love. Parents may need reassurance that this phenomenon of competition and romance in preschoolers is normal and is only one step in the development of their child's gender role identity. Preschooler development is further discussed in Chapter 31.

School-Age Child

Early school-age children typically spend play time imitating adult roles as a way of learning gender roles (Fig. 5.16). They form strong impressions of what a female or male role should be. Where once schools promoted differences between males and females by separating activities into those only for girls and those only for boys and promoting beliefs such as expecting boys to be poorer readers, to write less neatly, and to act rougher in the school hallways, grade schools have become more attuned to unisex activities.

Girls may participate in activities that were once male dominated, such as Little League and auto repair courses; boys may take cooking or ballet lessons, formerly the province of girls. For more information about school-age development, see Chapter 32.

Adolescent

At puberty, as the adolescent begins the process of establishing a sense of identity, the problem of final gender role identification surfaces again. Most early adolescents maintain strong ties to their gender group, boys with boys and girls with girls. The advent of menstruation may provide a common bond for girls at this stage. Some adolescents choose a child of their own gender a few years older than themselves to use as their model of gender role behavior. This is a way that adolescents can be certain that they understand and feel comfortable with their own sex before they reach out and interact with members of the opposite sex.

FIGURE 5.16 Early school-age children imitate adult roles to learn more about them. Here a girl "tries on" what being a nurse will feel like. (© Barbara Proud.)

When interviewing adolescents for a sexual history, appreciate that this is a new and sensitive area for them so they may feel embarrassed at being questioned about this area of their life. Although behavior varies in different communities, as many as 50% of adolescents past the age of 15 are already sexually active (Centers for Disease Control and Prevention [CDC], 2009). This means that children as young as the early teen years need guidelines for safer sex (Box 5.4). Including such instructions as part of sexual counseling should help to reduce the incidence of STIs as well as empower adolescents with better self-care skills. When discussing safer sex practices, be certain that adolescents understand not only when but how they can incorporate them into their lifestyle. One of the reasons that preventive measures for human immunodeficiency virus (HIV) and other STIs have not been as successful as first predicted may be that adolescents' total lifestyle and interpretation of sexuality were not at first considered (Box 5.5).

Adolescence can be a very stressful time for the boy who first realizes that he is gay or the girl who first realizes that she is a lesbian. Part of the reason for the high suicide rate in adolescence may be because homosexual teenagers feel so lost in a heterosexual-dominant culture (Kipke et al., 2007). Chapter 33 discusses adolescence in greater detail.

Young Adult

When young adults move away from home to attend college or establish their own home, the change in their eating patterns can increase or decrease their weight that lead to

BOX 5.4 ✻ Guidelines for Safer Sex Practices

1. Abstinence is the only 100% guarantee against not contracting a sexually transmitted infection.
2. If you do have sex, be selective in choosing sexual partners. When you have sex, you are exposing yourself to the infections of everyone with whom your partner has ever had sex. The more partners you have relations with, the greater your danger of contracting a sexually transmitted infection.
3. Do not be reluctant to ask a sexual partner about his or her sexual lifestyle before engaging in sexual relations. If a partner has a history of casual contacts or bisexual or unprotected sex, there is a greater hazard of infection for you than if your partner is also choosy about partners.
4. Avoid sexual relations with intravenous drug users or prostitutes (male or female) or sexual partners who have had sexual relations with such people, because such people have a greater than usual chance of carrying the human immunodeficiency virus (HIV) and hepatitis B or C infection.
5. Inspect your sexual partner for any lesions or abnormal drainage in the genital area. Do not engage in sexual relations with anyone who exhibits these signs.
6. The use of a condom is the best protection against infection. Condoms should be latex; the chance of the condom tearing is less if it is a prelubricated brand. Use water-based lubricants such as KY Jelly on condoms, because oil-based lubricants can weaken the rubber.
7. Condoms should be protected from excessive heat to avoid rubber deterioration and should be inspected to be certain they are intact before use. Do not inflate condoms before use to test for intactness, because this weakens the rubber.
8. Condoms should be fitted over the erect penis with a small space left at the end to accept semen. The condom should be held against the sides of the penis while the penis is withdrawn to prevent spillage of semen.
9. Void immediately after sexual relations to help wash away contaminants on the vulva or in the urinary tract.
10. Anal intercourse carries a high risk for HIV and hepatitis infection as well as infection from intestinal organisms. Always use a condom. Use lubricants for anal penetration to keep bleeding and condom resistance to a minimum.
11. Do not engage in oral-penile sex unless the male wears a condom, because even preejaculatory fluid may contain viruses and bacteria. For safer oral-vaginal sex, a condom split in two or a plastic dental dam (like that used for pediatric dentistry) covering the mouth should be used to protect against the exchange of body fluids.
12. Hand-to-genital contact may be hazardous if open cuts are present on hands. Use a latex glove or finger cot for protection.
13. To decrease the possibility of transferring germs, do not share sexual aids such as vibrators.
14. If you think you have contracted a sexually transmitted infection, do not engage in sexual relations until you have contacted a health care provider and are again infection free. Alert any recent sexual partners that you might have an infection so they also can receive treatment.

changes in their body image (Box 5.6). During this time, they choose the way they will express their sexuality along with other life patterns. Many young adults marry with a commitment to one sexual partner. Others establish relationships (cohabitation) that are less binding by legal definitions but perhaps equally binding in concern and support. Young adults may view cohabitation as a means of learning more about a possible marriage partner on a day-to-day basis, in the hope that a future marriage will then be stronger and more lasting. Homosexuality or bisexuality may be overtly expressed for the first time during this period.

Conflicts in parenting can occur if an individual's gender role does not meet the expectations of a family, or if an individual's partner has different expectations regarding gender role. It is time well spent for parents-to-be to take time to discuss with each other the views they have on parenting to see whether they agree on male and female roles and their relationship with their children. A single parent may be concerned about how both roles can be fulfilled and can benefit from talking with a health care provider about this area of concern. Conflicts in the roles parents have chosen often come to light for the first time during pregnancy, as they worry about what type of parents they are going to be or whether they are adequately prepared to be parents. Being able to talk to health care personnel about the gender roles they have adopted in life can be a major step in promoting feelings of adequacy and preparing themselves to raise a child.

Young adulthood is the time when many couples begin childbearing. Early in pregnancy, a woman may experience a decreased desire for coitus because of the increased estrogen in her body. As pregnancy advances and her abdomen increases in size, she and her sexual partner may need to use new positions for intercourse such as a side-by-side position or the woman in a superior position. Caution women with a nonmonogamous sexual partner that she or her partner need to use a condom to prevent transmission of an STI during pregnancy (Katsufrakis & Workowski, 2008).

BOX 5.5 ✻ Focus on Communication

Kevin brings his 16-year-old nephew, Mark, into your health care clinic because Mark has had painful urination for 2 days. A culture is taken to determine whether he has contracted a sexually transmitted infection (STI).

Less Effective Communication

Nurse: Mark, because you're sexually active you may have a sexually transmitted infection.
Mark: Uh-huh.
Nurse: Do you practice safer sex?
Mark: Uh, yeah.
Nurse: I assume that means you always use a condom.
Mark: Right.
Nurse: It would be hard to contract an STI if you always do.
Mark: Guess I'm just unlucky.

More Effective Communication

Nurse: Mark, because you're sexually active you may have a sexually transmitted infection.
Mark: Uh-huh.
Nurse: Do you practice safer sex?
Mark: Uh, yeah.
Nurse: What measures do you use?
Mark: My girlfriend's on the pill, so we don't really need to use anything else.
Nurse: The pill will help prevent pregnancy, but it won't protect you from contracting an STI.
Mark: No kidding.
Nurse: Let's talk about the different protection needed to prevent pregnancy and STIs.

Adolescents are often so concerned about protecting their privacy from adults that they may offer as little information as possible at a health care visit, especially in regard to sexual issues. Asking them specific, open-ended questions is important to ensure a positive exchange of information and effective health teaching. As they offer details, remain nonjudgmental to encourage them to continue to elaborate.

BOX 5.6 ✻ Focus on Evidence-Based Practice

Does gender affect college weight gain?
It is often noted that college freshmen gain "freshman fifteen" or a significant weight gain during their first college year. To examine whether college weight gain is affected by gender, researchers asked 396 college freshman to complete a 40-item health survey and measured their height and weight at the study beginning and again at the end.

Results of the study showed that the amount of weight gained by the differing genders was not greatly different but the reason for the gains varied greatly. In this study, the average weight gain for men was 5.04 lb. It was 5.49 lb for women. Gains in weight for men were associated with increased alcohol consumption. An increased study workload was credited for the reason for weight gain in women.

Would the results of this study influence the way you would counsel college students who are interested in avoiding a freshmen weight gain?

Source: Economos, C. D., Hildebrandt, M. L., & Hyatt, R. R. (2008). College freshman stress and weight change: differences by gender. *American Journal of Health Behavior, 32*(1), 16–25.

Middle-Age Adult

For many women and men in midlife, sexuality has achieved a degree of stability. A sense of masculinity or femininity and comfortable patterns of behavior have been established. This increased security in identity can promote greater intimacy in sexual and social relationships. This may also be a time when adults allow themselves more freedom in exploring and satisfying sexual needs.

Although menopause alters reproductive functioning, it does not physically inhibit sexual functioning. Generally, a woman with a strong self-image, positive sexual and social relationships, and knowledge regarding her body and menopause is likely to progress through this natural biologic stage without problems and remain sexually active and satisfied. Nurses can be instrumental in teaching women what to expect at menopause so that it is not a surprise and in helping them maintain self-esteem through this natural process.

During midlife, men may begin to experience changes in sperm production, erectile power, achievement of orgasm, and sex drive, although these changes usually do not significantly alter reproductive or sexual functioning. Some men feel that these changes threaten their sexuality and "maleness" and may respond negatively. Other men feel that these changes make sex more pleasurable and intimate and often respond positively. Actual sexual dysfunctions, as a result of physical or psychosocial changes, may arise at this time. Teaching men about normal biophysical changes, providing them with methods to improve sexual functioning, and offering them support are important health education roles.

Midlife is often a time when both men and women reexamine life goals, careers, accomplishments, value systems, and familial and social relationships. As a result, some people adapt, whereas others experience stress or a crisis. This reexamination can positively or negatively affect an individual's gender identity and sexuality. For example, a woman may realize that she is not able to be both a homemaker and a career person. She may either modify her belief that it is important for a woman to assume both roles or try harder to achieve both goals, believing that she has personally failed. The increased incidence of sexual encounters that men have with younger women at this age may be a man's way of reassuring himself of his attractiveness and virility and denying that he is aging.

Certain medications, such as antihypertensives, antianxiety agents, and narcotics, may diminish sexual response in both men and women. Being aware of this fact is important

not only for clients, so that they can understand that it is an expected response, but also for their partners.

The individual who comments about the need to maintain a reduced activity level at work or a reduced social schedule may also be seeking information and direction in other important areas of life, such as sexual relations.

Some women have surgery at midlife such as hysterectomy (removal of the uterus). If both ovaries are also removed (oophorectomy), an immediate surgical menopause occurs. For some women, the loss of a uterus and ovaries can be synonymous with the loss of femininity. Women who have such surgery need sensitive caregivers to listen to their concerns about the meaning of the experience for them.

Older Adult

Both male and female older adults continue to enjoy active sexual relationships. Some men experience less erectile firmness or ejaculatory force than when they were younger, but others discover that they are able to maintain an erection longer. Older women may have less vaginal secretions because they have less estrogen after menopause. Use of a water-soluble lubricant before coitus can enhance their comfort and enjoyment. Both sexes need to follow safer sex practices throughout life. Because males remain fertile throughout life, they must continue to be responsible sex partners in terms of reproductive planning.

The Individual Who Is Physically Challenged

Individuals who are physically challenged have sexual desires and needs the same as all others (Piotrowski & Snell, 2007). However, they may have difficulty with sexual identity or sexual fulfillment because of their condition. Males with upper spinal cord injury may have difficulty with erection and ejaculation, because these actions are governed at the spinal level. Manual stimulation of the penis or psychological stimulation achieves erection in most men with spinal cord lesions, allowing the man a satisfying sexual relationship with his partner. Most women with spinal cord injuries cannot experience orgasm but are able to conceive and have children.

Anyone who interprets a procedure such as a colostomy as disfiguring may be reluctant to participate in sexual activities, fearing that the sight of an apparatus will diminish their partner's satisfaction or enjoyment. People with chronic pain (e.g., arthritis) may be too uncomfortable to enjoy sexual relations. Individuals with urinary catheters may be concerned about their ability to enjoy coitus with the catheter in place. For women, a retention catheter should not interfere with sexual intercourse. Men can be taught how to replace their own catheter, so that they can remove it for sexual relations. In all instances in which one sexual partner is disabled in some way, the response of a loving partner does much to enhance body image and feelings of adequacy of a mate. Encouraging these clients to ask questions and work on specific difficulties is a nursing role.

Sexuality is a facet of rehabilitation that has not always received attention. If a person can accomplish activities of daily living such as eating, elimination, and mobility, then he or she is considered to be leading a normal or near-normal life. Establishment of a satisfying sexual relationship is an important part of living, however, so should be included in assessments of clients in rehabilitation programs.

HUMAN SEXUAL RESPONSE

Sexuality has always been a part of human life, but it is only in the past few decades that it has been studied scientifically. One common finding of researchers has been that feelings and attitudes about sex vary widely: the sexual experience is unique to each individual, but sexual physiology (i.e., how the body responds to sexual arousal) has common features (Baram & Basson, 2007).

Sexual Response Cycle

Two of the earliest researchers of sexual response were Masters and Johnson. In 1966, they published the results of a major study of sexual physiology based on more than 10,000 episodes of sexual activity among more than 600 men and women (Masters, 1998). In this study, they described the human sexual response as a cycle with four discrete stages: excitement, plateau, orgasm, and resolution. Stages may actually be more individualized than Masters proposed; they may blend together much more into one smooth process of desire, arousal, and orgasm.

Excitement

Excitement occurs with physical and psychological stimulation (i.e., sight, sound, emotion, or thought) that causes parasympathetic nerve stimulation. This leads to arterial dilation and venous constriction in the genital area. The resulting increased blood supply leads to vasocongestion and increasing muscular tension. In women, this vasocongestion causes the clitoris to increase in size and mucoid fluid to appear on vaginal walls as lubrication. The vagina widens in diameter and increases in length. The nipples become erect. In men, penile erection occurs, as well as scrotal thickening and elevation of the testes. In both sexes, there is an increase in heart and respiratory rates and blood pressure.

Plateau

The plateau stage is reached just before orgasm. In the woman, the clitoris is drawn forward and retracts under the clitoral prepuce; the lower part of the vagina becomes extremely congested (formation of the orgasmic platform), and there is increased nipple elevation.

In men, the vasocongestion leads to distention of the penis. Heart rate increases to 100 to 175 beats per minute and respiratory rate to approximately 40 respirations per minute.

Orgasm

Orgasm occurs when stimulation proceeds through the plateau stage to a point at which the body suddenly discharges accumulated sexual tension. A vigorous contraction of muscles in the pelvic area expels or dissipates blood and fluid from the area of congestion. The average number of contractions for a woman is 8 to 15 contractions at intervals of 1 every 0.8 seconds. In men, muscle contractions surrounding the seminal vessels and prostate project semen into the proximal urethra. These contractions are followed immediately by three to seven propulsive ejaculatory contractions, occurring at the same time interval as in the woman, which force semen from the penis.

As the shortest stage in the sexual response cycle, orgasm is usually experienced as intense pleasure affecting the whole body, not just the pelvic area. It is also a highly personal experience: descriptions of orgasms vary greatly from person to person.

Resolution

Resolution is a 30-minute period during which the external and internal genital organs return to an unaroused state. For the male, a refractory period occurs during which further orgasm is impossible. Women do not go through this refractory period, so it is possible for women who are interested and properly stimulated to have additional orgasms immediately after the first.

Controversies About Female Orgasm

The female orgasm has been a topic of much controversy over the years, beginning with Freud, who deducted that there were two types of female orgasms: clitoral and vaginal. He believed that clitoral orgasms (originating from masturbation or other noncoital acts) represented sexual immaturity and that only vaginal orgasms were the authentic, mature form of sexual behavior in women. Accordingly, he considered women to be neurotic if they could not achieve orgasm through intercourse.

Masters (1998) showed that there is no physiologic difference between an orgasm achieved through intercourse and one achieved by direct stimulation of the clitoris. Women have reported a difference in intensity and character between orgasms achieved through coitus and through other means, and some prefer one to the other, but there is no physiologic difference between them. For most women, adequate time for foreplay is essential for them to be orgasmic.

In recent years, a subject of controversy regarding female sexuality has arisen: the existence or not of "the G spot." First described in 1950 by the German physician Gräfenberg, the G spot, presumably located on the inner portion of the vaginal wall, halfway between the pubic bone and the cervix, has been promoted as an area of heightened erotic sensitivity (Baram & Basson, 2007). Several studies carried out in the past 10 years have not been able to verify the existence of this particular anatomic site, although some women do claim to possess such an erotic trigger.

Influence of the Menstrual Cycle on Sexual Response

During the second half of the menstrual cycle—the luteal phase—there is increased fluid retention and vasocongestion in a woman's lower pelvis. Because some vasocongestion is already present at the beginning of the excitement stage of the sexual response, women appear to reach the plateau stage more quickly and achieve orgasm more readily during this time. Women also may be more interested in initiating sexual relations at this time.

Influence of Pregnancy on Sexual Response

Pregnancy is another time in life when there is vasocongestion of the lower pelvis because of the blood supply needed by a rapidly growing fetus. This causes some women to experience a first orgasm during their first pregnancy. Following a pregnancy, many women experience increased sexual interest because the new growth of blood vessels during pregnancy lasts for some time and continues to facilitate pelvic vasocongestion. This is why discussing sexual relationships is an important part of health teaching during pregnancy. At a time when a woman may want sexual contact very much, she needs to be free of myths and misconceptions, such as the notion that orgasm will cause a spontaneous miscarriage (see Focus on Nursing Care Planning Box 5.7). Although the level of oxytocin does appear to rise in women after orgasm, this rise is not sufficient to lead to worry that sexual relations will lead to premature labor in the average woman.

For some women, the increased breast engorgement that accompanies pregnancy results in extreme breast sensitivity during coitus. Foreplay that includes sucking or massaging of the breasts may cause the release of oxytocin, but it is not contraindicated unless the woman has a history of premature labor (Purinton & Goldstein, 2007).

BOX 5.7 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Couple Needing Sexual Counseling

Suzanne and Kevin Matthews, a young adult couple, 6 months pregnant, come to your antepartal clinic for a routine visit. Suzanne, in tears, states, "My husband isn't interested in me anymore. We haven't had sex since I became pregnant." Couple engaged in coitus two to three times per week prior to this pregnancy. Kevin states, "I'm afraid I'll hurt the baby."

Family Assessment ✻ Couple has been married for 4 years; lives in two-bedroom apartment in refurbished downtown loft. Husband works as a high school teacher; wife works as a baker in a local coffeehouse.

Client Assessment ✻ A previous pregnancy, 2 years ago, ended at 8 weeks with a spontaneous miscarriage. Blood pressure today is 118/70 mm Hg; overall health is good.

Nursing Diagnosis ✻ Altered sexuality pattern related to pregnancy and fear of harming fetus.

Outcome Criteria ✻ Couple states that they recognize coitus is not harmful in normal pregnancy; reports engaging in sexual intercourse as well as pleasurable noncoital sexual activities by next visit.

(continued)

BOX 5.7 ✻ Focus on Nursing Care Planning (continued)

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Assess lifestyle and sexual concerns.	Encourage couple to continue routine prenatal care. Discuss alternative sexual activities, such as cuddling or massage, at each visit.	As pregnancy progresses, discomfort, fatigue, and increasing abdominal size and pressure may interfere with a satisfying sexual relationship. Advanced planning prepares the couple for adaptations that may be necessary.	Couple continues prenatal care. Describes other ways of sexual expression.
		Consultations		
Nurse	Assess signs and symptoms of pregnancy; note any indication of complications.	Consult with team primary care provider to be certain the client has no contraindications to remaining sexually active during pregnancy.	In a few women who have had previous miscarriages, or if vaginal bleeding is present, sexual relations may be contraindicated or the pregnancy will be threatened.	The couple's primary care provider supplies information on ability of couple to remain sexually active throughout pregnancy.
		Procedures/Medications		
Nurse	Assess whether alternative types of sexual activity would fulfill couple's needs.	Review alternative sexual positions for optimal comfort and pleasure.	Alternative sexual positions may be necessary to provide comfort late in pregnancy as the woman's abdomen expands.	Couple describes alternative positions or ways they relate to each other.
		Patient/Family Education		
Nurse in consultation with physician	Assess what couple understands about reproductive anatomy and usual sexual response.	Explain that sexual relations are allowed during pregnancy until labor begins. Use charts and illustrations to show how the fetus is protected in utero.	Barring complications, couples can engage in coitus to the extent that it is comfortable and desired. Visual aids enhance learning.	Couple states they understand sexual relations are allowed during a normal pregnancy and they understand that minimal contractions may occur with orgasm but that these are not harmful unless the woman has a history of premature labor.
		Spiritual/Psychosocial/Emotional Needs		
Nurse	Assess whether couple knows that hormones can change sexual desire during pregnancy.	Encourage the couple to talk openly about their feelings, concerns, desires, and changes in interest to each other throughout the pregnancy.	Physical and psychological changes occur in both the pregnant woman and her partner throughout pregnancy. Open communication enhances the relationship.	Couple reports that they are able to voice their feelings and concerns during the pregnancy.

Nurse	Assess what communication pattern couple uses to share information with each other.	Teach importance for a couple of maintaining communication.	Beginning a sound communication pattern during pregnancy can lay a foundation for a sound future relationship.	Couple reports that they appreciate the importance of good communication for their ongoing relationship.
		Discharge Planning		
Nurse	Assess whether couple's questions and concerns were answered satisfactorily.	Review concern about sexual relations at each visit.	Continued interest in a couple's problem allows them to continue to voice concerns.	Chart documents that questions were asked and answered at continuing visits.

Types of Sexual Orientation

Sexual gratification is experienced in several ways. What is considered normal varies greatly among cultures, although general components of accepted sexual activity are that it is an activity of adults and privacy, consent, and lack of force are included. Most individual value systems are closely aligned to these cultural norms.

Heterosexuality

A heterosexual is a person who finds sexual fulfillment with a member of the opposite gender. Because interest in the opposite sex and sexual relationships may begin as early as the beginning of puberty, it is important to provide information on safer sex practices and planning for their use to children as young as 10 to 12 years of age. Otherwise, this knowledge comes too late to be most helpful.

Homosexuality

A homosexual is a person who finds sexual fulfillment with a member of his or her own sex. Many homosexual men prefer to use the term "gay." "Lesbian" refers to a homosexual woman. More recent terms are "men who have sex with men" (abbreviated as "MWM") and "women who have sex with women" (WWW).

Why homosexual gender identity develops is unknown, although evidence that this orientation is genetically determined or develops because of the effect of an unusual level of estrogen or testosterone in utero is increasing. Even before puberty, most individuals who are homosexual know they are "different" in that they are not interested in opposite-sex classmates. It is during adolescence, in seeking a sense of identity, that they realize that the reason they feel "different" is because they are homosexual. This can be a stressful time, because a homosexual identity may not be easy to reveal to family or friends. Although attitudes are changing, some people refuse to associate with homosexuals to such an extent that a fear termed *homophobia* still exists (Newman, 2007).

Although men who have sex with men and women who have sex with women often have demonstrated behavior that is inconsistent with expected gender roles from early childhood, young adulthood is the time most persons begin to assume a homosexual lifestyle. Many young adults are worried about the stigma of being labeled homosexual and therefore keep their identity secret from heterosexual acquaintances. Others "commit" or "come out" or are able to reveal their sexual identity to friends and family (Avery et al., 2007).

Because the period of identity confusion during adolescence can be so traumatic to people with alternative lifestyles, it is important for health care providers to be extremely sensitive to needs in this area. Men who have sex with men may need additional counseling to help them avoid acquiring HIV and other STIs, because issues such as avoiding contact through anal intercourse may not be routinely covered in sex education classes (Sandfort, Melendez, & Diaz, 2007). If women who have sex with women cohort with bisexuals, they have the same risk of STIs as other people. If they avoid partners who are bisexual, they may be at less risk for STIs because of the low incidence of these diseases in a strictly female population.

Bisexuality

People are said to be bisexual if they achieve sexual satisfaction from both homosexual and heterosexual relationships. Like men who have sex with men, bisexual men may be at greater risk for HIV and STIs than are others. Female partners of bisexual men need to be aware that they are also at increased risk for HIV and other STIs.

Transsexuality

A **transsexual** or transgender person is an individual who, although of one biologic gender, feels as if he or she is of the opposite gender (Jain & Bradbeer, 2007). Such people may have sex change operations so that they appear cosmetically as the gender they feel that they are. Such operations do not change the person's chromosomal structure, however, so although capable of sexual relations in this new role (a synthetic vagina or penis is created), the person is incapable of reproduction. The incidence of sex change operations has decreased in recent years because of potential disappointment after the surgery:

despite a new outward appearance, people realize that they are still not totally the person they wished to become. Children of a transsexual parent may have a great deal of difficulty understanding why their parent changed from male to female or female to male (White & Ettner, 2007).

Types of Sexual Expression

Because people are individuals, types of sexual expression are individualized.

Sexual Abstinence

Sexual abstinence (celibacy) is separation from sexual activity (Ott, Labbett, & Gold, 2007). It is the avowed state of certain religious orders. It is also a way of life for many adults and one that is becoming fashionable among a growing number of young adults. It is the main point of many high school sex education classes (Kelly & Schwartz, 2007). The theoretical advantage of sexual abstinence is the ability to concentrate on means of giving and receiving love other than through sexual expression and, of course, is the most effective way to prevent pregnancy or an STI.

Masturbation

Masturbation is self-stimulation for erotic pleasure; it can also be a mutually enjoyable activity for sexual partners. It offers sexual release, which may be interpreted by the person as overall tension or anxiety relief. Masters (1998) reported that women may find masturbation to orgasm the most satisfying sexual expression and use it more commonly than men. Children between 2 and 6 years of age discover masturbation as an enjoyable activity as they explore their bodies. Children who are under a high level of tension may become accustomed to using masturbation as a means of falling asleep at night or at naptime. They do this without any attempt at concealment because they have not yet been affected by society's view that such activity should not be public.

School age children continue to use masturbation for enjoyment or to relieve tension, but they perform such activities in private. Counseling parents about masturbation is discussed in Chapters 31 through 33. In a hospital setting, a school age child may assume that he or she has more privacy than actually exists. Such an assumption means that a child may be discovered masturbating if someone walks unannounced into the room.

After reproductive tract surgery or childbirth, many adult men and women voice concern about how soon they will be able to have sexual relations again without feeling pain. They may masturbate to orgasm to test whether everything in their body is still functioning, much as the preschooler does.

Autoerotic asphyxia is the extreme practice of causing oxygen deficiency (usually by hanging) during masturbation with the goal of producing a feeling of extreme sexual excitement. Not aware that the act can be fatal, adolescents are killed by this practice each year (Musshoff et al., 2007).

Erotic Stimulation

Erotic stimulation is the use of visual materials such as magazines or photographs for sexual arousal. Although this is thought to be mostly a male phenomenon, there is increasing interest in centerfold photographs in magazines marketed primarily to women. Some parents of adolescents may need to be assured that an interest in this type of material is developmental and normal. Respect this type of reading material when straightening patients' rooms in a health care facility.

Fetishism

Fetishism is sexual arousal resulting from the use of certain objects or situations. Leather, rubber, shoes, and feet are frequently perceived to have erotic qualities. The object of stimulation does not just enhance the experience; rather, it becomes a focus of arousal and a person may come to require the object or situation for stimulation (Scorolli et al., 2007).

Transvestism

A **transvestite** is an individual who dresses in the clothes of the opposite sex. Transvestites can be heterosexual, homosexual, or bisexual. Many are married. Some transvestites, particularly married heterosexuals, may be under a great deal of strain to keep their lifestyle a secret from friends and neighbors.

Voyeurism

Voyeurism is obtaining sexual arousal by looking at another person's body. Almost all children and adolescents pass through a stage when voyeurism is appealing; this passes with more active sexual expressions. That some voyeurism exists in almost everyone is illustrated by the large number of R-rated movies shown on television and in movie theaters and by the erotic descriptions in modern novels. If voyeurism is practiced to the exclusion of other sexual experiences, such an extreme probably reflects insecurity or the inability to feel confident enough to relate to others on more personal levels. Stalking, a crime that includes elements of voyeurism, is discussed in Chapter 33.

Sadomasochism

Sadomasochism involves inflicting pain (sadism) or receiving pain (masochism) to achieve sexual satisfaction. It is a practice generally considered to be within the limits of normal sexual expression as long as the pain involved is minimal and the experience is satisfying to both sexual partners.

Other Types of Sexual Expression

A multitude of other types of sexual expression exist (e.g., exhibitionism, making obscene telephone calls, bestiality, and pedophilia). Exhibitionism is revealing one's genitals in public. Bestiality is sexual relations with animals. Pedophiles are individuals who are interested in sexual encounters with children. Known pedophiles are registered as sex offenders. When they move into a new community, families are notified of the move according to Megan's Law, a national law designed to alert citizens to the presence of a sex offender in a community. Ways to keep children safe from sex offenders are discussed in Chapter 31, along with other aspects of community safety for young children.

What if... When Kevin unpacks his suitcase at a hospital admission, you discover that he has brought a wardrobe of women's clothing? What would you do?

SEXUAL HARASSMENT

Sexual harassment is unwanted and repeated sexual advances, remarks, or behavior toward another that (a) is offensive to the recipient and (b) interferes with job or school performance. It can involve actions as obvious as a job superior demanding sexual favors or a job superior sending sexist jokes by e-mail to a person supervised. In school it can refer to bullying (Gruber & Fineran, 2007).

Two types exist. One is *quid pro quo* (an equal exchange), in which an employer asks for something in return for sexual favors, such as a hiring or promotion preference. The second is *hostile work environment,* in which an employer creates an environment in which an employee feels uncomfortable and exploited (e.g., being addressed as "honey," asked to wear revealing clothing, working where walls are decorated with sexist posters).

Sexual harassment rules apply to same-gender as well as opposite-gender harassment. In addition to causing occupational disruption, sexual harassment may be so distressing that it leads to short- and long-term psychosocial consequences for victims and their families such as emotional distress (anxiety, depression, posttraumatic stress disorder, substance abuse), interpersonal conflict, and impaired intimacy and sexual functioning (Street et al., 2007). Sexual harassment has been illegal in the United States since 1964. Clients who report being subjected to harassment should be advised to report the situation to their personnel supervisor. Nurses should be aware of the sexual harassment guidelines in their own work setting and likewise report such behavior to keep their workplace free of this type of strain.

DISORDERS OF SEXUAL FUNCTIONING

Disorders involving sexual functioning can be lifelong (primary) or acquired (secondary). They can have a psychogenic origin (produced by psychic rather than organic factors), a biogenic origin (produced by biologic processes), or both. They occur in both men and women.

Inhibited Sexual Desire

Lessened interest in sexual relations is normal in some circumstances, such as after the death of a family member, a divorce, or a stressful job change. The support of a caring sexual partner or relief of the tension causing the stress allows a return to sexual interest.

Decreased sexual desire can also be a side effect of many medicines. Chronic diseases, such as peptic ulcers or chronic pulmonary disorders, that cause frequent pain or discomfort may interfere with a man's or a woman's overall well-being and interest in sexual activity. Obese men and women may not feel as much satisfaction from sexual relations as others, because they have difficulty achieving deep penetration because of the bulk of their abdomens. An individual with an STI such as genital herpes may choose to forgo sexual relations rather than inform a partner of the disease. Some women experience a decrease in sexual desire during perimenopause. Administration of androgen (testosterone) to women may be helpful at that time, because it can improve interest in sexual activity (MacKay, 2009).

Failure to Achieve Orgasm

The failure of a woman to achieve orgasm can be a result of poor sexual technique, concentrating too hard on achievement, or negative attitudes toward sexual relationships. Treatment is aimed at relieving the underlying cause. It may include instruction and counseling for the couple about sexual feelings and needs.

Erectile Dysfunction

Erectile dysfunction (ED), formerly referred to as impotence, is the inability of a man to produce or maintain an erection long enough for vaginal penetration or partner satisfaction (Wessells et al., 2007). Most causes of ED are physical, such as aging, atherosclerosis, or diabetes, which limit blood supply. It may also occur as a side effect of certain drugs (Basson & Schultz, 2007). The problem is compounded by doubt about the ability to perform and reluctance to discuss the problem with health care providers. Examples of drugs prescribed today for ED are sildenafil (Viagra), tadalafil (Cialis), and vardenafil (Levitra), which are taken up to once a day to stimulate penile erection (Karch, 2009) (Box 5.8). If

BOX 5.8 ✻ Focus on Pharmacology

Sildenafil Citrate (Viagra)

Classification: A phosphodiesterase (PDE) inhibitor. Prescribed as therapy for erectile dysfunction; also pulmonary artery hypertension

Action: Causes smooth muscle relaxation and inflow of blood to the corpus cavernosum of the penis, achieving erection (Karch, 2009)

Dosage: 50 mg PO prn 1 hour before sexual activity, up to one dose per day

Possible Adverse Effects: The most common side effects are headache, facial flushing, and upset stomach. Less commonly, ventricular arrhythmia, bluish vision, blurred vision, impairment of blue/green discrimination, or sensitivity to light may briefly occur. Advise patients not to take this drug within 4 hours of taking an alpha-blocker agent.

Nursing Implications

- Assess patient for pre-existing cardiovascular risk.
- Caution patient that dose should be limited to one time per day; use is contradicted if the patient is taking nitrates or an alpha-blocker.
- Erection lasting more than 4 hours (priapism) can occur. Caution patient to alert health care provider if this occurs to avoid penile tissue damage.
- Caution patients that this drug does not protect against sexually transmitted infections or pregnancy, so the user must continue to use safer sex practices.
- In rare instances, men taking PDE5 inhibitors have reported a sudden decrease or loss of vision. Caution patient that if he experiences sudden decrease or loss of vision to stop taking the medication and call a doctor right away.

these are not successful (they are contradicted in men with a risk of cardiovascular illness and in those who are taking medications that contain nitrates), a surgical implant to aid erection by the use of vacuum pressure is a possible alternative (Hossein, 2007). Testosterone injections may be helpful in some men. In all instances, frank discussion about the cause of the problem and currently available therapies is helpful. Various herbal products such as fennel extracts are available for women that may improve sexual libido. Vibration or vacuum devices are also available to increase clitoral enlargement and sexual arousal in women. Sildenafil citrate (Viagra) can be used with women taking serotonin reuptake inhibitors who notice decreased sexual arousal (Nurberg, et al., 2008).

Premature Ejaculation

Premature ejaculation is ejaculation before penile–vaginal contact (Docherty, 2007). The term also is often used to mean ejaculation before the sexual partner's satisfaction has been achieved. Premature ejaculation can be unsatisfactory and frustrating for both partners.

The cause, like that of ED, can be psychological. Masturbating to orgasm (in which orgasm is achieved quickly because of lack of time) may play a role. Other reasons suggested are doubt about masculinity and fear of impregnating a partner, which prevent the man from sustaining an erection. Sexual counseling for both partners to reduce stress, as well as serotonergic antidepressants such as Mirtazapine, may be helpful in alleviating the problem.

Persistent Sexual Arousal Syndrome

Persistent sexual arousal syndrome (PSAS) is excessive and unrelenting sexual arousal in the absence of desire (Mahoney & Zarate, 2007). It may be triggered by medications or psychological factors. When assessing someone with the disorder, be certain to ask if the person is taking any herbal remedies such as *Ginkgo biloba* because some of these can have arousal effects.

Pain Disorders

Because the reproductive system has a sensitive nerve supply, when pain occurs in response to sexual activities, it can be acute and severe and impair a person's ability to enjoy this segment of their life.

Vaginismus

Vaginismus is involuntary contraction of the muscles at the outlet of the vagina when coitus is attempted that prohibits penile penetration (Engman, Wijma, & Wijma, 2007). Vaginismus may occur in women who have been raped. Other causes are unknown, but it could also be the result of early learning patterns in which sexual relations were viewed as bad or sinful. As with other sexual problems, sexual or psychological counseling to reduce this response may be necessary.

Dyspareunia and Vestibulitis

Dyspareunia is pain during coitus. This can occur because of endometriosis (abnormal placement of endometrial tissue), vestibulitis (inflammation of the vestibule), vaginal infection, or hormonal changes such as those that occur with menopause and cause vaginal drying. A psychological component may be present. Treatment is aimed at the underlying cause. Encouraging open communication between sexual partners can be instrumental in resolving the problem.

✔ Checkpoint Question 5.5

The Matthews' neighbor Cindy is a woman who has sex with women. When you see Cindy in your clinic, you would want to teach her:

a. Falling estrogen levels are apt to cause her an early menopause.
b. She does not need to practice safer sex as she does not have male partners.
c. Her risk for contracting an STI is less than if she were heterosexual.
d. As she will never be sexually active, she needs no advice in this area.

Key Points for Review

- The reproductive and sexual organs form early in intrauterine life; full functioning occurs at puberty.
- The female internal organs of reproduction include the ovaries, fallopian tubes, uterus, and vagina.
- The female external organs of reproduction include the mons veneris, labia minora and majora, vestibule, clitoris, fourchette, perineal body, hymen, and Skene's and Bartholin's glands.
- The male external reproductive structures are the penis, scrotum, and testes. Internal organs are the epididymis, vas deferens, seminal vesicles, ejaculatory ducts, prostate gland, urethra, and bulbourethral glands.
- A menstrual cycle is periodic uterine bleeding in response to cyclic hormones. Menarche is the first menstrual period. Menopause is the end of menstruation. Menstrual cycles are possible because of the interplay between the hypothalamus, pituitary, ovaries, and uterus.
- Biologic gender is determined by a person's chromosomes (XX or XY) and is set at conception. Gender identity is a person's concept of being male or female. This develops over a lifetime. Gender role is yet a third aspect and is the behavior a person demonstrates based on his or her gender identity as male or female.
- Masters and Johnson identified a sexual response cycle consisting of excitement, plateau, orgasm, and resolution stages. Disorders of sexual dysfunction include failure to achieve orgasm, vaginismus, dyspareunia, inhibited sexual desire, premature ejaculation, and erectile dysfunction.
- People assume varying sexual orientations, such as heterosexual, homosexual (women who have sex with women or men who have sex with men), or bisexual. Common sexual expressions are voyeurism, fetishism, and celibacy.
- Educating people about reproductive function is an important primary health strategy because it teaches people to better monitor their own health through vulvar or testicular self-examination.

- Teach adolescents that with sexual maturity comes sexual responsibility. They need to be aware of safer sex practices as protection against both an STI or an unintentional pregnancy.

CRITICAL THINKING EXERCISES

1. At the beginning of the chapter, you met Suzanne and Kevin Matthews, a young adult couple, 6 months pregnant, who came to your antepartal clinic for a routine visit. Suzanne, in tears, stated, "My husband isn't interested in me anymore. We haven't had sex since I became pregnant." Kevin states, "I'm afraid I'll hurt the baby." How would you counsel them?
2. Kevin's adolescent nephew Mark comes into the clinic because he has an STI. What would you advise Mark regarding safer sex practices?
3. Suzanne tells you that she hopes her new daughter won't be a "tomboy." She asks you the best way to convince a girl to be more of a "lady." What advice would you give her? Suppose she was concerned because a son was not "boyish" enough? Would your answer be any different?
4. Examine the National Health Goals related to reproductive tract or sexual functioning. Most government-sponsored money for nursing research is allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that could advance evidence-based practice in relation to the Matthews family?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX types of questions related to reproductive and sexual health. Confirm your answers are correct by reading the rationales.

Chapter 6

Assisting the Family With Reproductive Life Planning

KEY TERMS

- abstinence
- barrier methods
- basal body temperature
- cervical cap
- coitus
- coitus interruptus
- condom
- contraceptive
- diaphragm
- elective termination of pregnancy
- fertile days
- fertility awareness
- intrauterine device
- laparoscopy
- natural family planning
- reproductive life planning
- spermicide
- transdermal contraception
- tubal ligation
- vaginal ring
- vasectomy

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe common methods of reproductive life planning and the advantages, disadvantages, and risk factors associated with each.
2. Identify National Health Goals related to reproductive life planning that nurses can help the nation achieve.
3. Use critical thinking to analyze ways that family-centered reproductive life planning can be accomplished.
4. Assess clients for reproductive life planning needs.
5. Formulate nursing diagnoses related to reproductive life planning concerns.
6. Identify expected outcomes for couples desiring reproductive life planning.
7. Plan nursing care related to reproductive life planning, such as helping a client select a suitable reproductive planning method.
8. Implement nursing care related to reproductive life planning, such as educating adolescents about the use of condoms as a safer sex practice as well as to prevent unwanted pregnancy.
9. Evaluate expected outcomes for achievement and effectiveness of care.
10. Identify areas related to reproductive life planning that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of reproductive life planning with nursing process to achieve quality maternal and child health nursing care.

Seventeen-year-old Dana Crews has come to your community health clinic for a pelvic examination and Pap smear. She is sexually active and tells you that her boyfriend "sometimes" uses a condom. She trusts he will "stop in time" when they aren't using one. She doesn't want to take the pill because she can't afford it and she's afraid her parents will find out that she's broken her abstinence pledge.

The previous chapter described the anatomy and physiology of the male and female reproductive systems and the importance of practicing safer sex. This chapter adds information about ways to prevent pregnancy or plan and space children. Such information builds a base for both care and health teaching of families.

What additional health teaching does Dana need to be well informed about reproductive life planning?

Reproductive life planning includes all the decisions an individual or couple make about whether and when to have children, how many children to have, and how they are spaced. Health teaching is necessary because some couples want counseling about how to avoid conception. Others need information on increasing fertility and their ability to conceive. Others need counseling because contraception has failed.

It is important for the health of children that as many pregnancies as possible be intended, because when a pregnancy is unintended or mistimed, both short-term and long-term consequences can result such as a woman being less likely to seek prenatal care, being less likely to breastfeed, and possibly being less careful to protect her fetus from harmful substances. A disproportionate share of women who bear children whose conception was unintended are unmarried; such women are less apt to complete high school or college and more likely to require public assistance and to live in poverty than are their peers who are not mothers. The child of such a pregnancy is at greater risk of low birth weight, dying in the first year, being abused, and not receiving sufficient resources for healthy development (Centers for Disease Control and Prevention [CDC], 2009). Planning for reproductive choices is so important that several National Health Goals speak directly to this area of care (Box 6.1).

BOX 6.1 * Focus on National Health Goals

Several National Health Goals speak directly to reproductive life planning:

- Reduce the proportion of females experiencing pregnancy despite use of a reversible contraceptive method from a baseline of 13% to a target of 7%.
- Increase the proportion of pregnancies that are intended from a baseline of 51% to a target of 70%.
- Decrease the proportion of births occurring within 24 months of a previous birth from a baseline of 11% to a target of 6%.
- Increase the proportion of females at risk for unintended pregnancy (and their partners) who use contraception from a baseline of 93% to a target of 100%.
- Increase the number of health care providers who provide emergency contraception (new goal; baseline to be determined).
- Increase male involvement in pregnancy prevention and family planning efforts (new goal; baseline to be determined) (http://www.nih.gov).

Nurses can help the nation achieve these objectives by teaching people, especially adolescents, about contraceptive options. This instruction must be done carefully to avoid indirectly encouraging sexual activity among teens. Investigation into which contraceptives adolescents prefer and why they make the choices they do could be an important area of nursing research.

Nursing Process Overview

For Reproductive Health

Assessment

As a result of changing social values and lifestyles, many women are interested in reproductive life planning and so are able to talk easily about types and methods today. Other people are uncomfortable or not interested in using a planning method so may not voice their interest in the subject independently. For this reason, at health assessments, ask clients if they want more information or need any help with reproductive life planning as part of obtaining a basic health history. Before people are begun on a new contraceptive, other information that needs to be obtained is:

- A Pap smear, pregnancy test, gonococcal and chlamydial screening, perhaps hemoglobin for detection of anemia or a mammogram to rule out breast disease
- Obstetric history, including sexually transmitted infections (STIs), past pregnancies, previous elective abortions, failure of previously used methods, and compliance record
- Subjective assessment of the client's desires, needs, feelings, and understanding of conception (teens, for example, may believe that they are too young to get pregnant; many women in the immediate postpartum period may believe that they cannot conceive immediately, especially if they are breastfeeding)
- Sexual practices, such as frequency, number of partners, feelings about sex and body image, or latex allergy

Nursing Diagnosis

Because reproductive life planning touches so many facets of life, nursing diagnoses can differ greatly depending on the circumstances. Examples might include:

- Health-seeking behaviors regarding contraception options related to desire to prevent pregnancy
- Deficient knowledge related to use of diaphragm
- Spiritual distress related to partner's preferences for contraception
- Decisional conflict regarding choice of birth control because of health concerns
- Decisional conflict related to unwanted pregnancy
- Powerlessness related to failure of chosen contraceptive
- Ineffective sexuality pattern related to fear of pregnancy
- Risk for ineffective health maintenance related to lack of knowledge about natural family planning method

Planning and Implementation

When establishing expected outcomes for care in this area, be certain that they are realistic for the individual. Women's decisions are influenced by many factors; a nurse's role is to educate about contraceptives and support a woman about her contraceptive decision. If a woman has a history of poor compliance with medication, for instance, it might not be realistic for her to plan to take an oral contraceptive every day. Be certain to be sensitive to a couple's religious, cultural, and moral beliefs before suggesting possible methods. It is equally

important to explore your own beliefs and values. This not only helps develop self-awareness of how these beliefs affect nursing care, but it allows you to become more sensitive to the beliefs of others.

Some couples cannot make realistic plans about contraception because they are uninformed or misinformed about the options. When counseling, be certain to emphasize safer sex practices as well as contraceptive ones (see Box 5.4). For example, although many contraceptive options offer reliable pregnancy prevention, only condoms provide protection against STIs, an important concern if the relationship is not a monogamous one.

Many women update their information on reproductive life planning before birth by using the Internet. Most postpartum services distribute printed information or have DVDs or information classes available for women before discharge. Women are then invited to ask questions as necessary about the material presented. Analyze these materials carefully to see that they are accurate before recommending them, and if suggestions are needed, make them to the correct health care facility committee. Be certain that unlicensed assistive personnel understand that if a woman has a question about the written material, their job is not to answer it but to refer the woman to someone (such as a nurse) who is more knowledgeable about the subject. Otherwise, they may suggest what method works for themselves rather than offering unbiased advice. This can result in a woman's choosing a contraceptive method that is not appropriate for her lifestyle and that may then be ineffective for her.

Clients are required to provide informed consent for surgical contraceptive methods or procedures. The risks, benefits, alternatives, and proper use of the method and the client's understanding of his or her rights and responsibilities should be included in the consent form. If you are helping to obtain a signature for consent for a procedure, always do so in the presence of a witness. Informed consent helps ensure that clients have weighed their options, know that the procedure may be irreversible, and have chosen a method that best meets their needs. An organization that is helpful for referral so people can learn more about reproductive life planning is Planned Parenthood (http://www.plannedparenthood.org).

Outcome Evaluation

Evaluation is important in reproductive life planning, because anything that causes clients to discontinue or misuse a particular method will leave them at risk of pregnancy. Reassess early (within 1 to 3 weeks) after a couple begins a new method of contraception, to prevent such an occurrence. Evaluate not only whether a chosen method is effective but whether the woman and her partner are satisfied with the method. Examples of expected outcomes include:

- Client voices correct technique for using chosen method
- Client voices confidence in chosen method by next visit
- Client expresses satisfaction with chosen method at follow-up visit
- Client consistently uses chosen method without pregnancy for 1 year's time

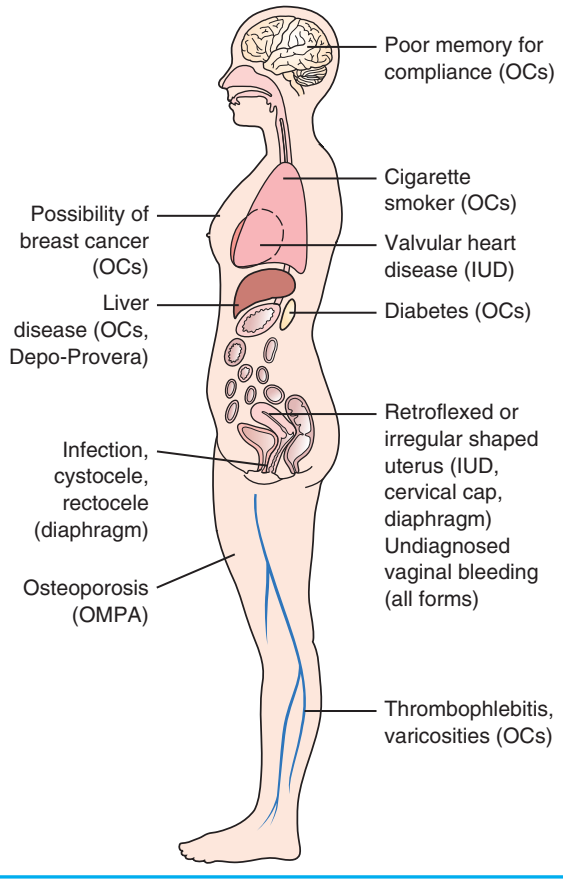
METHODS OF CONTRACEPTION

Until the 1950s, **contraceptive** products (products to prevent pregnancy) were not very reliable or could not be easily purchased. Today, as many as 40 million women in the United States use some form of contraception, a figure that represents 65% of women of childbearing age (CDC, 2009). Women not only use different methods but use different methods throughout their lifetime. Individuals or couples should choose a contraceptive method carefully, considering the advantages, disadvantages, and side effects of the various options (Box 6.2). Important things to consider when doing this are:

- Personal values
- Ability to use a method correctly
- How the method will affect sexual enjoyment
- Financial factors
- Status of a couple's relationship
- Prior experiences
- Future plans

The widespread use of contraceptives today points to both an increased awareness of responsibility for contraception and the wider range of options available. As nurses' roles are to

Box 6.2 Assessment
Assessing a Client for Possible Contraindications to Contraceptive Use



educate couples on what methods are available and how to use methods, understanding how various methods of contraception work and how they compare in terms of benefits and disadvantages is necessary for successful counseling. A major benefit of contraception that has occurred is that there are both fewer adolescent pregnancies today and fewer elective terminations of pregnancy than formerly (CDC, 2009). It is still necessary to be able to answer questions about elective termination of pregnancy with up-to-date knowledge and objectivity for couples whose contraceptive method has failed and are considering this. Legal and ethical issues, such as not allowing the enforced use of contraception for the physically or cognitively challenged, must be considered when counseling clients on the use of contraceptives. With information and the ability to discuss specific concerns, clients can be better prepared to make the decisions that are right for them (Nettleman, Brewer, & Ayoola, 2007).

An ideal contraceptive should be:

- Safe
- One hundred percent effective
- Compatible with religious and cultural beliefs and personal preferences of both the user and sexual partner
- Free of side effects
- Convenient to use and easily obtainable
- Affordable and needing few instructions for effective use
- Free of effects after discontinuation and on future pregnancies

How well contraceptive methods meet these requirements are discussed with each type. The effectiveness of frequently used contraceptive methods is shown in Table 6.1. This table shows the effectiveness of each method for couples by listing the ideal failure rate (the number of unwanted pregnancies that will occur) for couples who use the method consistently and correctly (the ideal rate) and the failure rate for routine use (less-than-perfect use). A method that shows a large difference in these two rates is a method that may not be easy and convenient to use.

Natural Family Planning and Fertility Awareness

The contraceptive approach of **natural family planning** (also called periodic abstinence methods) involves no introduction of chemical or foreign material into the body or sustaining from sexual intercourse during a fertile period. Many people hold religious beliefs that rule out the use of birth control pills or devices; others simply prefer natural methods because no expense or foreign substance is involved; still others believe that a "natural" way of planning pregnancies is simply best for them. The effectiveness of these methods varies greatly from 25% to 85%, depending mainly on the couple's ability to refrain from having sexual relations on **fertile days** or days on which the woman has the most likely chance to become pregnant (Schorge et al., 2008). **Fertility awareness** involves detecting when a woman is fertile so she can use periods of abstinence during that time.

Methods

There are a variety of ways, or methods, to determine a fertile period such as calculating the period based on a set formula, measuring the woman's body temperature, observing the consistency of cervical mucus, using an over-the-counter ovulation test kit, or using a combination of these methods.

Abstinence. **Abstinence,** or refraining from sexual relations, has a theoretical 0% failure rate and is also the most effective way to prevent STIs. However, clients, particularly adolescents, may find it difficult to adhere to abstinence, or they may completely overlook it as an option. Because it fails as an effective birth prevention measure for so many people, use of no contraceptive has a failure rate of 85% (Cunningham et al., 2008). In a moment of passion, many otherwise responsible people are unable to remain abstinent. Only 67% of women still use the method after a year. Many sex education classes advocate abstinence as the only contraceptive measure, so adolescents who take these courses may know little about other options. When discussing abstinence as a contraceptive method, be sure to provide information not only on the method but suggestions of ways to comply with this method (Box 6.3). A worry is that adolescents who make "abstinence pledges" to not have sexual intercourse until they are married may "tune out" not only additional information on contraception but on safer sex practices as well. Then, if they break their pledge (about 50% do), that could leave them more vulnerable to STIs and pregnancy than others (Cherlin, 2008).

Calendar (Rhythm) Method. The calendar method requires a couple to abstain from **coitus** (sexual relations) on the days of a menstrual cycle when the woman is most likely to conceive (3 or 4 days before until 3 or 4 days after ovulation). To plan for this, the woman keeps a diary of six menstrual cycles. To calculate "safe" days, she subtracts 18 from the shortest cycle documented. This number represents her first fertile day. She subtracts 11 from her longest cycle. This represents her last fertile day. If she had six menstrual cycles ranging from 25 to 29 days, her fertile period would be from the 7th day (25 minus 18) to the 18th day (29 minus 11). To avoid pregnancy, she would avoid coitus during those days (Fig. 6.1A).

Basal Body Temperature Method. Just before the day of ovulation, a woman's **basal body temperature (BBT),** or the temperature of her body at rest, falls about 0.5° F. At the time of ovulation, her BBT rises a full degree because of the influence of progesterone. This higher level is then maintained for the rest of her menstrual cycle. This pattern is the basis of the BBT method of contraception.

To use this method, the woman takes her temperature each morning immediately after waking either orally or with an ear thermometer before she undertakes any activity; this is her BBT. As soon as she notices a slight dip in temperature followed by an increase, she knows that she has ovulated. She refrains from having coitus for the next 3 days (the life of the discharged ovum). Because sperm can survive for at least 4 days in the female reproductive tract, it is usually recommended that the couple combine this method with a calendar method, so that they abstain for a few days before ovulation as well. The calendar method has an ideal failure rate of 9%, a typical rate of 25% (MacKay, 2009). For more information on BBT and how its use can aid fertility, see Chapter 8 and Figure 8.2.

A problem with assessing BBT for fertility awareness is that many factors, such as taking an antipyretic, can affect the BBT. For example, a temperature rise caused by illness could be mistaken as the signal of ovulation. If this

TABLE 6.1 ✻ Contraceptive Failure Rates

Type of Contraceptive	Ideal Failure Rate* (%)	Typical Use Failure Rate (%)	% of Women Still Using at 1 Year	Advantages	Disadvantages
Natural Family Planning					
Abstinence	85	85	—	No cost	High motivation needed; highly unreliable
Lactation, amenorrhea	—	—	0	Effective for short term	Temporary measure; not reliable if infant takes supplemental feedings
Calendar	5	25	65	No cost	Requires motivation, cooperation
Ovulation method	3	25	65	No cost	Requires motivation, cooperation
Symptothermal	2	25	65	No cost	Requires motivation, cooperation
Postovulation	1	25	65	Easy to use	Needs funds for monthly kit
Barrier Methods					
Cervical cap (parous woman)	23	35	55	Can use for several days if desired	May be difficult to insert; can irritate cervix
Cervical cap (nulliparous woman)	9	16	57	Can use for several days if desired	May be difficult to insert; can irritate cervix
Sponge (parous woman)	20	35	42	Easy to insert; no prescription	May cause leakage
Sponge (nulliparous woman)	9	18	55	Easy to insert; no prescription	May cause leakage
Diaphragm	6	18	55	Easy to insert	Prescription needed
Female condom	5	15	55	Protection against STIs	Insertion may be difficult
Male condom	2	15	53	Protects against STIs; male responsibility; no prescription necessary	Requires interruption of sexual activity
Hormonal Methods					
Transdermal patch	0.3	5	70	Easy to apply	Irritation at local site
Vaginal ring	0.3	5	65	Easy to insert	May need reminder to insert monthly
IUD (copper T)	0.1	0.1	80	No memory or motivation needed	Cramping, bleeding; expulsion possible; not recommended if risk of STIs
IUD LNG-IUS Mirena	0.1	0.1	80	No memory or motivation needed	Cramping, bleeding; expulsion possible; not recommended if risk of STIs
Combination oral contraceptives (COCs)	0.3	8	70	Coitus independent	Continual cost; possible side effects
Injectable progesterone (Depo-Provera)	0.3	3	55	Coitus independent; dependable for 4 to 12 weeks	Continual cost; continual injections
Intradermal Implants	0.05	0.05	80	Coitus independent; dependable for 5 years	Initial cost; appearance on arm
Surgical Methods					
Female sterilization	0.5	0.5	100	Permanent and highly reliable	Initial cost; irreversible
Male sterilization	0.1	0.15	100	Permanent and highly reliable	Initial cost; irreversible

*Couples who use the method consistently and correctly during 1 year's time.

BOX 6.3 * Focus on Family Teaching

Suggestions for Promoting Abstinence

Q. Suppose Dana, the 17-year-old you met at the beginning of the chapter, asks you how she can avoid being pressured into unwanted sex?

A. Here are a few suggestions:

- Discuss with your partner in advance what sexual activities you will permit and what you will not.
- Try to avoid high-pressure situations such as a party with known drug use, excessive alcohol consumption, or no adult supervision.
- If pressured, say "no," and be sure that your partner understands that you mean it.
- Be certain your partner understands that you consider being forced into relations against your wishes the same as rape, not simply irresponsible conduct.
- Do not accept any drugs to "help you relax" or "be cool," as such a drug could impair your judgment. The drug could also be the "date rape" drug flunitrazepam (Rohypnol), which causes unconsciousness and loss of memory for recent events.

happens, a woman could mistake a fertile day for a safe one. Changes in the woman's daily schedule, such as starting an aerobic program, can also influence the BBT. A woman who works nights should take her temperature after awakening from her longer sleep period, no matter what the time of day.

Cervical Mucus Method. Yet another method to predict ovulation is to use the changes in cervical mucus that occur naturally with ovulation (Fig. 6.1B). Before ovulation each month, the cervical mucus is thick and does not stretch when pulled between the thumb and finger. Just before ovulation, mucus secretion increases. With ovulation (the peak day), cervical mucus becomes copious, thin, watery, and transparent. It feels slippery and stretches at least 1 inch before the strand breaks, a property known as *spinnbarkeit* (see Chapter 5, Fig. 5.15). In addition, breast tenderness and an anterior tilt to the cervix occur. All the days on which cervical mucus is copious, and for at least 1 day afterward, are considered to be fertile days, or days on which the woman should abstain from coitus to avoid conception (Germano & Jennings, 2007).

A woman using this method must be conscientious about assessing her vaginal secretions every day, or she will miss the change in cervical secretions. The feel of vaginal secretions after sexual relations is unreliable, because seminal fluid (the fluid containing sperm from the male) has a watery, postovulatory consistency and can be confused with ovulatory mucus. Figure 6.1B shows a hypothetical month using this method. The typical failure rate is about 25% (Burkman, 2007).

Symptothermal Method. The symptothermal method of birth control combines the cervical mucus and BBT methods. The woman takes her temperature daily, watching for the rise in temperature that marks ovulation. She also analyzes her cervical mucus every day and observes for other signs of ovulation such as *mittelschmertz* (midcycle abdominal pain). The couple must abstain from intercourse until 3 days after the rise in temperature or the fourth day after the

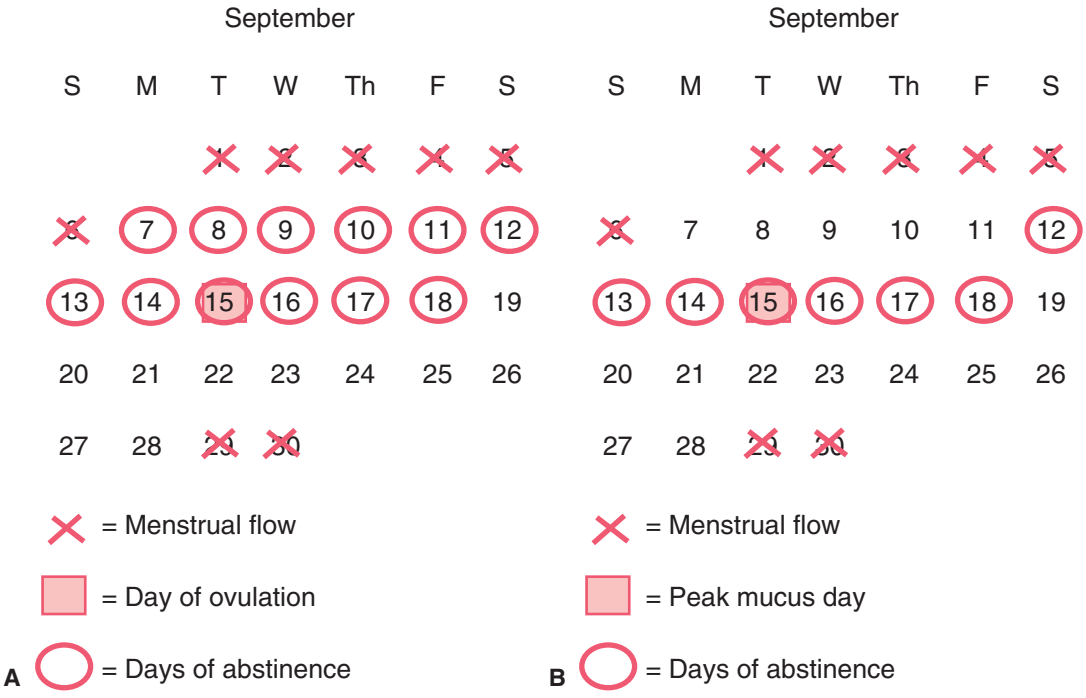

FIGURE 6.1 (**A**) A typical month using the calendar method as a natural family planning method. (**B**) A typical month using the cervical mucus method of natural family planning. Unmarked days are those safe for sexual relations.

peak of mucus change, because these are the woman's fertile days. The symptothermal method is more effective than either the BBT or the cervical mucus method alone (ideal failure rate, about 2%).

Ovulation Detection. Still another method to predict ovulation is by the use of an over-the-counter ovulation detection kit. These kits detect the midcycle surge of luteinizing hormone (LH) that can be detected in urine 12 to 24 hours before ovulation. Such kits are 98% to 100% accurate in predicting ovulation. Although they are fairly expensive, use of such a kit in place of cervical mucus testing makes this form of natural family planning more attractive to many women. Combining it with assessment of cervical mucus is becoming the method of choice for many families using natural family planning (Box 6.4).

Lactation Amenorrhea Method. As long as a woman is breastfeeding an infant, there is some natural suppression of ovulation. Because women may ovulate, however, but not menstruate, a woman may still be fertile even if she has not had a period since childbirth. If the infant is receiving a supplemental feeding or not sucking well, the use of lactation as an effective birth control method is questionable (Van der Wijden, Brown, & Kleijnen, 2009). As a rule, after 3 months of breastfeeding, the woman should be advised to choose another method of contraception (Burkman, 2007).

Coitus Interruptus. **Coitus interruptus** is one of the oldest known methods of contraception. The couple proceeds with coitus until the moment of ejaculation. Then the man withdraws and spermatozoa are emitted outside the vagina. Unfortunately, ejaculation may occur before withdrawal is complete and, despite the care used, some spermatozoa may be deposited in the vagina. Furthermore, because there may be a few spermatozoa present in preejaculation fluid, fertilization may occur even if withdrawal seems controlled. For these reasons, coitus interruptus is only about 75% effective (Stubblefield, Carr-Ellis, & Kapp, 2007).

Postcoital Douching. Douching following intercourse, no matter what solution is used, is ineffective as a contraceptive measure as sperm may be present in cervical mucus as quickly as 90 seconds after ejaculation.

Effect on Sexual Enjoyment

Once a couple is certain of a woman's nonfertile days using one of the natural planning methods, more spontaneity in sexual relations is possible than with methods that involve vaginal insertion products. On the other hand, the required days of abstinence may make a natural planning method unsatisfactory and unenjoyable for a couple. Coitus interruptus may be unenjoyable because of the need to withdraw before ejaculation.

Use by the Adolescent

Natural methods of family planning (with the exception of abstinence) are usually not the contraceptive method of choice for adolescents as they require a great deal of thought and persistence. Adolescent boys may lack the control or experience to use coitus interruptus effectively. Girls tend to have occasional anovulatory menstrual cycles for several years after menarche so they do not always experience definite cervical changes or an elevated body temperature. In addition, these methods require adolescents to say "no" to sexual intercourse on fertile days, a task that may be difficult to complete under peer pressure.

Use by the Perimenopausal Woman

Perimenopausal women are good candidates for natural family planning methods because they may not be able to use hormonal methods such as birth control pills because of histories of high blood pressure, thromboembolic disease, or cigarette smoking. As menopause approaches, however, they may not have as much cervical mucus as previously, making the contrast between fertile and nonfertile days difficult to detect.

Use by the Postpartal Woman

After a successful pregnancy, most women are interested in delaying their next pregnancy until this new baby is older. They are good candidates for natural family planning as they can breastfeed with these methods without worrying about hormonal contaminations of breast milk.

BOX 6.4 ✻ Focus on Evidence-Based Practice

Does electronic fertility monitoring improve cervical mucus observations?

To answer this question, nurse researchers taught 195 women (mean age, 29.8 years) at five clinical sites in four cities to track their fertility by both self-observation of cervical mucus and an electronic monitor that measured urinary levels of estrone-3-glucuronide and luteinizing hormone. There were a total of 26 unintended pregnancies, 3 with correct use. After 1795 months of use, the pregnancy rate was 2.1% per 12 months of use (i.e., 97.9% effective in avoiding pregnancy) when rules of the method were always followed. The pregnancy rate was 14.2% per 12 months of use (i.e., 85.8% effective in avoiding pregnancy) when rules of the method were not always followed.

These are important findings because the combination of the two systems elevated the effectiveness of natural family planning to a level almost equal to hormonal methods of contraception. The study also documents how much instruction and perhaps follow-up is needed for women to use contraception methods consistently and accurately.

How could you use the findings of this study when discussing national family planning with women?

Source: Fehring, R. J., Schneider, M., Raviele, K., et al. (2007). Efficacy of cervical mucus observations plus electronic hormonal fertility monitoring as a method of natural family planning. *JOGNN: Journal of Obstetric, Gynecologic, and Neonatal Nursing, 36*(2), 152–160.

✔ Checkpoint Question 6.1

Suppose Dana, 17 years old, tells you that she wants to use a fertility awareness method of contraception. How will she determine her fertile days?

a. She will notice that she feels hot, as if she has an elevated temperature.
b. She should assess whether her cervical mucus is thin and watery.
c. She should monitor her emotions for sudden anger or crying.
d. She should assess whether her breasts feel sensitive to cool air.

Hormonal Contraception

Hormonal contraceptives are, as the name implies, hormones that cause such fluctuations in a normal menstrual cycle that ovulation does not occur. Hormonal contraceptives may be administered orally, transdermally, vaginally, by implantation, or through injection.

Oral Route

Oral contraceptives, commonly known as the pill, OCs (for oral contraceptive), or COCs (for combination oral contraceptives), are composed of varying amounts of synthetic estrogen combined with a small amount of synthetic progesterone (progestin). The estrogen acts to suppress follicle-stimulating hormone (FSH) and LH, thereby suppressing ovulation. The progesterone action complements that of estrogen by causing a decrease in the permeability of cervical mucus, thereby limiting sperm motility and access to ova. Progesterone also interferes with tubal transport and endometrial proliferation to such degrees that the possibility of implantation is significantly decreased.

Popular COCs prescribed in the United States are monophasic or provide fixed doses of both estrogen and progestin throughout a 21-day cycle. Biphasic preparations deliver a constant amount of estrogen throughout the cycle but an increased amount of progestin during the last 11 days. Triphasic preparations vary in both estrogen and progestin content throughout the cycle. Triphasic types more closely mimic a natural cycle, thereby reducing breakthrough bleeding (bleeding outside the normal menstrual flow). Caution women to always take pills in the order designated by the dispenser or the progesterone level could be inaccurate and ineffective for that day.

COCs must be prescribed by a physician, nurse practitioner, or nurse-midwife after a pelvic examination and a Papanicolaou (Pap) smear (Fig. 6.2). When used correctly, they are 99.7% effective in preventing conception. Women who forget to take them as scheduled, however, experience a failure rate of 95% (Schorge et al., 2008).

Oral contraceptives have noncontraceptive benefits such as decreased incidences of:

- Dysmenorrhea, because of lack of ovulation
- Premenstrual dysphoric syndrome and acne, because of the increased progesterone levels
- Iron deficiency anemia, because of the reduced amount of menstrual flow
- Acute pelvic inflammatory disease (PID) and the resulting tubal scarring

FIGURE 6.2 Counseling women on how to follow an oral contraceptive schedule and what to do if they miss a day or more is an important nursing responsibility. (© Caroline Brown, RNC, MS, DEd.)

- Endometrial and ovarian cancer, ovarian cysts, and ectopic pregnancies
- Fibrocystic breast disease
- Possibly osteoporosis, endometriosis, uterine myomata (fibroid uterine tumors), and progression of rheumatoid arthritis
- Colon cancer (Stubblefield, Carr-Ellis, & Kapp, 2007)

Because estrogen interferes with lipid metabolism, it may lower the concentration of low-density lipoproteins (LDL) and increase the high-density lipoprotein (HDL) level.

COCs are packaged with 21 or 28 pills in a convenient dispenser. It is generally recommended that the first pill be taken on a Sunday (the first Sunday after the beginning of a menstrual flow), although a woman may choose to begin on any day. Beginning pills as soon as they are prescribed this way (a Quick Start system) rather than have to wait for a set day may increase compliance (Noone, 2007). After childbirth, a woman should start the contraceptive on the Sunday closest to 2 weeks after birth; after an elective termination of pregnancy, she should start on the first Sunday after the procedure. Because COCs are not effective for the first 7 days, advise women to use a second form of contraception during the initial 7 days on which they take pills. A woman prescribed a 21-day cycle brand takes a pill at the same time every day for 21 days. Pill taking by this regimen will end on a Saturday. The woman would then not take any pills for 1 week. She would restart a new month's supply of pills on the Sunday 1 week after she stopped. A menstrual flow will begin about 4 days after the woman finishes a cycle of pills.

To eliminate having to count days between pill cycles, most brands of OCs are packaged with 28 pills—21 active pills and 7 placebo pills. With these brands, a woman starts a second dispenser of pills the day after finishing the first dispenser. There is no need to skip days because of the placebo tablets. Menstrual flow will begin during the 7 days on which she is taking the placebo tablets.

Not routinely, but to accommodate special circumstances, if a woman does not want to have menstrual flows, she can eliminate them by beginning a new 21-day cycle of pills immediately after finishing a first one rather than waiting the usual 7 days to begin a new cycle (with the 28-day cycle

BOX 6.5 ✻ Focus on Family Teaching

Suggestions on Oral Contraceptive Management

Q. Suppose that Dana, the 17-year-old you met at the beginning of the chapter, asks what to do if she forgets to take an oral contraceptive pill.

A. The answer differs, depending on your situation:

1. If the pill omitted was one of the placebo ones, ignore it and just take the next pill on time the next day.
2. If you forget to take one of the active pills, take it as soon as you remember. Continue the following day with your usual schedule. Doing so might mean taking two pills on one day, if you don't remember until the second day. *Missing one pill this way should not initiate ovulation.*
3. If you miss two consecutive active pills, take two pills as soon as you remember and two pills again the following day. Then continue the following day with your usual schedule. You may experience some breakthrough bleeding (vaginal spotting) with two forgotten pills. Do not mistake this bleeding for your menstrual flow. *Missing two pills may allow ovulation to occur, so an added contraceptive should be used for the remainder of the month.*
4. If you miss three or more pills in a row, throw out the rest of the pack and start a new pack of pills. *You might not have a period because of this routine and should use extra protection until 7 days after starting a new pack of pills.*
5. If you think that you might be pregnant, stop taking pills and notify your health care provider.

regimens, she can omit taking the placebo pills and immediately begin a new dispenser).

A new generation of pills are designed to be taken for 91 days (an extended-use regimen) or using these, a woman will only have a menstrual flow every 3 months or 4 times a year. *Lybrel* is a new U.S. Food and Drug Administration (FDA)-approved low-dose combination estrogen and progestin pill that is taken 365 days a year without a placebo or pill-free interval so menstrual periods are completely eliminated. Such pills are especially attractive to physically active women or those who work long schedules such as military deployment (Trego, 2007).

For ovulation suppressants to be effective, women must take them consistently and conscientiously. Some women leave them in plain sight on the bathroom or kitchen counter so that they are easily reminded to take them. Caution women with young children in the house that this is a potentially dangerous practice. Poisoning with increased blood clotting from the high estrogen content could result if a small child ingested the pills accidentally. Women who have difficulty remembering to take a contraceptive in the morning may find it easier to take a daily pill at bedtime or with a meal (the time of day makes no difference; it is the consistency that is important) (Box 6.5). Also, some women find that taking pills at bedtime rather than in the morning eliminates any nausea they otherwise experience.

Side Effects and Contraindications. Box 6.6 lists risk factors and contraindications associated with COCs. The main side effects that women may experience are:

- Nausea
- Weight gain
- Headache
- Breast tenderness
- Breakthrough bleeding (spotting outside the menstrual period)
- Monilial vaginal infections
- Mild hypertension
- Depression

Side effects such as nausea and breakthrough bleeding usually subside after a few months of use. They may be lessened by using a different routine or brand of contraceptive.

It is no longer believed that the use of COCs leads to an increased risk of myocardial infarction, and the risk of increased clotting or blood pressure elevation is low. Nevertheless, COCs are not routinely prescribed for women with a history of thromboembolic disease or a family history of cerebral or cardiovascular accident, who are over 40 years of age, or who smoke because of the increased tendency toward clotting as an effect of increased estrogen (Karch, 2009).

BOX 6.6 ✻ Contraindications to Oral Contraceptive Use

- Breastfeeding and less than 6 weeks' postpartum
- Age 35 years or older and smoking 15 or more cigarettes per day
- Multiple risk factors for arterial cardiovascular disease, such as older age, smoking, diabetes, hypertension
- Elevated blood pressure of 160 mm Hg systolic or above or 100 mm Hg diastolic or above
- Current or history of deep vein thrombosis or pulmonary embolism
- Major surgery that requires prolonged immobilization
- Current or history of ischemic heart disease
- Stroke
- Complicated valvular heart disease
- Migraine with focal neurologic symptoms (migraine with aura)
- Migraine without focal neurologic symptoms and age 35 years or older
- Current breast cancer
- Diabetes with nephropathy, retinopathy, neuropathy, vascular disease, or diabetes of more than 20 years' duration
- Severe cirrhosis
- Liver tumors

Stubblefield, P. G., Carr-Ellis, S., & Kapp, N. (2007). Family planning. In Berek, J. S. (Ed.) *Berek & Novak's gynecology.* Philadelphia: Lippincott Williams & Wilkins.

Advise all women taking COCs to notify their health care provider if symptoms of myocardial or thromboembolic complications occur. These are:

- Chest pain (pulmonary embolus or myocardial infarction)
- Shortness of breath (pulmonary embolus)
- Severe headache (cerebrovascular accident)
- Severe leg pain (thrombophlebitis)
- Eye problems such as blurred vision (hypertension, cerebrovascular accident)

Early studies of birth control pills found that breastfed infants had lower weight gains when the mother was taking an OC because the estrogen content decreased the woman's milk supply. Although there is less estrogen in today's preparations, it is still not recommended that breastfeeding women take estrogen-based COCs until their milk supply is well established. Women may take progesterone-only pills (mini-pills) during breastfeeding (see later discussion).

COCs can interfere with glucose metabolism. For this reason, women with diabetes mellitus or a history of liver disease, including hepatitis, are evaluated individually before COCs are prescribed. COCs apparently do not increase the risk of breast cancer as was once feared (Stubblefield, Carr-Ellis, & Kapp, 2007).

Typically, COCs increase or strengthen the action of caffeine and corticosteroids. COCs may interact with several drugs such as acetaminophen, anticoagulants, and some anticonvulsants, reducing their therapeutic effect so women may be advised to temporarily change their method of birth control while prescribed these drugs. Several drugs, such as barbiturates, griseofulvin, isoniazid, penicillin, and tetracycline, decrease the effectiveness of COCs, so women might want to change their contraceptive method temporarily while taking these drugs as well (Karch, 2009).

When discussing COCs, be certain to assess both a woman's ability to pay for them and her ability to follow instructions faithfully (Box 6.7). Women using COCs should return for a follow-up visit yearly (for a pelvic examination, Pap smear, and breast examination), as long as they continue to use this form of birth control. Women without risk factors may continue to take low-dose OCs until they reach menopause.

Mini-pills. Oral contraceptives containing only progestins are popularly called mini-pills. The progesterone content thickens cervical mucus and helps prevent sperm entry into the uterine cervix. Ovulation may occur but, because the endometrium does not develop fully, implantation will not take place. Such a pill has advantages for the woman who cannot take an estrogen-based pill because of the danger of thrombophlebitis but who wants high-level contraception assurance (they are as effective as estrogen/progestin pills). They have the disadvantage of causing more breakthrough bleeding than combination pills. They are taken every day, even through the menstrual flow. Because it does not interfere with milk production, they may be taken during breastfeeding.

Effect on Sexual Enjoyment. For the most part, not having to worry about pregnancy because the contraceptive being used is so reliable makes sexual relations more enjoyable for couples. Some women appear to lose interest in coitus after taking the pill for about 18 months, possibly because of the long-term effect of altered hormones in their body. Sexual interest increases again after they change to another form of contraception. Some women experience nausea with the pill and find that this interferes with sexual enjoyment as well as with other activities. If they are having side effects with one brand, they might be able to take another brand that has a different strength of estrogen without problems.

Effect on Pregnancy. If a woman taking an estrogen/progestin combination COC suspects that she is pregnant, she should discontinue taking any more pills if she intends to continue the pregnancy. High levels of estrogen or progesterone might be teratogenic to a growing fetus, although the actual risk is thought to be no higher than normally occurs (Burkman, 2007).

Use by the Adolescent. It is usually recommended that adolescent girls have well-established menstrual cycles for at least 2 years before beginning COCs. This reduces the chance that the estrogen content will cause permanent suppression of pituitary-regulating activity. Estrogen has the side effect of causing the epiphyses of long bones to close and growth to halt; therefore, waiting at least 2 years also

BOX 6.7 ✻Focus on Communication

You notice that Dana, 17 years old, is reading a pamphlet on oral contraceptives while she waits to be seen by the nurse practitioner.

Less Effective Communication

Nurse: Is that pamphlet helpful? Tell you everything you need to know?

Dana: Not really. I need some way to remind me to take a pill every day.

Nurse: If you're old enough to be sexually active, you should be responsible enough to do that without a separate reminder.

More Effective Communication

Nurse: Is that pamphlet helpful? Tell you everything you need to know?

Dana: Not really. I need some way to remind me to take a pill every day.

Nurse: Will that be a problem?

Dana: I think so.

Nurse: It's good to see you considering your individual lifestyle before making a choice. Some women use a pill dispenser so they have a daily reminder. Or if you'd like, I could help you make out a reminder chart. There are some methods of birth control that don't require reminders at all or more often than once a month. Why don't I discuss all the different types with you?

Reproductive life planning measures must be individualized to fit a person's lifestyle; otherwise, they will be quickly discontinued. Taking the time to help a woman assess how particular measures fit her lifestyle is better than just giving advice with a "one size fits all" philosophy.

ensures that the preadolescent growth spurt will not be halted. Because adolescents' compliance with most medications is low, adolescent girls may not take pills reliably enough to make them effective. In addition, the cost of a continuing supply of pills may be prohibitive for teens. COCs have side benefits of improving facial acne in some girls because of the increased estrogen/androgen ratio created and of decreasing dysmenorrhea. These effects are appealing to adolescents so increase the COC compliance rate. The pill may be prescribed to some adolescents specifically to decrease dysmenorrhea, especially if endometriosis is present (see Chapter 47).

Use by the Perimenopausal Woman. As women near menopause, they are likely over age 35 so are less likely to be candidates for COCs than when they were younger. Help women in this age group to find an alternative method that will meet their personal preferences as well as still be maximally effective for them.

Use by the Postpartal Woman. It is not recommended that women who are lactating take estrogen-based contraceptives as a small amount of the hormone will be excreted in breast milk. Women are, therefore, usually prescribed "mini-pills" or OCs that contain only progestin until they are no longer breastfeeding.

Discontinuing Use. After women stop taking COCs, they may not be able to become pregnant for 1 or 2 months, and possibly 6 to 8 months, because the pituitary gland requires a recovery period to begin cyclic gonadotropin stimulation again. If ovulation does not return spontaneously after this time, it can be stimulated by clomiphene citrate (Clomid) therapy to restore fertility.

Emergency Postcoital Contraception. Several regimens, often referred to as "morning-after pills," are available for emergency postcoital contraception (Godding, 2008). The high level of estrogen they contain apparently interferes with the production of progesterone, thereby prohibiting good implantation. The Yuzpe regimen consists of the administration of two fixed-dose combination pills (usually Ovral), taken within 72 hours after unprotected intercourse. This is followed by two additional pills 12 hours later. This high dose of estrogen (200 mcg) almost always causes nausea and vomiting. Pretreatment with an antiemetic, such as 50 mg meclizine (Bonine), is usually recommended to decrease the possibility of vomiting. If vomiting should occur within 2 hours after administration, the pills should be repeated.

A specially designed emergency contraceptive kit (Preven) is a second method available for use after unprotected intercourse, particularly after a sexual assault has occurred. The kit consists of a urine pregnancy test to determine whether pregnancy has occurred and four pills that contain concentrations of estrogen/progestin (the first two taken within 72 hours after intercourse and the next two taken 12 hours later).

A progestin-only method termed "Plan B" is available over the counter or can be purchased from a licensed pharmacist without a prescription by anyone (male or female) over the age of 18 (Shacter, Gee, & Long, 2007). A prescription is required for anyone under age 18. With this plan, two pills containing high doses of levonorgestrel are taken (one pill immediately and one 12 hours later). This plan results in less nausea and may actually prevent more pregnancies than the estrogen-based regimen. Internet drug companies have become a resource for emergency contraception as they provide both privacy protection and competitive prices (Wu et al., 2007).

Overall, the rate of effectiveness for emergency postcoital methods of contraception is between 75% and 85%. These methods should always be used cautiously because of the potential danger that estrogen may be associated with congenital anomalies in the fetus if the pregnancy is not prevented. Mifepristone, discussed later as an abortifacient, or insertion of an intrauterine device (the copper T380) may also be prescribed for emergency postcoital contraception. An ethical question being asked is whether the availability of emergency contraception will encourage risky sexual behavior. This does not seem to be occurring (Wu et al., 2007). Fear of side effects is a major reason limiting the number of these products being used (Rocca, 2007).

Transdermal Route

Transdermal contraception refers to patches that slowly but continuously release a combination of estrogen and progesterone (Fig. 6.3). Patches are applied each week for 3 weeks. No patch is applied the fourth week. During the week on which the woman is patch free, a menstrual flow will occur. After the patch-free week, a new cycle of 3 weeks on/1 week off begins again. The efficiency of transdermal patches is equal to that of COCs, although they may be less effective in women who weigh more than 90 kg (198 lb). Because they contain estrogen, they have the same risk for thromboembolitic symptoms as COCs (Cole et al., 2007).

Patches may be applied to one of following four areas: upper outer arm, upper torso (front or back, excluding the breasts), abdomen, or buttocks. They should not be placed on any area where makeup, lotions, or creams will be applied; at the waist where bending might loosen the patch; or anywhere the skin is red or irritated or has an open lesion.

FIGURE 6.3 Estrogen/progesterone-based patches help adherence because they need attention only once a week. They may be applied on arms, the trunk, or buttocks.

Patches can be worn in the shower, while bathing, or while swimming. If a patch comes loose, the woman should remove it and immediately replace it with a new patch. No additional contraception is needed if the woman is sure the patch has been loose for less than 24 hours. If the woman is not sure how long the patch has been loose, she should remove it and apply a new patch, but this will start a new 4-week cycle, with a new day 1 and a new day to change the patch. She also should use a backup contraception method, such as a condom or **spermicide,** a product that is inserted vaginally and kills sperm, for the first week of this new cycle.

Transdermal patches have the potential to increase adherence, because the woman does not need to remember to take a daily pill. Mild breast discomfort and irritation at the application site may occur.

Vaginal Insertion

A **vaginal ring** (NuvaRing) is a silicone ring that surrounds the cervix and continually releases a combination of estrogen and progesterone (Fig. 6.4). The ring was FDA approved in 2001. It is inserted vaginally by the woman and left in place for 3 weeks, then removed for 1 week (Roumen, 2007). Menstrual bleeding occurs during the ring-free week. The hormones released are absorbed directly by the mucous membrane of the vagina, thereby avoiding a "first pass" through the liver, as happens with COCs; this is an advantage for women with liver disease. The effectiveness is equal to that of COCs. Fertility returns immediately after discontinuing using the ring. Women may need to make out a calendar that they post conspicuously to remind themselves to remove and replace the ring. Women may need to be encouraged to use vaginal rings as introducing a ring vaginally may at first seem more complicated than taking a pill every day (Gilliam, Holmquist, & Berlin, 2007). Some women experience vaginal discomfort, which makes a ring not a desirable contraceptive for them. While rings do not need to be removed for intercourse, if a woman senses that a vaginal ring is in place, this could interfere with sexual enjoyment.

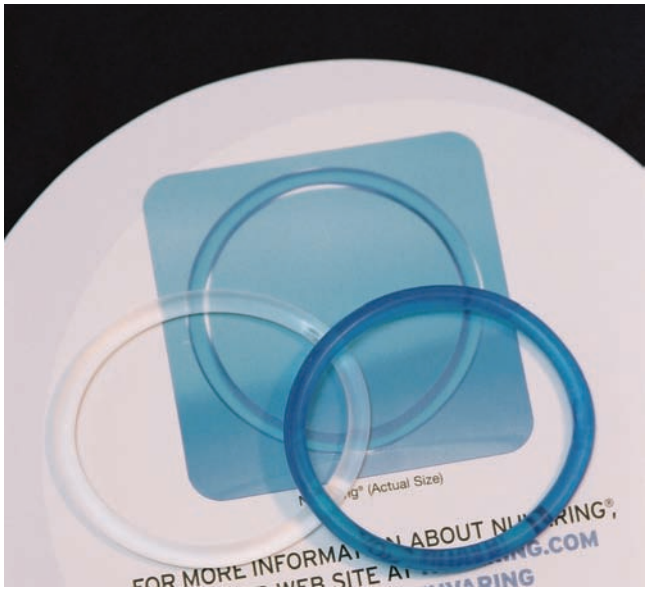

FIGURE 6.4 A vaginal ring. Both estrogen and progesterone are gradually released to be absorbed by the vaginal walls.

✔ Checkpoint Question 6.2

Suppose Dana, 17 years old, chooses to use a combination oral contraceptive (COC) as her family planning method? What is a danger sign of COCs you would ask her to report?

a. A stuffy or runny nose
b. Arthritis-like symptoms
c. Weight gain over 5 lb
d. Severe migraine headache

Implantation

Five subdermal implants, rods the size of pencil lead are embedded just under the skin on the inside of the upper arm, once used extensively by U.S. women are no longer available. One- or two-rod versions (Jadelle, Implanon) have been approved by the FDA and will soon be available and probably back in favor (Stubblefield, Carr-Ellis, & Kapp, 2007). The rods contain etonogestrel, the metabolite of desogestrel, the same progestin that is used in the NuvaRing. Once embedded, the implants appear as irregular lines on the skin, simulating small veins. Over the next 3 to 5 years, the implants slowly release the hormone, suppressing ovulation, stimulating thick cervical mucus, and changing the endometrium so that implantation is difficult.

The implants are inserted with the use of a local anesthetic, during the menses or no later than day 7 of the menstrual cycle, to be certain that the woman is not pregnant at the time of insertion. They can be inserted immediately after an elective termination of pregnancy or 6 weeks after the birth of a baby. The failure rate is less than 1% (Cunningham et al., 2008). At the end of 3 to 5 years, the implants are removed under local anesthesia (a quick minutes-only procedure).

A disadvantage of the implant method is its cost ($500 on average) and side effects such as:

- Weight gain
- Irregular menstrual cycle such as spotting, breakthrough bleeding, amenorrhea, or prolonged periods
- Depression
- Scarring at the insertion site
- Need for removal

A major advantage of this long-term reversible contraceptive is that compliance issues associated with COCs are eliminated. It also offers an effective and reliable alternative to the estrogen-related side effects of COCs. Sexual enjoyment is not inhibited, as may happen with condoms, spermicides, diaphragms, and natural family planning methods. Implants can be used during breastfeeding without an effect on milk production. Also, implants can be used safely in adolescents. The rapid return to fertility (about 3 months after removal) is an advantage for women who wish to have children.

Contraindications to subdermal rods are pregnancy, desire to be pregnant within 1 to 2 years, and undiagnosed uterine bleeding. A complication (rare) that can occur is an infection at the insertion site. If pregnancy does occur with the rods in place, they can be removed to reduce the small possibility of birth defects in a fetus.

Injection

A single intramuscular injection of medroxyprogesterone acetate (Depo-Provera [DMPA]), a progesterone, given every

12 weeks inhibits ovulation, alters the endometrium, and changes the cervical mucus (Box 6.8). The effectiveness rate of this method is almost 100%, making it an increasingly popular contraceptive method (Chrousos, 2008). Do not massage the injection site after administration as you want the drug to absorb slowly from the muscle. Because Depo-Provera contains only progesterone, it can be used during breastfeeding. Advantageous effects are reduction in ectopic pregnancy, endometrial cancer, endometriosis, and, for unknown reasons, reduction in the frequency of sickle cell crises (Burkman, 2007). Potential side effects are similar to those of subdermal implants: irregular menstrual cycle, headache, weight gain, and depression. Depo-Provera may impair glucose tolerance in women at risk for diabetes. Because there also may be an increase in the risk for osteoporosis from loss of bone mineral density, advise women to include an adequate amount of calcium in their diet (up to 1200 mg/day) and to engage in weight-bearing exercise daily to minimize this risk, rules that are good for all women. Depo-Provera is not routinely prescribed to adolescents, to protect their bone mineral density (Glasier, Yan, & Wellings, 2007).

Like subdermal implants, intramuscular injections have the advantage of longer-term reliability without many of the side effects and contraindications associated with COCs. An advantage of intramuscular injections over implants is that there is no visible sign that a birth control measure is being used; this makes them attractive to adolescents (Rickert et al., 2007). Two disadvantages are that a woman must return to a health care provider for a new injection every 4 to 12 weeks for the method to remain reliable, and the return to fertility is often delayed by 6 to 12 months. A reminder system, such as a postcard mailed by the prescribing agency, may be necessary to be certain that women return on time for their next injection. Alternative methods of administration, such as allowing pharmacists to give the injections or selling them over the counter so that women can inject themselves, are being studied.

BOX 6.8 * Focus on Pharmacology

Medroxyprogesterone Acetate (Depo-Provera)

Classification: Contraceptive
Action: Medroxyprogesterone acetate (Depo-Provera or DMPA) is a progesterone derivative that inhibits the secretion of pituitary gonadotropins, thereby altering the endometrium and preventing follicular maturation and ovulation (Karch, 2009).
Pregnancy Category: X
Dosage: 150 mg intramuscular injection every 3 months
Possible Adverse Effects: Spotting, breakthrough bleeding, amenorrhea, irregular menstrual flow, headaches, weight fluctuations, fluid retention, edema, rash or acne, abdominal discomfort, glucose intolerance, pain at injection site or osteoporosis (loss of bone density).

Nursing Implications

- Advise client to have an annual physical examination that includes breast examination, pelvic examination, and Pap smear.
- Caution the client that potential side effects may occur.
- Advise client to maintain a high calcium intake to reduce development of osteoporosis.
- Advise the client to report pain or swelling of the legs, acute chest pain or shortness of breath, tingling or numbness in the extremities, loss of vision, sudden severe headaches, dizziness, or fainting; these are signs of potentially serious cardiovascular complications.

✔ Checkpoint Question 6.3

Suppose Dana, 17 years old, chooses intramuscular injections as her method of reproductive life planning. What advice would you give her in regard to this method?

a. Limit cigarette smoking to one pack per day.
b. Drink at least three glasses of milk each day.
c. Do not swim for long periods at a time.
d. Do not expose the injection site to direct sunlight.

Intrauterine Devices

An **intrauterine device (IUD)** is a small plastic object that is inserted into the uterus through the vagina (Postlethwaite et al., 2007). IUDs became popular as a method of birth control in the 1980s, and although still a popular choice worldwide, IUDs are used by only a small number of U.S. women. Few manufacturers continue to provide them since several lawsuits were filed in association with the increased incidence of pelvic inflammatory disease (PID) in women using one particular brand, now no longer available.

Although the insertion of foreign objects into the uterus for contraceptive purposes dates back thousands of years (ancient camel drivers used the technique on their animals), the mechanism of action for the method is still not fully understood. Originally, it was thought that the presence of a foreign substance in the uterus interfered with the ability of an ovum to develop as it traversed the fallopian tube. Today, the IUD is thought to prevent fertilization as well as creating a local sterile inflammatory condition that prevents implantation. When copper is added to the device, sperm mobility appears to be affected as well. This decreases the possibility that sperm will successfully cross the uterine space and reach the ovum.

An IUD must be fitted by a physician, nurse practitioner, or nurse-midwife, who first performs a Pap test and pelvic examination. The device is inserted before a woman has had coitus after a menstrual flow, so the health care provider can be assured that the woman is not pregnant at the time of insertion.

The insertion procedure is performed in an ambulatory setting such as a physician's office or a reproductive planning clinic. The device is inserted in a collapsed position, then enlarged to its final shape in the uterus when the inserter is withdrawn. The woman may feel a sharp cramp as the device is passed through the internal cervical os, but she will not feel the IUD after it is in place. Properly fitted, such devices are contained wholly within the uterus, although the attached string protrudes through the cervix into the vagina (Burkman, 2007).

Two common types of IUDs used in the United States are the Copper T380 (ParaGard), a T-shaped plastic device

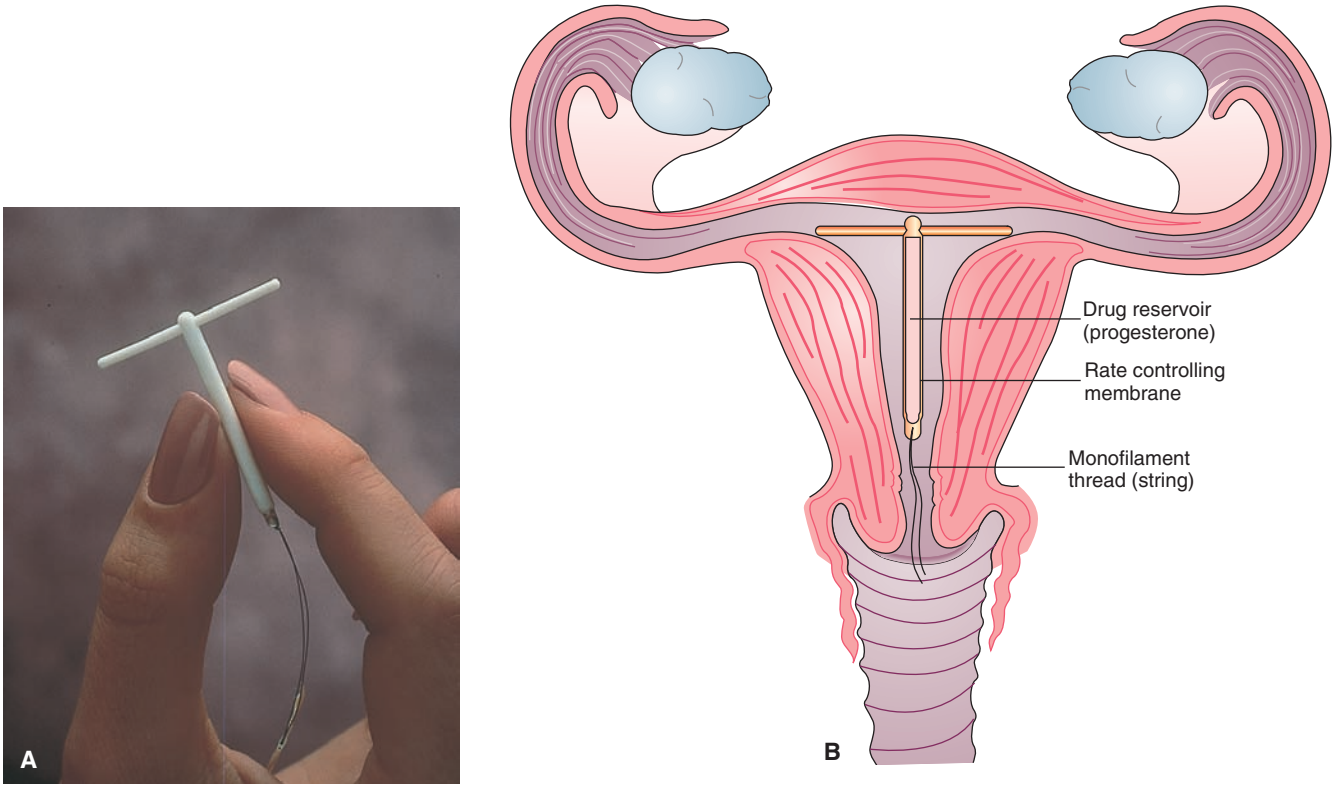

FIGURE 6.5 (**A**) Intrauterine device. (**B**) An IUD in place in the uterus. (Courtesy of ALZA Pharmaceuticals, Palo Alto, CA.)

wound with copper, and LNG-IUS (Mirena), which holds a drug reservoir of progesterone in the stem (Fig. 6.5). The progesterone in the drug reservoir gradually diffuses into the uterus through the plastic; it both prevents endometrium proliferation and thickens cervical mucus. The Mirena type is effective for 5 years (possibly as long as 7 years). It has a failure rate as low as 0.1% to 1.5%. The Copper T380, because of the added copper, has a comparable failure rate (Cunningham et al., 2008). It is effective for 10 years, after which it should be removed and replaced with a new IUD.

IUDs have several advantages over other contraceptives. Only one insertion is necessary, so there is no continuing expense. The device does not require daily attention or interfere with sexual enjoyment. It is appropriate for women who are at risk for complications associated with COCs or who wish to avoid some of the systemic hormonal side effects. They may create lighter or fewer periods. Teach women to regularly check after each menstrual flow, to make sure the IUD string is in place, and to obtain a yearly pelvic examination.

Side Effects and Contraindications

A woman may notice some spotting or uterine cramping the first 2 or 3 weeks after IUD insertion; as long as this is present, she should use an additional form of contraception, such as vaginal foam. Theoretically, a woman with an IUD in place has a higher-than-usual risk for pelvic inflammatory disease (PID), although this does not bear out in practice (Campbell, Cropsey, & Matthews, 2007). This may be because copper wound around the device may help resist infection. Some women have a heavier than usual menstrual flow for 2 or 3 months and experience more dysmenorrhea than other women. Ibuprofen, a prostaglandin inhibitor, is helpful in relieving the pain. Occasionally, a woman continues to have cramping and spotting after insertion; in such instances, she is likely to expel the device spontaneously. Women with IUDs in place should take active steps to avoid toxic shock syndrome (TSS; a staphylococcal infection from the use of tampons), because infection might travel by the IUD string into the uterus to cause uterine infection. TSS is discussed in Chapter 47.

IUDs are not recommended for women with an increased risk of contracting STIs, such as those who have multiple sexual partners, because this combination could lead to pelvic infection (Stubblefield, Carr-Ellis, & Kapp, 2007). They also are not recommended for women who have never been pregnant (their small uterus could be punctured with insertion) or who have a history of having had PID. If PID is suspected, the device should be removed and the woman should receive antibiotic therapy to treat the infection. All women need to know the most common symptoms of PID (fever, lower abdominal tenderness, and pain on intercourse) so they can report these to their health care provider immediately if they occur (see Chapter 47).

IUDs are also contraindicated in the woman whose uterus is distorted in shape (the device might perforate an abnormally shaped uterus). They are not advised for women with severe dysmenorrhea (painful menstruation), menorrhagia (bleeding between menstrual periods), or a history of ectopic (tubal) pregnancy, because their use may increase the symptoms or incidence of these conditions. Women with valvular heart disease may be advised against the use of an IUD because the increased risk of PID could lead to accompanying valve involvement from bacterial endocarditis. Because IUDs

can cause a heavier than usual menstrual flow, women with anemia are also not usually considered to be good candidates for IUD use.

Effect on Pregnancy

If a woman with an IUD in place suspects that she is pregnant, she should alert her primary health care provider. Although the IUD may be left in place during the pregnancy, it is usually removed vaginally to prevent the possibility of infection or spontaneous miscarriage during the pregnancy. The woman should receive an early ultrasound to document placement of the IUD. This can also rule out ectopic pregnancy, which has an increased incidence among IUD users who become pregnant with the IUD in place.

Use by the Adolescent

IUDs are rarely prescribed for adolescents, because teens tend to have variable sexual partners and no prior pregnancies, both contraindications to IUD use.

Use by the Perimenopausal Woman

Women who are premenopausal are, overall, good candidates for IUDs unless they have a history of any of the specific contraindications to their use such as multiple sexual partners or a history of pelvic inflammatory disease.

Use by the Postpartal Woman

Although postpartum insertion is usually done at a 6-week postpartal checkup, it can be done immediately after childbirth. An IUD inserted soon after childbirth does not affect uterine involution or its return to a prepregnancy uterine size (Grimes et al., 2009).

Barrier Methods

Barrier methods are forms of birth control that work by the placement of a chemical or other barrier between the cervix and advancing sperm so that sperm cannot enter the uterus or fallopian tubes and fertilize the ovum. A major advantage of barrier methods is that they lack the hormonal side effects associated with COCs. However, compared with COCs, their failure rates are higher and sexual enjoyment may be lessened.

Chemical Barriers

A spermicide is an agent that causes the death of spermatozoa before they can enter the cervix. Such agents are not only actively spermicidal but also change the vaginal pH to a strong acid level, a condition not conducive to sperm survival. They do not protect against STIs. In addition to the general benefits for barrier contraceptives, the advantages of spermicides include:

- They may be purchased without a prescription or an appointment with a health care provider, so they allow for greater independence and lower costs.
- When used in conjunction with another contraceptive, they increase the other method's effectiveness.
- Various preparations are available, including gels, creams, sponges, films, foams, and suppositories.

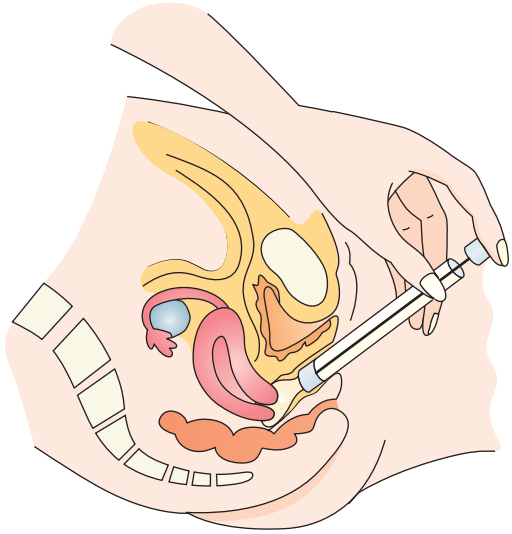

FIGURE 6.6 Vaginal insertion of a spermicidal agent.

Gels or creams are inserted into the vagina before coitus with an applicator (Fig. 6.6). The woman should do this no more than 1 hour before coitus for the most effective results. She should not douche to remove the spermicide for 6 hours after coitus, to ensure that the agent has completed its spermicidal action.

Another form of spermicidal protection is a film of glycerin impregnated with a spermicidal agent that is folded and inserted vaginally. On contact with vaginal secretions or precoital penile emissions, the film dissolves and a carbon dioxide foam forms to protect the cervix against invading spermatozoa.

Still other vaginal products are cocoa butter and glycerin-based vaginal suppositories filled with a spermicide. Inserted vaginally, these dissolve and release the spermicidal ingredients. Because it takes about 15 minutes for a suppository to dissolve, it must be inserted 15 minutes before coitus.

Sponges are foam-impregnated synthetic sponges that are moistened to activate the impregnated spermicide and then inserted vaginally to block sperm access to the cervix. Well liked by most users, they are easy to insert and have an efficiency rate of 80% (ideal) and a typical use failure rate of about 60% (Cunningham et al., 2008). They should remain in place for 6 hours after intercourse to ensure sperm destruction.

Side Effects and Contraindications. Vaginally inserted spermicidal products are contraindicated in women with acute cervicitis, because they might further irritate the cervix. They are generally inappropriate for couples who must prevent conception (perhaps because the woman is taking a drug that would be harmful to a fetus or the couple absolutely does not want the responsibility of children), because the overall failure rate of all forms of these products is about 20%. Some women find the vaginal leakage after use of these products bothersome. Vaginal suppositories, because of the cocoa butter or glycerin base, are the most bothersome in this regard.

Effect on Sexual Enjoyment. Although spermicidal products must be inserted fairly close to the time of coitus, they also

are so easily purchased over the counter that many couples find the inconvenience of insertion only a minor problem. If a couple is concerned that the method does not offer enough protection, worry about becoming pregnant may interfere with sexual enjoyment. Some couples find the foam or moisture irritating to vaginal and penile tissue during coitus and therefore are unable to use them.

Effect on Pregnancy. If conception should occur, there is no reason to think that the fetus will be affected by a spermicide. Some women worry that a sperm that survived the spermicide must have been weakened by migrating through it and therefore will produce a defective child. They can be assured that conception occurred most likely because the product did not completely cover the cervical os, so the sperm that reached the uterus was free of the product and unharmed.

Use by the Adolescent. Many adolescents use vaginal products as their chief method of birth control because no parental permission or extensive expense is involved. Caution adolescents that this method has a high failure rate (20%). All women need to be cautioned that preparations labeled "feminine hygiene" products are for vaginal cleanliness and are not spermicidal; therefore, they are not effective contraceptives.

Because of the nontraditional settings in which adolescents may engage in coitus (such as in cars, on couches), some young women find inserting the product awkward and consequently do not use it, even though they have purchased it and intended to be more cautious. Many use a vaginal foam and ask their partner to use a condom, doubling their protection.

Use by the Perimenopausal Woman. The use of vaginal film or suppositories is not recommended for women near menopause as this is a time in life when vaginal secretions are lessening so the film or suppository might not dissolve completely. Spermicide foam can help lubricate the vagina and so increase sexual enjoyment.

Use by the Postpartal Woman. Vaginal spermicides are appealing to postpartal women as these can be purchased over the counter and used in the time period before a postpartal checkup when a more permanent form of contraception will be prescribed. They have no effect on breastfeeding.

Mechanical Barriers

Mechanical barriers, such as a diaphragm, work by blocking the entrance of sperm into the cervix. A **diaphragm** is a circular rubber disk that is placed over the cervix before intercourse (Fig. 6.7). A Lea's Shield, made of silicone rubber and bowl shaped, is a new design. Although use of a spermicide is not required for diaphragms, use of a spermicidal gel with a diaphragm combines a barrier and a chemical method of contraception. With this, the failure rate of the diaphragm is as low as 6% (ideal) to 16% (typical use) (Cunningham et al., 2008).

A diaphragm is prescribed and fitted initially by a physician, nurse practitioner, or nurse-midwife to ensure a correct fit. Because the shape of a woman's cervix changes with pregnancy, miscarriage, cervical surgery (dilatation and curettage [D&C]), or elective termination of pregnancy, teach women to return for a second fitting if any of these circumstances occur. A woman should also have the fit of the diaphragm checked if she gains or loses more than 15 lb, because this could also change her pelvic and vaginal contours. A diaphragm is inserted into the vagina, after first coating the rim and center portion with a spermicide gel, by sliding it along the posterior wall and pressing it up against the cervix so that it is held in place by the vaginal fornices. A woman should check her diaphragm with a finger after insertion to be certain that it is fitted well up over the cervix; she can palpate the cervical os through the diaphragm.

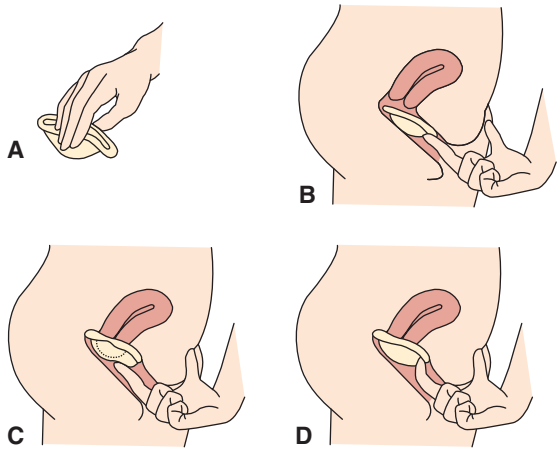

FIGURE 6.7 Proper insertion of a diaphragm. (**A**) After spermicidal jelly or cream is applied to the rim, the diaphragm is pinched between the fingers and thumb. (**B**) The folded diaphragm is then inserted into the vagina and pushed backward as far as it will go. (**C**) To check for proper positioning, the woman should feel the cervix to be certain it is completely covered by the soft rubber dome of the diaphragm. (**D**) To remove the diaphragm, a finger is hooked under the forward rim and the diaphragm is pulled down and out.

A diaphragm should remain in place for at least 6 hours after coitus, because spermatozoa remain viable in the vagina for that length of time. It may be left in place for as long as 24 hours. If it is left in the vagina longer than this, the stasis of fluid may cause cervical inflammation (erosion) or urethral irritation. A diaphragm is removed by inserting a finger into the vagina and loosening the diaphragm by pressing against the anterior rim and then withdrawing it vaginally. A Lea's Shield has an attached rubber loop to grasp for easy removal. After use, a diaphragm should be washed in mild soap and water, dried gently, and stored in its protective case. With this care, a diaphragm will last for 2 to 3 years.

Side Effects and Contraindications. Diaphragms may not be effective if the uterus is prolapsed, retroflexed, or anteflexed to such a degree that the cervix is also displaced in relation to the vagina. Intrusion on the vagina by a cystocele or rectocele, in which the walls of the vagina are displaced by bladder or bowel, may make insertion of a diaphragm difficult. Users of diaphragms may experience a higher number of urinary tract infections (UTIs) than nonusers, probably because of pressure on the urethra. Diaphragms should not be used

in the presence of acute cervicitis or a papillomavirus infection, because the close contact of the rubber and the use of a spermicide can cause additional irritation. Other contraindications include:

- History of toxic shock syndrome (TSS; staphylococcal infection introduced through the vagina)
- Allergy to rubber or spermicides
- History of recurrent UTIs

To prevent TSS while using a diaphragm, advise women to:

1. Wash their hands thoroughly with soap and water before insertion or removal.
2. Do not use a diaphragm during a menstrual period.
3. Do not leave a diaphragm in place longer than 24 hours.
4. Be aware of the symptoms of TSS, such as elevated temperature, diarrhea, vomiting, muscle aches, and a sunburn-like rash.
5. If symptoms of TSS should occur, immediately remove the diaphragm and call a health care provider.

Effect on Sexual Enjoyment. Some women dislike using diaphragms because they must be inserted before coitus (although they may be inserted up to 2 hours beforehand, minimizing this problem) and they should be left in place for 6 hours afterward. Use of a vibrator as a part of foreplay, frequent penile insertion, or the woman-superior position during coitus may dislodge a diaphragm; therefore, this may not be the contraceptive of choice for some couples. If coitus is repeated before 6 hours, the diaphragm should not be removed and replaced, but more spermicidal gel should be added. Some couples may find this precaution restricting. An advantage of the diaphragm is that it allows sexual relations during menses (although see the earlier precaution on TSS). It may offer some protection against STIs. If a woman should become pregnant while using a diaphragm, there is no risk of harm to the fetus.

Use by the Adolescent. Adolescents may be fitted for diaphragms. However, because an adolescent girl's vagina will change in size as she matures and begins sexual relations, the device may not remain as effective as it does with older women. Adolescents may need to be reminded that pelvic examinations will be necessary to ensure that a diaphragm continues to fit properly. Some adolescents may not know where their cervix is or how to feel for it when checking the placement of the diaphragm. Use an anatomic diagram or model to show them or give them a mirror to use to view their own cervix during a pelvic examination. Caution them not to accidentally tear the diaphragm with long or sharp fingernails.

What if... Dana, 17 years old, tells you that she and a friend intend to share a diaphragm because they do not have enough money for each to buy one? Is this good planning?

Use by the Perimenopausal Woman. Women over age 35 have a higher incidence of cystocele or rectocele than younger women so diaphragms may not be the ideal contraceptive for them.

Use by the Postpartal Woman. As the cervix changes considerably with childbirth, women must be refitted for diaphragms and cervical caps (see later discussion on cervical caps) after childbirth. This is usually done at a 4- or 6-week checkup.

Cervical Caps

A **cervical cap** is yet another barrier method of contraception. Caps are made of soft rubber, are shaped like a thimble with a thin rim, and fit snugly over the uterine cervix (Fig. 6.8). The failure rate is estimated to be as high as 26% (ideal) to 32% (typical use) (MacKay, 2009). The precautions for use are the same as for diaphragm use except they can be kept in place longer.

Although popular in Europe, many women cannot use cervical caps because their cervix is too short for the cap to fit properly. Also, caps tend to dislodge more readily than diaphragms during coitus. An advantage is that cervical caps can remain in place longer than diaphragms, because they do not put pressure on the vaginal walls or urethra; however, this time period should not exceed 48 hours, to prevent cervical irritation. Cervical caps, like diaphragms, must be fitted individually by a health care provider. They include a small strap, which can be grasped for easy removal. They are contraindicated in any woman who has:

- An abnormally short or long cervix
- A previous abnormal Pap smear
- A history of TSS
- An allergy to latex or spermicide
- A history of pelvic inflammatory disease, cervicitis, or papillomavirus infection
- A history of cervical cancer
- An undiagnosed vaginal bleeding

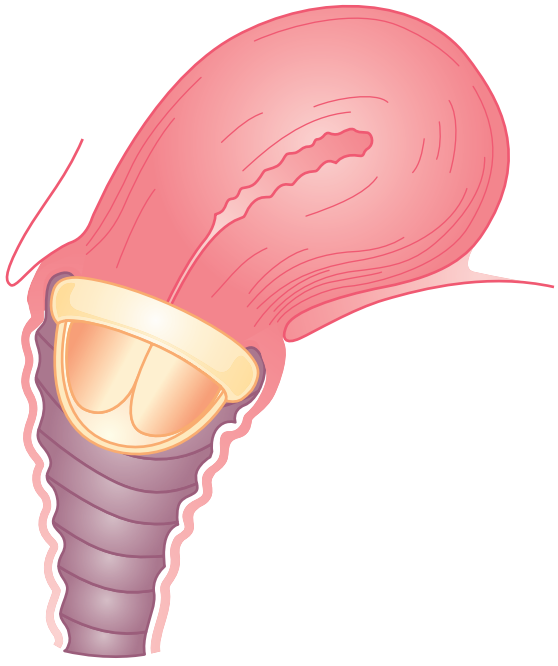

FIGURE 6.8 A cervical cap is placed over the cervix and used with a spermicidal jelly the same as a diaphragm.

Male Condoms

A **condom** is a latex rubber or synthetic sheath that is placed over the erect penis before coitus to trap sperm (Fig. 6.9). Condoms have an ideal failure rate of 2% and a typical failure rate of about 15%, because breakage or spillage occurs in up to 15% of uses (Kaplan & Love-Osborne, 2007). A major advantage of condoms is that they are one of the few "male-responsibility" birth control measures available, and no health care visit or prescription is needed. Latex condoms have the additional potential of preventing the spread of STIs, and their use has become a major part of the fight to prevent infection with human immunodeficiency virus (HIV). Recommend them for any partners who do not maintain a monogamous relationship.

Side Effects and Contraindications. There are no contraindications to the use of condoms except for a sensitivity to latex. If either the male or his partner has a sensitivity to latex, he can use a polyurethrane or natural membrane condom type. Caution him that these types do not give the same level of protection against STIs as does latex.

Effect on Sexual Enjoyment. To be effective, condoms must be applied before any penile-vulvar contact, because even preejaculation fluid may contain some sperm. A condom should be positioned so that it is loose enough at the penis tip to collect the ejaculate without placing undue pressure on the condom. The penis (with the condom held carefully in place) must be withdrawn before it begins to become flaccid after ejaculation. If it is not withdrawn at this time, sperm may leak from the now loosely fitting sheath into the vagina. Some men find that condoms dull their enjoyment of coitus; some couples do not like the fact that the male must withdraw promptly after ejaculation. Concern that the condom may break or slip also may inhibit sexual pleasure.

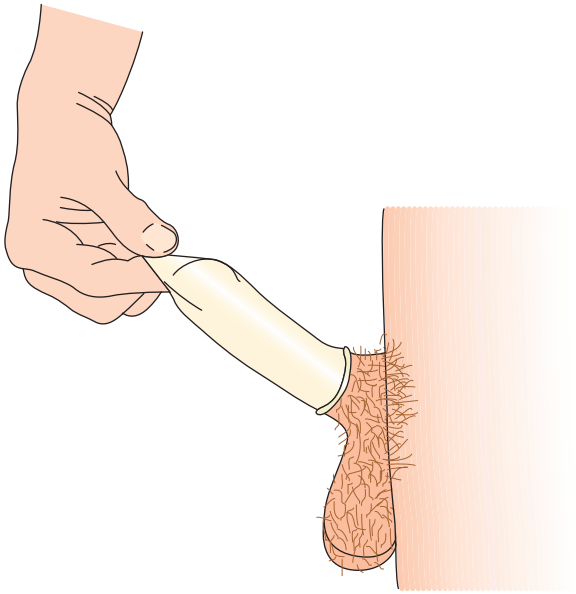

FIGURE 6.9 Male condom. Being certain that space is left at the tip helps to ensure the condom will not break with ejaculation.

Female Condoms

Condoms for females are latex sheaths made of polyurethane and prelubricated with a spermicide. The inner ring (closed end) covers the cervix, and the outer ring (open end) rests against the vaginal opening. The sheath may be inserted any time before sexual activity begins and then removed after ejaculation occurs. Like male condoms, they are intended for one-time use and offer protection against both conception and STIs (Fig. 6.10). Female con-

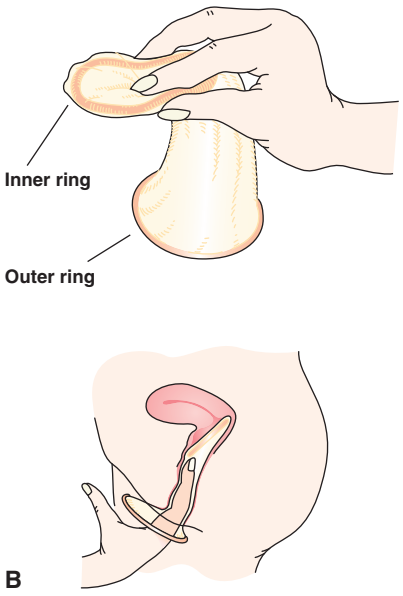

FIGURE 6.10 A female condom. Such a device is effective protection against both STIs and pregnancy. (**A**) The REALITY (WP-333) female condom. (© Barbara Proud.) (**B**) Insertion technique. (Courtesy of Wisconsin Pharmaceutical Company, Inc.)

doms can be purchased without a prescription but are more expensive than male condoms. Male and female condoms should not be used together. The failure rate is somewhat greater than the failure rate for male condoms, 12% to 22%. Most failures occur because of incorrect or inconsistent use. Although female condoms may reduce the risk of acquiring an HIV infection by as much as 90%, they have not gained great popularity, because of their bulk and difficulty in use (Burkman, 2007).

Use of Mechanical Barrier Methods by the Adolescent. Male adolescents are showing an increase in their ability to use condoms responsibly. Adolescents may need to be cautioned that condoms should never be reused, because even a pinpoint hole can allow thousands of sperm to escape. Adolescent boys who have infrequent coitus may use condoms that they have owned and stored for a long time. The effectiveness of these old condoms, especially if they are carried in a warm pocket, is questionable. For many adolescent couples, use of a dual method, such as a vaginally inserted spermicide by the girl and a condom by her partner, is a preferred method of birth control. The effectiveness of these two methods used in conjunction becomes about 95% (Kaplan & Love-Osborne, 2007).

✔ Checkpoint Question 6.4

Dana, 17 years old, wants to try female condoms as her reproductive planning method. Which instruction would you give her?

a. The hormone the condom releases may cause mild weight gain.
b. She should insert the condom before any penile penetration.
c. She should coat the condom with a spermicide before use.
d. Female condoms, unlike male condoms, can be reused.

Surgical Methods of Reproductive Life Planning

Surgical methods of reproductive life planning, often called sterilization, include tubal ligation for women and vasectomy for men. Tubal ligation is chosen by about 28% of all women in the United States of childbearing age as their contraceptive of choice. Vasectomy is the contraceptive method of choice for about 11% of men, making these two procedures the most frequently used methods of contraception in the United States for couples older than 30 years of age (Warehime, Bass, & Pedulla, 2007). Many people choose these surgical methods because they are the most effective methods of contraception besides abstinence, because there are no further costs, and because they have no effect on sexual enjoyment.

Between 6% and 7% of men and women in the United States seek a reversal of the procedure. Although reversal procedures are possible, such techniques are much more complicated and expensive than the sterilization itself, and success rates are only 70% to 80%. For this reason, surgical methods should be chosen with great thought and care and should be considered permanent. Counseling should be especially intensive for men and women younger than 25 years of age, because the possibility of divorce, death of a sexual partner, loss of a child, or remarriage could change a person's philosophy toward childbearing in the future. In addition, sterilization is not recommended for individuals whose fertility is important to their self-esteem.

Vasectomy

In a **vasectomy,** a small incision or puncture wound is made on each side of the scrotum. The vas deferens at that point is then located, cut and tied, cauterized, or plugged, blocking the passage of spermatozoa (Cook et al., 2009) (Fig. 6.11). Vasectomy can be done under local anesthesia in an ambulatory setting, such as a physician's office or a reproductive life planning clinic. The man experiences a small amount of local pain afterward, which can be managed by taking a mild analgesic and applying ice to the site. The procedure is 99.5% effective (MacKay, 2009). Spermatozoa that were present in the vas deferens at the time of surgery can remain viable for as long as 6 months. Therefore, although the man can resume sexual intercourse within 1 week, an additional birth control method should be used until two negative sperm reports have been obtained (proof that all sperm in the vas deferens have been eliminated, usually requiring 10 to 20 ejaculations).

Some men resist the concept of vasectomy because they are not sufficiently aware of their anatomy to know exactly

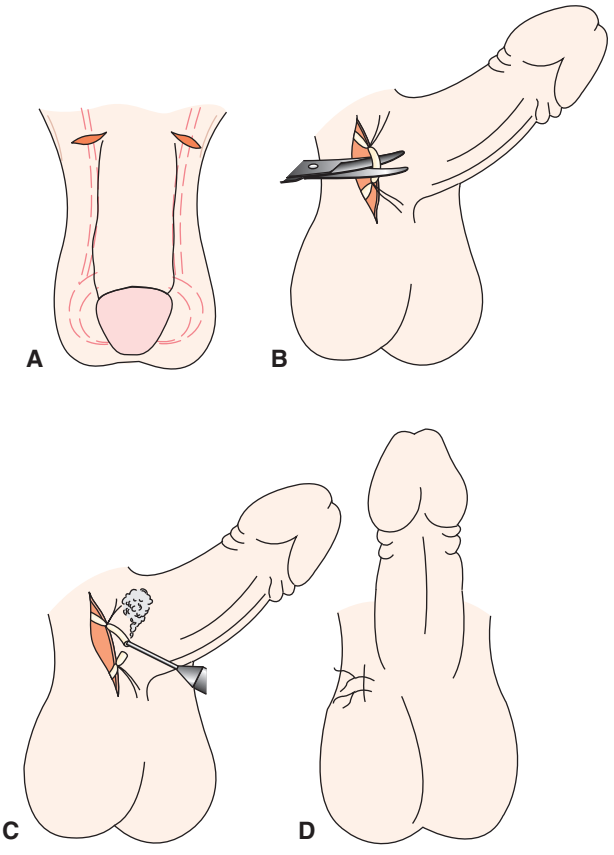

FIGURE 6.11 Vasectomy. (**A**) Site of vasectomy incisions. (**B**) The vas deferens being cut with surgical scissors. (**C**) Cut ends of the vas deferens are cauterized to completely ensure blockage of the passage of sperm. (**D**) Final skin suture.

what the procedure involves. They can be assured that vasectomy does not interfere with the production of sperm; the testes continue to produce sperm as always, but the sperm simply do not pass beyond the severed vas deferens and are absorbed at that point. The man will still have full erection capacity. Because he also continues to form seminal fluid, he will ejaculate seminal fluid—it will just not contain sperm.

There are very few complications associated with vasectomy. A hematoma at the surgical site may occur, although this is seen less frequently with "no scalpel" or puncture incisions (Cook et al., 2009). The procedure may be associated with the development of urolithiasis (kidney stones). A few men develop chronic pain after vasectomy (postvasectomy pain syndrome); having the procedure reversed relieves this pain. Some men develop autoimmunity or form antibodies against sperm, so that even if reconstruction of the vas deferens is successful, the sperm they produce do not have good mobility and are incapable of fertilization. Men who feel a need to have their sperm available for the future can have it stored in a sperm bank before vasectomy.

Tubal Ligation

Sterilization of women could include removal of the uterus or ovaries (hysterectomy), but it usually refers to a minor surgical procedure, such as **tubal ligation,** where the fallopian tubes are occluded by cautery, crushing, clamping, or blocking, thereby preventing passage of both sperm and ova. A fimbriectomy, or removal of the fimbria at the distal end of the tubes, is another possible but little used technique. Tubal ligation has a 99.5% effectiveness rate (Cunningham et al., 2008). Although the reason is not clear, tubal ligation is associated with a decreased incidence of ovarian cancer.

The most common operation to achieve tubal ligation is **laparoscopy.** After a menstrual flow and before ovulation, an incision as small as 1 cm is made just under the woman's umbilicus with the woman under general or local anesthesia. A lighted laparoscope is inserted through the incision. Carbon dioxide is then pumped into the incision to lift the abdominal wall upward and out of the line of vision. The surgeon locates the fallopian tubes by viewing the field through a laparoscope. An electrical current to coagulate tissue is then passed through the instrument for 3 to 5 seconds, or the tubes are clamped by plastic, metal, or rubber rings, then cut or filled with a silicone gel to seal them (Fig. 6.12). The procedure provides immediate contraception.

The procedure can also be done by culdoscopy (a tube inserted through the posterior fornix of the vagina) or colpotomy (incision through the vagina), but the incidence of pelvic infection is higher with these procedures and visualization is less. The woman is discharged from the hospital a few hours after the procedure. She may notice abdominal bloating for the first 24 hours, until the carbon dioxide infused at the beginning of the procedure is absorbed. This can also cause sharp diaphragmatic or shoulder pain if some of the carbon dioxide escapes under the diaphragm and presses on ascending nerves. Complications include bowel perforation, hemorrhage, and the risks of general anesthesia with the procedure (Warehime, Bass, & Pedulla, 2007). A woman may notice a day or two of abdominal discomfort caused by local necrosis if clips were used.

A new system, Essure, consists of a spring-loaded mechanism that, when inserted through the vagina and uterus into the outer end of a fallopian tube (a hysteroscopy procedure), releases a soft micro-insert into the tube that effectively seals the tube (Pavone & Burke, 2007). This can be done as an office procedure. Women must use a second form of contraception afterward until at 3 months, when a hysterosalpingogram is done to confirm that the fallopian tubes are blocked.

A woman may return to having coitus as soon as 2 to 3 days after the procedure. Be certain that they understand

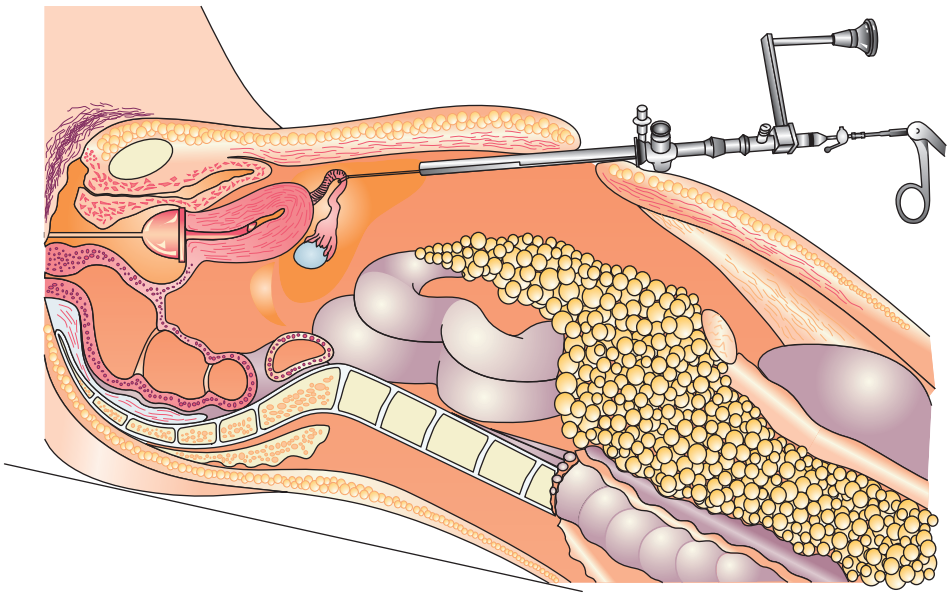

FIGURE 6.12 Laparoscopy for tubal sterilization. (From Richard Wolf Medical Instruments Corporation, with permission).

that tubal ligation, unlike a hysterectomy, does not affect the menstrual cycle, so they will still have a monthly menstrual flow. Be certain that women know to have no unprotected coitus before a tubal ligation (sperm trapped in the tube could fertilize an ovum there and cause an ectopic pregnancy).

Contraindications to tubal ligation surgery if done by laparoscopy are an umbilical hernia, because bowel perforation might result, and extensive obesity, which would probably require a full laparotomy to allow adequate visualization. Some women develop vaginal spotting, intermittent vaginal bleeding, and even severe lower abdominal cramping after tubal ligation; these symptoms are labeled posttubal ligation syndrome. Removal of the fallopian tubes appears to relieve the symptoms.

Not only is it difficult to reconstruct fallopian tubes after they have been cauterized, but there is also a possibility that afterward, the anastomosis site, because of its irregular surface, could cause an ectopic (tubal) pregnancy. If a silicone gel has been instilled into the tubes as a blocking agent, it can be removed at a later date to reverse the procedure. As with vasectomy, however, women should view tubal ligation as a permanent, irreversible procedure. Otherwise, they can regret having the procedure. This happens most in women under age 30 (Pavone & Burke, 2007).

Effect on Sexual Enjoyment. Both tubal ligation and vasectomy may lead to increased sexual enjoyment, because they largely eliminate the possibility of pregnancy. However, if either partner changes his or her mind about having children, the surgery may become an issue between them that interferes not only with sexual enjoyment but also with their entire relationship.

Use by the Adolescent. Counsel adolescents to use more temporary forms of birth control because their future goals may change so drastically that what they think they want at age 16 or 18 years may not be what they want at all at age 30. Later, if they still feel that vasectomy or tubal ligation is the method of reproductive life planning for them, the option will still be available.

Use by the Perimenopausal Woman. When a woman realizes that childbearing for her is complete, vasectomy for her partner or tubal ligation for her are the two most frequently requested forms of contraception.

Use by the Postpartal Woman. Tubal ligation can be done as soon as 4 to 6 hours after the birth of a baby or after an elective termination of a pregnancy, although it is more often done at 12 to 24 hours after birth. The abdominal distention at this time may make locating the tubes difficult, so a mini-laparotomy may be used. Such procedures can be done in an ambulatory surgery department with the patient under local anesthesia. A 2- to 3-cm incision is made transversely just above the pubic hair. The fallopian tubes are pulled to the surface and lifted out of the incision to be visualized. Metal or plastic clips or rubber rings are then used to seal the tubes. Clips cause necrosis at that point in the tubes.

✔ Checkpoint Question 6.5

Dana, 17 years old, asks you how a tubal ligation prevents pregnancy. Which would be the best answer?

a. Sperm can no longer reach the ova, because fallopian tubes are blocked.
b. Sperm cannot enter the uterus, because the cervical entrance is blocked.
c. Prostaglandins released from the cut fallopian tubes effectively kill sperm.
d. The ovary no longer releases ova, as there is nowhere for them to go.

THE COUPLE WITH A PHYSICAL OR COGNITIVE CHALLENGE

Reproductive life planning can be a greater concern than usual for a couple with a physical or cognitive challenge as finding a suitable contraceptive may be more difficult for them than for average couples. For example, a man who has unsteady coordination might not have adequate hand coordination to place a condom effectively. A woman with a similar handicap might have difficulty inserting a diaphragm or vaginal ring, and a woman who is cognitively challenged might not understand the need to take COCs daily. Morbidly obese clients may have difficulty with diaphragm insertion (Cowett, 2007). Women with recurrent convulsions may be unable to take COCs because of the interaction of these with common seizure medications. For these reasons, subdermal implants or surgical intervention may be the ideal contraceptive for many couples with a disability.

What if... Dana, 17 years old, tells you that the reason she wants a birth control method prescribed is to stop menstrual cramps. What advice would you give her?

FUTURE TRENDS IN CONTRACEPTION

Although COCs contain much less estrogen today than originally, because estrogen is responsible for most of the side effects associated with COCs, studies are being conducted using even lower-dose estrogen in pills. Biodegradable implants that do not have to be removed may be used in the future. A progesterone-filled vaginal ring that is permanently implanted is another possibility. A birth control vaccine consisting of antibodies against human chorionic gonadotropin hormone or injections of testosterone for males (which halts sperm production, just as estrogen halts ova production in women) are being tested at major centers. Until some method satisfies all of the criteria for an ideal contraceptive (i.e., completely safe, no side effects, low cost, easy availability, easy reversibility, and user acceptability), research in the field will continue. Both men and women need opportunities to discuss options to find the method that will be right for them (see Focus on Nursing Care Planning Box 6.9).

BOX 6.9 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for an Adolescent Seeking Contraceptive Information

Seventeen-year-old Dana Crews has come to your community health clinic for a pelvic examination and Pap smear. She is sexually active and tells you that her boyfriend "sometimes" uses a condom. She trusts he will "stop in time" when they aren't using one. She doesn't want to take the pill because she can't afford it and she's afraid her parents will find out that she's broken her abstinence pledge.

Family Assessment ✻ Client lives at home with parents and younger sister, 12 years old. Father works as Boy Scout Administrator. Mother is stay-at-home mom. Client states family finances are "good; no problem."

Client Assessment ✻ Past medical history is negative for major health problems. Menarche was at age 12. Menstrual cycles range from 28 to 35 days, with a moderately heavy flow lasting 5 to 7 days. She has enough cramping monthly that she "usually has to stay home from school for one day." Last menstrual flow was 1 week ago. Uses contraception inconsistently. Denies any history of sexually transmitted infections or other reproductive problems. Weight is appropriate for her height. Secondary sex characteristics are present. You notice her smoking a cigarette in the hallway. Following her health care visit, she is prescribed Ortho-ovum 7/7/7, a 28-day-cycle triphasic oral contraceptive.

Nursing Diagnosis ✻ Health-seeking behaviors related to knowledge deficit concerning contraception

Outcome Criteria ✻ Client identifies options available to her; states valid reasons for method chosen; demonstrates correct use of and appropriate follow-up care for chosen method; voices satisfaction with method chosen by 1 month's time.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Assess client's lifestyle.	Discuss when she will take pill and where she will store them. Help make out a reminder sheet. Caution against smoking while taking an estrogen-based pill.	Reviewing lifestyle may provide clues to possible reasons why the method will be ineffective or not continued.	Client describes lifestyle to health care provider and actively participates in devising lifestyle changes that will add to contraceptive's effectiveness.
		Consultations		
Nurse	Consult with M.D., N.P., or nurse-midwife to determine whether method client chooses will be optimal, safe, and effective.	Secure prescription for medication.	Effective health care is a collaborative effort drawing on interdisciplinary expertise.	Consultation reveals that the contraceptive method chosen will be optimal, safe, and effective; client receives prescription.
		Procedures/Medications		
Nurse/nurse practitioner	Assess what form of contraceptive client thinks she could use most effectively.	Complete preprescription procedures such as a Pap test and pelvic exam. Review method of administration with client and steps to take if she forgets to take a pill.	Medication administration invariably requires discussion to help clients comply.	Any procedure necessary for prescription of a contraceptive is carried out safely with optimal respect for client privacy and concern.
Nurse	Determine whether client has any questions regarding pelvic exam or other procedures scheduled.	Assist with procedures such as Pap test; meet with client to answer any questions regarding contraceptive chosen.	Nurses can be instrumental in lending psychological and physical support during procedures.	Client states that she understands the importance of prescription procedures to ensure her safety.

		Nutrition		
Nurse/ nutritionist	Determine whether client commonly eats a dietary source of folic acid such as green vegetables.	Discuss with client that oral contraceptive use can lead to folic acid deficiency.	Knowledge of side effects is important to create informed consumers.	Client acknowledges that she needs to be conscious of the need for folic acid; names two good sources of folic acid in food.
		Patient/Family Education		
Nurse	Determine whether client has any further questions regarding chosen contraceptive measure.	Instruct client about the method selected. Have client repeat information for return demonstration.	Instruction provides an opportunity for learning to improve compliance.	Client describes the action of oral contraceptives and the need to take them conscientiously.
		Psychosocial/Spiritual/Emotional Needs		
Nurse	Assess if client has discussed with boyfriend that contraception is different than safer sex practices.	Review and discuss the need for safer sex practices in addition to contraception.	Safer sex practices promote health, empower the client, and minimize the risk of sexually transmitted infections.	Client acknowledges need for safer sex practices to prevent STIs and states she will ask her partner to use a condom.
		Discharge Planning		
Nurse	Assess if client understands she will need continued health supervision while on an oral contraceptive.	Explain the need for routine follow-up in 1 month and yearly pelvic exams.	Follow-up is essential for evaluating adherence and satisfaction and for reducing the risk of possible complications.	Client states that she will return for a follow-up visit in 1 month and every year after that.

ELECTIVE TERMINATION OF PREGNANCY (INDUCED ABORTION)

An **elective termination of pregnancy** is a procedure performed to end a pregnancy before fetal viability. Such procedures are also referred to as therapeutic, medical, or induced abortions. Having such a procedure is a woman's choice; nurses employed in health care agencies where induced abortions are performed are asked to assist with and offer support as a part of their duties. In the United States, although drugs are available, elective termination of pregnancy is still mainly a surgical procedure. Elective termination of pregnancy should not be viewed as a method of reproductive planning but as remediation for failed contraception. It is requested to end a pregnancy:

- That threatens a woman's life such as pregnancy in a woman with class IV heart disease
- That involves a fetus found on amniocentesis to have a chromosomal defect
- That is unwanted because it is the result of rape or incest
- Of a woman who chooses not to have a child at this time in her life for such reasons as being too young, not wanting to be a single parent, wanting no more children, having financial difficulties, or from failed contraception.

The majority of pregnancy terminations are done for these reasons.

Be certain that women who are choosing to have elective terminations are aware of all their options such as adoption or single parenthood before the procedure. Laboratory studies typically performed before the procedure include a pregnancy test, complete blood count, blood typing (including Rh factor), gonococcal smear, serologic test for syphilis, urinalysis, and Pap smear. Pregnancies are confirmed and dated by ultrasound.

In 1973, the U.S. Supreme Court ruled that elective terminations must be legal in all states as long as the pregnancy is less than 12 weeks. Individual states can regulate the termination of second-trimester pregnancies and can prohibit termination of third-trimester pregnancies that are not life-threatening. They can also mandate additional regulations regarding the procedure, such as requiring a 24-hour waiting period for counseling or requiring parental approval for minors. Whether a particular institution or health care provider provides elective termination services depends on the policy and choice of that institution or individual.

About 20 in every 1000 U.S. women will elect to terminate a pregnancy in their lifetime (one half of unintended pregnancies end with elective termination) (CDC, 2009).

The majority of these procedures are done when the pregnancy is less than 12 weeks. The maternal mortality rate of elective terminations is 0.6 per 100,000 procedures performed. This makes elective termination about 11 times safer for women than childbirth, for which the mortality rate is closer to 6 per 100,000 births (Stubblefield, Carr-Ellis, & Kapp, 2007).

Medically Induced Termination

Mifepristone (a progesterone antagonist) is a compound that blocks the effect of progesterone, preventing implantation of the fertilized ovum and therefore causing abortion (Box 6.10). Mifepristone has additional approved applications, such as regression of uterine leiomyomas, induction of labor, and detoxification in cocaine overdose. For a medical termination, the compound is taken as a single oral dose of 600 mg any time within 49 days of gestational age (Kulier, 2009). Rh_oD-negative women should receive $Rh_o(D)$ immune globulin at the time the mifepristone is administered. Three days later, misoprostol (a prostaglandin) is administered in a single oral (400 mcg) or vaginal dose (800 mcg). This causes uterine contractions with cramping and pregnancy expulsion. Women can administer the misoprostol to themselves at home. Mifepristone has a 90% effectiveness rate when it is administered alone within 49 days of the last menstrual period and 95% when it is followed by a prostaglandin such as misoprostol. Methotrexate is an antimetabolite that causes trophoblastic cell death, so it may also be used for medical terminations. Methotrexate is more commonly used to end ectopic pregnancies or trophoblastic disease (see Chapter 21).

Most women notice continued bleeding, indistinguishable from bleeding that occurs after a spontaneous miscarriage, for up to 2 weeks after a medical termination procedure. Teach women the instructions in Box 6.11—to watch for signs of complications and to contact a health care practitioner if any are apparent.

Medical termination of pregnancy is contraindicated if the woman has a(n):

- Confirmed or suspected ectopic pregnancy
- Intrauterine device in place
- Serious medical condition such as chronic adrenal failure
- History of current long-term systemic corticosteroid therapy
- History of allergy to mifepristone, misoprostol, or other prostaglandins
- Hemorrhagic disorder or is taking concurrent anticoagulant therapy

The complications of medical termination are incomplete abortion and the possibility of prolonged bleeding. Advantages of medical over surgical termination are the decreased risk of damage to the uterus through instrument insertion and decreased use of anesthesia necessary for surgically performed procedures. A woman should return for a postprocedure ultrasound or pregnancy test to ensure that the pregnancy has ended. Misoprostol can cause nausea, vomiting, diarrhea, and severe abdominal cramping. Research is being conducted on whether the dose of either mifepristone or misoprostol can be reduced while still producing satisfactory results.

BOX 6.10 ✻ Focus on Pharmacology

Mifepristone (Mifegyne)
Classification: Abortifacient
Action: A progesterone antagonist that stimulates uterine contractions and sloughing of endometrium, causing an implanted trophoblast to loosen from the placental wall (can be used up to 49 days, possibly 63 days gestational age) (Karch, 2009)
Pregnancy Category: X
Dosage: One-time dose of 600 mg PO
Possible Adverse Effects: Headache, vomiting, diarrhea, heavy uterine bleeding

Nursing Interventions
- Drug can cause such nausea that client may appreciate being premedicated with an antiemetic.
- Drug is usually followed within 48 hours with a prostaglandin for greater effect.
- Client may need a uterine D&C if heavy bleeding does not resolve.
- Counsel client regarding effective birth control measures to avoid having to take mifepristone again in the future.

BOX 6.11 ✻ Common Instructions After Elective Termination of Pregnancy

1. You may have slight vaginal spotting for 2 weeks. Cramping may also occur.
2. Use sanitary pads rather than tampons to help avoid infection.
3. Do not douche as this can invite infection.
4. If you need something for discomfort, take acetaminophen (Tylenol) or ibuprofen (Advil or Motrin). Do not take aspirin as this can increase bleeding.
5. Resume regular activities but avoid heavy lifting or strenuous exercise for 3 days.
6. Take your temperature once a day for 1 week. Call your health care provider if your oral temperature is above 100.4° F.
7. Your regular menstrual period should return in 4 to 6 weeks.
8. It is best if you do not have sexual relations until your scheduled checkup to avoid infection. If you do, ask your partner to use a condom to avoid a second pregnancy.
9. Be sure to call your health care provider if you have any of the following symptoms:
   - Heavy vaginal bleeding (more than two pads saturated in 1 hour)
   - Passing of clots
   - Abdominal pain or tenderness
   - Severe depression
10. Keep your follow-up appointment in 2 weeks to be certain that your pregnancy has ended.

Be certain that women receive contraceptive counseling after the procedure so they can avoid having to undergo such a procedure again in the future.

Surgical Elective Termination Procedures

Elective surgical terminations involve several different techniques, depending on the gestational age at the time the termination is performed.

Menstrual Extraction

Menstrual extraction or suction evacuation is the simplest type of surgical termination procedure. It is performed on an ambulatory basis 5 to 7 weeks after the last menstrual period. The woman voids, and her perineum is washed with an antiseptic (shaving is unnecessary). A speculum is then introduced vaginally, the cervix is stabilized by a tenaculum, and a narrow polyethylene catheter is introduced through the vagina into the cervix and uterus (Fig. 6.13A). The lining of the uterus that would be shed with a normal menstrual flow is then suctioned and removed by means of the vacuum pressure of a syringe. Menstrual extraction is completed quickly and with a minimum of discomfort (some abdominal cramping may occur as the tenaculum grasps the cervix or as the last of the endometrium is suctioned away). Caution a woman to remain supine for about 15 minutes after the procedure until uterine cramping quiets, to prevent hypotension on standing. She may be prescribed oral oxytocin to ensure full uterine contraction after the procedure. Teach the signs and symptoms of complications (see Box 6.11) and to contact a health care practitioner if any are apparent. Because a pliable catheter is used for the procedure, uterine perforation is unlikely. However, the possibility of hemorrhage and infection is the same as in other surgical termination procedures.

Dilatation and Curettage

If the gestational age of a pregnancy is less than 13 weeks, a D&C procedure may be used. This procedure is usually done in an ambulatory setting using a paracervical anesthetic block. A paracervical block does not eliminate pain but limits what the woman experiences to cramping and a feeling of pressure at her cervix.

In preparation for the procedure, the woman voids, the perineum is washed, an anesthetic block is administered, and the cervix is dilated. The uterus is then scraped clean with a curette, removing the zygote and trophoblast cells with the uterine lining (see Fig. 6.13B). After the procedure, caution the woman to remain in the hospital or clinic for 1 to 4 hours so she can have careful assessment of vital signs and perineal care. She may be prescribed oxytocin to ensure firm uterine contraction and minimize bleeding. If there are no complications, she can return home after approximately 4 hours. Teach her signs and symptoms of complications (see Box 6.11) and offer contraceptive counseling so that she can avoid a repeat procedure.

A D&C has the potential risk of uterine perforation from the instruments used and carries an increased risk of uterine infection compared with menstrual extraction, because of the greater cervical dilatation. A woman may be prescribed prophylactic antibiotics to help prevent infection.

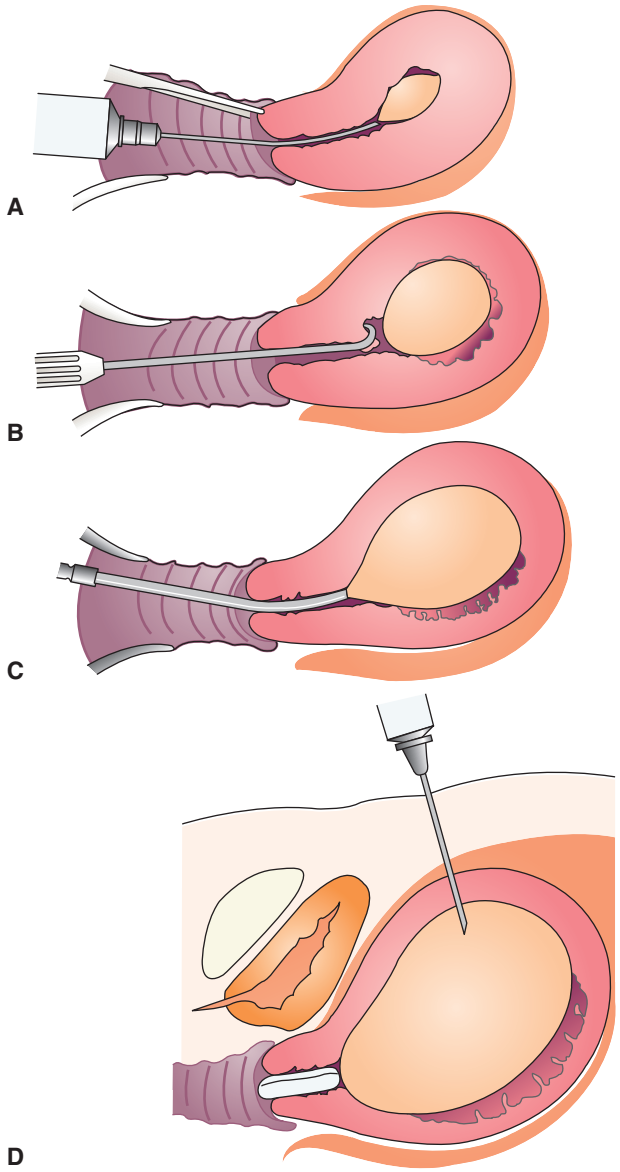

FIGURE 6.13 Techniques of surgical elective termination of pregnancy. (**A**) Menstrual extraction. (**B**) Dilatation and curettage (D&C). (**C**) Dilatation and vacuum extraction (D&E). (**D**) Saline induction.

Dilatation and Vacuum Extraction

Most second-trimester terminations (those between 12 and 16 weeks) are done by dilatation and vacuum extraction (D&E), which can be either an inpatient or an ambulatory procedure. In some centers, dilatation of the cervix is begun the day before the procedure by administration of oral misoprostol or insertion of a laminaria tent (seaweed that has been dried and sterilized) into the cervix. In a moist body part such as the cervix, the seaweed absorbs fluid and swells in size. Over a 24-hour period, gradually, painlessly, and without trauma, it dilates the cervix enough for a vacuum extraction tip to be inserted. There is some concern that frequent surgical dilatation of the cervix can lead to a cervix that dilates so easily it will not remain contracted during a subsequent pregnancy. Therefore, laminaria dilatation is often chosen for young

women who may have more than one pregnancy termination in their lifetime as the gradual dilation of a cervix by this method helps to safeguard their childbearing potential. Antibiotic prophylaxis may be initiated at the time of the laminaria insertion to protect against infection. The woman is cautioned not to have sexual relations until the process is complete to further reduce the possibility of infection.

After either misoprostol or laminaria dilatation or dilatation by traditional dilators, a narrow suction tip specially designed for the incompletely dilated cervix is introduced into the cervix (see Fig. 6.13C). The negative pressure of a suction pump or vacuum container then gently evacuates the uterine contents over a 15-minute period. The woman will feel pain as the cervical dilatation is performed and some pressure and cramps, similar to menstrual cramps, during suction, but it is not a markedly painful procedure.

Advise the woman to remain flat for at least 15 minutes after the procedure to prevent hypotension. She needs to remain in the hospital or clinic for about 4 hours so she can have careful assessment of vital signs and perineal care. She usually receives oxytocin to ensure firm uterine contraction and minimize bleeding.

Because a rigid cannula is used for the procedure, D&E has the potential for uterine perforation, although this is rare. Because the cervix was dilated, there is a potential, as in all surgical termination procedures, for postprocedure infection. Be sure to teach the danger signals (see Box 6.11).

Prostaglandin or Saline Induction

Prostaglandin or saline induction is used if a pregnancy is between 16 and 24 weeks (see Fig. 6.13D). It is done on an inpatient or ambulatory basis. The woman is given prostaglandin $F_{2\alpha}$ by injection or prostaglandin E_2 by suppository. Both of these prostaglandins cause cervical dilation and uterine cramping, which expels the products of conception.

The woman is admitted to a same-day surgery unit and has oral misoprostol or vaginal laminaria inserted to help prepare the cervix for dilatation. The prostaglandin is then administered. Labor, which takes several hours after the administration of the prostaglandin, may be shortened by administration of a dilute intravenous solution of oxytocin. Because the products of conception are small, the actual expulsion causes only a momentary stinging pain as the perineum is stretched.

During the procedure, the woman needs the same care as any woman in labor:

- Frequent explanations of what is happening
- Medication for discomfort (breathing exercises may be helpful to minimize this)
- Presence of people important to her and health care personnel for support

If large amounts of oxytocin are necessary to induce labor, observe the woman for signs of water intoxication or body fluid accumulating in body tissue such as severe headache, confusion, drowsiness, edema, and decreased urinary output. These are the same symptoms that can occur when oxytocin is used to induce labor with term birth. They occur subtly at first, then grow in severity. If such symptoms occur, stop the oxytocin drip immediately. The symptoms will then decrease as body fluid shifts back to normal compartments. Always infuse oxytocin using a piggyback method during a termination procedure, the same as with a woman in term labor, so the infusion of oxytocin can be stopped quickly this way while still maintaining a fluid line for emergency drugs or fluid.

After expulsion of the products of conception, all the tissue expelled should be examined to determine whether the entire conceptus (fetus and placenta and membranes) has been expelled. If a woman wishes to see the fetus, wrap it as if it were a full-term infant and allow her to do this to begin effective grieving or closure. Observe women conscientiously for vaginal hemorrhage following the procedure, the same as after a term birth. If the procedure was prolonged, the woman may develop disseminated intravascular coagulation from trauma (see Chapter 21); if this occurs, she is very susceptible to hemorrhage, because her blood-clotting mechanism is compromised.

The use of saline for induction is based on the principle that hypertonic (20%) saline causes fluid shifts and sloughing of the placenta and endometrium. For this type of induction, a woman voids to reduce the size of her bladder so it will not be accidentally punctured by the saline injection. A sterile spinal needle is then inserted into the uterus through the anesthetized abdominal wall, and 100 to 200 mL of amniotic fluid is removed by a syringe with amniocentesis technique (see Chapter 19). A 20% hypertonic saline solution of up to 200 mL is then injected by the same needle, through the abdominal wall, into the amniotic fluid. The needle is then withdrawn. Within 12 to 36 hours after the injection, labor contractions begin.

A serious potential complication of saline termination is hypernatremia from accidental injection of the hypertonic saline solution into a blood vessel within the uterine cavity. The presence of such a concentrated salt solution in the bloodstream could cause body fluid to shift into the blood vessels in an attempt to equalize osmotic pressure. Serious dehydration of tissue could result. If an intravascular puncture should occur, the woman immediately experiences an increased pulse rate, a flushed face, and a severe headache. If such symptoms occur, the injection must be stopped immediately and an intravenous solution such as 5% dextrose begun to dilute the saline solution and restore fluid balance.

Hysterotomy

If the gestational age for a pregnancy is more than 16 to 18 weeks, a hysterotomy, or removal of the fetus by surgical intervention similar to a cesarean birth, may be performed. Surgery is necessary at this point, because the uterus becomes resistant to the effect of oxytocin as it reaches this phase of pregnancy and may not respond either to saline induction or prostaglandins, even with the assistance of oxytocin. Furthermore, the chance is great at this gestational age, because the uterus is so enlarged, that it will not respond and contract afterward, leading to hemorrhage. The technique for hysterotomy is identical to that of cesarean birth (see Chapter 24). Because this is so late in pregnancy, fewer than 1% of surgical terminations are done using this technique.

"Partial Birth Abortion"

"Partial birth abortion" was a surgical technique formerly used during the last 3 months of pregnancy if the fetus was

discovered to have a congenital anomaly that would be incompatible with life or would result in a severely compromised child such as encephalocele or high spinal meningocele. Labor was induced by a combination of oxytocin and cervical ripening. The fetus was turned so that the breech presented to the birth canal. A clamp was then inserted into the base of the fetal skull and the head contents were destroyed. The head was then collapsed and delivered. "Partial birth abortion" is no longer legal in the United States (Greene, 2007). A cesarean birth or vaginal birth of the infant is scheduled instead.

Isoimmunization

Whenever a placenta is dislodged, either by spontaneous birth or by surgical or medical intervention at any point in pregnancy, blood from the placental villi (the fetal blood) may enter the maternal circulation. This has implications for the Rh-negative woman. If the fetus is Rh-positive, enough Rh-positive blood may enter her circulation to cause isoimmunization or the production by her immunologic system of antibodies against Rh-positive blood. If the fetus in her next pregnancy should also be Rh-positive, those antibodies would attempt to destroy the red blood cells of that infant during the months in utero.

Because the blood type of the conceptus is unknown with either medical or surgical termination, all women with Rh-negative blood should receive Rh_o(D) immune globulin (RhoGAM or RHIG) within 72 hours after the procedure to prevent the buildup of antibodies in the event the conceptus was Rh positive (see Chapter 26 for a full discussion of Rh disease).

Psychological Aspects of Elective Termination of Pregnancy

Women of all ages, married or unmarried, with or without children, request elective terminations. The usual profile of a woman who is having such a procedure

- Is young and unmarried
- Has no previous live births
- Undergoes the procedure to end an unwanted pregnancy
- Has not taken any or adequate protection against becoming pregnant

Adolescents, often blamed for not using responsible contraception, do not appear to have been using a contraceptive any more carelessly than adult women at the time they ask for an elective termination of pregnancy (Harvey & Gaudoin, 2007). Be certain to give women of all ages having elective termination the same kind of explanations and support that women in labor receive (women do not share termination experiences with each other the same way as they share labor experiences, so women usually have received little advance preparation).

Most women feel anxious when they appear at the hospital or clinic for an elective termination procedure. Some of the anxiety comes from having made a difficult decision to reach this step; some comes from having to face the unknown; some may come from feelings of loss or shame and sadness that they had to make a decision with which they are not totally comfortable. Remembering that this is not a decision taken lightly helps in planning nursing care aimed at making an elective termination as nontraumatic as possible.

A few women express sadness and guilt after abortion. These women may need to be referred for professional counseling so they can integrate and accept this event in their lives.

Key Points for Review

- Reproductive life planning involves personal decisions based on each individual's background, experiences, and sociocultural beliefs. It involves thorough planning to be certain that the method chosen is acceptable and can be used effectively.
- Natural family planning (periodic abstinence and fertility awareness) methods are varied but involve determining the fertile period each month and then avoiding sexual relations during that time.
- Oral contraceptives are combinations of estrogen and progesterone. They provide one of the most reliable forms of contraception outside of abstinence. Women older than 40 years of age who smoke are not candidates for OC use because of the danger of cardiovascular complications. They should be counseled to find a form of contraception that is reliable and allows them to remain sexually active.
- Subdermal implants (renewed every 3 to 5 years) and intramuscular injections (renewed every 1 or 3 months), transdermal patches, and vaginal rings are equally effective.
- Intrauterine devices are placed in the uterus to prevent fertilization and implantation. Women with intrauterine devices should limit their number of sexual partners to help prevent sexually transmitted infections, and be aware of the signs and symptoms of pelvic inflammatory disease.
- Barrier methods of contraception include the diaphragm, cervical cap, sponges, vaginal spermicides, and condoms (male and female). Such methods are low in cost but are not as effective as ovulation suppressant methods. Use of diaphragms may be associated with urinary tract infections.
- "Morning-after" or "Plan B" protection involves administration of a high dose of estrogen or progesterone that prevents follicle-stimulating hormone release, preventing ovulation in case unprotected intercourse occurred.
- Surgical methods of contraception are tubal ligation in women and vasectomy in men. Counsel individuals who wish to undergo these procedures that they are largely irreversible.
- Elective termination of pregnancy can be accomplished surgically by menstrual extraction, dilatation and curettage, dilatation and vacuum extraction, or prostaglandin or saline induction, or medically by administration of mifepristone and misoprostol. Counsel women not to think of elective termination of pregnancy as a contraceptive method, but as a recourse to be used only if preventive measures fail. Women who are Rh negative need to receive Rh_o(D) immune globulin after these procedures.

- When counseling clients about reproductive life planning, nurses have a responsibility to teach about safer sex practices as well, such as using a condom during sexual intercourse to avoid HIV infection or other sexually transmitted infections.

CRITICAL THINKING EXERCISES

1. What patient education information would you provide for Dana Crews, the 17-year-old described at the beginning of this chapter? What method of reproductive life planning would you recommend for her? Would your recommendation be different if she had a guaranteed monogamous relationship?
2. Suppose Dana was 39 years old, had high blood pressure, and smoked? Would your teaching and recommendations differ?
3. Suppose Dana does not follow your advice for reproductive life planning and is admitted to the hospital for a prostaglandin induction to electively terminate a pregnancy. Her mother asks you to give her only a minimum of analgesia so that she will remember the experience as painful and therefore will not get pregnant again. Do you agree with this philosophy of care?
4. Examine the National Health Goals related to reproductive life planning. Most government-sponsored money for nursing research is allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that could advance evidence-based practice in relation to Dana's family?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX types of questions related to reproductive life planning. Confirm your answers are correct by reading the rationales.

Chapter 7

The Nursing Role in Genetic Assessment and Counseling

KEY TERMS

- alleles
- chromosomes
- cytogenetics
- dermatoglyphics
- genes
- genetics
- genome
- genotype
- heterozygous
- homozygous
- karyotype
- meiosis
- nondisjunction
- phenotype

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe the nature of inheritance, patterns of recessive and dominant mendelian inheritance, and common chromosomal aberrations that cause physical or cognitive disorders.
2. Identify National Health Goals related to genetic disorders that nurses can help the nation achieve.
3. Use critical thinking to analyze ways that nurses can make genetic assessment or education more family centered.
4. Assess a family for their adjustment to the probability of inheriting a genetic disorder.
5. Formulate nursing diagnoses related to genetic disorders.
6. Establish expected outcomes that meet the needs of the family undergoing genetic assessment and counseling.
7. Plan nursing care related to a potential alteration in genetic health, such as assisting with an amniocentesis.
8. Implement nursing care such as counseling a family with a genetic disorder.
9. Evaluate expected outcomes for achievement and effectiveness of care.
10. Identify areas related to genetic assessment that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of genetic inheritance with nursing process to achieve quality maternal and child health nursing care.

Amy Alvarez, 26 years old, is a woman you meet at a genetic counseling center. She was adopted as a newborn and never felt a need to locate her birth parents because her adoptive parents provided a "close to perfect" childhood for her. After college, she married the most eligible bachelor in her hometown. She is now pregnant with her first child. At 15 weeks into her pregnancy, after serum and ultrasound testing, she has been advised that her child may have translocation Down syndrome. She asks you, "How could this happen? There's no disease like that in either of our families."

Previous chapters described common family types and how they are affected by sociocultural and community influences. This chapter discusses the basic principles by which disorders can be inherited and information about the necessary assessments, care, and guidelines for counseling of families if it is discovered that there is a potential for a genetic disorder in the family. Such information can influence the health of a childbearing or childrearing family for generations to come.

How would you answer Amy?

As many as 1 in 20 newborns inherits a genetic disorder. As many as 70% of pediatric hospital admissions may be for genetic-influenced disorders (Pyeritz, 2009). The possibility that a child could have a genetic disorder crosses the minds of most pregnant women and their partners at some point in a pregnancy, whether or not there is any family history of such disorders. This causes pregnant couples to ask health care providers about their chances of having a child with a genetic disorder and about genetic testing. Due to the Human Genome Project and the determination of the location of specific genes in the human genome, the necessity to improve techniques of screening for genetic disorders has become a national priority (see National Health Goals, Box 7.1).

Nursing Process Overview

For Genetic Assessment and Counseling

Assessment

Assessment measures for genetic disorders include a detailed family history, preferably of three generations; physical examination of both the parents and any affected children; and an ever-growing series of laboratory assays of blood, amniotic fluid, and maternal and fetal cells. For example, women are offered routine screening of maternal serum levels of alpha-fetoprotein (MSAFP) early in pregnancy to evaluate for neural tube or chromosomal disorders in the fetus. Chorionic villi sampling (CVS) and amniocentesis are follow-up techniques that may be offered to women who are older than 35 years of age, or to those whose MSAFP level is abnormal, to further screen for genetic disorders. Couples who already know of the existence of a genetic disorder in their family or those who have had a previous child born with a congenital anomaly can have additional, more extensive testing. Nurses serve as members of genetic assessment and counseling teams to help obtain the initial family history, assist with physical examination, obtain blood serum for analysis, and assist with procedures such as amniocentesis in this process.

Certain genetic disorders are more commonly found in some ethnic groups than in others, because people often marry within their own racial or ethnic group. β-Thalassemia, for example, a blood dyscrasia, occurs most frequently in families of Greek or Italian heritage, whereas α-thalassemia occurs most often in persons from the Philippines or Southeast Asia. Sickle cell anemia occurs most often in African Americans. Tay-Sachs disease occurs most often in people of Jewish ancestry.

Identifying which families might be at risk for particular genetic disorders because of their ethnic heritage and being certain they are informed of the incidence of these disorders and that genetic screening is available is a nursing responsibility.

Nursing Diagnosis

Typical nursing diagnoses related to the area of genetic disorders include:

- Decisional conflict related to testing for an untreatable genetic disorder
- Fear related to outcome of genetic screening tests
- Situational low self-esteem related to identified chromosomal abnormality
- Deficient knowledge related to inheritance pattern of the family's inherited disorder
- Health-seeking behaviors related to potential for genetic transmission of disease
- Altered sexuality pattern related to fear of conceiving a child with a genetic disorder

Outcome Identification and Planning

Outcome identification and planning for families undergoing genetic assessment differ according to the types of assessments performed and the results obtained. This may include determining what information the couple needs to know before testing can proceed or helping couples arrange for further assessment measures. Be certain that goals are realistic and consistent with the individual's or couple's lifestyle (not all people want to be totally informed about family illnesses). Helpful websites to use for referral are the March of Dimes Birth Defects Foundation (http://www.marchofdimes.com), the American Association of Klinefelter Syndrome Information and Support (http://www.AAKSIS.org), the National Fragile X Foundation (http://www.NFXF.org), the National Down Syndrome Society (http://www.ndss.org), and the Turner Syndrome Society (http://www.Turner-syndrome-us.org).

Implementation

Parental reactions to the knowledge that their child has a possible genetic disorder or to the birth of a child with a genetically inherited disorder usually involves a grief reaction, similar to that experienced by parents whose child has died at birth (their "perfect" child is gone). Both parents

BOX 7.1 * Focus on National Health Goals

A number of National Health Goals speak directly to genetic disease and screening:

- Ensure that all newborns are screened at birth for conditions mandated by their State-sponsored newborn screening programs.
- Ensure that follow-up testing for screened positives is performed.
- Increase the proportion of children with special health care needs who receive their care in family-centered, comprehensive, and coordinated systems from 35% to 100% (http://www.nih.gov).

Nurses can help the nation achieve these goals by being sensitive to the need for genetic screening and counseling in prenatal and birth settings. Questions such as when are people most responsive to genetic counseling or what effect on bonding occurs, if any, when the parents learn about an abnormal alpha-fetoprotein level during pregnancy, are unanswered so would be good topics for nursing research.

may pass through stages of shock and denial ("This cannot be true"), anger ("It's not fair that this happened to us"), and bargaining ("If only this would go away") before they reach reorganization and acceptance ("It has happened to us and it is all right"). For some couples, a genetic disorder is diagnosed during the pregnancy; for others, it may not be discovered until birth, or possibly not even until the child is of school age. For these parents, the reaction will occur at that later point of diagnosis.

As a rule, when parents are under stress, it is most helpful to guide them to concentrate on short-term goals and actions. Help them look first at the immediate needs of their family, the fetus, or the newborn, and later on at what type of continued follow-up will be necessary. For instance, after the birth, will the baby need to be hospitalized for immediate surgical correction of accompanying congenital anomalies, or will the parents be able to take the baby home? These decisions must be made immediately. What kind of special schooling the child will need is a decision that can wait until later.

It is helpful to identify support people who can be helpful to the parents during their time of disorganization. These people may be usual family resources, such as grandparents or other family members. In some families, these people are as disturbed by the diagnosis as the parents and therefore cannot offer their usual support. That makes secondary support sources such as the March of Dimes Foundation necessary.

Not all parents are ready to talk to members of such organizations at the time of diagnosis, however. To contact such an organization may make the diagnosis seem "real" for the first time or move them out of denial before they are ready. Help also to identify health care personnel with whom the parents will need to maintain contact during the next few months such as a surgeon or an orthopedist. Ensuring that the parents have health care providers they know they can turn to, especially when they are moving out of denial, helps them move forward to their next step in accepting their child's diagnosis.

Outcome Evaluation

Examples of expected outcomes for a family with a known genetic disorder might be:

- Couple states they feel capable of coping no matter what the outcome of genetic testing.
- Client accurately states the chances of a genetic disorder occurring in her next child.
- Couple states they have resolved their feelings of low self-esteem related to birth of a child with a genetic disorder.

A couple's decisions about genetic testing and childbearing can change over time. For example, a decision made at age 25 not to have children because of a potential genetic disorder may be difficult to maintain at age 30, as the couple sees many of their friends with growing families. Be certain that such couples have the telephone number of a genetic counselor. Urge them to call periodically for news of recent advances in genetic screening techniques or disease treatments so they can remain current and well informed for future planning.

GENETIC DISORDERS

Inherited or genetic disorders are disorders that can be passed from one generation to the next. They result from some disorder in gene or chromosome structure and occur in 5% to 6% of newborns. **Genetics** is the study of the way such disorders occur. **Cytogenetics** is the study of chromosomes by light microscopy and the method by which chromosomal aberrations are identified.

Genetic disorders may occur at the moment an ovum and sperm fuse or even earlier, in the meiotic division phase of the gametes (ovum and sperm). Some genetic abnormalities are so severe that normal fetal growth cannot continue past that point. This early cell division is so precarious a process, in fact, that up to 50% of first-trimester spontaneous miscarriages may be the result of chromosomal abnormalities (Schorge et al., 2008). Other genetic disorders do not affect life in utero, so the result of the disorder becomes apparent only at the time of fetal testing or after birth. Women having in vitro fertilization (IVF) can have both the egg and sperm examined for genetic disorders of single gene or chromosome concerns before implantation (Van Voorhis, 2007). In the near future, it may be possible not only to identify aberrant genes for disorders this way but also to insert healthy genes in their place using stem cell implantation. Gene replacement therapy this way is encouraging in the treatment of blood, spinal cord, and immunodeficiency syndromes (Cardone, 2007). Women can arrange to have a newborn's cord blood frozen and banked to be available for bone marrow or other cell transplantation procedures in the future (Scott, 2007). As stem cells for replacement therapy can be obtained from menstrual blood, this also may be a future contribution source (Goldman, 2007).

Nature of Inheritance

Genes are the basic units of heredity that determine both the physical and cognitive characteristics of people. Composed of segments of DNA (deoxyribonucleic acid), they are woven into strands in the nucleus of all body cells to form **chromosomes.**

In humans, each cell, with the exception of the sperm and ovum, contains 46 chromosomes (22 pair of autosomes and 1 pair of sex chromosomes). Spermatozoa and ova each carry only half of the chromosome number, or 23 chromosomes. For each chromosome in the sperm cell, there is a like chromosome of similar size and shape and function (autosome, or homologous chromosome) in the ovum. Because genes are always located at fixed positions on chromosomes, two like genes **(alleles)** for every trait are represented in the ovum and sperm on autosomes. The one chromosome in which this does not occur is the chromosome for determining gender. If the sex chromosomes are both type X (large symmetric) in the zygote formed from the union of a sperm and ovum, the individual is female (Fig. 7.1A). If one sex chromosome is an X and one a Y (a smaller type), the individual is a male (Fig. 7.1B).

A person's **phenotype** refers to his or her outward appearance or the expression of genes. A person's **genotype** refers to his or her actual gene composition. It is impossible to predict a person's genotype from the phenotype, or outward appearance.

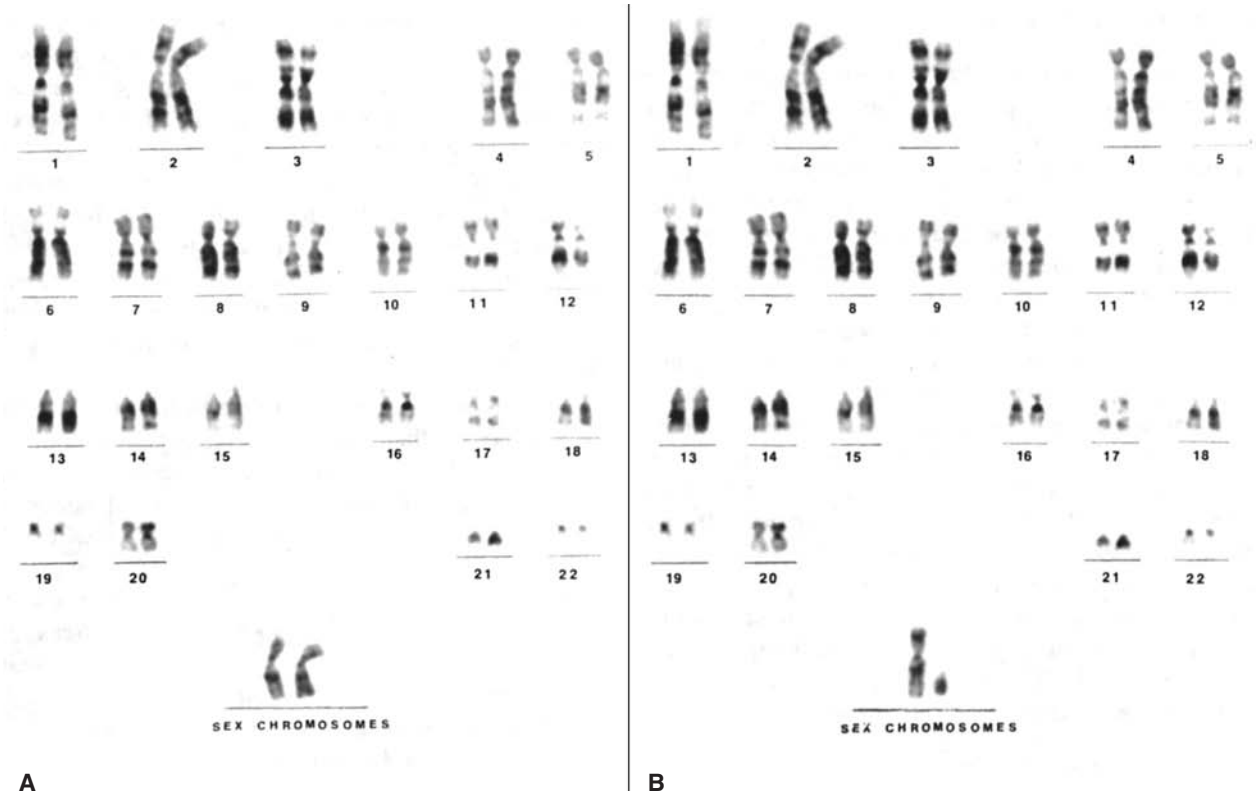

FIGURE 7.1 Photomicrographs of human chromosomes (karyotypes). (**A**) Normal female karyotype. (**B**) Normal male karyotype.

A person's **genome** is the complete set of genes present (about 50,000 to 100,000). A normal genome is abbreviated as 46XX or 46XY (designation of the total number of chromosomes plus a graphic description of the sex chromosomes present). If a chromosomal aberration exists, it is listed after the sex chromosome pattern. In such abbreviations, the letter *p* stands for short arm defects and *q* stands for defects on the long arm of the chromosome. The abbreviation 46XX5p−, for example, is the abbreviation for a female with 46 total chromosomes but with the short arm of chromosome 5 missing (cri-du-chat syndrome). In Down syndrome, the person has an extra chromosome 21, which is abbreviated as 47XX21+ or 47XY21+.

Mendelian Inheritance: Dominant and Recessive Patterns

The principles of genetic inheritance of disease are the same as those that govern genetic inheritance of other physical characteristics, such as eye or hair color. These principles were discovered and described by Gregor Mendel, an Austrian naturalist, in the 1800s and are known as mendelian laws.

A person who has two like genes for a trait—two healthy genes, for example (one from the mother and one from the father)—on two like chromosomes is said to be **homozygous** for that trait. If the genes differ (a healthy gene from the mother and an unhealthy gene from the father, or vice versa), the person is said to be **heterozygous** for that trait. Many genes are dominant in their action over others. When paired with nondominant (recessive) genes, dominant genes are always expressed in preference to the recessive genes. An individual with two homozygous genes for a dominant trait is said to be homozygous dominant; an individual with two genes for a recessive trait is homozygous recessive.

✔ Checkpoint Question 7.1

Amy Alvarez is pregnant with her first child. Her phenotype refers to:

a. Her concept of herself as male or female
b. Whether she has 46 chromosomes
c. Her actual genetic composition
d. Her outward appearance

Inheritance of Disease

Since the entire human genome has been mapped, an increasing number of types of disease inheritance have been identified. (Manipalviratn, Trivax, & Huang, 2007).

Autosomal Dominant Disorders

Although more than 3000 autosomal dominant disorders are known, only a few are commonly seen because the majority of these are not compatible with life after birth. Most of those that do occur cause structural defects. With an autosomal dominant condition, either a person has two unhealthy genes (is homozygous dominant) or is heterozygous, with the gene causing the disease stronger than the corresponding healthy recessive gene for the same trait.

If a person who is heterozygous for an autosomal dominant trait (the usual pattern) mates with a person who is free of the trait, as shown in Figure 7.2A, the chances are even (50%) that a child born to the couple would have the disorder or would be disease and carrier free (i.e., carrying no affected gene for the disorder).

Two heterozygous people with a dominantly inherited disorder are unlikely to choose each other as reproductive partners. If they do, however, their chances of having children free from the disorder decline. There would be only a 25% chance of a child's being disease and carrier free, a 50% chance that the child would have the disorder as both parents do, and a 25% chance that a child would be homozygous dominant (i.e., have two dominant disorder genes), a condition that probably would be incompatible with life (Fig. 7.2B).

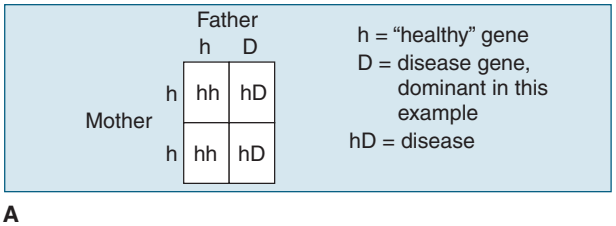
Huntington disease is a progressive neurologic disorder, characterized by loss of motor control and intellectual deterioration, that is a heterozygous inherited autosomal dominant disorder. The symptoms do not manifest themselves until people reach 35 to 45 years of age. Because some people who might develop this disorder want to know before that age if they will develop the disease, a test is now available to analyze for the specific gene on chromosome 4 that causes the disorder (Roze, Saudou, & Caboche, 2008). Unfortunately, there is no cure for Huntington disease, so potentially affected individuals have to make the difficult choice to decide to have the analysis or not, as there is nothing but palliative care for this ultimately fatal disorder (Manipalviratn, Trivax, & Huang, 2007).

Other examples of autosomal dominantly inherited disorders include facioscapulohumeral muscular dystrophy (a disorder that results in muscle weakness), a form of osteogenesis imperfecta (a disorder in which bones are exceedingly brittle), Marfan syndrome (a disorder of connective tissue that results in an individual being thinner and taller than usual and perhaps with associated heart disorders (Stuart & Williams, 2007), and breast and breast/ovarian cancer syndrome that accounts for 5% to 10% of breast cancer in women (Weitzel et al., 2007).

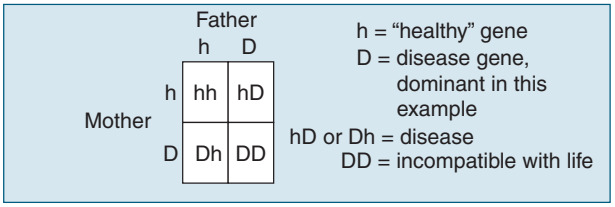
In assessing family genograms (maps of family relationships) for the incidence of inherited disorders, a number of common findings are usually discovered when a dominantly inherited pattern is present in a family:

1. One of the parents of a child with the disorder also will have the disorder (a vertical transmission picture).
2. The sex of the affected individual is unimportant in terms of inheritance.
3. There is usually a history of the disorder in other family members.

Figure 7.3 shows a typical genogram of a family with an autosomal dominantly inherited disorder.



A



B

FIGURE 7.2 Autosomal dominant inheritance.

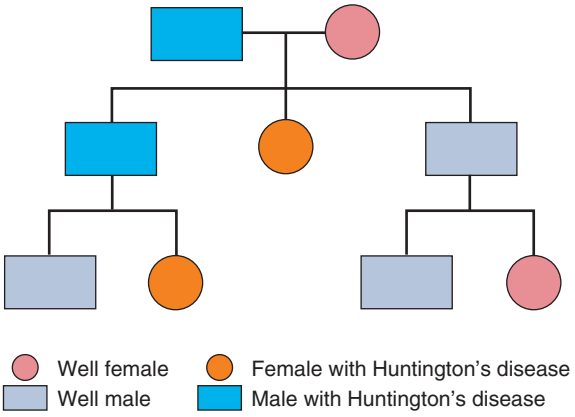


FIGURE 7.3 Family genogram: autosomal dominant inheritance.

Autosomal Recessive Inheritance

More than 1500 autosomal recessive disorders have been identified. In contrast to structural disorders, these tend to be biochemical or enzymatic. Such diseases do not occur unless two genes for the disease are present (i.e., a homozygous recessive pattern). Examples include cystic fibrosis, adrenogenital syndrome, albinism, Tay-Sachs disease, galactosemia, phenylketonuria, limb-girdle muscular dystrophy, and Rh-factor incompatibility.

An example of autosomal recessive inheritance is shown in Figure 7.4A. Both parents are disease free of cystic fibrosis, but both are heterozygous in genotype, so they carry a recessive gene for cystic fibrosis. When this genetic pattern occurs, there is a 25% chance that a child born to a couple will be disease and carrier free (homozygous dominant for the healthy gene); a 50% chance that the child will be, like the parents, free of disease but carrying the unexpressed disease gene (heterozygous); and a 25% chance that the child will have the disease (homozygous recessive).

Suppose a woman with the heterozygous genotype shown in Figure 7.4A mates with a man who has no trait for cystic fibrosis. There is a 50% chance that a child born to them will be completely disorder and carrier free, like the father. Likewise, there is a 50% chance that their child will be heterozygous (i.e., a carrier), like the mother (see Fig. 7.4B). There is no chance in this instance that any of their children will have the disorder. However, they should be counseled that if a child of theirs who carries the trait has children with a sexual partner who also has a recessive gene for the trait, grandchildren could manifest the disease. Cystic fibrosis is caused by an errant gene on the seventh chromosome. As

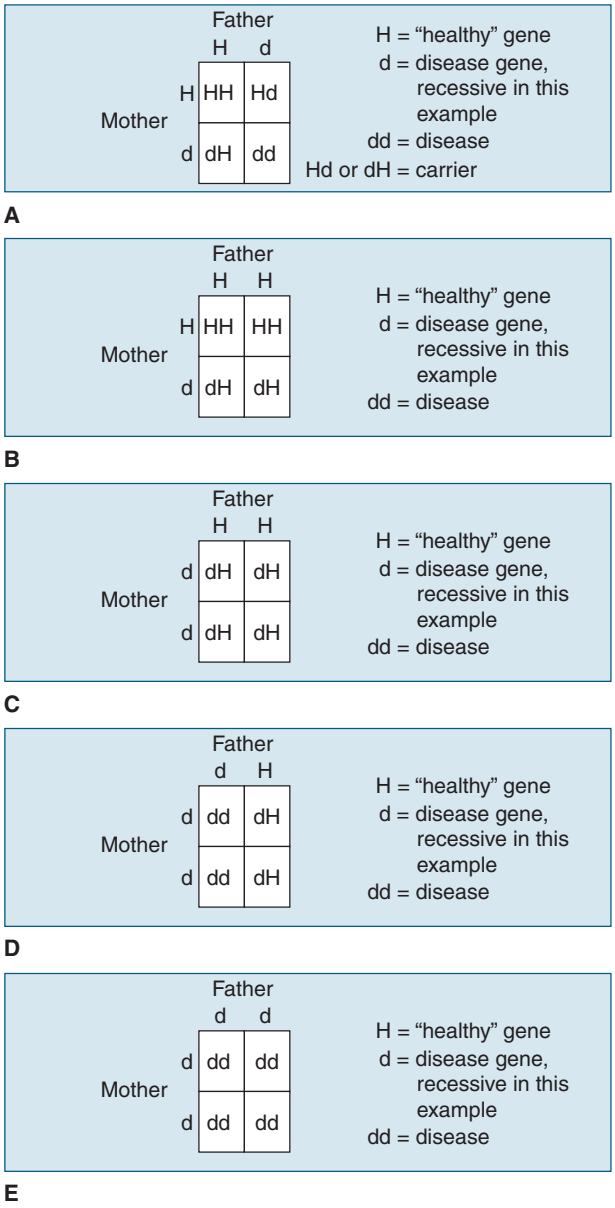

FIGURE 7.4 Autosomal recessive inheritance.

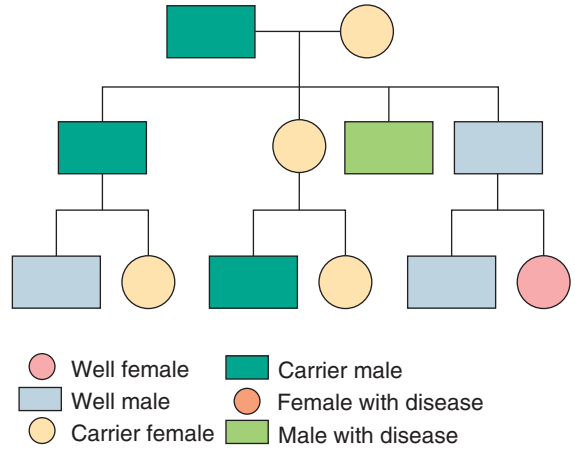

FIGURE 7.5 Family genogram: autosomal recessive inheritance.

many as 1 in every 29 Caucasian people carries the trait. People who are concerned as to whether they have a recessive gene for the disorder can have a DNA analysis to reveal their status (Gardner, 2007).

Twenty years ago, most children with cystic fibrosis died in early childhood and therefore never reached childbearing age. Today, with good management, such children can live to adulthood and have children of their own. If a person with cystic fibrosis (homozygous recessive) should choose a sexual partner without the trait, none of their children would have the disorder, but all would be carriers of a recessive gene for the disorder (see Fig. 7.4C).

If a person with cystic fibrosis mated with a person with an unexpressed gene for the disease, there would be a 50% chance that a child would have the disorder (homozygous) and a 50% chance that he or she would be heterozygous for the disorder (see Fig. 7.4D). If a person with the disorder mated with a person who also had the disorder, as shown in Figure 7.4E, there is a 100% chance that their child would have the disorder.

When family genograms are assessed for the incidence of inherited disease, situations commonly discovered when a recessively inherited disease is present in the family include:

1. Both parents of a child with the disorder are clinically free of the disorder.
2. The sex of the affected individual is unimportant in terms of inheritance.
3. The family history for the disorder is negative—that is, no one can identify anyone else who had it (a horizontal transmission pattern).
4. A known common ancestor between the parents sometimes exists. This explains how both male and female came to possess a like gene for the disorder.

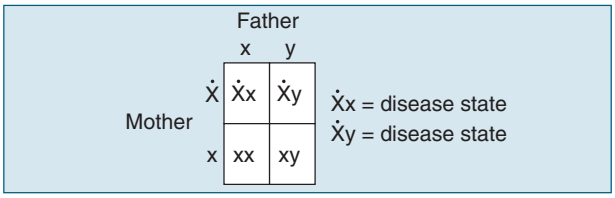
Figure 7.5 shows a typical genogram of a family with an autosomal recessive inherited disorder.

X-Linked Dominant Inheritance

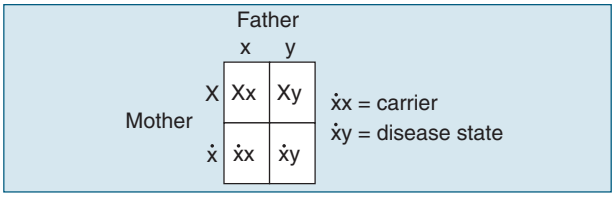
Some genes for disorders are located on, and therefore transmitted only by, the female sex chromosome (the X chromosome). There are about 300 known disorders associated this way and their transmission is termed X-linked inheritance. If the affected gene is dominant, only one X chromosome with the trait need be present for symptoms of the disorder to be manifested (Fig. 7.6A). Family characteristics seen with this type of inheritance usually include:

1. All individuals with the gene are affected (the gene is dominant).
2. All female children of affected men are affected; all male children of affected men are unaffected.
3. It appears in every generation.
4. All children of homozygous affected women are affected. Fifty percent of the children of heterozygous affected women are affected (Fig. 7.7).

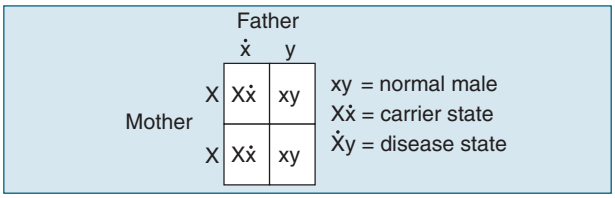
An example of a disease in this group is Alport's syndrome, a progressive kidney failure disorder.



A



B



C

FIGURE 7.6 Sex-linked inheritance: (**A**) sex-linked dominant; (**B, C**) sex-linked recessive.

X-Linked Recessive Inheritance

The majority of X-linked inherited disorders are not dominant, but recessive. When the inheritance of a recessive gene comes from both parents (homozygous recessive) it appears to be incompatible with life. Therefore, females who inherit the affected gene will be heterozygous, and, because a normal gene is also present, the expression of the disease will be blocked. On the other hand, because males have only one X chromosome, the disease will be manifested in any male children who receive the affected gene from their mother.

Hemophilia A and Christmas disease (blood-factor deficiencies), color blindness, Duchenne (pseudohypertrophic) muscular dystrophy, and fragile X syndrome (a cognitive challenge syndrome) are examples of this type of inheritance. Such a pattern is shown in Figure 7.6B, in which the mother has the affected gene on one of her X chromosomes and the father is disease-free. When this occurs, the chances are 50% that a male child will manifest the disease and 50% that a female child will carry the disease gene. If the father has the disease and chooses a sexual partner who is free of the disease gene, the chances are 100% that a daughter will have the sex-linked recessive gene, but there is no chance that a son will have the disease (see Fig. 7.6C).

When X-linked recessive inheritance is present in a family, a family genogram will reveal:

1. Only males in the family will have the disorder.
2. A history of girls dying at birth for unknown reasons often exists (females who had the affected gene on both X chromosomes).
3. Sons of an affected man are unaffected.
4. The parents of affected children do not have the disorder.

Figure 7.8 shows a typical family genogram in which there is an X-linked recessive inheritance pattern.

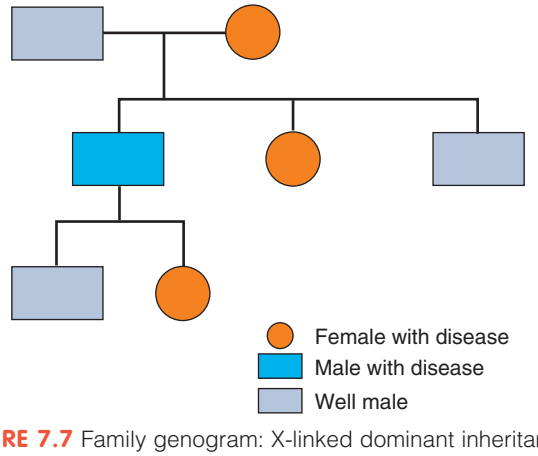


FIGURE 7.7 Family genogram: X-linked dominant inheritance.

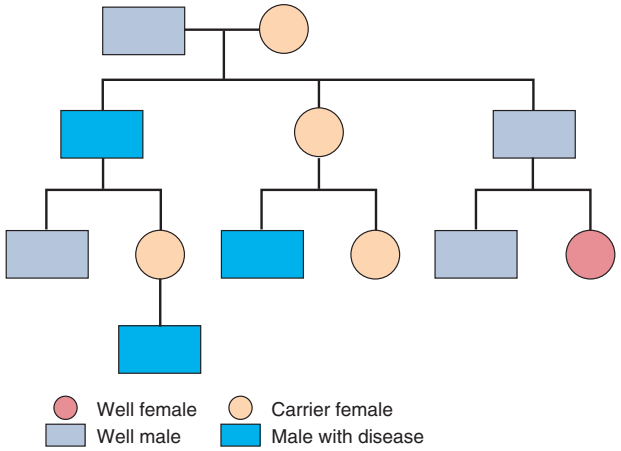

FIGURE 7.8 Family genogram: X-linked recessive inheritance.

Y-Linked Inheritance. Although genes responsible for features such as height and tooth size are found on the Y chromosome, tall stature and perhaps aggressive personality are the only consistent phenotypic features associated with having an extra Y chromosome (karyotype 47XYY) (Pyeritz, 2009).

What if... Amy Alvarez had a recessive X-linked chromosome for a disorder such as, hemophilia, and said that she wanted to have all boys because they would not show symptoms? Would she be well informed?

Multifactorial (Polygenic) Inheritance

Many childhood disorders such as heart disease, diabetes, pyloric stenosis, cleft lip and palate, neural tube disorders, hypertension, and mental illness tend to have a higher-than-usual incidence in some families. They appear to occur from multiple gene combinations possibly combined with environmental factors. Diabetes has been extensively studied in this regard. Certain human lymphocyte antigens (HLAs)

inherited from both parents appear to play a role in genetic susceptibility to diabetes mellitus. Children who will develop diabetes mellitus can be shown to have an increased frequency of HLA B8, B15, DR3, and DR4 on chromosome 6. They lack DR2, an HLA that appears to be protective against diabetes mellitus.

Diseases caused by multiple factors this way do not follow Mendelian laws because more than a single gene or HLA is involved. It may be more difficult for parents to understand why these disorders occur because their incidence is so unpredictable. A family history, for instance, may reveal no set pattern. Some of these conditions have a predisposition to occur more frequently in one sex (cleft palate occurs more often in girls than boys), but they can occur in either sex.

Mitochondrial Inheritance. Mitochondria are cell organelles that are found outside the cell nucleus. They are inherited solely from the cytoplasm of the ovum. Male carriers cannot pass a disorder carried in the mitochondria to any of their children. Females, on the other hand, will pass mitochondrial disorders to 100% of their children. A number of rare myopathies (muscle diseases) are inherited in this way (Manipalviratn, Trivax, & Huang, 2007).

Imprinting

Imprinting refers to the differential expression of genetic material and allows researchers to identify whether the chromosomal material has come from the male or female parent. In some instances, such as hydatidiform mole, an embryonic disorder (see Chapter 21), it can be shown that two separate sperm fertilized an ovum (Dorigo, Martinez-Maza, & Berek, 2007). In Prader-Willi syndrome, a chromosome 15 abnormality in which children are severely obese and cognitively challenged, no paternal contribution is present at certain gene points (Benarroch et al., 2007).

Chromosomal Abnormalities (Cytogenic Disorders)

In some instances of genetic disease, the abnormality occurs not because of dominant or recessive gene patterns but through a fault in the number or structure of chromosomes which results in missing or distorted genes. When chromosomes are photographed and displayed, the resulting arrangement is termed a **karyotype.** The number of chromosomes and specific parts of chromosomes can be identified by karyotyping or by a process termed fluorescent in situ hybridization (FISH).

Nondisjunction Abnormalities

Meiosis is the type of cell division in which the number of chromosomes in the cell is reduced to the haploid (half) number for reproduction (i.e., 23 rather than 46 chromosomes). All sperm and ova undergo a meiosis cell division early in formation. During this division, half of the chromosomes are attracted to one pole of the cell and half to the other pole. The cell then divides cleanly, with 23 chromosomes in the first new cell and 23 chromosomes in the second new cell. Chromosomal abnormalities occur if the division is uneven **(nondisjunction).** The result may be that one new sperm cell or ovum has 24 chromosomes and the other has only 22 (Fig. 7.9). If a spermatozoon or ovum

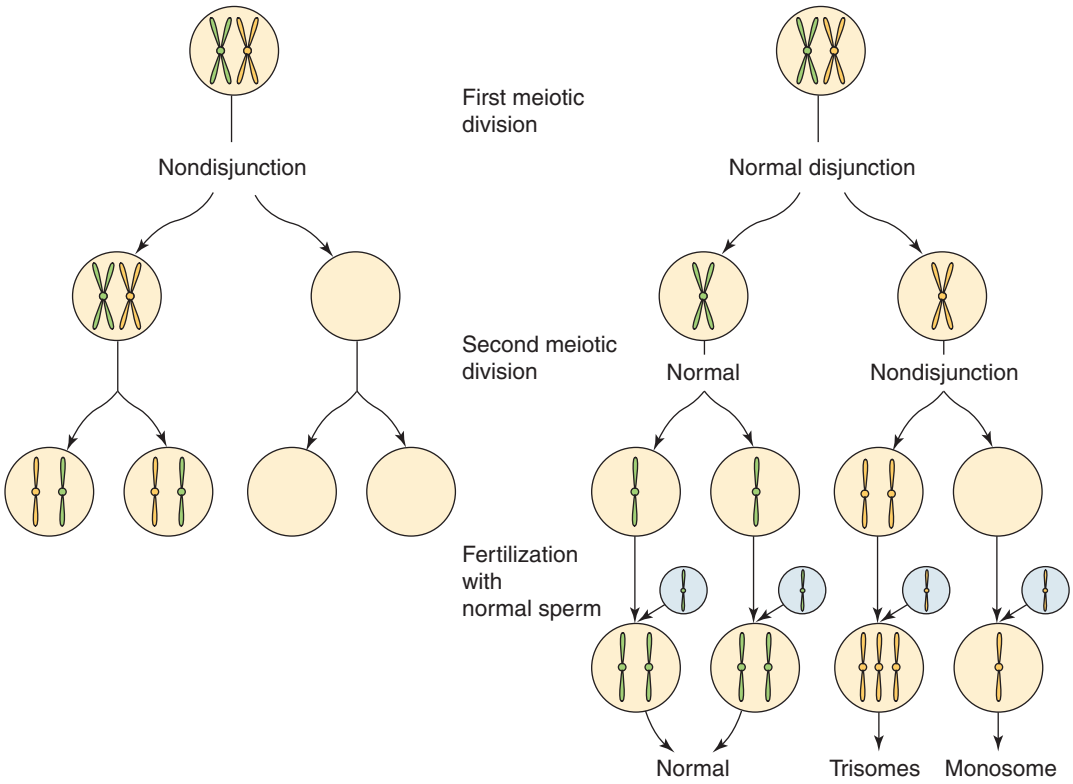

FIGURE 7.9 Process of nondisjunction at the first and second meiotic divisions of the ovum and fertilization with normal sperm.

with 24 or 22 chromosomes fuses with a normal spermatozoon or ovum, the zygote (sperm and ovum combined) will have either 47 or 45 chromosomes, not the normal 46. The presence of 45 chromosomes does not appear to be compatible with life, and the embryo or fetus probably will be aborted. Down syndrome (trisomy 21) (47XX21+ or 47XY21+) is an example of a disease in which the individual has 47 chromosomes. There are three rather than two copies of chromosome 21 (Fig. 7.10).

The incidence of Down syndrome increases with advanced maternal age and is highest if the mother is older than 35 years and the father is older than 55. Thus, aging seems to present an obstacle to clean cell division. The incidence is 1:100 in women older than 40 years, compared with 1:1500 in women younger than 20 years (Dorigo, Martinez-Maza, & Berek, 2007). Other examples of cell nondisjunction include trisomy 13 (Fig. 7.11) and trisomy 18 (cognitively challenged syndromes).

If nondisjunction occurs in the sex chromosomes, other types of abnormalities occur. Turner and Klinefelter syndromes are the most common types. In Turner syndrome (45XO), marked by webbed neck, short stature, sterility, and possibly cognitive challenge, the individual, although female, has only one X chromosome (or has two X chromosomes but one is defective). Her appearance (phenotype) is female because of the one X chromosome. In Klinefelter's syndrome (marked by sterility and possibly cognitive challenge), the individual has male genitals but the sex chromosomal pattern is 47XXY or an extra X chromosome is present.

Deletion Abnormalities

Deletion abnormalities are a form of chromosome disorder in which part of a chromosome breaks during cell division, causing the affected person to have the normal number of chromosomes plus or minus an extra portion of a chromosome, such as 45.75 chromosomes or 47.5. For example, in cri-du-chat syndrome (46XY5q−), one portion of chromosome 5 is missing.

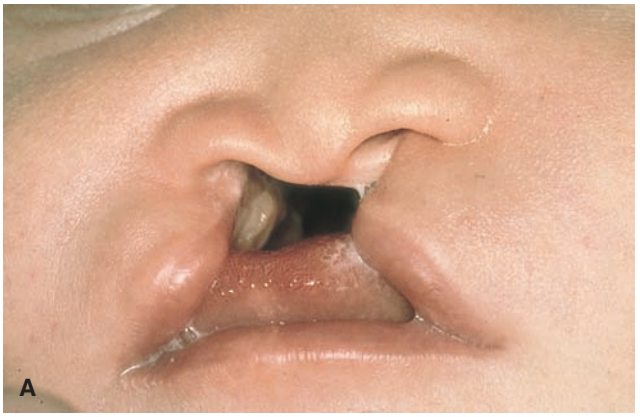

FIGURE 7.11 An infant with trisomy 13 has (**A**) a cleft palate and (**B**) supernumerary digits (polydactyly). (© NMSB/Custom Medical Stock Photograph.)

Translocation Abnormalities

Translocation abnormalities are perplexing situations in which a child gains an additional chromosome through another route. A form of Down syndrome occurs as an example of this. In this instance, one parent of the child has the correct number of chromosomes (46), but chromosome 21 is misplaced; it is abnormally attached to another chromosome, such as chromosome 14 or 15. The parent's appearance and functioning are normal because the total chromosome count is a normal 46. He or she is termed a balanced translocation carrier.

If, during meiosis, this abnormal chromosome 14 (carrying the extra 21 chromosome) and a normal chromosome 21 from the other parent are both included in one sperm or ovum, the resulting child will have a total of 47 chromosomes because of the extra number 21. Such a child is said to have an unbalanced translocation syndrome. The phenotype (appearance) of the child will be indistinguishable from that of a child with the form of Down syndrome that occurs from simple nondisjunction.

About 2% to 5% of children with Down syndrome have this type of chromosome pattern. It is important that parents who are translocation carriers are identified because their chance of having a child born with Down syndrome is higher than normal and not associated with aging. If the father is the carrier, this risk is about 5%; if the mother is the carrier, the risk is about 15%. As many as 15% of couples who have frequent early spontaneous miscarriages may have

this type of chromosomal aberration (Manipalviratn, Trivax, & Huang, 2007).

Mosaicism

Usually, a nondisjunction abnormality occurs during the meiosis stage of cell division, when sperm and ova halve their number of chromosomes. Mosaicism is an abnormal condition that is present when the nondisjunction disorder occurs after fertilization of the ovum, as the structure begins mitotic (daughter-cell) division. If this occurs, different cells in the body will have different chromosome counts. The extent of the disorder depends on the proportion of tissue with normal chromosome structure to tissue with abnormal chromosome constitution. Children with Down syndrome who have near-normal intelligence may have this type of pattern. The occurrence of such a phenomenon at this stage of development suggests that a teratogenic (harmful to the fetus) condition, such as x-ray or drug exposure, existed at that point to disturb normal cell division. This genetic pattern in a female with Down syndrome caused by mosaicism would be abbreviated as 46XX/47XX21+ to show that some cells contain 46 and some 47 chromosomes.

Isochromosomes

If a chromosome accidentally divides not by a vertical separation but by a horizontal one, a new chromosome with mismatched long and short arms can result. This is an isochromosome. It has much the same effect as a translocation abnormality when an entire extra chromosome exists. Some instances of Turner syndrome (45XO) may occur because of isochromosome formation.

✔ Checkpoint Question 7.2

Amy Alvarez is a balanced translocation carrier for Down syndrome. This means that:

a. All of her children will be born with some aspect of Down syndrome.
b. All of her female but none of her male children will have Down syndrome.
c. She has a greater than average chance a child will have Down syndrome.
d. It is impossible for any of her children to be born with Down syndrome.

GENETIC COUNSELING

Any individual concerned about the possibility of transmitting a disease to his or her children should have access to genetic counseling for advice on the inheritance of disease. Such counseling can serve to:

- Provide concrete, accurate information about the process of inheritance and inherited disorders
- Reassure people who are concerned that their child may inherit a particular disorder that the disorder will not occur
- Allow people who are affected by inherited disorders to make informed choices about future reproduction
- Offer support to people who are affected by genetic disorders

Genetic counseling can result in making individuals feel "well" or free of guilt for the first time in their lives if they discover that the disorder they were worried about was not an inherited one but was rather a chance occurrence.

In other instances, counseling results in informing individuals that they are carriers of a trait that is responsible for a child's condition. Even when people understand that they have no control over this, knowledge about passing a genetic disorder to a child can cause guilt and self-blame. Marriages and relationships can end unless both partners receive adequate support.

It is essential that information revealed in genetic screening be kept confidential, because such information could be used to damage a person's reputation or harm a future career or relationship. This necessity to maintain confidentiality prevents health care providers from alerting other family members about the inherited characteristic unless the member requesting genetic assessment has given consent for the information to be revealed. In some instances, a genetic history reveals information, such as that a child has been adopted or is the result of artificial insemination, or that a current husband is not the child's father information that a family doesn't want revealed. The member of the family seeking counseling has the right to decide whether this information may be shared with other family members.

The ideal time for counseling is before a first pregnancy. Some couples take this step even before committing themselves to marriage so they can offer not to involve their partner in a marriage if children of the marriage would be subject to a serious inherited disorder. Other couples first become aware of the need for genetic counseling after the birth of a first child with a disorder. It is best if they receive counseling before a second pregnancy. A couple may not be ready for this, however, until the initial shock of their first child's condition and the grief reaction that may accompany it have run their course. Only then are they ready for information and decision making (Box 7.2).

Even if a couple decides not to have any more children, it is important that they know that genetic counseling is available should their decision change. Also be certain that they are aware that as their children reach reproductive age, they, too, may benefit from genetic counseling. Couples who are most apt to benefit from a referral for genetic testing or counseling include:

- *A couple who has a child with a congenital disorder or an inborn error of metabolism.* Many congenital disorders occur because of teratogenic invasion during pregnancy that has gone unrecognized. Learning that the abnormality occurred by chance rather than inheritance is important, because the couple will not have to spend the remainder of their childbearing years in fear that another child may be born with the disorder (although a chance circumstance could occur again). If a definite teratogenic agent, such as a drug a woman took during pregnancy, can be identified, the couple can be advised about preventing this occurrence in a future pregnancy.
- *A couple whose close relatives have a child with a genetic disorder such as a translocation disorder or an inborn error of metabolism.* It is difficult to predict the expected occurrence of many "familial" or multifactorial disorders. In these instances, counseling should be aimed at educating the couple about the disorder, treatment available, and the

BOX 7.2 * Focus on Family Teaching

Genetic Screening

Q. Amy Alvarez is anxious to have her fetus' health confirmed. She asks you, "Why do I have to wait so late in pregnancy for genetic studies by amniocentesis?"

A. Genetic analysis is done on skin cells obtained from amniotic fluid. The test cannot be scheduled until enough amniotic fluid is present for analysis. Fortunately, this analysis now can be done as early as the 12th week of pregnancy.

Q. Why do laboratories take so long to return karyotyping results?

A. Karyotyping has traditionally (and by necessity) been done on cells at the metaphase (center phase) of division, so the laboratory had to delay testing until the cells had grown to reach this phase. New techniques now allow analysis to be done immediately so that results are available much sooner.

Q. If there are no inherited diseases in a couple's family, should the couple have a karyotype done "just to be sure" before they have their first baby?

A. A genetic analysis is not routinely recommended unless there is evidence or suspicion of genetic disease in the family. Remember that karyotyping reveals only diseases that are present on chromosomes. A "perfect" karyotype does not guarantee that a newborn will not be ill in a noninherited way.

Q. If chorionic villi are part of the placenta, how does testing them reveal the chromosome picture of the fetus?

A. Because the fetus and all accessory structures arise from the same single ovum and sperm, the placenta contains the same cells as the fetus.

prognosis or outcome of the disorder. Based on this information, the couple can make an informed reproductive choice about children.

- *Any individual who is a known balanced translocation carrier.* Understanding of his or her own chromosome structure and the process by which future children could be affected can help such an individual make an informed choice about reproduction or can alert him or her to the importance of fetal karyotyping during any future pregnancy (sees Focus on Nursing Care Planning Box 7.3).
- *Any individual who has an inborn error of metabolism or chromosomal disorder.* Any person with a disease should know the inheritance pattern of the disease and, like those who are balanced translocation carriers, should be aware if prenatal diagnosis is possible for his or her particular disorder.
- *A consanguineous (closely related) couple.* The more closely related are two people, the more genes they have in common, so the more likely it is that a recessively inherited disease will be expressed. A brother and sister, for example, have about 50% of their genes in common; first cousins have about 12% of their genes in common.
- *Any woman older than 35 years and any man older than 55 years.* This is directly related to the association between advanced parental age and the occurrence of Down syndrome.
- *Couples of ethnic backgrounds in which specific illnesses are known to occur.* Mediterranean people, for example, have a high incidence of thalassemia, a blood disorder; those with a Chinese ancestry have a high incidence of glucose-6-phosphate dehydrogenase (G6PD) deficiency, a blood disorder where destruction of red cells can occur (Cappellini & Fiorelli, 2008).

Nursing Responsibilities

Nurses play important roles in assessing for signs and symptoms of genetic disorders, in offering support to individuals who seek genetic counseling, and in helping with reproductive genetic testing procedures by such actions as:

- Explaining to a couple what procedures they can expect to undergo
- Explaining how different genetic screening tests are done and when they are usually offered
- Supporting a couple during the wait for test results
- Assisting couples in values clarification, planning, and decision making based on test results

A great deal of time may need to be spent offering support for a grieving couple confronted with the reality of how tragically the laws of inheritance have affected their lives. Genetic counseling is a role for nurses, however, only if they are adequately prepared in the study of genetics because without this background, genetic counseling can be dangerous and destructive (Box 7.4).

Whether one is acting as a nursing member of a genetic counseling team or as a genetic counselor, some common principles apply. First, the individual or couple being counseled needs a clear understanding of the information provided. People may listen to the statistics of their situation ("Your child has a 25% chance of having this disease") and construe a "25% chance" to mean that if they have one child with the disease, they can then have three other children without any worry. A 25% chance, however, means that with each pregnancy there is a 25% chance that the child will have the disease (chance has no "memory" of what has already happened). It is as if the couple had four cards, all aces, with the ace of spades representing the disease. When a card is drawn from the set of four, the chance of it being the ace of spades is 1 in 4 (25%). When the couple is ready to have a second child, it is as if the card drawn during the first round is returned to the set, so the chance of drawing the ace of spades in the second draw is exactly the same as in the first draw. Similarly, the couple's chances of having a child with the disease remain 1 in 4 in each successive pregnancy.

Second, it is never appropriate for any health care provider to impose his or her own values or opinions on others. Individuals with known inherited diseases in their family must face difficult decisions, such as how much genetic testing to undergo or whether to terminate a pregnancy that will result in a child with a specific genetic disease. Be certain that couples have been made aware of all the options available to them; then leave them to think about the options and make their own decisions by themselves. Help them to understand that nobody is judging their decision because they are the ones who must live with the decision.

BOX 7.3 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Couple Concerned About a Genetic Disorder in Future Children

Amy Alvarez is a woman you meet at a genetic counseling center. She was adopted as a newborn and never felt a need to locate her birth parents because her adoptive parents provided a "close to perfect" childhood for her. After college, she married the most eligible bachelor in her hometown. She is now pregnant with her first child. At 15 weeks into her pregnancy, she has been advised her child may have translocation Down syndrome. She asks you, "Why is this happening? There's no disease like this in either of our families."

Family Assessment ✻ Client's family history is unknown because she was adopted. Husband's family has no history of Down syndrome. Client is presently attending law school. Husband works as a county public defender. Family lives in condo by lakefront. Finances rated as "good."

Client Assessment ✻ Client's and husband's past medical histories show no evidence of major health problems. Pregnancy is at 15 weeks. Maternal serum alpha-fetoprotein showed decreased level.

Nursing Diagnosis ✻ Health-seeking behaviors related to knowledge of possible genetic disorder inheritance

Outcome Criteria ✻ Couple accurately states the cause of this genetic disorder; agrees to further genetic testing; describes range of options open to them so any decision they make regarding the pregnancy is an informed one.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		History		
Nurse practitioner/ nurse	Obtain a detailed history and physical examination of the client and spouse, including information about family members and other relatives.	Perform a physical examination to document current health.	A thorough history and physical examination provide baseline information to direct need for follow-up testing.	Couple participates fully in health examination, so family history obtained is as complete as possible.
		Activities of Daily Living		
Nurse	Explore the meaning of genetic testing with the couple and ask how this will affect their everyday life.	Encourage couple to verbalize feelings and concerns. Allow time for questions and answers.	Exploration, verbalization, and active questioning provide a safe outlet for feelings, help to increase the other partner's awareness of needs, and open lines of communication.	Couple describes the effect on their life of needing genetic screening; asks questions as needed.
		Consultations		
Physician/ nurse	Assess whether couple would like to speak to an expert in the field of genetics to clarify their understanding.	Refer client to genetic counselor so she can be made aware of exact inheritance pattern and options available.	Couples cannot make informed choices without being aware of extent of problem.	Couple meets with genetic counselor within 1 week's time

(continued)

BOX 7.3 ✻ Focus on Nursing Care Planning (continued)

		Procedures/Medications		
Physician/ nurse	Schedule an amniocentesis for karyotyping. Develop a family genogram for client and spouse.	Be certain couple receives written documentation of chromosome disorder to take to genetic counselor.	Good communication between health care providers helps to ensure a positive outcome. A family genogram may provide additional information about the client's and spouse's family histories.	Couple receives results of tests in a timely and appropriate manner. A family genogram is developed and maintained with health documentation.
		Nutrition		
Dietitian/nurse	Assess the couple's nutrition patterns.	Analyze whether couple maintains healthy diet during testing and consultation period.	A healthy diet during pregnancy is important if pregnancy will be continued.	Client confirms that she continues to take prenatal vitamins and adequate protein intake.
		Patient/Family Education		
Nurse practitioner/ nurse	Ask couple if they have further questions about their particular inheritance pattern.	Review with the couple the mode of transmission and chances for manifesting Down syndrome in children.	Down syndrome may be inherited at a higher incidence in a balanced translocation carrier than in others.	Couple describes accurately the mode of transmission of Down syndrome.
		Spiritual/Psychosocial/Emotional Needs		
Nurse	Assess whether couple would be interested in learning some activities to reduce stress.	Instruct the couple in positive coping mechanisms. Include activities such as information sharing, relaxation and breathing exercises, and physical activity. Provide emotional support and guidance to the couple throughout testing.	Positive coping mechanisms assist in controlling fear and minimizing its intensity, thus promoting effective problem solving. Emotional support from a variety of sources helps to alleviate some of the stress and anxiety associated with genetic testing.	Couple demonstrates positive coping mechanisms. Couple states that the emotional support they received throughout their period of genetic screening and counseling was adequate.
		Discharge Planning		
Social worker/ nurse	Assess community for support organizations available.	If the couple chooses to continue the pregnancy, refer them to national support group (Down Syndrome Foundation) and local parents support group.	Additional counseling and support may be necessary as pregnancy progresses or at birth of child. Use of community resources can provide additional support and help reduce feelings of isolation and loneliness.	Couple records the names and telephone numbers of support groups as well as the genetic counseling team and states they will keep numbers available if they should need further future information.

BOX 7.4 ✻ Focus on Communication

Amy Alvarez tells you that her mother has advised her not to have more children, rather than risk having a child with Down syndrome.

Less Effective Communication

Nurse: Hello, Amy. What's the reason you've come to the clinic today?
Amy: I need to know what is the chance that all my children will have Down syndrome.
Nurse: You're only 26, far too young to be worrying about that. Down syndrome only occurs in older women.
Amy: Thanks. It's good to get good information.

More Effective Communication

Nurse: Hello, Amy. What's the reason you've come to the clinic today?
Amy: I need to know what is the chance that all my children will have Down syndrome.
Nurse: That isn't the kind of question I can answer off the top of my head. Let me ask you some questions about your family to get started toward an answer.

Because we live in an age in which information can be obtained quickly, people may believe that predictions about the inheritance of disorders can also be supplied quickly. More important than getting information to people quickly is being certain they are getting it accurately. Because Amy is a balanced translocation carrier, more aspects than her age must be considered.

✔ Checkpoint Question 7.3

Amy Alvarez was told at a genetic counseling session that she is a balanced translocation carrier for Down syndrome. What would be your best action regarding this information?

a. Be certain all of her family members understand what this means.
b. Discuss the cost of various abortion techniques with Amy.
c. Be sure Amy knows that she should not have any more children.
d. Ask Amy if she has any questions that you could answer for her.

Assessment for Genetic Disorders

Genetic assessment begins with careful study of the pattern of inheritance in a family. A history, physical examination of family members, and laboratory analysis, such as karyotyping or DNA analysis, are performed to define the extent of the problem and the chance of inheritance.

History

Taking a health history for a genetic diagnosis is often difficult because the facts detailed may evoke uncomfortable emotions such as sorrow, guilt, or inadequacy in parents. Try, however, to obtain information and document diseases in family members for a minimum of three generations. Remember to include half brothers and sisters or anyone related in any way as family. Document the mother's age because some disorders increase in incidence with age. Document also whether the parents are consanguineous or related to each other.

Documenting the family's ethnic background can reveal risks for certain disorders that occur more commonly in some ethnic groups than others. If the couple seeking counseling is unfamiliar with their family history, ask them to talk to senior family members about other relatives (grandparents, aunts, uncles) before they come for an interview. Have them ask specifically for instances of spontaneous miscarriage or children in the family who died at birth. In many instances, these children died of unknown chromosomal disorders or were miscarried because of one of the 70 or more known chromosomal disorders that are inconsistent with life. Many people have only sketchy information about their families, such as, "The baby had some kind of nervous disease" or "Her heart didn't work right." Attempt to obtain more information by asking the couple to describe the appearance or activities of the affected individual or asking for permission to obtain health records.

An extensive prenatal history of any affected person should be obtained to determine whether environmental conditions could account for the condition. Based on the above information, draw a family genogram (see Fig. 7.7). Such a diagram helps to not only identify the possibility of a chromosomal disorder occurring in a particular couple's children but also helps to identify other family members who might benefit from genetic counseling.

When a child is born dead, parents are advised to have a chromosomal analysis and autopsy performed on the infant. If at some future date they wish genetic counseling, this would allow their genetic counselor to have additional medical information.

Physical Assessment

Because genetic disorders often occur in varying degrees of expression, a careful physical assessment of any family member with a disorder, that child's siblings, and the couple seeking counseling is needed. It is possible for an individual to have a minimal expression of a disorder that has gone previously undiagnosed. During inspection, pay particular attention to certain body areas, such as the space between the eyes; the height, contour, and shape of ears; the number of fingers and toes, and the presence of webbing. **Dermatoglyphics** (the study of surface markings of the skin) can also be helpful. Note any abnormal fingerprints or palmar creases as these are present with some disorders. Abnormal hair whorls or coloring of hair can also be present.

Careful inspection of newborns is often sufficient to identify a child with a potential chromosomal disorder. Infants with multiple congenital anomalies, those born at less than 35 weeks' gestation, and those whose parents have had other children with chromosomal disorders need extremely close assessment. Table 7.1 lists the physical characteristics suggestive of some common inherited syndromes in children.

Diagnostic Testing

Many diagnostic tests are available to provide important clues about possible disorders (Pyeritz, 2009). Before pregnancy, karyotyping of both parents and an already affected

TABLE 7.1 ✻ Common Physical Characteristics of Children With Chromosomal Syndromes

Characteristic	Probable Syndrome
Late closure of fontanelles	Down syndrome
Bossing (prominent forehead)	Fragile X syndrome
Microcephaly	Trisomy 18, trisomy 13
Low-set ears	Trisomy 18, trisomy 13
Slant of eyes	Down syndrome
Epicanthal fold	Down syndrome
Abnormal iris color	Down syndrome
Large tongue	Down syndrome
Prominent jaw	Fragile X syndrome
Low-set hairline	Turner syndrome
Multiple hair whorls	Trisomy 18, trisomy 13
Webbed neck	Turner syndrome
Wide-set nipples	Trisomy 13
Heart abnormalities	Many syndromes
Large hands	Fragile X syndrome
Clinodactyly	Down syndrome
Overriding of fingers	Trisomy 18
Rocker-bottom feet	Trisomy 13
Abnormal dermatoglyphics	Down syndrome
Simian crease on palm	Down syndrome
Absence of secondary sex characteristics	Klinefelter and Turner syndromes

child provides a picture of the chromosome pattern that can be used to predict occurences in future children. Once a woman is pregnant, several other tests may be performed to help in the prenatal diagnosis of a genetic disorder. These include maternal serum alpha-fetoprotein (MSAFP), chronic villi sampling (CVS), amniocentesis, percutaneous umbilical blood sampling (PUBS), ultrasound, and fetoscopy.

Karyotyping. For karyotyping, a sample of peripheral venous blood or a scraping of cells from the buccal membrane is taken. Cells are allowed to grow until they reach metaphase, the most easily observed phase. Cells are then stained, placed under a microscope, and photographed. Chromosomes are identified according to size, shape, and stain; cut from the photograph, and arranged as in Figure 7.1. Any additional, lacking, or abnormal chromosomes can be visualized by this method.

A newer method of staining, FISH, allows karyotyping to be done immediately, rather than waiting for the cells to reach metaphase. This makes it possible for a report to be obtained in only 1 day. Fetal skin cells can be obtained by amniocentesis or CVS. A few fetal cells circulate in the maternal bloodstream, most noticeably trophoblasts, lymphocytes, and granulocytes. They are present but few in number during the first and second trimesters but plentiful during the third trimester. Such cells can be cultured and used for genetic testing for such disorders as the trisomies.

Maternal Serum Screening. Alpha-fetoprotein (AFP) is a glycoprotein produced by the fetal liver that reaches a peak in maternal serum between the 13th and 32nd week of pregnancy. The level is elevated with fetal spinal cord disease (more than twice the value of the mean for that gestational age) and is decreased in a fetal chromosomal disorder such as trisomy 21. Most pregnant women have an MSAFP test done routinely at the 15th week of pregnancy. If the result is abnormal, amniotic fluid is then assessed. Unfortunately, the MSAFP test has a false-positive rate of about 30% if the date of conception is not well documented. Use of a "triple study" (AFP, estriol, and hCG) reduces this false-positive rate, although false-positive reports still occur.

Analysis of a pregnancy-associated plasma protein A, which is also increased with a Down syndrome pregnancy, and measurement of the fetal neck thickness by ultrasound are still other measures used for analysis if an MSAFP test is positive. Women with an elevated serum result need support while they wait for ultrasound or amniocentesis confirmation as they are facing what may be a very grave finding in their infant. Receiving a false-positive report is unfortunate as it can potentially interfere with the mother's bonding with her infant.

Chorionic Villi Sampling. CVS is a diagnostic technique that involves the retrieval and analysis of chorionic villi from the growing placenta for chromosome or DNA analysis (Alfirevic, Mujezinovic, & Sundbert, 2009). The test is highly accurate and yields no more false-positive results than does amniocentesis. Although this procedure may be done as early as week 5 of pregnancy, it is more commonly done at 8 to 10 weeks. With this technique, the chorion cells are located by ultrasound. A thin catheter is then inserted vaginally, or a biopsy needle is inserted abdominally or intravaginally, and a number of chorionic cells are removed for analysis (Fig. 7.12). CVS carries a small risk (less than 1%) of causing excessive bleeding, leading to pregnancy loss. There have been some instances of children being born with missing limbs after the procedure (limb reduction syndrome). This has occurred with a high enough frequency that women need to be well informed of these risks beforehand.

After CVS, instruct a woman to report chills or fever suggestive of infection or symptoms of threatened miscarriage (uterine contractions or vaginal bleeding). Women with an Rh-negative blood type need Rh immune globulin administration after the procedure to guard against isoimmunization in the fetus.

The cells removed in CVS are karyotyped or submitted for DNA analysis to reveal whether the fetus has a genetic disorder. Because chorionic villi cells are rapidly dividing, results are available quickly, perhaps as soon as the next day. If a twin or multiple pregnancy is present, with two or more separate placentas, cells should be removed separately from each placenta. Because fraternal twins are derived from separate ova, one twin could have a chromosomal abnormality while the other does not.

Not all inherited diseases can be detected by CVS. Be certain that parents understand that only those disorders involving abnormal chromosomes or nondisjunction, and those whose specific gene location is known, can be identified by CVS. The test is not apt to reveal the extent of spinal cord abnormalities, for example.

Table 7.2 shows common chromosomal disorders that can be diagnosed prenatally through karyotyping. Additional

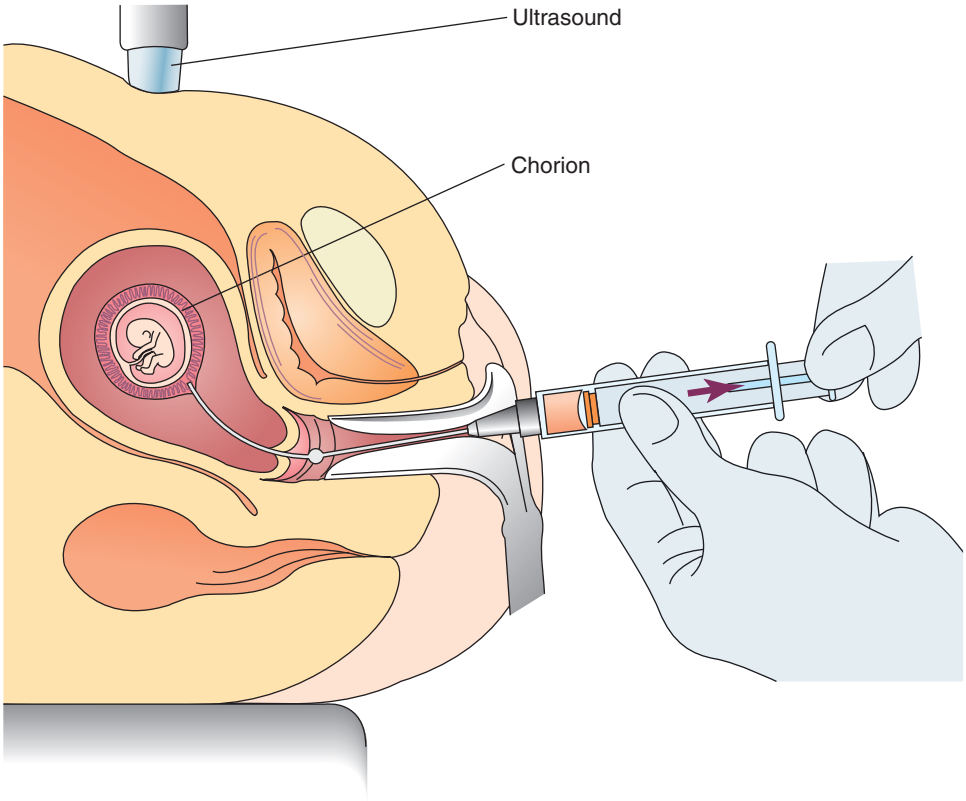

FIGURE 7.12 Chorionic villi sampling. Since the villi arise from trophoblast cells, their chromosome structure is the same as in the fetus.

TABLE 7.2 ✻ Common Genetic Disorders That Can Be Detected by Amniocentesis or Chorionic Villi Sampling

Syndrome	Chromosomal Characteristics	Clinical Signs
Down syndrome	Extra chromosome 21	Cognitively challenged Protruding tongue Epicanthal folds Hypotonia
Translocation Down syndrome	Translocation of a chromosome, perhaps 21/14	Same clinical signs as trisomy 21
Trisomy 18	Extra chromosome 18	Cognitively challenged Congenital malformations
Trisomy 13	Extra chromosome 13	Cognitively challenged Multiple congenital malformations Eye agenesis
Cri-du-chat syndrome	Deletion of short arm of chromosome 5	Cognitively challenged Facial structure anomalies Peculiar cat-like cry
Fragile X syndrome	Distortion of the X chromosome	Cognitively challenged
Philadelphia chromosome	Deletion of one arm of chromosome 21	Chronic granulocytic leukemia
Turner syndrome	Only one X chromosome present	Short stature Streak ovaries Infertility Webbed neck
Klinefelter syndrome	An extra X chromosome present (XXY)	Small testes Gynecomastia Subfertility

disorders that can be identified by DNA analysis are retinoblastoma, myotonic dystrophy, Huntington disease, sickle cell anemia, β-thalassemia, and Duchenne muscular dystrophy.

The decision to undergo CVS is a major one for a couple. As a rule, they are not making a decision simply for CVS. If the CVS reveals that their child is abnormal, they then have to make a second decision about the future of the pregnancy.

Deciding to terminate a pregnancy based on a laboratory finding is rarely easy. The couple may need a great deal of support with their decision, both to carry it through and to live with the decision afterward. If they decide not to terminate the pregnancy, they will need support during the remainder of the pregnancy and in the days following birth. It may be difficult for a couple to believe that what the test showed is true. Only when they inspect the baby and see that the test was accurate—the child does have a genetic disorder—do they see the reality. This can result in long-lasting depression.

Amniocentesis. Amniocentesis is the withdrawal of amniotic fluid through the abdominal wall for analysis at the 14th to 16th week of pregnancy (Alfirevic, Mujezinovic, & Sunberg, 2009). Because amniotic fluid has reached about 200 mL at this point, enough fluid can be withdrawn for karyotyping of skin cells found in the fluid as well as an analysis of AFP or acetylcholinesterase. If no acetylcholinesterase, a breakdown product of blood, is found in the specimen, it confirms that an elevated AFP level is not a false-positive reading caused by blood in the fluid.

For the procedure, a pocket of amniotic fluid is located by ultrasound. Then a needle is inserted transabdominally, and about 20 mL of fluid is aspirated. Skin cells in the fluid are karyotyped for chromosomal number and structure. The level of AFP is analyzed. Some disorders, such as Tay-Sachs disease, can be identified by the lack of a specific enzyme, such as hexosaminidase A, in amniotic fluid.

Amniocentesis has the advantage over CVS of carrying only a 0.5% risk of spontaneous miscarriage. Unfortunately, it usually is not done until the 14th to 16th week of pregnancy. This may prove to be a difficult time because, by this date, a woman is beginning to accept her pregnancy and bond with the fetus. In addition, termination of pregnancy during the second trimester is more difficult than during a first trimester. Support women while they wait for test results and to make a decision about the pregnancy. Women with an Rh-negative blood type need Rh immune globulin administration after the procedure to protect against isoimmunization in the fetus. All women need to be observed for about 30 minutes after the procedure to be certain that labor contractions are not beginning and that the fetal heart rate remains within normal limits. Because amniocentesis is also a common assessment for fetal maturity, it is discussed further in Chapter 9 (see also Fig. 9.14).

Percutaneous Umbilical Blood Sampling. PUBS, or cordocentesis, is the removal of blood from the fetal umbilical cord at about 17 weeks using an amniocentesis technique (Fig. 7.13). This allows analysis of blood components as well as more rapid karyotyping than is possible when only skin cells are removed. PUBS is discussed further in Chapter 9.

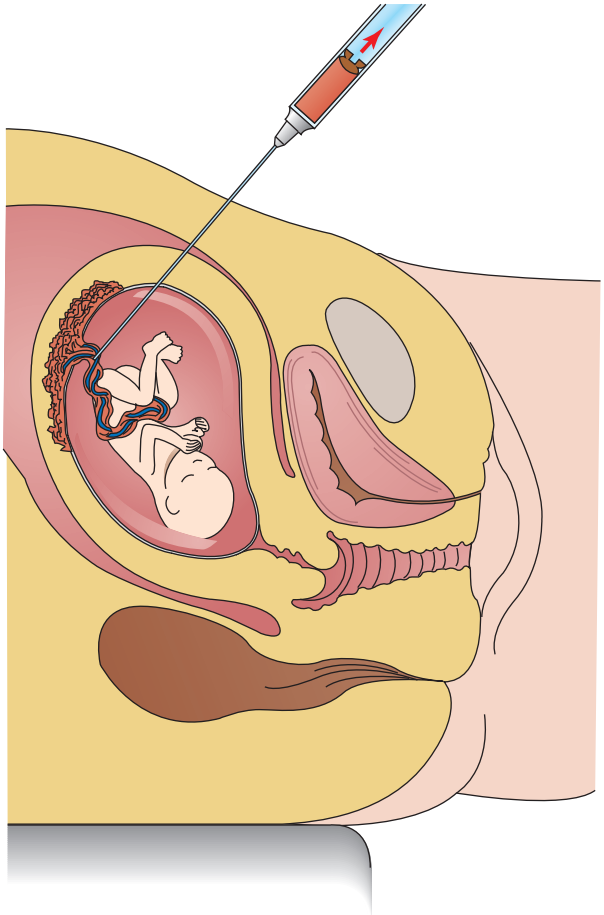

FIGURE 7.13 Percutaneous umbilical blood sampling. Blood is withdrawn from the umbilical cord using amniocentesis technique.

Fetal Imaging. Magnetic resonance imaging (MRI) and ultrasound are diagnostic tools used to assess a fetus for general size and structural disorders of the internal organs, spine, and limbs. Because some genetic disorders are associated with physical appearance, both of these methods may be helpful. Ultrasound is used concurrently with amniocentesis.

Fetoscopy. Fetoscopy is the insertion of a fiberoptic fetoscope through a small incision in the mother's abdomen into the uterus and membranes to visually inspect the fetus for gross abnormalities. It can be used to confirm an ultrasound finding, to remove skin cells for DNA analysis, or to perform surgery for a congenital disorder such as a stenosed urethra.

Preimplantation Diagnosis. Preimplantation diagnosis is possible for in vitro fertilization procedures. It may be possible in the future for a naturally fertilized ovum to be removed from the uterus by lavage before implantation and studied for DNA analysis this same way. The ovum would then be reinserted or not, depending on the findings and the parents' wishes. This would provide genetic information extremely early in a pregnancy.

Reproductive Alternatives

Some couples are reluctant to seek genetic counseling because they are afraid they will be told it would be unwise to have children. Helping them to realize that viable alternatives for having a family exist allows them to seek the help they need.

Artificial insemination by donor (AID) is an option for couples if the genetic disorder is one inherited by the male partner or is a recessively inherited disorder carried by both partners. AID is available in all major communities and can permit the couple to experience the satisfaction and enjoyment of a usual pregnancy (Burney, Schust, & Yao, 2007).

If the inherited problem is one arising from the female partner, surrogate embryo transfer is an assisted reproductive technique that is a possibility (van Berkel, Candido, & Pijffers, 2007). An oocyte donated by a friend or relative or provided by an anonymous donor is fertilized by the husband's sperm in the laboratory and then implanted into a woman's uterus. Like AID, donor embryo transfer offers the couple a chance to experience a normal pregnancy.

Use of a surrogate mother (a woman who agrees to be artificially inseminated, typically by the male partner's sperm, and bear a child for the couple) is still another possibility (Reilly, 2007). All of these procedures are expensive and, depending on individual circumstances, may have disappointing success rates. Assisted reproductive techniques are discussed in more detail in Chapter 8.

Adoption is an alternative many couples can also find rewarding (see Chapter 3). Choosing to remain child-free should not be discounted as a viable option. Many couples who have every reason to think they would have children without a genetic disorder choose this alternative because they believe their existence is full and rewarding without the presence of children.

Diagnosis of a disorder during pregnancy with prompt treatment at birth to minimize the prognosis and outcome of the disorder is another route to explore. Termination of a pregnancy that reveals a chromosomal or metabolic abnormality is a final option.

Help couples decide on an alternative that is correct for them, not one that they sense a counselor feels would be best. They need to consider the ethical philosophy or beliefs of other family members when making their decision, although ultimately they must do what they believe is best for them as a couple. A useful place to start counseling is with values clarification, to be certain a couple understands what is most important to them.

Future Possibilities

Stem cell research is looking at the possibility that immature cells (stem cells) could be implanted into an embryo with a known abnormal genetic makeup, replacing the abnormal cells or righting the affected child's genetic composition (Wiener et al., 2007). Although presently possible, stem cell research is costly and produces some ethical questions (e.g., although stem cells can be harvested from cord blood, adult skin cells or menstrual blood, will these be able to serve as main sources of donor DNA for the new technology?).

Legal and Ethical Aspects of Genetic Screening and Counseling

Nurses can be instrumental in seeing that couples who seek genetic counseling receive results in a timely manner and with compassion about what their results may mean to future childbearing. Always keep in mind several legal responsibilities of genetic testing, counseling, and therapy, including:

- Participation by couples or individuals in genetic screening must be elective.
- People desiring genetic screening must sign an informed consent for the procedure.
- Results must be interpreted correctly yet provided to the individuals as quickly as possible.
- The results must not be withheld from the individuals and must be given only to those persons directly involved.
- After genetic counseling, persons must not be coerced to undergo procedures such as abortion or sterilization. Any procedure must be a free and individual decision.

Failure to heed these guidelines could result in charges of invasion of privacy, breach of confidentiality, or psychological injury caused by "labeling" someone or imparting unwarranted fear and worry about the significance of a disease or carrier state. If couples are identified as being at risk for having a child with a genetic disorder and are not informed of the risk and offered appropriate diagnostic procedures (e.g., amniocentesis) they can bring a "wrongful birth" lawsuit if their child is born with the detected genetic disorder (Box 7.5).

What if... Amy Alvarez was pregnant with twins? One twin fetus is diagnosed as having Down syndrome, and the other is not. How would you counsel her if she wanted to abort the affected child, when the procedure also might endanger the child without the disorder?

COMMON CHROMOSOMAL DISORDERS RESULTING IN PHYSICAL OR COGNITIVE DEVELOPMENTAL DISORDERS

Several chromosomal disorders, particularly nondisjunction disorders, are easily detected at birth on physical examination. Many of these disorders leave children cognitively challenged. Care of the child who is cognitively challenged is discussed in Chapter 54.

Trisomy 13 Syndrome (47XY13+ or 47XX13+)

In trisomy 13 syndrome (Patau syndrome), the child has an extra chromosome 13 and is severely cognitively challenged. The incidence of the syndrome is low, approximately 0.45 per 1000 live births. Midline body disorders such as cleft lip and palate, heart defects, particularly ventricular septal defects, and abnormal genitalia are present (see Fig. 7.11). Other common findings include microcephaly with abnormalities of the forebrain and forehead; eyes that are smaller than normal (microphthalmos) or absent; and low-set ears. Most of these children do not survive beyond early childhood.

BOX 7.5 ✻ Focus on Evidence-Based Practice

What is the most effective way to present the risk of Down syndrome to pregnant women?

Healthy women under 34 years of age have only a small risk (1 in 100) of having a child with Down syndrome. Explaining what a low risk this is can be difficult, however, if all that women hear is that there is a risk. To find the best way to present this material, researchers recruited 150 pregnant women, all under 32 years of age, and asked them what they perceived a risk of 1 in 100 to mean. They then assigned the woman to three different means of illustrating the risk. In the first group, women viewed a photo showing 99 smiling faces and 1 frowning face. In the second group, women read a paragraph of text describing a room full of 100 people, all dressed alike but 1 person. In a third group, women were shown a plastic box containing 100 ping-pong balls and asked to pull out 1 ball. Women were then re-asked how they perceived their risk of having a child with Down syndrome. Of the visual and written groups, only 37% said they perceived the risk as less than before whereas 66% of the interactive group said they perceived the risk as less than before. The researchers concluded that women worry less when an interactive demonstration is used to illustrate risk. Also, that risk seems less when women are told the chances are 99 to 1 that their child will not have Down syndrome rather than being told that their chance is 1 in 100 of having a child with the syndrome.

Would the above findings be helpful to you when talking to women about their risk of a genetic disorder in pregnancy?

Source: Hinshaw, K., et al. (2007). Randomised controlled trial comparing three methods of presenting risk of Down's syndrome. *European Journal of Obstetrics, Gynecology & Reproductive Biology, 133*(1), 40–46.

Trisomy 18 Syndrome (47XY18+ or 47XX18+)

Children with trisomy 18 syndrome have three copies of chromosome 18. The incidence is approximately 0.23 per 1000 live births. These children are severely cognitively challenged and tend to be small for gestational age at birth, have markedly low-set ears, a small jaw, congenital heart defects, and usually misshapen fingers and toes (the index finger deviates or crosses over other fingers). Also, the soles of their feet are often rounded instead of flat (rocker-bottom feet). As in trisomy 13 syndrome, most of these children do not survive beyond early infancy.

Cri-du-Chat Syndrome (46XX5p− or 46XY5P−)

Cri-du-chat syndrome is the result of a missing portion of chromosome 5. In addition to an abnormal cry, which sounds much more like the sound of a cat than a human infant's cry, children with cri-du-chat syndrome tend to have a small head, wide-set eyes, and a downward slant to the palpebral fissure of the eye. They are severely cognitively challenged.

Turner Syndrome (45X0)

The child with Turner syndrome (gonadal dysgenesis) has only one functional X chromosome. The child is short in stature and has only streak (small and nonfunctional) ovaries. She is sterile and with the exception of pubic hair, secondary sex characteristics do not develop at puberty. The hairline at the nape of the neck is low set, and the neck may appear to be webbed and short. A newborn may have appreciable edema of the hands and feet and a number of congenital anomalies, most frequently coarctation (stricture) of the aorta and kidney disorders. The incidence of the syndrome is approximately 1 per 10,000 live births. The disorder can be identified with an ultrasound during pregnancy because of the increased neck folds.

Although children with Turner syndrome may be severely cognitively challenged, difficulty in this area is more commonly limited to learning disabilities. Socioemotional adjustment problems may accompany the syndrome because of the lack of fertility and if the nuchal folds are prominent.

Human growth hormone administration may help children with Turner syndrome achieve additional height (Baxter et al., 2009). If treatment with estrogen is begun at approximately 13 years of age, secondary sex characteristics will appear, and osteoporosis from lack of estrogen during growing years may be prevented. If females continue taking estrogen for three out of every four weeks, this produces withdrawal bleeding that results in a menstrual flow. This flow, however, does not correct the problem of sterility. Gonadal tissue is scant and inadequate for ovulation because of the basic chromosomal aberration.

Klinefelter Syndrome (47XXY)

Infants with Klinefelter syndrome are males with an extra X chromosome. Characteristics of the syndrome may not be noticeable at birth. At puberty, secondary sex characteristics do not develop; the child has small testes that produce ineffective sperm (Porche, 2007). Affected individuals tend to develop gynecomastia (increased breast size) and have an increased risk of male breast cancer (Pyeritz, 2009). The incidence is about 1 per 1000 live births. Karyotyping can be used to reveal the additional X chromosome.

Fragile X Syndrome (46XY23q−)

Fragile X syndrome is the most common cause of cognitive challenge in males. It is an X-linked disorder in which one long arm of an X chromosome is defective which results in inadequate protein synaptic responses (Bear et al., 2008). The incidence is about 1 in 1000 live births.

Before puberty, boys with fragile X syndrome typically may demonstrate maladaptive behaviors such as hyperactivity and autism. They may have reduced intellectual functioning, with marked deficits in speech and arithmetic (Kornman et al., 2007). They may be identified by the presence of a large head, a long face with a high forehead, a prominent lower jaw, and large protruding ears. Hyperextensive joints and cardiac

disorders may also be present. After puberty, enlarged testicles may become evident. Affected individuals are fertile and can reproduce.

Carrier females may show some evidence of the physical and cognitive characteristics. Although intellectual function from the syndrome cannot be improved, both folic acid and an antipsychotic drug such as phenothiazines may improve symptoms of poor concentration and impulsivity.

Down Syndrome (Trisomy 21) (47XY21+ or 47XX21+)

Trisomy 21, the most frequently occurring chromosomal abnormality, occurs in about 1 in 800 pregnancies. The number of children born with the disorder is considerably less as many women choose to end pregnancies when the diagnosis is made (Witters & Fryns, 2008).

The physical features of children with Down syndrome are so marked that fetal diagnosis is possible by ultrasound in utero. The nose is broad and flat. The eyelids have an extra fold of tissue at the inner canthus (an epicanthal fold), and the palpebral fissure (opening between the eyelids) tends to slant laterally upward. The iris of the eye may have white specks, called Brushfield spots. The tongue may protrude from the mouth because the oral cavity is smaller than usual. The back of the head is flat, the neck is short, and an extra pad of fat at the base of the head causes the skin to be so loose it can be lifted easily. The ears may be low-set. Muscle tone is poor, giving the baby a rag-doll appearance. This can be so lax that the child's toe can be touched against the nose (not possible in the average mature newborn). The fingers of many children with Down syndrome are short and thick, and the little finger is often curved inward. There may be a wide space between the first and second toes and between the first and second fingers. The palm of the hand shows a peculiar crease (a simian line), which is a single horizontal palm crease rather than the usual three creases in the palm (Fig. 7.14).

Children with Down syndrome are usually cognitively challenged to some degree. The challenge can range from an intelligence quotient (IQ) of 50 to 70 to a child who is profoundly affected (IQ less than 20). The extent of the cognitive challenge is not evident at birth. The fact that the brain is not developing well is evidenced by a head size that is usually smaller than the 10th or 20th percentile at well-child health care visits.

These children also appear to have altered immune function as they are prone to upper respiratory tract infections. Congenital heart disease, especially atrioventricular defects, is common. Stenosis or atresia of the duodenum, strabismus, and cataract disorders are also common. For as yet undetected reasons, acute lymphocytic leukemia occurs approximately 20 times more frequently in children with Down syndrome than in the general population. Even if children are born without an accompanying disorder such as heart disease, their lifespan usually is only 50 to 60 years, because aging seems to occur faster than normal.

It's important for children with Down syndrome to be enrolled in early educational and play programs (see Chapter 54). Because they are prone to infections, sensible precautions such as using good handwashing technique are important when caring for them. The enlarged tongue may interfere with swallowing and cause choking unless the child is fed slowly. As their neck may not be fully stable, a radiograph to ensure stability is recommended before they engage in strenuous activities such as competitive sports. As with all newborns, these infants need physical examination at birth to enable detection of the genetic disorder and initiation of parental counseling and support.

Childhood Tumors

A number of cancers in children are also associated with chromosomal aberrations. Chief among these are retinoblastoma (chromosome 13), Wilms' tumor (chromosome 11) and neuroblastoma (chromosome 1 or 11) (Pyeritz, 2009).

✔Checkpoint Question 7.4

Amy Alvarez's child is born with Down syndrome. What is a common physical feature of newborns with this disorder?

a. Spastic and stiff muscles
b. Loose skin at back of neck
c. A white lock of forehead hair
d. Wrinkles on the soles of the feet

Key Points for Review

- Genetic disorders are disorders resulting from a defect in the structure or number of genes or chromosomes. Genetics is the study of how and why such disorders occur.
- A phenotype is a person's outward appearance. Genotype refers to the actual gene composition. A person's genome is the complete set of genes present. A karyotype is a graphic representation of the chromosomes that are present.
- A person is homozygous if he or she has two like genes for a trait and heterozygous if he or she has two unlike genes for a trait.
- Mendelian laws can predict the likely incidence of recessive or dominant diseases in children. Division disorders, including nondisjunction abnormalities, deletion, translocation, and mosaicism, also create genetic disorders.
- Genetic counseling can be a role for nurses with advanced preparation and education. Assessment of genetic disorders consists of a health history, physical examination, and diagnostic studies such as chorionic villi sampling, amniocentesis, and maternal serum levels of alpha-fetoprotein analysis.
- Some karyotyping tests, such as chorionic villi sampling and amniocentesis, introduce a risk of spontaneous or threatened miscarriage. Be certain that women undergoing these tests remain in the health care facility for at least 30 minutes after the procedure to be sure that a complication such as vaginal bleeding, uterine cramping, or abnormal fetal heart rate is not present. Women with an Rh-negative blood type need Rh immune globulin administration after these procedures.
- An important aspect of genetic counseling is respecting a couple's right to privacy. Be certain that information gained from testing remains confidential and is not given indiscriminately to others, including other family members.
- People who are told that a genetic abnormality does exist in their family may suffer a loss of self-esteem. Offering support to help them deal with the feelings they experience is an important nursing intervention.
- Common nondisjunction genetic disorders include Down syndrome (trisomy 21), trisomy 13, trisomy 18, Turner syndrome, and Klinefelter syndrome. Most of these syndromes include some degree of cognitive challenge.

CRITICAL THINKING EXERCISES

1. Amy Alvarez, whom you met at the beginning of the chapter, doesn't know her family history so is unable to answer questions about family members. What questions would you want to ask about her husband's family? Suppose Mr. Alvarez tells you he had two brothers who died at birth. Would that finding be important?
2. Suppose Amy's husband's sister and her husband both carry a gene for a recessively inherited disorder, yet they have had five children and none of the children shows symptoms of the disorder. Is it possible for them to have had five children without any symptoms of the disease? What are the chances that their sixth child will also be disease free?
3. Amy tells you, "My family will be so ashamed if a genetic defect happens in our family." What does her statement tell you about her family's knowledge of genetic disorders?
4. Examine the National Health Goals related to genetic disorders. Most government-sponsored money for nursing research is allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to the Alvarez family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX types of questions related to inheritance. Confirm your answers are correct by reading the rationales.

Chapter

8 Nursing Care of the Subfertile Couple

KEY TERMS

- anovulation
- cryptorchidism
- endometriosis
- erectile dysfunction
- in vitro fertilization
- pelvic inflammatory disease
- sperm count
- sperm motility
- spermatogenesis
- sterility
- subfertility
- therapeutic insemination
- varicocele

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe common causes of subfertility in both men and women.
2. Identify National Health Goals related to subfertility that nurses can help the nation achieve.
3. Use critical thinking to analyze ways that a fertility assessment can be more family centered.
4. Describe common assessments necessary to detect subfertility.
5. Formulate nursing diagnoses related to subfertility.
6. Identify appropriate outcomes for the subfertile couple.
7. Plan nursing interventions to meet the needs of a couple with a diagnosis of subfertility.
8. Implement nursing care associated with the diagnosis of subfertility or measures to promote fertility, such as health teaching.
9. Evaluate outcomes for achievement and effectiveness of care.
10. Identify areas of nursing care related to fertility that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge about subfertility with the nursing process to achieve quality maternal and child health nursing care.

Cheryl and Bob Carl married when they were both 25 and planned to wait 5 years before beginning their family so they could save money for a house. At the end of 5 years, they bought the house. On the day they moved in, Mrs. Carl stopped taking her birth control pills. At the end of a year, however, she still was not pregnant. Three years later, the Carls began fertility testing. They are now undergoing their second cycle of in vitro fertilization and embryo transfer. The Carls have applied for a second mortgage on their house to finance the fertility testing and fertilization procedures. At her last visit, Mrs. Carl stated, "This is my fault because I'm so rigid. I can't relax enough to get pregnant. Look how I had to buy the house before I could even consider getting pregnant, and now we'll probably lose it. Besides that, it feels like our whole life revolves around trying to get pregnant."

Previous chapters described normal anatomy and physiology and ways to prevent pregnancy. This chapter adds information to expand your knowledge base about care of the couple who is unable to conceive.

How could you best help the Carls?

Many marriage customs, such as throwing rice, originate from old rituals to promote fertility. The existence of such common rituals provides evidence about the importance of having children for the average couple and society as a whole.

Infertility is a term used to describe the inability to conceive a child or sustain a pregnancy to birth. Because most couples have the potential to conceive but they are just less able to do this without additional help, the term **subfertility** is more often used today.

Subfertility affects as many as 14% of couples who desire children (Kumar et al., 2007). Couples exploring fertility testing come in all different types: many are married couples who are having trouble conceiving; some are couples who have plans to marry and wonder if they will have trouble conceiving; some desire to remain single or partner with someone of their own sex and bear a child, through an assisted fertility method. Occasionally, people want assurance that they are unable to have children so they can discontinue using a contraceptive.

When a couple first pursues fertility counseling, they usually have fears and anxieties not only about their inability to conceive but also about what this condition will mean to their future lifestyle and family. Without information about the cause of their subfertility, partners can blame themselves or carry unexpressed anger toward a partner. Some couples may strongly desire a child but also feel anxious about impending parenthood, which would bring with it loss of independence and their established lifestyle. For all these reasons, subfertility screening and counseling can be an emotionally difficult and physically demanding process, often creating a high level of strain on a couple's relationship (MacKay, 2009).

Having healthy children is such a priority that a National Health Goal aimed at reducing subfertility has been established (Box 8.1). Because most fertility tests are conducted in ambulatory settings, nurses play key roles in educating couples about the variety of tests and procedures that may be performed. They are important members of fertility health care teams, often assuming responsibility for health assessment, client education, and counseling and helping clients identify and express their feelings about their desire to have a child, express how far they are willing to go in terms of testing and procedures to achieve this desire, and how they might feel if they are not able to have a child. In addition, educating clients about advanced procedures, many of which are complex and demand knowledgeable, ongoing involvement, and participating in the complex planning and implementation of treatment strategies are also important roles. If pregnancy cannot be achieved, nurses can counsel clients about available alternatives, such as adoption or child-free living.

BOX 8.1 ✻ Focus on National Health Goals

One National Health Goal directly addresses the problem of subfertility:

- Reduce the proportion of married couples whose ability to conceive or maintain a pregnancy is impaired from a baseline of 13% to a target of 10% (http://www.nih.gov).

To meet this health goal, nurses need to be active in health promotion and early identification and prevention of problems that could lead to subfertility, playing active roles in teaching clients about safer sex practices (see Chapter 5) to help reduce the incidence of sexually transmitted infections and pelvic inflammatory disease, both of which can contribute to subfertility. Counseling on healthy nutrition can also be important. Good nursing research topics include investigation of how to help women better recognize the symptoms of pelvic inflammatory disease or manage stress when self-esteem is low.

Nursing Process Overview

For the Couple With Subfertility

Assessment

Subfertility assessment used to require many months and many tests, all of which had the potential to interfere with a couple's self-image and self-esteem. Today, a subfertility investigation is usually limited to three assessments: semen analysis, ovulation monitoring, and tubal patency. Even with this more sensible approach to evaluation, nursing assessment often reveals that one or both partners feel inadequate or angry and frustrated by what has happened to them and the need to undergo testing. Questions such as, "How do you feel about what has happened?" or "How do you think your partner feels about not being able to conceive?" may be enough to encourage partners to express these concerns. Talking with both partners together may be advantageous, because they may feel more comfortable speaking about their problem together. On the other hand, it is important to spend some time alone with each client in case there is anything a partner wishes to discuss privately. This might be the only opportunity one of them has to ask that one "silly" question or voice a fear that they believe is too foolish to ask or bring up in front of their partner.

Nursing Diagnosis

Nursing diagnoses related to subfertility are likely to focus on psychosocial issues associated with the inability to conceive and the potentially nerve-wracking process of fertility testing and management. Examples of possible diagnoses include:

- Fear related to possible outcome of subfertility studies
- Situational low self-esteem related to the apparent inability to conceive
- Anxiety related to what the process of fertility testing will entail
- Deficient knowledge related to measures to promote fertility
- Anticipatory grieving related to failure to conceive or sustain a pregnancy
- Powerlessness related to repeated unsuccessful attempts at achieving conception
- Hopelessness related to perception of no viable alternatives to usual conception

If required tests interfere with a couple's relationship (including sexual patterns), "Sexual dysfunction related to command performance of subfertility therapy" might be applicable.

Expected Outcomes and Planning

In establishing expected outcomes with a couple undergoing fertility testing and counseling, be certain that the couple realizes that results may not be instantaneous. A couple may need to change or modify their goals if tests begin to show that what they first wanted—to have a child without medical intervention—is impossible. Participation in a support group may allow a couple to work through the stress that fertility testing places on their lives. Resolve (http://www.resolve.org), a national support group for couples with subfertility, can be helpful in offering referral sources and support that a couple can use in planning. A second helpful organization is the American Society of Reproductive Medicine (htpp://www.asrm.org).

Implementation

Fertility testing can be costly for a couple; however, more and more insurance companies are providing reimbursement for subfertility-related tests and procedures. Couples need to be informed beforehand of specific estimates of the cost of testing or therapy. They also may need help budgeting and planning their resources accordingly.

Suggesting that a couple combine involvement with fertility testing with ongoing activities or that they begin a new activity together (e.g., taking a night school course, planting a garden, learning a new sport or hobby) at the same time they begin fertility testing is a way of helping them reduce the feeling that their entire existence revolves around the testing procedures. It also may help provide them with time for sharing experiences and increasing intimacy, helping to compensate for any decreased enjoyment that comes from "scheduled" sexual relations.

Throughout testing, couples need thorough education about the various procedures. Make sure to review any specific instructions about preprocedural and postprocedural care. Depending on their motivations, a couple's reaction to study results may vary from relief, to stoic acceptance, to grief for children never to be born. Each partner may wonder whether the other will be able to continue the relationship if he or she turns out to be the "subfertile" one. Couples need the active support of health care personnel from the first day they braced themselves to ask, "Exactly why are we childless?" until the end, regardless of the results.

Outcome Evaluation

Examples of expected outcomes in this area include:

- Client rearranges work plans to manage schedule of fertility testing by 1 month's time.
- Couple verbalizes that they understand their individual subfertility problem after preliminary testing.
- Couple demonstrates a high level of self-esteem after fertility studies, even in the face of disappointing study outcomes.

For the couple with the problem of subfertility, evaluation is best if it is ongoing because, as circumstances around them change, so may their goals and desires. Until they can accept an alternative method of having children—adoption or an assisted reproductive technique such as **therapeutic insemination** (deposition of sperm into a woman's cervix or uterus) or **in vitro fertilization** (IVF; the union of sperm and ovum under laboratory conditions)—former plans have been crushed. It is not unusual to see a couple move through steps of denial, anger, bargaining, and depression before they reach a level of acceptance that they are different in this one area of life from others but not limited in their ability to achieve in other areas. Only after acceptance are they able to make adjustments in their wants or plans to feel fulfilled again.

Future evaluation is also important, because a couple who decides at age 20 to choose child-free living may change their minds at a later date. A couple who chooses an assisted reproductive technique may decide after several unsuccessful attempts that they are no longer interested in this method of conception. Keeping evaluation an ongoing process allows such plans to be modified as necessary. Encourage couples seen for subfertility to call or visit their subfertility setting every 6 to 12 months to inquire about new discoveries in the field and how these might apply to their situation.

SUBFERTILITY

Subfertility is said to exist when a pregnancy has not occurred after at least 1 year of engaging in unprotected coitus (Kumar et al., 2007). In *primary subfertility*, there have been no previous conceptions; in *secondary subfertility*, there has been a previous viable pregnancy but the couple is unable to conceive at present. **Sterility** is the inability to conceive because of a known condition, such as the absence of a uterus.

In about 40% of couples with a subfertility problem, the cause of subfertility is multifactorial; in about 30% of couples, it is the man who is subfertile. In women seen for a fertility concern, 20% to 25% experience ovulatory failure; another 20% experience tubal, vaginal, cervical, or uterine problems. In about 10% of couples, no known cause for the subfertility can be discovered despite all the diagnostic tests currently available. Such couples are categorized as having unexplained subfertility (Rybak & Wallach, 2007).

Some couples, because they are unaware of the average length of time it takes to achieve a pregnancy, may worry that they are subfertile when they are not. When engaging in coitus an average of four times per week, 50% of couples will conceive within 6 months, and 85% within 12 months. These periods will be longer if sexual relations are less frequent (Burney, Schust, & Yao, 2007).

Couples who engage in coitus daily, hoping to cause early impregnation, may actually have more difficulty conceiving than those who space coitus to every other day. This is because too-frequent coitus can lower a man's sperm count (number of sperm in a single ejaculation) to a level below optimal fertility. Also, couples who focus their sexual relations on trying to increase sperm/ovum exposure may find their lives governed by temperature charts and "good days"

and "bad days" to such an extent that their relationship suffers.

The chance of subfertility increases with age. Because of this gradual decline in fertility, women who defer pregnancy to their late 30s are apt to have more difficulty conceiving than their younger counterparts. Women who are using oral, injectable, or implanted hormones for contraception may have difficulty becoming pregnant for several months after discontinuing these medications, because it takes that long for the body to restore normal functioning.

Male Subfertility Factors

Several factors typically lead to male subfertility:

- Disturbance in **spermatogenesis** (production of sperm cells)
- Obstruction in the seminiferous tubules, ducts, or vessels preventing movement of spermatozoa
- Qualitative or quantitative changes in the seminal fluid preventing **sperm motility** (movement of sperm)
- Development of autoimmunity that immobilizes sperm
- Problems in ejaculation or deposition preventing spermatozoa from being placed close enough to a woman's cervix to allow ready penetration and fertilization

Inadequate Sperm Count

The **sperm count** is the number of sperm in a single ejaculation or in a milliliter of semen (Kumar et al., 2007). The minimum sperm count considered normal is 20 million per milliliter of seminal fluid, or 50 million per ejaculation. At least 50% of sperm should be motile, and 30% should be normal in shape and form. Spermatozoa must be produced and maintained at a temperature slightly lower than body temperature to be fully motile. This is why the testes, in which sperm are produced and stored, are suspended in the scrotal sac away from body heat. Any condition that significantly increases body temperature such as a chronic infection from tuberculosis or recurrent sinusitis can lower a sperm count. Actions that increase scrotal heat, such as working at desk jobs or driving a great deal every day (e.g., salesmen, motorcyclists) may produce lower sperm counts compared with men whose occupations allow them to be ambulatory at least part of each day. Frequent use of hot tubs or saunas may also lower sperm counts appreciably.

Congenital abnormalities such as **cryptorchidism** (undescended testes) may lead to lowered sperm production if surgical repair of this problem was not completed until after puberty or if the spermatic cord became twisted after the surgery.

A worry is that a **varicocele** (varicosity of the spermatic vein) could increase temperature within the testes and slow and disrupt spermatogenesis although whether this actually causes much difference is in doubt (Evers & Collins, 2009). If this is happening, surgery to repair the varicocele has the potential to increase the chance for conception (Davis, Hall, & Kaufmann, 2007).

Other conditions that may inhibit sperm production are trauma to the testes; surgery on or near the testicles that results in impaired testicular circulation; and endocrine imbalances, particularly of the thyroid, pancreas, or pituitary glands. Drug use or excessive alcohol use and environmental factors such as exposure to x-rays or radioactive substances have also been found to negatively affect spermatogenesis. Men who are exposed to radioactive substances in their work environment should be provided adequate protection of the testes. When undergoing pelvic radiography, be certain that men and boys are always furnished with a protective lead testes shield.

Obstruction or Impaired Sperm Motility

Obstruction may occur at any point along the pathway that spermatozoa must travel to reach the outside: the seminiferous tubules, the epididymis, the vas deferens, the ejaculatory duct, or the urethra (see Chapter 5, Figure 5.2). Diseases such as *mumps orchitis* (testicular inflammation and scarring because of the mumps virus), epididymitis (inflammation of the epididymis), and tubal infections such as gonorrhea or ascending urethral infection can result in this type of obstruction because adhesions form and occlude sperm transport (Tracy, Steers, & Costabile, 2008). Congenital stricture of a spermatic duct may occasionally be seen. Benign hypertrophy of the prostate gland occurs in most men beginning at about 50 years of age. Pressure from the enlarged gland on the vas deferens can interfere with sperm transport. Infection of the prostate, through which the seminal fluid must pass, or infection of the seminal vesicles (spread from urinary tract infections) can change the composition of the seminal fluid enough to reduce sperm motility (Parsons, 2007).

A few men who have vasectomies develop an autoimmune reaction or form antibodies that immobilize their own sperm (Burney, Schust, & Yao, 2007). It is also conceivable that men with obstruction in the vas deferens from other causes, such as scarring after an infection, could also develop an autoimmune reaction that immobilizes sperm in the same way.

Anomalies of the penis, such as hypospadias (urethral opening on the ventral surface of the penis) or epispadias (urethral opening on the dorsal surface), can cause sperm to be deposited too far from the sexual partner's cervix to allow optimal cervical penetration. Extreme obesity in a male may also interfere with effective penetration and deposition.

Ejaculation Problems

Psychological problems, diseases such as a cerebrovascular accident, diabetes, or Parkinson's disease, and some medications (e.g., certain antihypertensive agents) may result in **erectile dysfunction** (formerly called impotence or the inability to achieve an erection). This condition is primary if the man has never been able to achieve erection and ejaculation and secondary if the man has been able to achieve ejaculation in the past but now has difficulty. Erectile dysfunction can be a difficult problem to solve if it is associated with stress, because this is not easily relieved. Solutions to the problem can include psychological or sexual counseling as well as use of a drug such as sildenafil (Viagra) (Wessells et al., 2007).

Premature ejaculation (ejaculation before penetration) is another factor that may interfere with the proper deposition of sperm. It is another problem often attributed to psychological causes. Adolescents may experience it until they become more experienced in sexual techniques.

✔Checkpoint Question 8.1

The Carls are a couple undergoing testing for subfertility. Subfertility is said to exist when:

a. A couple has been trying to conceive for 1 year.
b. A woman has no children from a marriage.
c. A woman has no uterus or fallopian tubes.
d. A couple has wanted a child for over 6 months.

Female Subfertility Factors

The factors that cause subfertility in women are analogous to those causing subfertility in men: anovulation (faulty or inadequate production of ova), problems of ova transport through the fallopian tubes to the uterus, uterine factors such as tumors or poor endometrial development, and cervical and vaginal factors that immobilize spermatozoa (Kumar et al., 2007). In addition, nutrition, body weight, and exercise may be responsible.

Anovulation

Anovulation (absence of ovulation), the most common cause of subfertility in women, may occur from a genetic abnormality such as Turner's syndrome (hypogonadism) in which there are no ovaries to produce ova. More often it results from a hormonal imbalance caused by a condition such as hypothyroidism that interferes with hypothalamus-pituitary-ovarian interaction. Ovarian tumors may also produce anovulation because of feedback stimulation on the pituitary. Chronic or excessive exposure to x-rays or radioactive substances, general ill health, poor diet, and stress may all contribute to poor ovarian function.

Nutrition, body weight, and exercise all influence the blood glucose/insulin balance. When either glucose or insulin levels are too high, they can disrupt the production of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) leading to subfertility from ovulation failure.

Women should try to maintain an ideal body weight and height, as represented by a body mass index (BMI) of 20 to 24 (Chavarro et al., 2007). This ideal BMI may also apply to men, as excessive weight may alter testosterone production and sperm production.

For nutrition, eating slowly digested carbohydrate foods such as brown rice, pasta, dark bread, beans, and fiber-rich vegetables rather than food such as white bread and cold breakfast cereals that have easily digested carbohydrates can not only increase fertility but perhaps prevent gestational diabetes when a woman does become pregnant.

Also important may be eating unsaturated fatty acids rather than saturated or trans-fatty acids. Trans-fatty acids are found in foods such as stick margarine, commercial French fries, and doughnuts. Saturated fats are those found in animal products such as cheese, meat, and butter. Unsaturated fats are those derived from plant sources such as corn or olive oil. Although eating adequate protein is important for fertility, excessive intake of protein may be yet another deterrent to fertility. To reduce a heavy protein intake, encourage women to eat plant sources of protein, such as soybeans, tofu, beans, or nuts rather than animal sources.

In addition to healthy eating habits, exercising 30 minutes a day by walking or doing mild aerobics can also help regulate blood glucose levels, thereby providing another way to increase fertility.

Stress reduces hypothalamic secretion of gonadotropin-releasing hormone (GnRH), which then lowers the production of LH and FSH, which leads to anovulation. Decreased body weight or a body/fat ratio of less than 10%, as may occur in female athletes (e.g., competitive runners) or in women who are excessively lean or anorexic, can reduce pituitary hormones such as FSH and LH and halt ovulation (termed hypogonadotrophic hypogonadism).

The most frequent cause, however, is naturally occurring variations in ovulatory patterns or polycystic ovary syndrome, a condition in which the ovaries produce excess testosterone, lowering FSH and LH levels. Polycystic ovary syndrome is associated with the metabolic syndrome (a waist circumference of 35 or above in women, a fasting blood glucose >100 mg/dL, serum triglycerides >150 mg/dL; blood pressure >135/85 mm Hg; and high-density lipoprotein cholesterol <50 mg/dL) (Vignesh & Mohan, 2007). The metabolic syndrome is associated with increased cardiac disease, so efforts to reduce weight and lower triglycerides and cholesterol can improve heart health as well as promote fertility.

Some women ovulate only a few times a year because of polycystic ovary syndrome. The condition can usually be detected by examining the menstrual history, but even if a woman experiences regular monthly menstruation, it does not necessarily indicate that she is ovulating on a regular basis (DuRant & Leslie, 2007).

Tubal Transport Problems

Difficulty with tubal transport usually occurs because scarring has developed in the fallopian tubes. This typically is caused by chronic salpingitis (chronic pelvic inflammatory disease). It can result from a ruptured appendix or from abdominal surgery involving infection that spread to the fallopian tubes and left adhesion formation in the tubes (Walker & Wiesenfeld, 2007). Tubal transport is the chief problem if a woman had a tubal ligation in years past but now wants to become pregnant.

Pelvic inflammatory disease (PID) is infection of the pelvic organs: the uterus, fallopian tubes, ovaries, and their supporting structures. The initial source of the infection is usually a sexually transmitted disease. In some women, infection can spread even further than reproductive organs or involve the pelvis, causing pelvic peritonitis. Many organisms can cause PID, but chlamydia and gonorrhea are among those most frequently seen. PID occurs at a rate of 25 per 100 women; in other words, one fourth of all women will experience this type of infection in a lifetime. About 12% of those who acquire PID are left subfertile (Burney, Schust, & Yao, 2007).

PID invasion of fallopian tubes is most apt to occur at the end of a menstrual period, because menstrual blood provides such an excellent growth medium. There also is loss of the normal cervical mucus barrier at this time, which increases the risk for initial invasion. If left unrecognized and untreated, PID enters a chronic phase, which causes the scarring that can lead to stricture of the fallopian tubes and the resulting fertility problem.

There is apparently a higher incidence of PID among women who use intrauterine devices (IUDs) although this may not bear out in practice (Campbell, Cropsey, & Matthews, 2007). It is good advice for women with IUDs to limit the number of their sexual partners to help reduce the incidence of sexually transmitted infections.

Uterine Problems

Tumors such as fibromas (leiomyomas) may be a rare cause of subfertility if they block the entrance of the fallopian tubes into the uterus or limit the space available on the uterine wall for effective implantation. A congenitally deformed uterine cavity may also limit implantation sites, but this also is rare.

Poor secretion of estrogen or progesterone from the ovary can result in inadequate endometrium formation (overproduction or underproduction), interfering with implantation and embryo growth. Endometriosis also can interfere with uterine fertility.

Endometriosis refers to the implantation of uterine endometrium, or nodules, that have spread from the interior of the uterus to locations outside the uterus (Yap, Furness, & Farquhar, 2007). The most common sites of endometrium spread include Douglas's cul-de-sac, the ovaries, the uterine ligaments, and the outer surface of the uterus and bowel (Fig. 8.1).

Some evidence of endometriosis occurs in as many as 50% of women, most probably from regurgitation through the fallopian tubes at the time of menstruation. Viable particles of endometrium that have been regurgitated in this way begin to proliferate and grow at the new sites, impeding fertility in a variety of ways. If growths occur in the fallopian tubes, tubal obstruction may result or adhesions forming from these growths may displace fallopian tubes away from the ovaries, preventing the entrance of ova into the tubes. Peritoneal macrophages that are drawn to these distant sites when the abnormal tissue is recognized can destroy sperm. The occurrence of endometriosis may indicate that the endometrial tissue has different or more friable qualities than usual (perhaps because of a luteal phase defect) and therefore is a type of endometrium that does not support embryo implantation as well as usual. Symptoms of endometriosis can begin in adolescence. The condition can be treated both medically and surgically (see Chapter 47).

Cervical Problems

At the time of ovulation, the cervical mucus is thin and watery and can be easily penetrated by spermatozoa for a period of 12 to 72 hours. If coitus is not synchronized with this time period, the cervical mucus may be too thick to allow spermatozoa to penetrate the cervix. Infection or inflammation of the cervix (erosion) is another reason that cervical mucus can thicken so much that spermatozoa cannot penetrate it easily or survive in it. A stenotic cervical os or obstruction of the os by a polyp may further compromise sperm penetration. However, this is rarely enough of a problem to be the sole cause of subfertility. A woman who has undergone dilatation and curettage (D&C) procedures several times or cervical conization (cervical surgery) should be evaluated in light of the possibility that scar tissue and tightening of the cervical os has occurred.

Vaginal Problems

Infection of the vagina can cause the pH of the vaginal secretions to become acidotic, limiting or destroying the motility of spermatozoa. Some women appear to have sperm-immobilizing or sperm-agglutinating antibodies in their blood plasma that act to destroy sperm cells in the vagina or cervix. Either of these problems can limit the ability of sperm to survive in the vagina and enter the uterus.

Unexplained Subfertility

In a small proportion of couples, no known cause for subfertility can be discovered. Possibly the problems of either partner alone are not significant, but when these are combined they become sufficient to create subfertility. It is obviously discouraging for couples to complete a fertility evaluation and be told that their inability to conceive cannot be explained. Offer active support to help the couple find alternative solutions, such

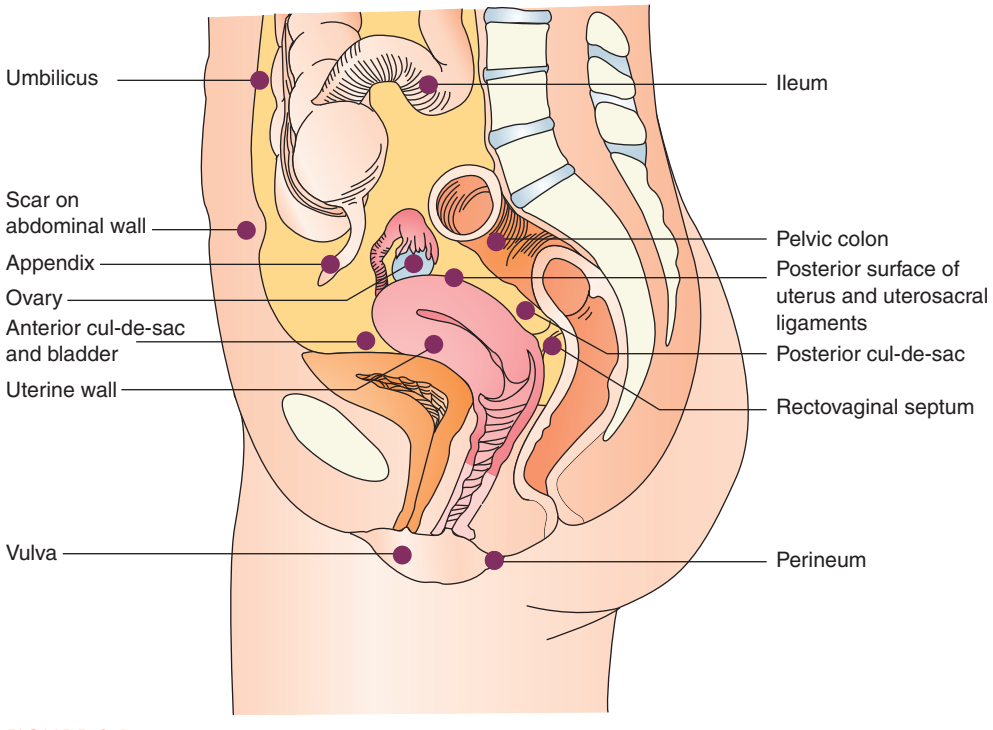

FIGURE 8.1 Common sites of endometriosis formation.

as continuing to try to conceive, using an assisted reproductive technique, choosing to adopt, or agreeing to a child-free life.

✔Checkpoint Question 8.2

Cheryl Carl is diagnosed as having endometriosis. This condition interferes with fertility because:

a. The ovaries stop producing adequate estrogen.
b. The uterine cervix becomes inflamed and swollen.
c. Pressure on the pituitary leads to decreased FSH levels.
d. Endometrial implants can block the fallopian tubes.

FERTILITY ASSESSMENT

Not all couples who desire fertility testing want to have children immediately. Some just want to know for their own peace of mind that they are fertile. Others want to know that they are indeed subfertile, so that they can discontinue contraceptive measures (although they need to be cautioned to maintain safer sex practices).

The age of the couple and the degree of apprehension they feel about possible subfertility make a difference in determining when they should be referred for fertility evaluation. Although some health care plans or specific settings set limits on the age range in which fertility testing can be scheduled (e.g., not before age 18 years and not after age 45 years), other settings do not establish such limits, allowing couples of any age to benefit from assessment. As a rule, if a woman is younger than 35 years of age, it is usually suggested that she have an evaluation after 1 year of subfertility; if older than 35 years, after 6 months of subfertility. Referral is recommended sooner for older women because of possible age limitations associated with adoption, assisted reproductive strategies such as in vitro fertilization (IVF), and embryo transfer, common alternatives to natural childbearing. It would be doubly unfortunate if a couple delayed fertility testing so long that they not only learned they could not conceive but also were considered to be "too old" to be prospective parents by an adoption agency or assisted reproductive setting. If the couple is extremely apprehensive or know of a specific problem, studies should never be delayed, regardless of the couple's age.

Basic fertility assessment begins with a health history and physical examination of both sexual partners.

Health History

Nurses often assume the responsibility for initial history taking with a subfertile couple. Because of the wide variety of factors that may be responsible for subfertility, a minimum history for the man should include:

- General health
- Nutrition
- Alcohol, drug, or tobacco use
- Congenital health problems such as hypospadias or cryptorchidism
- Illnesses such as mumps orchitis, urinary tract infection, or sexually transmitted diseases
- Radiation to his testes because of childhood cancer or another cause
- Operations such as surgical repair of a hernia, which could have resulted in a blood compromise to the testes
- Current illnesses, particularly endocrine illnesses or low-grade infections
- Past and current occupation and work habits (e.g., does his job involve sitting at a desk all day or exposure to x-rays or other forms of radiation?)
- Sexual practices such as the frequency of coitus and masturbation, failure to achieve ejaculation, premature ejaculation, coital positions used, and use of lubricants
- Past contraceptive measures, and existence of any children produced from a previous relationship
- Any complementary alternative therapy such as herbal additives the couple is using

Asking about alternative therapy is important because a couple who wants to have a child could be investigating nontraditional as well as traditional methods that they believe will aid in conception. Acupuncture, for example, is an alternative method frequently seen (Anderson et al., 2007). Ask about herbs specifically to be certain that a couple is not using an herb that could possibly be causing subfertility or will interfere with any procedure or medication prescribed for them after their subfertility investigation.

Most couples assume that subfertility is the woman's problem. Many women, even after careful explanation that the problem is their male partner's and not theirs, continue to show low self-esteem, as if the fault did rest with them. For a thorough women's health history, ask about:

- Current or past reproductive tract problems, such as infections
- Overall health, emphasizing endocrine problems such as galactorrhea (breast nipple secretions) or symptoms of thyroid dysfunction
- Abdominal or pelvic operations that could have compromised blood flow to pelvic organs
- Past history of a childhood cancer treated with radiation that might have reduced ovarian function
- The use of douches or intravaginal medications or sprays that could interfere with vaginal pH
- Exposure to occupational hazards such as x-rays or toxic substances
- Nutrition including an adequate source of folic acid and avoidance of trans-fats
- If she can detect ovulation through such symptoms as breast tenderness, midcycle "wetness," or lower abdominal pain (mittelschmerz)

Also obtain a menstrual history including:

- Age of menarche
- Length, regularity, and frequency of menstrual periods
- Amount of flow
- Any difficulties experienced, such as dysmenorrhea or premenstrual dysphoric disorder (PDD) (see Chapter 47)
- History of contraceptive use
- History of any previous pregnancies or abortions

While obtaining the history, take time with each partner individually and as a couple to encourage questions and to discuss overall attitudes toward sexual relations, pregnancy, and parenting. A frank discussion centered on resolving the couple's fears and clearing up any long-standing confusion or misinformation will help to set a positive tone for future interactions, establish a feeling of trust with health care personnel, and increase self-esteem. Talking with both partners

BOX 8.2 ✻ Focus on Communication

Cheryl Carl has been trying to get pregnant for 4 years. She and her husband agreed to in vitro fertilization at a cost of approximately $10,000 per month, even though her religion does not approve of this technique. Every time you see her at the fertility clinic, she seems sadder than the previous time.

Less Effective Communication

Nurse: How is everything going, Mrs. Carl?
Mrs. Carl: Fine. I'm just tired of no results.
Nurse: You know that's partly your fault, Mrs. Carl. You waited 4 years before you came for an evaluation.
Mrs. Carl: I guess I don't make good decisions. I'll probably make a lousy parent if I ever do get pregnant.

More Effective Communication

Nurse: How is everything going, Mrs. Carl?
Mrs. Carl: Fine. I'm just tired of no results.
Nurse: Considering that you have been trying for such a long time, I think you're doing very well. Subfertility management is always difficult.
Mrs. Carl: It is, but practicing to be patient should stand me in good stead the day I do have a child.

Clients may not make the same choices about fertility testing or management that you might make because such decisions are based on individual circumstances and situations. Be careful not to criticize clients for making choices that you think are poor ones. A more effective technique is to support them at that point and help them find ways to continue to feel good about themselves to maintain self-esteem.

can also help them clarify their feelings about subfertility and why they are seeking help in this area (Box 8.2).

Obtaining a sexual history is often difficult because cultural taboos can make couples feel uncomfortable discussing this part of their life. Simple factors, such as how often couples engage in sexual relations, for example, are influenced by culture and religion. According to Orthodox Jewish law, a couple may not engage in sexual relations for 7 days following menstruation (the *nida* period). This practice can result in fertility problems if a woman ovulates within the 7-day period. Some cultures forbid therapeutic insemination because preserving male lineage is so important. Being aware of cultural differences this way can influence how a couple reacts to a diagnosis of subfertility and help you appreciate the meaning of this diagnosis to an individual couple.

Physical Assessment

After a thorough history, both men and women need a complete physical examination. For the man, important aspects of this are detection of the presence of secondary sexual characteristics and genital abnormalities, such as the absence of a vas deferens or the presence of undescended testes or a varicocele (enlargement of a testicular vein). The presence of a hydrocele (collection of fluid in the tunica vaginalis of the scrotum) is rarely associated with subfertility but should be documented if present.

For a woman, a thorough physical assessment including breast and thyroid examination is necessary to rule out current illness. Of particular importance are secondary sex characteristics, which indicate maturity and good pituitary function (see Chapter 33 for a discussion of Tanner stages). A complete pelvic examination including a Pap test (see Chapter 11) is needed to rule out anatomic disorders and infection.

Fertility Testing

Basic fertility testing involves only three tests: semen analysis in the male and ovulation monitoring and tubal patency assessment in the female. Nurses play key roles in preparing couples for these tests, helping them schedule the studies appropriately, and supporting them while they wait for results.

Additional testing for men, if warranted, can include urinalysis; a complete blood count; blood typing, including Rh factor; a serologic test for syphilis; a test for the presence of human immunodeficiency virus (HIV); erythrocyte sedimentation rate (an increased rate indicates inflammation); protein-bound iodine (a test for thyroid function); cholesterol level (arterial plaques could interfere with pelvic blood flow); and gonadotropin and testosterone levels.

Advanced testing for a woman may include a rubella titer, a serologic test for syphilis, and an HIV evaluation. If a woman has symptoms of thyroid dysfunction, a thyroid uptake determination and thyroid-stimulating hormone level may be ordered. If a woman has a history of menstrual irregularities, blood may be assayed for FSH, estrogen, LH, and progesterone levels. If a woman has a history of galactorrhea, a serum prolactin level will be obtained. A pelvic ultrasound may be performed to rule out ovarian, tubal, or uterine structural disorders.

Semen Analysis

For a semen analysis, after 2 to 4 days of sexual abstinence, the man ejaculates by masturbation into a clean, dry specimen jar. The number of sperm in the specimen are counted and then examined under a microscope within 1 hour (Box 8.3). An average ejaculation should produce 2.5 to 5.0 mL of semen and should contain a minimum of 20 million spermatozoa per milliliter of fluid (the average normal sperm count is 50 to 200 million per milliliter). The analysis may need to be repeated after 2 or 3 months, because spermatogenesis is an ongoing process, and 30 to 90 days is needed for new sperm to reach maturity (Anderson & Genadry, 2007). Men can test their sperm motility at home with a self-test kit (Fertell) (Milkin, 2007).

Sperm Penetration Assay and Antisperm Antibody Testing

For impregnation to take place, sperm must be motile enough to navigate the vagina, uterus, and a fallopian tube to reach the ova. Although sperm penetration studies are rarely necessary, they may be scheduled to determine whether a man's sperm, once they reach an ovum, can penetrate it

BOX 8.3 ✻ Focus on Family Teaching

Tips for Ensuring an Accurate Semen Analysis

Q. Bob Carl asks you, "What can I do to make sure that the analysis of my semen sample is as accurate as possible?"

A. When obtaining a semen sample for analysis:

- Use a clean, dry plastic or glass container with a secure lid to collect the sample.
- Collect the specimen as close as possible to your usual schedule of sexual activity.
- Avoid using any lubricants when you collect the specimen.
- After you have collected the specimen in the container, close it securely and write down the time you collected it.
- Keep the specimen at body temperature while transporting it. Carrying it next to your chest is one way to do this.
- Take the specimen to the laboratory or health care provider's office immediately so it can be analyzed within 1 hour of collection.

effectively. With the use of an assisted reproductive technique such as IVF, poorly motile sperm or those with poor penetration can be injected directly into a woman's ovum under laboratory conditions (intracytoplasmic sperm injection), bypassing the need for sperm to be fully motile.

Ovulation Monitoring

The least costly way to determine a woman's ovulation pattern is to ask her to record her basal body temperature (BBT) for at least 4 months. To determine this, a woman takes her temperature each morning, before getting out of bed or engaging in any activity, eating, or drinking, using a special BBT or tympanic thermometer. She plots this daily temperature on a monthly graph, noticing conditions that might affect her temperature (e.g., colds, other infections, sleeplessness). At the time of ovulation, the basal temperature can be seen to dip slightly (about 0.5° F); it then rises to a level no higher than normal body temperature and remains at that level until 3 or 4 days before the next menstrual flow. This increase in BBT marks the time of ovulation, because it occurs immediately after ovulation (actually at the beginning of the luteal phase of the menstrual cycle, which can occur only if ovulation occurred). A temperature rise should last approximately 10 days. If it does not, a luteal phase defect is suggested (i.e., progesterone production begins but is not sustained). Typical graphs of BBT are shown in Figure 8.2.

What if... Cheryl Carl tells you that she works nights as a cocktail waitress, goes to bed at 4 AM, then wakes at 6 AM to drive her husband to work? Starting at noon, she sleeps for 4 or 5 hours before getting up to go to work. When during the day should she record her basal body temperature?

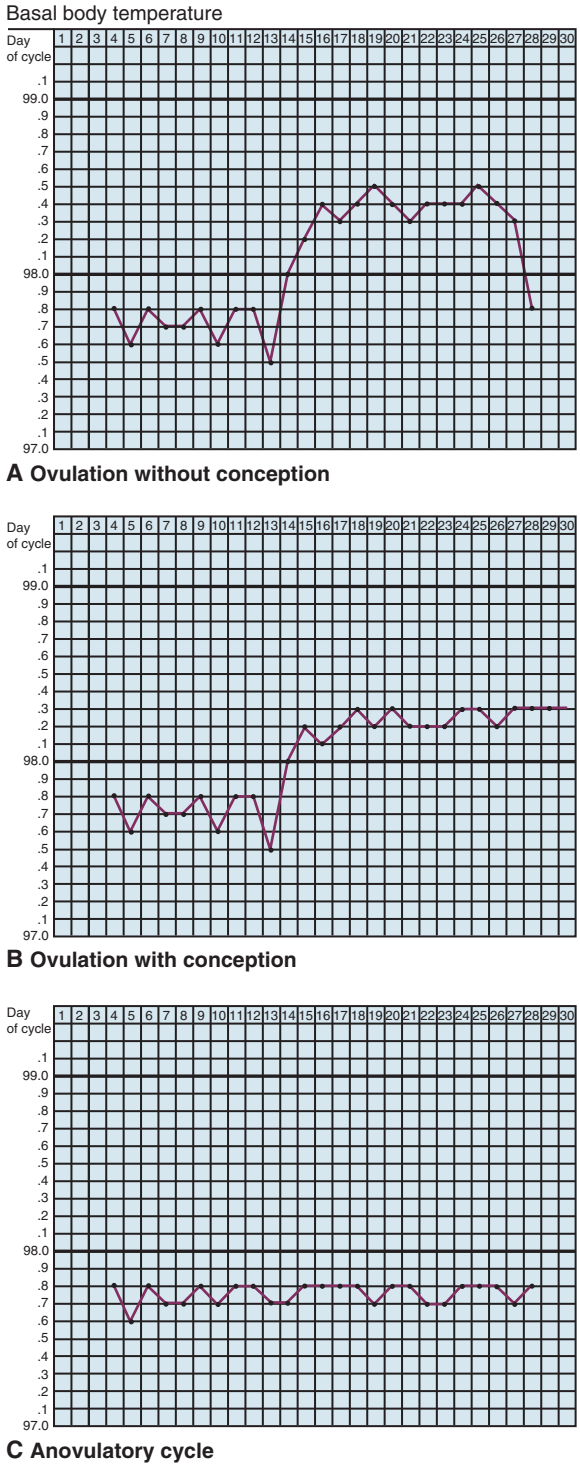

FIGURE 8.2 Basal body temperature graph. (**A**) A woman's temperature dips slightly at midpoint in the menstrual cycle, then rises sharply, an indication of ovulation. Toward the end of the cycle (the 24th day), her temperature begins to decline, indicating that progesterone levels are falling or that she did not conceive. (**B**) A woman's temperature rises at the midpoint in the cycle and remains at that elevated level past the time of her normal menstrual flow, suggesting that pregnancy has occurred. (**C**) There is no preovulatory dip, and no rise of temperature anywhere during the cycle. This is the typical pattern of a woman who does not ovulate.

Ovulation Determination by Test Strip

Various brands of commercial kits are available for assessing the upsurge of LH that occurs just before ovulation. These can be used in place of BBT monitoring. A woman dips a test strip into a midmorning urine specimen and then compares it with the kit instructions for a color change. Such kits are purchased over the counter, are easy to use, and have the advantage of marking the point just before ovulation occurs rather than just after ovulation, as is the case with BBT. They are not as economical as simple temperature recording, but they are advantageous for women with irregular work or daily activity schedules (e.g., working the night shift, arising at varying times in the morning), which can make BBT measurements inaccurate.

Another type of testing kit (Fertell) contains both materials to test FSH the third day of a woman's menstrual cycle (an abnormally high level is an indicator that her ovaries are not responding well to ovulation) and a sperm motility test for the male (Milkin, 2007). The woman's result is available in 30 minutes, the man's in 90 minutes. The kits are expensive but can be helpful to a couple as a first step in fertility testing. Be certain a woman realizes this is not a test of her time of ovulation but a test of whether she has adequate FSH to stimulate egg growth, so she does not use the test at the midpoint of her menstrual cycle.

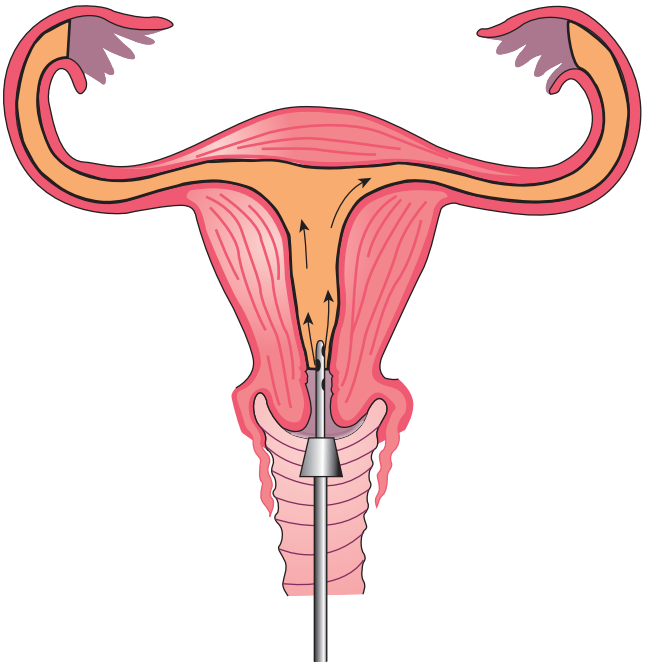

FIGURE 8.3 Insertion of dye for a hysterosalpingogram. The contrast dye outlines the uterus and fallopian tubes on radiographs to demonstrate patency.

Tubal Patency

Both ultrasound and x-ray imaging can be used to determine the patency of fallopian tubes and assess the depth and consistency of the endometrial lining.

Sonohysterography. Sonohysterography is an ultrasound technique designed for inspecting the uterus. The uterus is filled with sterile saline, introduced through a narrow catheter inserted into the uterine cervix. A transvaginal ultrasound transducer is then inserted into the vagina to inspect the uterus for abnormalities such as septal deviation or the presence of a myoma. Because this is a minimally invasive technique, it can be done at any time during the menstrual cycle.

Hysterosalpingography. Hysterosalpingography (uterosalpingography), a radiologic examination of the fallopian tubes using a radiopaque medium, is a second frequently used technique. The procedure is scheduled immediately after a menstrual flow to avoid reflux of menstrual debris up the tubes and unintentional irradiation of a growing zygote. It is contraindicated if infection of the vagina, cervix, or uterus is present (infectious organisms might be forced into the pelvic cavity). For the procedure, iodine-based radiopaque material is introduced into the cervix under pressure (Fig. 8.3). The radiopaque material outlines the uterus and both tubes, provided that the tubes are patent. Because the medium is thick, it distends the uterus and tubes slightly, causing momentary painful uterine cramping. After the study, the contrast medium drains out through the vagina. The instillation of radiopaque material can be therapeutic as well as diagnostic: the pressure of the solution may actually break up adhesions as it passes through the fallopian tubes, thereby increasing their patency (Johnson et al., 2009). Although extremely rare, the procedure carries a small risk of infection, allergic reaction to the contrast medium, or embolism from dye entering a uterine blood vessel.

Advanced Surgical Procedures

If common assessments do not reveal the cause of subfertility, several surgical procedures may be scheduled.

Uterine Endometrial Biopsy

Uterine endometrial biopsy may be used to reveal an endometrial problem such as a luteal phase defect. If the endometrium removed by biopsy resembles a corkscrew (a typical progesterone-dominated endometrium) in the second half of a menstrual cycle, this suggests that ovulation has occurred. Endometrial biopsies are being performed less commonly than previously, having been replaced with serum progesterone level evaluations that also suggest that ovulation occurred.

Endometrial biopsies are done 2 or 3 days before an expected menstrual flow (day 25 or 26 of a typical 28-day menstrual cycle). After a paracervical block, a thin probe and biopsy forceps are introduced through the cervix. A woman may experience mild to moderate discomfort from the maneuvering of the instruments. There may be a moment of sharp pain as the biopsy specimen is taken from the anterior or posterior uterine wall. Possible complications include pain, excessive bleeding, infection, and uterine perforation. This procedure is contraindicated if pregnancy is suspected (although the chance that it would interfere with a pregnancy is probably less than 10%) or if an infection such as acute PID or cervicitis is present. Caution a woman that she might notice a small amount of vaginal spotting after the procedure. For follow-up, she needs to call her primary care

provider if she develops a temperature greater than 101° F, has a large amount of bleeding, or passes clots. She needs to call the health care agency when she has her next menstrual flow. This helps "date" the endometrium and the accuracy of the analysis.

Hysteroscopy

Hysteroscopy is visual inspection of the uterus through the insertion of a hysteroscope, a thin hollow tube, through the vagina, cervix, and into the uterus. This is helpful to further evaluate uterine adhesions or other abnormalities that were discovered on hysterosalpingogram.

Laparoscopy

Laparoscopy is the introduction of a thin, hollow, lighted tube (a fiberoptic telescope or laparoscope) through a small incision in the abdomen, just under the umbilicus, to examine the position and state of the fallopian tubes and ovaries (see Fig. 6.12). It allows the examiner to view the proximity of the ovaries to the fallopian tubes. If this distance is too great, the discharged ovum cannot enter the tube. It is rarely done unless the results of uterosalpingography are abnormal. It is scheduled during the follicular phase of a menstrual period and is done under general anesthesia because of the pain caused by extensive maneuvering. This also allows for good relaxation and a steep Trendelenburg position (which brings the reproductive organs down out of the pelvis). Carbon dioxide is introduced into the abdomen to move the abdominal wall outward and offer better visualization. Women may feel bloating of the abdomen from the infusion of the CO_2 after such a procedure. If some CO_2 escapes under the diaphragm, there may be extremely sharp shoulder pain from pressure.

During the procedure, dye can be injected into the uterus through a polyethylene cannula placed in the cervix to assess tubal patency. Tubes are patent if the dye appears in the abdominal cavity. A scope may be passed directly into a fallopian tube to reveal information about the presence and condition of the fimbria and endometrium lining the tube. If the fimbria have been destroyed by PID, the chance for a normal conception is in doubt, because ova seem to be unable to enter a tube if fimbrial currents are absent.

✔ Checkpoint Question 8.3

Cheryl Carl is scheduled to have a hysterosalpingogram. Which of the following instructions would you give her regarding this procedure?

a. She may feel some mild cramping when the dye is inserted.
b. The ultrasound of the uterus will reveal any tumors present.
c. She will not be able to conceive for 3 months after the procedure.
d. Many women experience mild bleeding as an after effect.

SUBFERTILITY MANAGEMENT

Management of subfertility focuses on correction of any underlying problem that was discovered during assessment. All couples can benefit from some practical information on how to increase the chances of achieving conception on their own (Box 8.4).

BOX 8.4 ✻ Focus on Family Teaching

Suggestions to Aid Conception

Q. Cheryl Carl asks, "Is there anything we can do to help increase our chances for conception?"

A. The following are time-honored suggestions to help aid conception:

- Determine the time of ovulation through the use of basal body temperature, analysis of cervical secretions, or a commercial ovulation determination kit, then plan sexual relations for every other day around the time of ovulation.
- Although frequent intercourse may stimulate sperm production, men need sperm recovery time after ejaculation to maintain an adequate sperm count. This is why coitus every other day, rather than every day, during the fertile period will probably yield faster results.
- The male-superior position is the best position for intercourse to achieve conception because it places sperm closest to the cervical opening.
- The male should try for deep penetration so ejaculation places sperm as close as possible to the cervix. Elevating a woman's hips on a small pillow can facilitate sperm collection near the opening to the cervix.
- A woman should remain on her back with knees drawn up for at least 20 minutes after ejaculation to help sperm remain near the cervix.
- Do not use douching or lubricants before or after intercourse so vaginal pH is unaltered, which could interfere with sperm motility.
- Eat a diet high in slowly digested carbohydrates, low in saturated or trans-fatty acids, and moderate in protein.
- Maintain a body weight that results in a body mass index between 20 and 24.
- Exercise about 30 minutes a day to help keep blood glucose and insulin levels stabilized.
- Choose a new activity the two of you can do together, such as learning how to bowl or ballroom dance, so you create an activity separate from planning a baby. This can help to pass the time in a positive way and also offer a positive outlook for a month when you do not conceive.

Correction of the Underlying Problem

Such underlying causes as chronic disease, inadequate hormone production, endometriosis, or infection need to be treated. If correction of these problems does not yield success, subfertility management focuses on achieving conception through an assisted reproductive technology such as IVF or sperm donation.

Increasing Sperm Count and Motility

If sperm are not motile because the vas deferens is obstructed, the obstruction is most likely to be extensive and difficult to relieve by surgery. If sperm are present but the total count is low, a man may be advised to abstain from coitus for 7 to 10 days at a time to increase the count.

Ligation of a varicocele (if present) and changes in lifestyle (e.g., wearing looser clothing, avoiding long periods of sitting, avoiding prolonged hot baths) may be helpful to reduce scrotal heat and increase the sperm count.

Sperm can be extracted by syringe from a point proximal to vas deferens blockage and used for intrauterine insemination (Verhulst et al., 2009). If the problem appears to be that sperm are immobilized by vaginal secretions because of an immunologic factor, the response can be reduced by abstinence or condom use for about 6 months. However, to avoid this prolonged time interval, washing of the sperm and intrauterine insemination may be preferred. The administration of corticosteroids to a woman may have some effect in decreasing sperm immobilization because it reduces her immune response and antibody production.

Reducing the Presence of Infection

If a vaginal infection is present, the infection will be treated according to the causative organism based on culture reports (see Chapter 47). Vaginal infections such as trichomoniasis and moniliasis tend to recur, requiring close supervision and follow-up. The possibility that the sexual partner is reinfecting a woman needs to be considered. Caution women who are prescribed metronidazole (Flagyl) for a trichomonal infection that it can be teratogenic early in pregnancy and therefore should not be continued if a pregnancy is suspected (Karch, 2009).

Hormone Therapy

If the problem appears to be a disturbance of ovulation, administration of GnRH is a possibility. Therapy with clomiphene citrate (Clomid, Serophene) may also be used to stimulate ovulation (Box 8.5). In other women, ovarian follicular growth can be stimulated by the administration of human menopausal gonadotropins (Pergonal), combinations of FSH and LH derived from postmenopausal urine in conjunction with administration of human chorionic gonadotropin (hCG) to produce ovulation. If increased prolactin levels are identified, bromocriptine (Parlodel) is added to the medication regimen to reduce prolactin levels and allow for the rise of gonadotropins (Karch, 2009).

Administration of either clomiphene citrate or human menopausal gonadotropins may overstimulate an ovary, causing multiple ova to come to maturity and possibly resulting in multiple births. Counsel women who receive these agents that this is a possibility. If sperm do not appear to survive in vaginal secretions because secretions are too scant or tenacious, a woman may be prescribed low-dose estrogen therapy to increase mucus production during days 5 to 10 of her cycle. Conjugated estrogen (Premarin) is a type of estrogen prescribed for this purpose.

If the problem appears to be a luteal phase defect, this can be corrected by progesterone vaginal suppositories begun on the third day of the temperature rise and continued for the next 6 weeks (if pregnancy occurs) or until a menstrual flow begins.

Surgery

Fallopian tubes that have been ligated can be reopened surgically but the success of the operation is not greater than 70% to 80%. Also, the irregular line left by the surgery may result in an ectopic pregnancy (a tubal pregnancy) if a fertilized ovum is stopped at the irregular point (Ahmad et al., 2009). Intrauterine insemination is more commonly used today and more apt to result in a viable pregnancy.

If a myoma (fibroid tumor) is interfering with fertility, a myomectomy, or surgical removal of the tumor, can be scheduled (Griffiths, D'Angelo, & Amso, 2009). Myomectomy can be done via a hysteroscopic ambulatory procedure if the growth is small. Uterine adhesions may also be lysed by hysteroscopy. After this procedure, a woman is prescribed estrogen for 3 months to prevent adhesions from reforming and an IUD may be inserted to help prevent the uterine sides from touching. This treatment can be difficult for a woman to accept, because preventing pregnancy (using an IUD) is exactly what she does not want to do.

For problems of abnormal uterine formation, such as a septate uterus, surgery is also available. However, these defects are usually related to early pregnancy loss, not subfertility.

BOX 8.5 * Focus on Pharmacology

Clomiphene Citrate (Clomid)

Action: Clomiphene citrate (Clomid) is an estrogen agonist used to stimulate the ovary. The drug binds to estrogen receptors, decreasing the number of available estrogen receptors and falsely signaling the hypothalamus to increase FSH and LH secretion. This results in ovulation (Hughes, 2009).

Pregnancy category: X

Dosage: Initially, 50 mg/day orally for 5 days (started anytime if no uterine bleeding has occurred recently or about the fifth day of the cycle if uterine bleeding occurs). If ovulation does not occur, this can be followed by 100 mg/day for 5 days started as early as 30 days after the initial course of therapy. This second course may be repeated one more time.

Possible adverse effects: Abdominal discomfort, distention, bloating, nausea, vomiting, breast tenderness, vasomotor flushing, ovarian enlargement, ovarian overstimulation, multiple births, visual disturbances.

Nursing Implications

- Ensure that women have had a pelvic examination and baseline hormonal studies before therapy.
- Review medication scheduling. Urge women to use a calendar to mark their treatment schedule and plot ovulation. Remind clients that timing intercourse with ovulation is important for achieving pregnancy.
- Advise clients that 24-hour urine samples may be necessary periodically.
- Caution clients to report any bloating, stomach pain, blurred vision, unusual bleeding, bruising, or visual changes.
- Inform clients that therapy can be repeated for a total of three courses; if no results are obtained, therapy will be discontinued at that point.

If the problem is tubal insufficiency from inflammation, diathermy or steroid administration may be helpful in reducing adhesions. Hysterosalpingography can be repeated to determine whether these produce a therapeutic effect. Canalization of the fallopian tubes and plastic surgical repair (microsurgery) are possible treatments. If peritoneal adhesions or nodules of endometriosis are holding the tubes fixed and away from the ovaries, these can be removed by laparoscopy or laser surgery (Jacobson et al., 2007). Additional hormonal therapy for endometriosis is discussed in Chapter 47.

Assisted Reproductive Techniques

If ovulation, sperm production, or sperm motility problems cannot be corrected, assisted reproductive strategies are the next step.

Therapeutic Insemination

Therapeutic insemination is the instillation of sperm into the female reproductive tract to aid conception (Burney, Schust, & Yao, 2007). The sperm is instilled into the cervix (intracervical insemination) or directly into the uterus (intrauterine insemination). Either the husband's sperm (therapeutic insemination by husband) or donor sperm (therapeutic insemination by donor or therapeutic donor insemination) can be used. Therapeutic insemination is used if the man has an inadequate sperm count or a woman has a vaginal or cervical factor that interferes with sperm motility. Donor insemination can be used if the man has a known genetic disorder that he does not want transmitted to children or if a woman has no male partner. It is a useful procedure for men who, feeling their family was complete, underwent a vasectomy but now wish to have children. In the past, men who underwent chemotherapy or radiation for testicular cancer had to accept being child-free afterward as they were no longer able to produce sperm. Today, sperm can be cryopreserved (frozen) in a sperm bank before radiation or chemotherapy and then used for insemination afterward (Bashore, 2007).

One disadvantage of using frozen sperm is that it tends to have slower motility than unfrozen specimens. However, although the rate of conception may be lower from this source, there appears to be no increase in the incidence of congenital anomalies in children conceived by this method. An advantage of cryopreserved sperm is that it can be used even after years of storage.

What if... Bob Carl has some sperm cryopreserved so that Cheryl could become pregnant, but he and Cheryl divorce before it is used? To whom would the cryopreserved sperm belong at that point?

To prepare for therapeutic insemination, a woman must record her BBT, assess her cervical mucus, or use an ovulation predictor kit to predict her likely day of ovulation. On the day after ovulation, the selected sperm are instilled into her cervix using a device similar to a cervical cap or diaphragm, or they are injected directly into the uterus using a flexible catheter (Fig. 8.4).

If therapeutic donor insemination is selected, the donors are volunteers who have no history of disease and no family history of possible inheritable disorders. The blood type, or at least the Rh factor, can be matched with the woman's to prevent incompatibility. Sperm from sperm banks can be selected according to desired physical or mental characteristics.

Some couples have religious or ethical beliefs that prohibit them from using therapeutic insemination. Some states have specific laws regarding inheritance, child support, and responsibility concerning children conceived by therapeutic insemination. In addition, because therapeutic insemination takes an average of 6 months to achieve conception, it may be a discouraging process for couples to have to wait this long to see results.

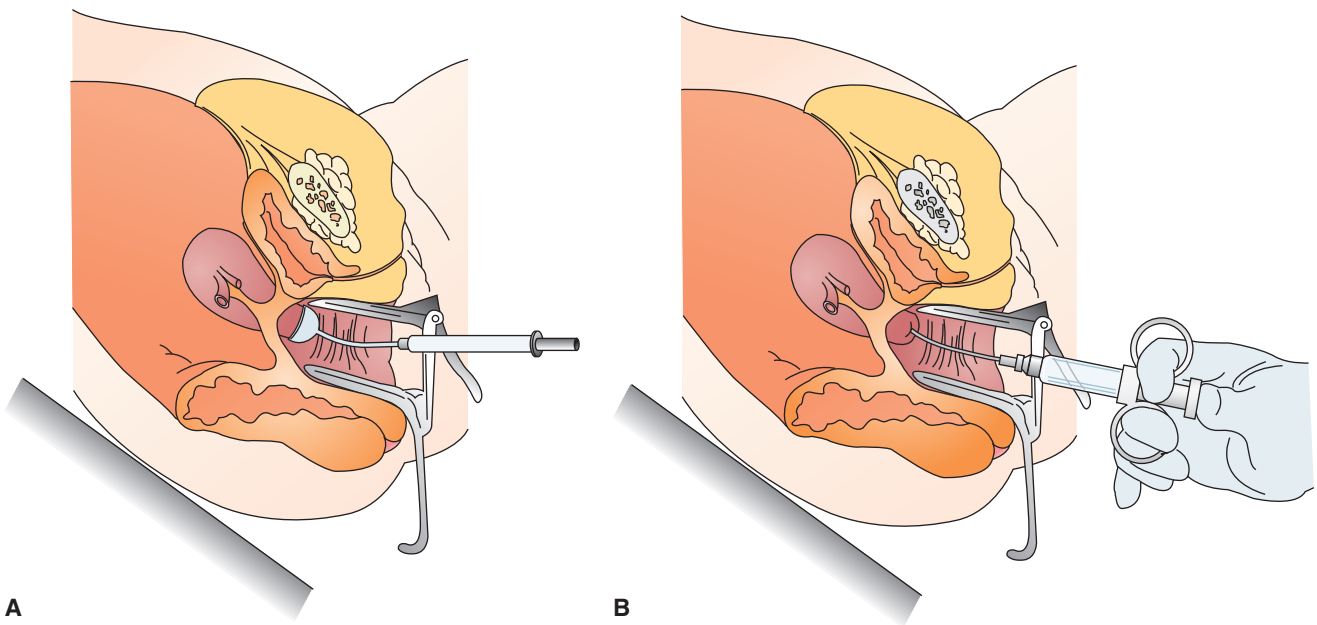

FIGURE 8.4 Therapeutic insemination. Sperm are deposited next to the cervix (**A**) or injected directly into the uterine cavity (**B**).

✔Checkpoint Question 8.4

Bob Carl asks you what therapeutic insemination by donor entails. Which would be your best answer?

a. Therapeutic sperm are injected vaginally to test tubal patency.
b. Donor sperm are introduced vaginally into the uterus or cervix.
c. The husband's sperm is administered intravenously weekly.
d. Donor sperm are injected intra-abdominally into each ovary.

In Vitro Fertilization

In IVF, one or more mature oocytes are removed from a woman's ovary by laparoscopy and fertilized by exposure to sperm under laboratory conditions outside a woman's body. About 40 hours after fertilization, the laboratory-grown fertilized ova are inserted into a woman's uterus, where ideally one or more of them will implant and grow (Van Voorhis, 2007).

IVF is most often used for couples who have not been able to conceive because a woman has blocked or damaged fallopian tubes. It is also used when the man has oligospermia or a very low sperm count, because the controlled, concentrated conditions in the laboratory require only one sperm. IVF may be helpful to couples when an absence of cervical mucus prevents sperm from traveling to or entering the cervix, or antisperm antibodies cause immobilization of sperm. In addition, couples with unexplained subfertility of long duration may be helped by IVF.

A donor ovum, rather than a woman's own ovum, also can be used for a woman who does not ovulate or who carries a sex-linked disease that she does not want to pass on to her children.

Before the procedure, a woman is given an ovulation-stimulating agent such as GnRH, clomiphene citrate (Clomid), or human menopausal gonadotropin (Pergonal). Beginning about the 10th day of the menstrual cycle, the ovaries are examined daily by ultrasound to assess the number and size of developing ovarian follicles. When a follicle appears to be mature, a woman is given an injection of hCG, which causes ovulation in 38 to 42 hours.

A needle is then introduced intravaginally, guided by ultrasound, and the oocyte is aspirated from its follicle. Because of the drugs given to induce ova maturation, many oocytes may ripen at once, and perhaps as many as 3 to 12 can be removed. The oocytes are incubated for at least 8 hours to ensure viability. In the meantime, the husband or donor supplies a fresh semen specimen. The sperm cells and oocytes are mixed and allowed to incubate in a growth medium. Genetic analysis to reveal chromosomal abnormalities or the potential sex can be completed at this point.

In the past, many sperm were necessary even under laboratory conditions to allow sperm to make their way through the resistant zona pellucida surrounding the ovum. Several techniques, such as creating passages through the resistant cells (zona drilling), have been discovered to help sperm cross the zona. In some instances, it has been possible to inject sperm directly under the zona pellucida (intracytoplasmic sperm injection). This is the technique that makes it possible for fertilization to take place with only one sperm. Worry that this technique could lead to an increased number of birth defects is unproven (Van Voorhis, 2007).

After fertilization of the chosen oocytes occurs, the zygotes formed almost immediately begin to divide and grow. By 40 hours after fertilization, they will have undergone their first cell division. In the past, multiple eggs were chosen and implanted to ensure a pregnancy resulted but this technique also resulted in many multiple births. Newborns from multiple births have a much lower chance of surviving the neonatal period than others. For that reason, today, only one or two fertilized eggs are chosen and transferred back to the uterine cavity through the cervix by means of a thin catheter (Van Voorhis, 2007) (Fig. 8.5).

If the couple desires, any eggs not used can be frozen for use at a later time. As with sperm cryopreservation, egg cryopreservation presents a range of ethical and religious dilemmas regarding who would "own" them if the couple should divorce; as well as whether the eggs should be saved, donated, or discarded.

A lack of progesterone can occur if the corpus luteum was injured by the aspiration of the follicle. Therefore, progesterone may be given to a woman if it is believed that she will not produce enough on her own to support implantation. Proof that the zygote has implanted can be demonstrated by a routine serum pregnancy test as early as 11 days after transfer.

In some centers, nurse practitioners are the health care providers who complete oocyte removal and transfer. In all

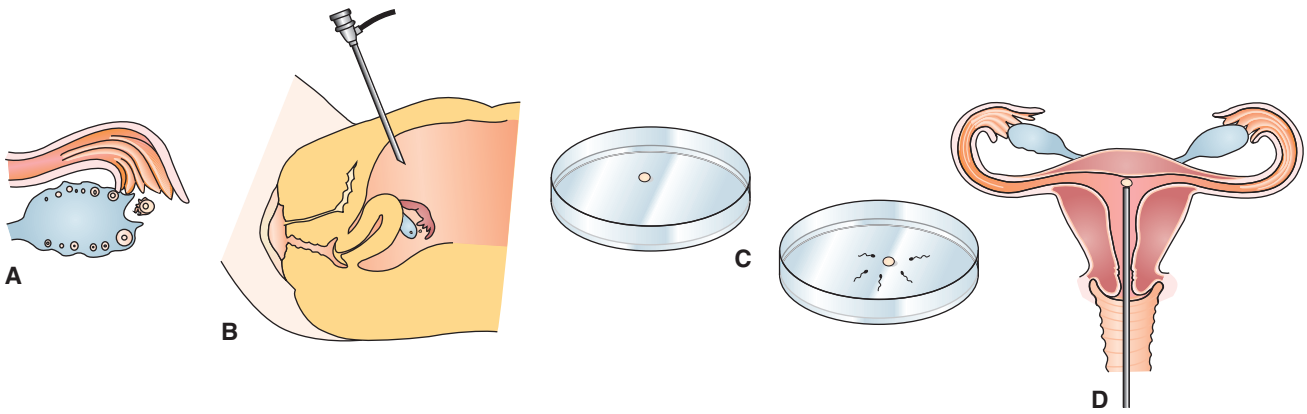

FIGURE 8.5 Steps involved with in vitro fertilization. (**A**) Ovulation. (**B**) Capture of ova (done here intra-abdominally). (**C**) Fertilization of ova and growth in culture medium. (**D**) Insertion of fertilized ova into uterus.

centers, nurses need to supply support and counseling to sustain the couple through the process. The recovery rate for harvesting ripened eggs is high (about 90%), as is the ability to fertilize eggs by sperm in vitro. The overall pregnancy rate by IVF is as low as 38% to 42% per treatment cycle, however (Van Voorhis, 2007). Although IVF programs do not result in an increase in birth defects, about 25% of pregnancies end in spontaneous abortion (the same rate as for natural pregnancies). Once a pregnancy has been successfully established, a woman's prenatal care is the same as that for any pregnancy. Research has shown that, because the couple was so committed to the procedure, they adjust to pregnancy and parenthood well.

If an ultrasound reveals that a multiple pregnancy of more than two zygotes has been achieved, selective termination of gestational sacs until only two are remaining may be recommended. This is done by intra-abdominal injection of potassium chloride into the gestational sacs chosen to be eliminated. Reducing the number of growing embryos to a number a woman can expect to carry to term without difficulty helps to ensure the success of the pregnancy.

IVF is expensive (about $10,000 per cycle) and is available only at specialized centers. There is a risk of maternal infection if bacteria are introduced at any point in the transfer. Waiting to be accepted by a center's program and waiting for the steps of obtaining the oocyte, laboratory growth, and pregnancy success is a major psychological strain (Box 8.6). Couples report a feeling of social isolation during this time and weariness answering friends' and family's questions about the procedure. Supply empathic support through this difficult time (see Focus on Nursing Care Planning Box 8.7).

BOX 8.6 * Focus on Evidence-Based Practice

Does a woman's emotional attitude affect her chance for success with in vitro fertilization?

Because subfertility can lower self-esteem, women may enter an IVF program with anxiety or depression. To determine if a negative (depressed) manner affects the success of IVF, researchers asked 391 women about to undergo the procedure to keep a daily journal documenting their anxiety and depression levels prior to and during the procedure.

In contrast to the expected results, in this study, women with less negative affects (happier) were less likely to achieve a successful IVF procedure and a live birth than were women who presented with a flatter or more sad outlook.

The researchers concluded that couples should be encouraged to express negative emotions about subfertility rather than try to hide them in attempts to be "good" patients or optimistically influence conception, as feelings of anxiety or depression do not interfere with fertility successes and expressing these emotions could allow a couple to receive counseling in this area.

How could you use the result of this study if you were talking to a couple about therapy for subfertility?

Source: de Klerk, C., et al. (2008). Low negative affect prior to treatment is associated with a decreased chance of live birth from a first IVF cycle. *Human Reproduction, 23*(1), 112–116.

Gamete Intrafallopian Transfer

In gamete intrafallopian transfer (GIFT) procedures, ova are obtained from ovaries exactly as in IVF. Instead of waiting for fertilization to occur in the laboratory, however, both ova and sperm are instilled within a matter of hours, using a laparoscopic technique, into the open end of a patent fallopian tube. Fertilization then occurs in the tube, and the zygote moves to the uterus for implantation. This procedure has a pregnancy rate equal to that of IVF. The procedure is contraindicated if a woman's fallopian tubes are blocked, because this could lead to ectopic (tubal) pregnancy.

Zygote Intrafallopian Transfer

Zygote intrafallopian transfer (ZIFT) involves oocyte retrieval by transvaginal, ultrasound-guided aspiration, followed by culture and insemination of the oocytes in the laboratory. Within 24 hours, the fertilized eggs are transferred by laparoscopic technique into the end of a waiting fallopian tube. ZIFT differs from GIFT in that fertilization takes place outside the body, allowing health care providers to be certain that fertilization has occurred before the growing structure is reintroduced. As in GIFT, a woman must have one functioning fallopian tube for the technique to be successful, because the zygotes are implanted into the fimbriated end of a tube rather than into the uterus. This technique allows for genetic analysis the same as IVF.

Surrogate Embryo Transfer

Surrogate embryo transfer is an assisted reproductive technique for a woman who does not ovulate. The process involves use of an oocyte that has been donated by a friend or relative or provided by an anonymous donor (van Berkel, Candido, & Pijffers, 2007). The menstrual cycles of the donor and recipient are synchronized by administration of gonadotropic hormones. At the time of ovulation, the donor's ovum is removed by a transvaginal, ultrasound-guided procedure. The oocyte is then fertilized in the laboratory by the recipient woman's male partner's sperm (or donor sperm) and placed in the recipient woman's uterus by embryonic transfer. Once pregnancy occurs, it progresses the same as an unassisted pregnancy.

Preimplantation Genetic Diagnosis

The individual retrieval of oocytes and their fertilization under laboratory conditions have led to close inspection and recognition of differences in sperm and oocytes. After the oocytes are fertilized in IVF and ZIFT procedures, the DNA of both sperm and oocytes can be examined for specific genetic abnormalities or specific genes such as Down's syndrome or hemophilia (Swanson et al., 2007).

Couples participating in intrauterine transfer and therapeutic insemination can also have the sex of their children predetermined using these methods. Such techniques can be useful, because popular methods to influence the sex of a child (such as douching with a baking soda mixture before coitus to have a boy or with a vinegar solution to have a girl) have proved to be more folklore than scientific fact. Allowing couples to choose the sex of children has ethical concerns because it could result in skewed male/female ratios if used by a majority of couples.

BOX 8.7 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Couple Seeking a Fertility Evaluation

Cheryl and Bob Carl married when they were both 25 and planned to wait 5 years before beginning their family so they could save money for a house. At the end of 5 years, they bought the house. On the day they moved in, Mrs. Carl stopped taking her birth control pills. At the end of a year, however, she still was not pregnant. Three years later, the Carls began fertility testing. They are now undergoing their second cycle of in vitro fertilization and embryo transfer. The Carls have applied for a second mortgage on their house to finance the fertility testing and fertilization procedures. At her last visit, Mrs. Carl stated, "This is my fault because I'm so rigid. I can't relax enough to get pregnant. Look how I had to buy the house before I could even consider getting pregnant, and now we'll probably lose it. Besides that, it feels like our whole life revolves around trying to get pregnant."

Family Assessment ✻ Couple lives in three-bedroom middle-income home; husband works as a bank manager; wife works as a receptionist in a medical office. Husband reports finances as "not good." Both appear discouraged about their apparent inability to have children.

Client Assessment ✻ Past medical history negative for any major health problems; wife reports a menstrual cycle of 5 days' duration with moderate flow every 30 to 32 days; moderate dysmenorrhea for the first 2 days of her menses. Oral contraceptive use for 6 years; discontinued 3 years ago. Baseline laboratory studies and vital signs within normal limits.

Nursing Diagnosis ✻ Situational low self-esteem related to seeming inability to conceive

Outcome Criteria ✻ Couple verbalizes feelings about possible subfertility and effect on self-esteem; participates actively in care and treatment decisions; states they feel some control over situation and required treatment.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Assess couple's lifestyle to identify areas in which they are successful.	Review and reinforce with client activities they have achieved successfully.	Identifying positive attributes can provide a foundation for rebuilding self-esteem.	Couple names at least three positive achievements, such as organizing at work or planting garden.
Nurse	Assess if there is a common interest they could draw on.	Ask couple to propose a new activity that would interest both of them.	Beginning a new activity can eliminate total concentration on fertility management.	Couple names and begins to participate in a new activity by 2 weeks' time.
		Consultations		
Nurse/social worker	Assess the couple's community for available community resources.	Ask couple if they would like a referral to a support group such as Resolve.	A national organization can help supply effective support during a family crisis.	Couple confirms they have contacted an outside support group and have attended at least one meeting or on-line chat group.
		Procedures/Medications		
Nurse/physician/nurse practitioner	Assess whether couple understands what procedures will be scheduled for a basic fertility series.	Encourage clients to ask questions about procedures; if prescribed an ovulation stimulant, review dosage and administration schedule.	Fully informed clients are better able to participate in their own care.	Clients show interest in procedures and medication by asking questions and demonstrating successful medication adherence.

(continued)

BOX 8.7 ✻ Focus on Nursing Care Planning (continued)

		Nutrition		
Nurse/ nutritionist	Assess whether couple ingests a healthy diet in light of busy lifestyle.	Remind client to take prenatal vitamin (because of folic acid content) during fertility studies to be well prepared when pregnancy is achieved.	Folic acid is necessary in early pregnancy to help prevent spinal cord anomalies. Overall health may contribute to fertility.	Client demonstrates that she has filled her prenatal vitamin prescription and confirms that she takes them. Client lists a healthy diet and states that she does not smoke or take recreational drugs.
		Patient/Family Education		
Nurse	Assess whether couple understands why ovulation and conception occur.	Discuss new fertility measures being instituted; include both members of couple in discussion as appropriate.	Discussing conception-related factors helps to provide a baseline for understanding possible procedures and treatments. Including the partners as a couple helps promote family-centered care.	Couple discusses options they need to follow for fertility testing.
		Spiritual/Psychosocial/Emotional Needs		
Nurse	Attempt to identify the meaning of fertility to each client individually and to the couple.	Clarify any misconceptions clients may have about fertility and subfertility.	Misconceptions can negatively affect self-esteem.	Clients accurately describe situation and manifest adequate self-esteem.
		Discharge Planning		
Nurse	Assess whether couple has any further questions about fertility testing and how they are active partners in it.	Stress that waiting for a much-desired pregnancy to come to term can be just as stressful as waiting for fertility measures to be effective.	Identifying stressful situations can help the couple prepare for them.	Couple states they feel well equipped to manage stress following fertility assessment.
Nurse	Determine who the couple has to turn to for support outside of health care providers.	Discuss possible support persons and groups.	Additional support can assist in reinforcing positive attributes, thus enhancing self-esteem.	Clients list appropriate persons or groups to use as support people.

ALTERNATIVES TO CHILDBIRTH

For some couples, even treatments for subfertility with procedures such as IVF are not successful. These couples need to consider still other options.

Surrogate Mothers

A surrogate mother is a woman who agrees to carry a pregnancy to term for a subfertile couple (Reilly, 2007). The surrogate may provide the ova and be impregnated by the man's sperm. In other instances, the ova and sperm both may be donated by the subfertile couple, or donor ova and sperm may be used. Surrogate mothers are often friends or family members who assume the role out of friendship or compassion, or they can be referred to the couple through an agency or attorney and receive monetary reimbursement for their expenses. The subfertile couple can enjoy the pregnancy as they watch it progress in the surrogate.

Several ethical and legal problems arise if the surrogate mother decides at the end of pregnancy that she has formed an attachment to the fetus and wants to keep the baby despite the prepregnancy agreement she signed. Court decisions have been split on whether the surrogate or the subfertile couple has the right to the child. Another potential problem occurs if the child is born imperfect and the subfertile couple then no longer want the child. Who should have responsibility in this instance? For these reasons, the

couple and the surrogate mother must be certain they have given adequate thought to the process, and to what will be the outcome should these problems occur, before they attempt surrogate mothering.

Adoption

Adoption, once a ready alternative for subfertile couples, is still a viable alternative, although today there are fewer children available for adoption from official agencies than formerly. Urge couples to consider foreign-born or physically or cognitively challenged children or children of other races to make their family feel complete. The process of adoption is discussed in Chapter 3.

Child-Free Living

Child-free living is an alternative lifestyle available to both fertile and subfertile couples. For many subfertile couples who have been through the rigors and frustrations of subfertility testing and unsuccessful treatment regimens, child-free living may emerge as the option they finally wish to pursue. A couple in the midst of fertility testing may begin to reexamine their motives for pursuing pregnancy and may decide that pregnancy and parenting are not worth the emotional or financial cost of future treatments. They may decide that the additional stress of going through an adoption is not for them, or they may simply decide that children are not necessary for them to complete their family unit. For these couples, child-free living is a positive choice.

Child-free living can be as fulfilling as having children, because it allows a couple more time to help other people and to contribute to society through personal accomplishments. It has advantages for a couple in that it allows time for both members to pursue careers. They can travel more or have more time to pursue hobbies or continue their education. If a couple still wishes to include children in their lives in some way, many opportunities are available to do this through family connections (most parents welcome offers from siblings or other family members to share in childrearing), through volunteer organizations (such as Big Brother or Big Sister programs), or through local schools and town recreational programs.

Many couples who believe that overpopulation is a major concern choose child-free living even if subfertility is not present. Parents who choose child-free living typically rate their marriage as happier than those with children, probably because of decreased expenses involved and more free time that allows them to follow their hearts (Cherlin, 2008).

✔ Checkpoint Question 8.5

Cheryl Carl is having a GIFT procedure. What makes her a good candidate for this procedure?

a. She has patent fallopian tubes, so fertilized ova can be implanted into them.
b. She is Rh negative, a necessary requirement to rule out Rh incompatibility.
c. She has a normal uterus, so sperm can be injected through the cervix into it.
d. Her husband is taking sildenafil (Viagra), so all sperm will be motile.

Key Points for Review

- Subfertility is said to exist when a pregnancy has not occurred after 1 year of unprotected coitus. Sterility refers to the inability to conceive because of a known condition.
- About 14% of couples today experience subfertility. The incidence increases with the age of the couple.
- Subfertility testing can be an intense psychological stressor for couples. Help couples not only to persist through the experience but also help them maintain their relationship as a couple.
- Couples who are told that a subfertility problem has been discovered are apt to suffer a loss of self-esteem. Offer support to help them look at other aspects of their lives in which they do achieve and to recognize that they are productive, healthy people in other ways.
- Male factors that contribute to subfertility are inadequate sperm count, obstruction or impaired sperm motility, and problems with ejaculation. Female factors that cause subfertility are problems with ovulation, tubal transport, or impaired implantation.
- Basic subfertility assessment procedures consist of a health history, physical examination, laboratory tests to document general health, and specific tests for semen, ovulation, and tubal patency.
- Measures to induce fertility are aimed at improving sperm number and transport, decreasing infections, stimulating ovulation, improving nutrition, and regulating hormones.
- Therapeutic insemination, donor egg transfer, in vitro fertilization, adoption, surrogate motherhood, and child-free living are all possible solutions for subfertility.

CRITICAL THINKING EXERCISES

1. Cheryl Carl, whom you met at the beginning of the chapter, stated that she believed her subfertility problem was her fault because she was too rigid. She said, "It feels like our whole life revolves around trying to get pregnant." Does a rigid personality affect subfertility? Does relaxation aid conception?
2. The Carls want to have a child as soon as possible. In addition to their subfertility assessment, what advice would you give them to help increase their chances of conceiving quickly?
3. Cheryl tells you that she eats a lot of "fast foods." Could this be creating a risk factor for subfertility?
4. Examine the National Health Goal related to subfertility. Most government-sponsored money for nursing research is allotted based on national health goals. What would be a possible research topic to explore pertinent to this goal that would be applicable to the Carl family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX types of questions related to couples with subfertility. Confirm your answers are correct by reading the rationales.

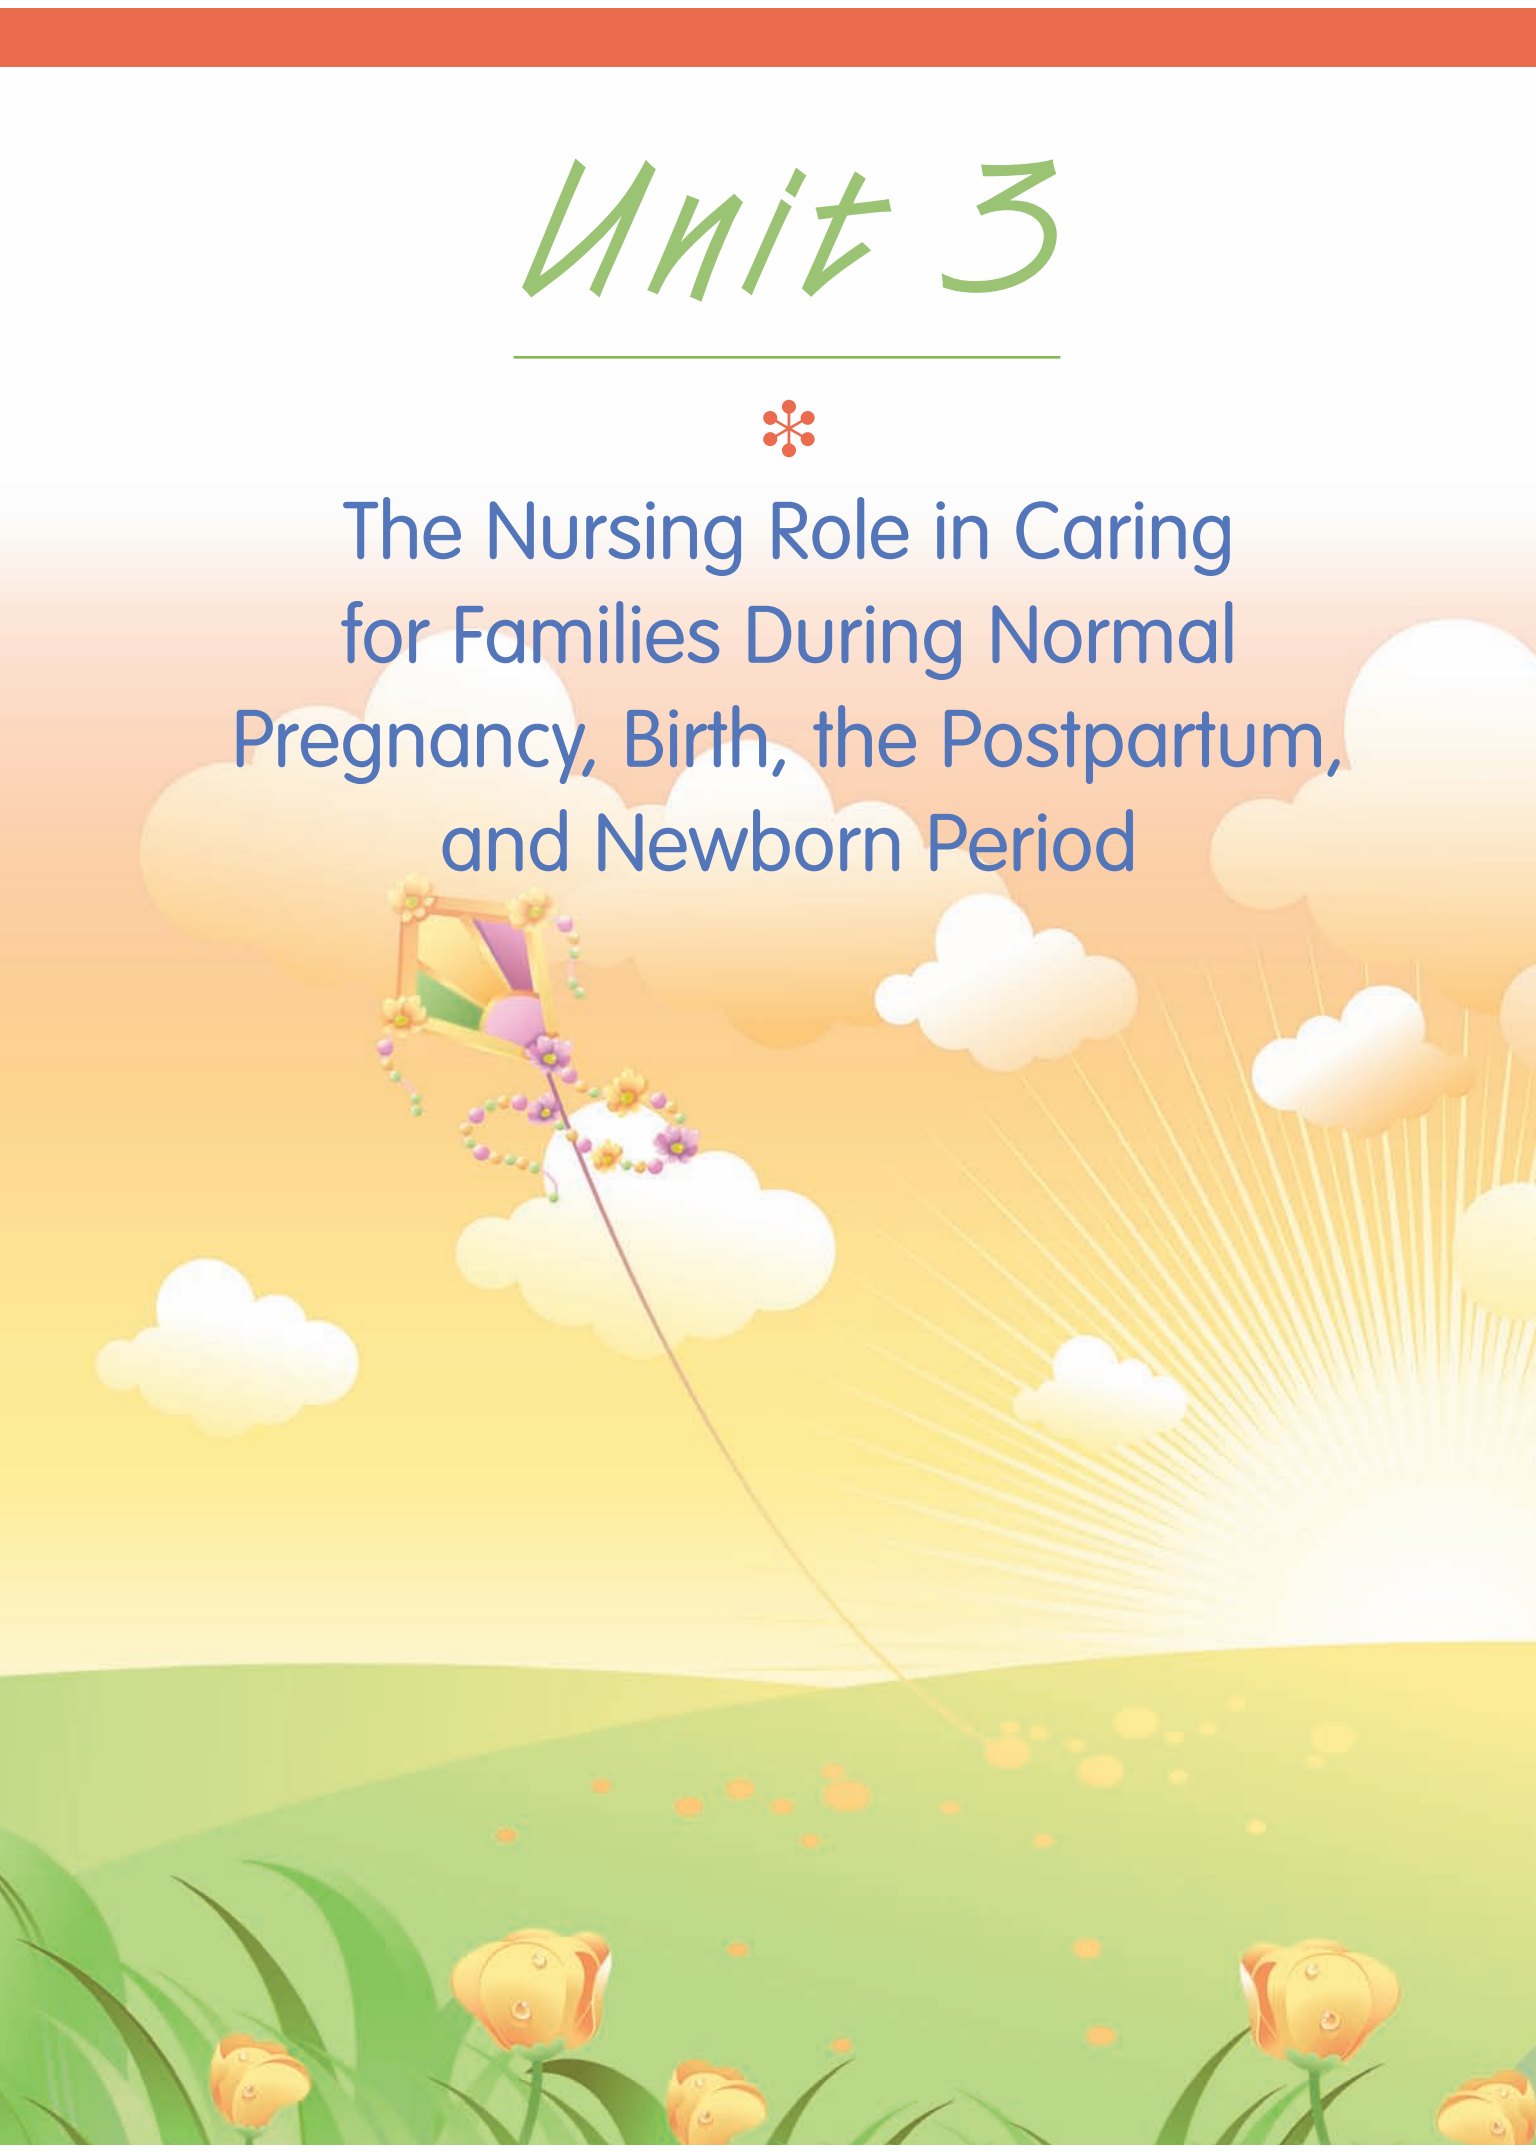
Unit 3

The Nursing Role in Caring for Families During Normal Pregnancy, Birth, the Postpartum, and Newborn Period



This page intentionally left blank.

Chapter 9

The Growing Fetus

KEY TERMS

- age of viability
- amniocentesis
- amniotic membrane
- cephalocaudal
- chorionic membrane
- chorionic villi
- decidua
- embryo
- estimated date of birth
- fertilization
- fetoscopy
- fetus
- foramen ovale
- hydramnios
- implantation
- McDonald's rule
- meconium
- nonstress test
- oligohydramnios
- rganogenesis
- surfactant
- trophoblast
- umbilical cord
- zygote

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe the growth and development of a fetus by gestation week.
2. Identify National Health Goals related to fetal growth that nurses can help the nation achieve.
3. Use critical thinking to analyze ways to make care family centered, even at this early point in life.
4. Assess fetal growth and development through maternal and pregnancy landmarks.
5. Formulate nursing diagnoses related to the needs of a fetus.
6. Establish expected outcomes to meet the needs of a growing fetus.
7. Plan nursing care that promotes healthy fetal growth and development such as nutrition counseling.
8. Implement nursing care to help ensure both a safe fetal environment and a safe pregnancy outcome.
9. Evaluate expected outcomes for achievement and effectiveness of care.
10. Identify areas of fetal health that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of fetal growth and development with nursing process to achieve quality maternal and child health nursing care.

Liz Calhorn, an 18-year-old, is 20 weeks pregnant. Although she says she knows she should have stopped smoking during pregnancy, she has not been able to do this. Twice during the pregnancy (at the 4th and 10th week), she drank beer at summer picnics. Today, at a clinic visit, she tells you she has felt her fetus move. She states, "Feeling the baby move made me realize there's someone inside me, you know what I mean? It made me know it's time I started being more careful with what I do." Her boyfriend (the father of the fetus) is supportive, but the couple has no plans to marry. The client states, "I'm not ready for that big a commitment." Feeling a fetus move is often the trigger that makes having a baby "real" for many women. The more women know about fetal development before and after this event, the easier it is for them to begin to think of the pregnancy not as something interesting happening to them but as an act that is producing a separate life. A previous chapter described reproductive anatomy. This chapter adds information about fetal growth and development and assessment of fetal health.

In light of Liz's realization, how would you modify your health teaching with her?

Throughout history, different societies have held a variety of beliefs and superstitions about the way the **fetus** (the infant during intrauterine life) grows. Medieval artists depicted a fetus as already formed as a miniature man. Leonardo da Vinci, in his notebooks of 1510 to 1512, made several sketches of unborn infants that suggest he believed the fetus was immobile and essentially a part of the mother, sharing her blood and internal organs. During the 17th and 18th centuries, a baby was thought to form to a miniature size in the mother's ovaries; when male cells were introduced, the baby expanded to birth size. A second theory was that the child existed in the head of the sperm cell as a fully formed being, the uterus serving only as an incubator in which it grew.

It was not until 1758 that Kaspar Wolff proposed that both parents contribute equally to the structure of the baby. Because of the work of modern medical researchers and photographers who have been able to capture the process of fertilization and fetal development by high-tech photography, there is now a clear picture of what a fetus looks like from the moment of conception until birth. Surveillance of the fetus by ultrasound documents this growth process.

Because a nation cannot have healthy children without healthy intrauterine growth, several National Health Goals speak to the importance of protecting fetal growth (Box 9.1).

BOX 9.1 ✻ Focus on National Health Goals

Several National Health Goals address fetal growth.

- Reduce the fetal death rate (death before 20 weeks of gestation) to no more than 4.1 per 1000 live births from a baseline of 6.8 per 1000.
- Reduce low birth weight to an incidence of no more than 5% of live births and very low birthweight to no more than 0.9% of live births from baselines of 7.6% and 1.4%.
- Increase the proportion of pregnancies begun with an optimum folic acid level from a baseline of 21% to 80% (http://www.nih.gov).

Nurses can help the nation achieve these goals by urging women to plan their pregnancies so they can enter a pregnancy in good health and with an optimum folic acid level. Educating women about the importance of attending prenatal care is another important role. Nursing research in such areas as the reasons why women avoid prenatal care or how soon women make lifestyle changes during pregnancy could help lead to achievement of these National Health Goals.

Nursing Process Overview

To Help Ensure Fetal Health

Assessment

Assessing fetal growth throughout pregnancy, by such means as fundal height and fetal heart rate, is important because these predictable signs of fetal development provide guides for determining the well-being of fetuses. For the expectant family, knowledge about fetal growth and development can provide an important frame of reference, helping a mother to understand some of the changes going on in her body and allowing all family members to begin thinking about and accepting the newest member of the family before the baby is actually born. For this reason, convey the findings gained from fetal assessment at prenatal visits in as much detail as the parents request.

Nursing Diagnosis

Common nursing diagnoses related to growth and development of the fetus focus on the mother and family as well as on the fetus. Examples might include:

- Health-seeking behaviors related to knowledge of normal fetal development
- Anxiety related to lack of fetal movement
- Deficient knowledge related to need for good prenatal care for healthy fetal well-being

Outcome Identification and Planning

Be certain that plans for care include ways to educate potential parents about teratogens (any substance that could be harmful to a fetus) that might interfere with fetal health. Be certain that outcome criteria established for teaching about fetal growth are realistic and based on the parents' previous knowledge and desire for information. When additional assessment measures are necessary, such as an amniocentesis or an ultrasound examination, add this information to the teaching plan, explaining why further assessment is necessary and what the parents can expect from the procedure. An interesting web site for parents that shows fetal development in photographs is http://www.paternityangel.com.

Implementation

Most expectant parents are interested in learning about how mature their fetus is at various points in pregnancy because this helps them visualize their coming newborn. This, in turn, helps them to understand the importance of implementing healthy behaviors, such as eating well and avoiding substances that may be dangerous to a fetus such as recreational drugs. Viewing an ultrasound and learning the fetal sex are big steps to help initiate bonding between the parents and the infant.

Outcome Evaluation

Outcome evaluation related to fetal growth and development usually focuses on determining whether a woman or family has made any necessary changes in lifestyle to ensure fetal growth and whether a woman voices confidence that her baby is healthy and growing. Examples of expected outcomes include:

- Parents describe smoke-free living at next prenatal visit.
- Client records number of movements of fetus for 1 hour daily.
- Couple attends all scheduled prenatal visits.
- Client states she is looking forward to the birth of her baby.

STAGES OF FETAL DEVELOPMENT

In just 38 weeks, a fertilized egg (ovum) matures from a single cell to a fully developed fetus ready to be born.

Fetal growth and development are typically divided into three periods: preembryonic (first 2 weeks, beginning with fertilization), embryonic (weeks 3 through 8), and fetal (from week 8 through birth). Table 9.1 lists common terms used to describe the fetus at various stages in this growth.

Fertilization: The Beginning of Pregnancy

Fertilization (also referred to as conception and impregnation) is the union of an ovum and a spermatozoon. This usually occurs in the outer third of a fallopian tube, the ampullar portion (Crombleholme, 2009).

Usually only one of a woman's ova will reach maturity each month. Once the mature ovum is released, fertilization must occur fairly quickly because an ovum is capable of fertilization for only 24 hours (48 hours at the most). After that time, it atrophies and becomes nonfunctional. Because the functional life of a spermatozoon is also about 48 hours, possibly as long as 72 hours, the total critical time span during which sexual relations must occur for fertilization to be successful is about 72 hours (48 hours before ovulation plus 24 hours afterward).

As the ovum is extruded from the graafian follicle of an ovary with ovulation, it is surrounded by a ring of mucopolysaccharide fluid (the zona pellucida) and a circle of cells (the corona radiata). The ovum and these surrounding cells (which increase the bulk of the ovum and serve as protective buffers against injury) are propelled into a nearby fallopian tube by currents initiated by the fimbriae—the fine, hairlike structures that line the openings of the fallopian tubes. A combination of peristaltic action of the tube and movements of the tube cilia help propel the ovum along the length of the tube.

Normally, an ejaculation of semen averages 2.5 mL of fluid containing 50 to 200 million spermatozoa per milliliter, or an average of 400 million sperm per ejaculation. At the time of ovulation, there is a reduction in the viscosity (thickness) of the cervical mucus, which makes it easy for spermatozoa to penetrate it. Sperm transport is so efficient close to ovulation that spermatozoa deposited in the vagina generally reach the cervix within 90 seconds and the outer end of a fallopian tube within 5 minutes after deposition. This is one reason why douching is not an effective contraceptive measure (Burkman, 2007).

The mechanism whereby spermatozoa are drawn toward an ovum is probably a species-specific reaction, similar to an antibody–antigen reaction. Spermatozoa move through the cervix and the body of the uterus and into the fallopian tubes, toward the waiting ovum by the combination of movement by their flagella (tails) and uterine contractions. Capacitation is a final process that sperm must undergo to be ready for fertilization. This process, which happens as the sperm move toward the ovum, consists of changes in the plasma membrane of the sperm head, which reveal the sperm-binding receptor sites.

All of the spermatozoa that achieve capacitation reach the ovum and cluster around the protective layer of corona cells. Hyaluronidase (a proteolytic enzyme) is released by the spermatozoa and dissolves the layer of cells protecting the ovum. One reason that an ejaculation contains such a large number of sperm is probably to provide sufficient enzymes to dissolve the corona cells. Under ordinary circumstances, only one spermatozoon is able to penetrate the cell membrane of the ovum. Once it penetrates the cell, the cell membrane changes composition to become impervious to other spermatozoa. An exception to this is the formation of hydatidiform mole, in which multiple sperm enter an ovum; this leads to abnormal zygote formation (see Chapter 21).

Immediately after penetration of the ovum, the chromosomal material of the ovum and spermatozoon fuse to form a **zygote.** Because the spermatozoon and ovum each carried 23 chromosomes (22 autosomes and 1 sex chromosome), the fertilized ovum has 46 chromosomes. If an X-carrying spermatozoon entered the ovum, the resulting child will have two X chromosomes and will be female (XX). If a Y-carrying spermatozoon fertilized the ovum, the resulting child will have an X and a Y chromosome and will be male (XY).

Fertilization is never a certain occurrence because it depends on at least three separate factors: equal maturation of both sperm and ovum, the ability of the sperm to reach the ovum, and the ability of the sperm to penetrate the zona pellucida and cell membrane and achieve fertilization.

From the fertilized ovum (zygote), both the future child and the accessory structures needed for support during intrauterine life (e.g., placenta, fetal membranes, amniotic fluid, and umbilical cord) are formed.

TABLE 9.1 ✻ Terms Used to Denote Fetal Growth

Name	Time Period
Ovum	From ovulation to fertilization
Zygote	From fertilization to implantation
Embryo	From implantation to 5–8 weeks
Fetus	From 5–8 weeks until term
Conceptus	Developing embryo or fetus and placental structures throughout pregnancy
Age of viability	The earliest age at which fetuses could survive if they were born at that time, generally accepted as 24 weeks, or fetuses weighing more than 400 g

Implantation

Once fertilization is complete, a zygote migrates over the next 3 to 4 days toward the body of the uterus, aided by the currents initiated by the muscular contractions of the fallopian tubes. During this time, mitotic cell division, or cleavage, begins. The first cleavage occurs at about 24 hours; cleavage divisions continue to occur at a rate of about one every 22 hours. By the time the zygote reaches the body of the uterus, it consists of 16 to 50 cells. At this stage, because of its bumpy outward appearance, it is termed a morula (from the Latin word *morus,* meaning "mulberry").

The morula continues to multiply as it floats free in the uterine cavity for 3 or 4 additional days. Large cells tend to collect at the periphery of the ball, leaving a fluid space surrounding an inner cell mass. At this stage, the structure becomes a blastocyst. It is this structure that attaches to the uterine endometrium. The cells in the outer ring are **trophoblast**

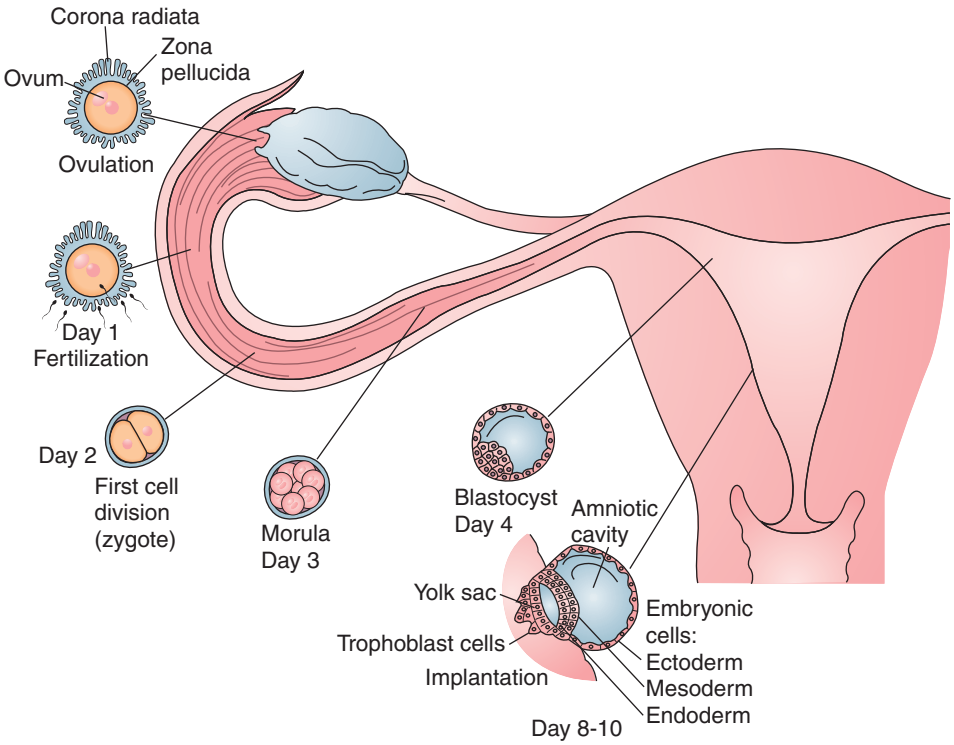


FIGURE 9.1 Ovulation, fertilization, and implantation. The blastocyst is differentiated into three germ layers (ectoderm, mesoderm, and endoderm). Cells at the periphery are trophoblast cells that mature into the placenta.

cells. They are the part of the structure that will later form the placenta and membranes. The inner cell mass (embryoblast cells) is the portion of the structure that will form the embryo.

Implantation, or contact between the growing structure and the uterine endometrium, occurs approximately 8 to 10 days after fertilization. After the third or fourth day of free floating (about 8 days since ovulation), the blastocyst sheds the last residues of the corona and zona pellucida. The structure brushes against the rich uterine endometrium (in the second [secretory] phase of the menstrual cycle), a process termed *apposition.* It attaches to the surface of the endometrium (adhesion) and settles down into its soft folds (invasion). Stages to this point are depicted in Figure 9.1.

The touching or implantation point is usually high in the uterus, on the posterior surface. If the point of implantation is low in the uterus, the growing placenta may occlude the cervix and make birth of the child difficult (placenta previa). The blastocyst is able to invade the endometrium because, as the trophoblast cells on the outside of the structure touch the endometrium, they produce proteolytic enzymes that dissolve any tissue they touch. This action allows the blastocyst to burrow deeply into the endometrium and receive some basic nourishment of glycogen and mucoprotein from the endometrial glands. As invasion continues, the structure establishes an effective communication network with the blood system of the endometrium.

Implantation is an important step in pregnancy, because as many as 50% of zygotes never achieve it (Knuppel, 2007). In these instances, the pregnancy ends as early as 8 to 10 days after conception, often before a woman is even aware she was pregnant. Occasionally, a small amount of vaginal spotting appears on the day of implantation because capillaries are ruptured by the implanting trophoblast cells. A woman who normally has a particularly scant menstrual flow may mistake implantation bleeding for her menstrual period. If this happens, the predicted date of birth of her baby (based on the time of her last menstrual period) will be calculated 4 weeks late. Once implanted, the zygote becomes an **embryo.**

✔ Checkpoint Question 9.1

Liz Calhorn asks how much longer her doctor will refer to the baby inside her as an embryo. The conceptus is an embryo:

a. Until the time of fertilization.
b. Until the placenta forms.
c. From implantation until 20 weeks.
d. From implantation until 5 to 8 weeks.

EMBRYONIC AND FETAL STRUCTURES

The placenta, which will serve as the fetal lungs, kidneys, and digestive tract in utero, begins growth in early pregnancy in coordination with embryo growth.

The Decidua

After fertilization, the corpus luteum in the ovary continues to function rather than atrophying, because of the influence of human chorionic gonadotropin (hCG), a hormone secreted by the trophoblast cells. This causes the uterine endometrium to continue to grow in thickness and vascularity,

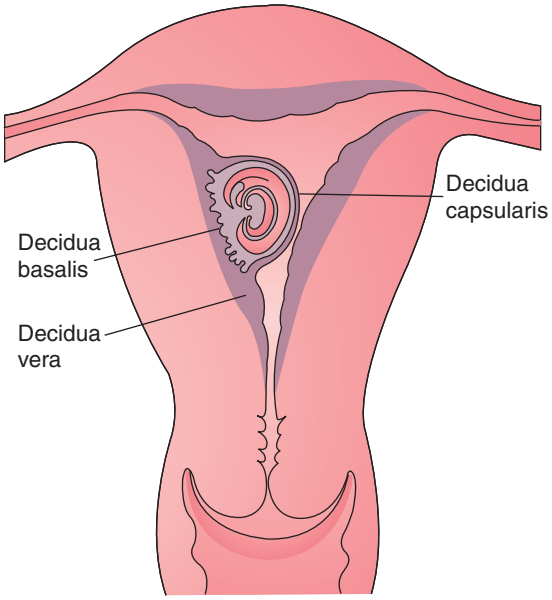

FIGURE 9.2 The three areas of uterine decidua.

instead of sloughing off as in a usual menstrual cycle. The endometrium is now termed the **decidua** (the Latin word for "falling off"), because it will be discarded after the birth of the child. The decidua has three separate areas (Fig. 9.2):

1. *Decidua basalis,* the part of the endometrium that lies directly under the embryo (or the portion where the trophoblast cells establish communication with maternal blood vessels)
2. *Decidua capsularis,* the portion of the endometrium that stretches or encapsulates the surface of the trophoblast
3. *Decidua vera,* the remaining portion of the uterine lining

As the embryo continues to grow, it pushes the decidua capsularis before it like a blanket. Eventually, the embryo enlarges so much that this action brings the decidua capsularis into contact with the opposite uterine wall (the decidua vera). Here, the two decidua areas fuse, which is why, at birth, the entire inner surface of the uterus is stripped away, leaving the organ highly susceptible to hemorrhage and infection.

Chorionic Villi

Once implantation is complete, the trophoblastic layer of cells of the blastocyst begins to mature rapidly. As early as the 11th or 12th day, miniature villi that resemble probing fingers, termed **chorionic villi,** reach out from the single layer of cells into the uterine endometrium to begin formation of the placenta. At term, almost 200 such villi will have formed (Knuppel, 2007).

All chorionic villi have a central core of connective tissue and fetal capillaries. A double layer of trophoblast cells surrounds these. The outer of the two covering layers is the *syncytiotrophoblast*, or the syncytial layer. This layer of cells produces various placental hormones, such as hCG, somatomammotropin (human placental lactogen [hPL]), estrogen, and progesterone. The middle layer, the *cytotrophoblast* or Langhans' layer, is present as early as 12 days' gestation. It appears to function early in pregnancy to protect the growing embryo and fetus from certain infectious organisms such as the spirochete of syphilis. This layer of cells disappears, however, between the 20th and 24th weeks. This is why syphilis is not considered to have a high potential for fetal damage early in pregnancy, only after the point at which cytotrophoblast cells are no longer present (Ainbinder, Ramin, & DeCherney, 2007). The layer appears to offer little protection against viral invasion at any point.

The Placenta

The placenta (Latin for "pancake," which is descriptive of its size and appearance at term) arises out of the continuing growth of trophoblast tissue. Its growth parallels that of the fetus, growing from a few identifiable cells at the beginning of pregnancy to an organ 15 to 20 cm in diameter and 2 to 3 cm in depth, covering about half the surface area of the internal uterus at term.

Circulation

Placental circulation is shown in Figure 9.3. As early as the 12th day of pregnancy, maternal blood begins to collect in the intervillous spaces of the uterine endometrium surrounding the chorionic villi. By the third week, oxygen and other nutrients, such as glucose, amino acids, fatty acids, minerals, vitamins, and water, osmose from the maternal blood through the cell layers of the chorionic villi into the villi capillaries. From there, nutrients are transported to the developing embryo.

Placental osmosis is so effective that all except a few substances are able to cross from the mother into the fetus. Because almost all drugs are able to cross into the fetal circulation, it is important that a woman take no nonessential drugs (including alcohol and nicotine) during pregnancy (Rogers-Adkinson & Stuart, 2007). Alcohol, as an example of a drug which can cause fetal growth disorders, perfuses across the placenta so well that pregnant women are advised to drink no alcohol at all during pregnancy (Crombleholme, 2009). The mechanisms that allow nutrients to cross the placenta are described in Table 9.2. All of these processes are influenced by maternal blood pressure and the pH of the fetal and maternal plasma. A potential complication of twins is that nutrients vessels may fuse in utero, causing one twin to receive more blood than the other (twin-to-twin transfusion) (Norton, 2007). Specific transport of substances and their effects on the fetus are discussed in Chapter 12.

For practical purposes, because the process of osmosis is so effective, there is no direct exchange of blood between the embryo and the mother during pregnancy. Because the outer chorionic villi layer is only one cell thick after the third trimester minute breaks do occur and allow occasional fetal cells to cross into the maternal bloodstream, as well as fetal enzymes such as alpha-fetoprotein (AFP) from the fetal liver.

As the number of chorionic villi increases with pregnancy, the villi form an increasingly complex communication network with the maternal blood. Intervillous spaces grow larger and larger, becoming separated by a series of partitions or septa. In a mature placenta, there are as many as 30 separate segments, or *cotyledons*. These compartments are what make the maternal side of the placenta look rough and uneven.

About 100 maternal uterine arteries supply the mature placenta. To provide enough blood for exchange, the rate of

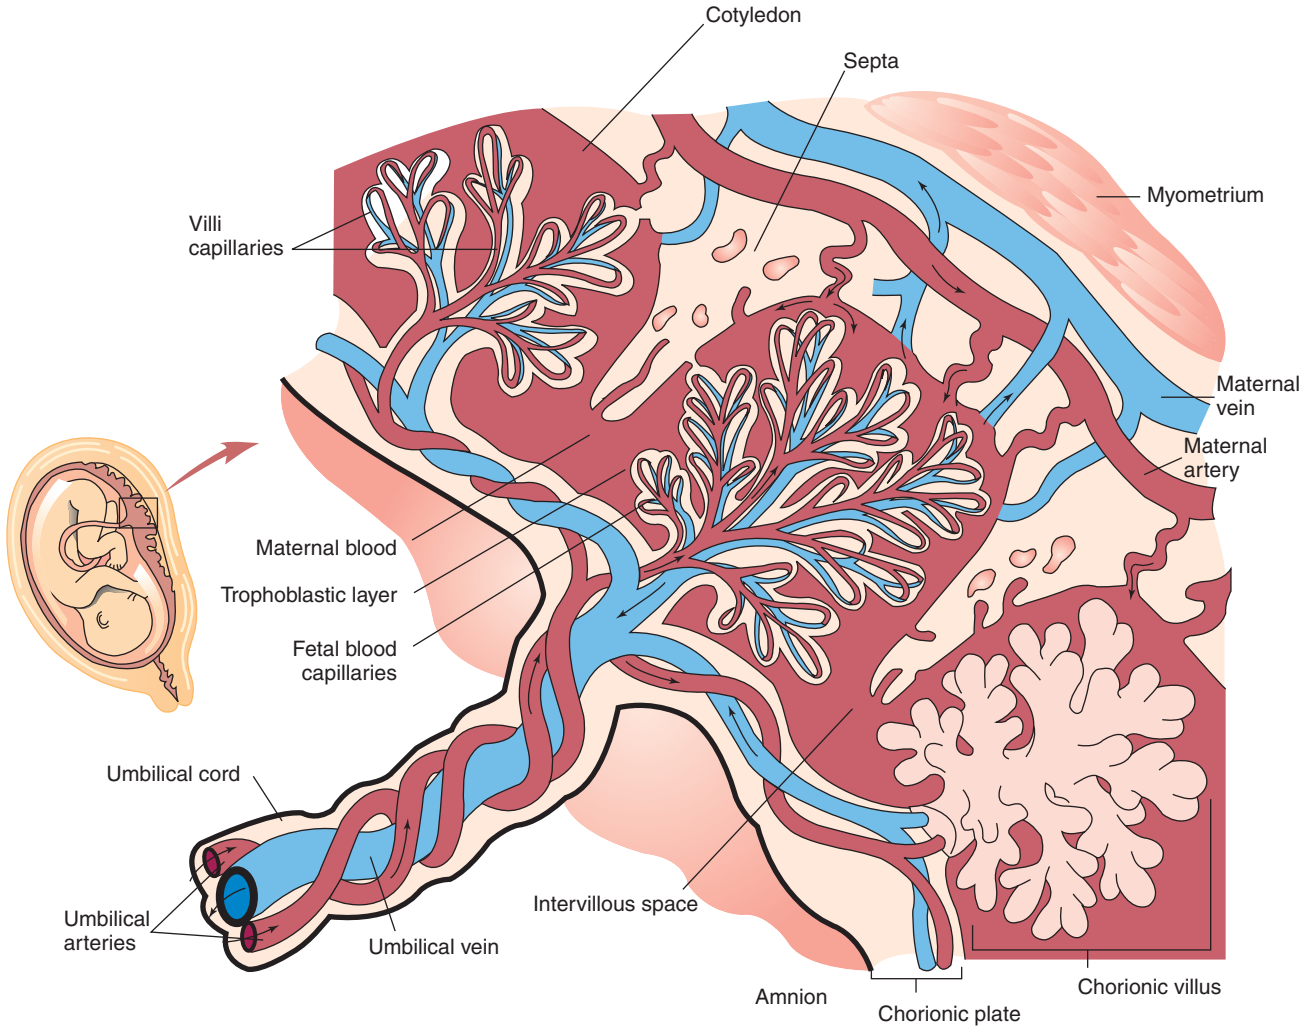

FIGURE 9.3 Placental circulation.

TABLE 9.2 ✻ Mechanisms by Which Nutrients Cross the Placenta

Mechanism	Description
Diffusion	When there is a greater concentration of a substance on one side of a semipermeable membrane than on the other, substances of correct molecular weight cross the membrane from the area of higher concentration to the area of lower concentration. Oxygen, carbon dioxide, sodium, and chloride cross the placenta by this method.
Facilitated diffusion	To ensure that a fetus receives sufficient concentrations of necessary nutrients, some substances cross the placenta guided by a carrier so move more rapidly or easily than would occur if only simple diffusion were operating. Glucose is an example of a substance that crosses by this process.
Active transport	This process requires the action of an enzyme to facilitate transport. Essential amino acids and water-soluble vitamins cross the placenta by this process. The process ensures that a fetus will have adequate amino acid concentrations for fetal growth.
Pinocytosis	This is absorption by the cellular membrane of microdroplets of plasma and dissolved substances. Gamma globulin, lipoproteins, and phospholipids all have molecular structures too large for diffusion so cross in this manner. Unfortunately, viruses that then infect the fetus can also cross in this manner.

uteroplacental blood flow in pregnancy increases from about 50 mL/min at 10 weeks to 500 to 600 mL/min at term. No additional maternal arteries appear after the first 3 months of pregnancy; instead, to accommodate the increased blood flow, the arteries increase in size. The woman's heart rate, total cardiac output, and blood volume increase to supply blood to the placenta.

In the intervillous spaces, maternal blood jets from the coiled or spiral arteries in streams or spurts and then is propelled from compartment to compartment by the currents initiated. As the blood circulates around the villi and nutrients osmose from maternal blood into the villi, the maternal blood gradually loses its momentum and settles to the floor of the cotyledons. From there, it enters the orifices of maternal veins located in the cotyledons and is returned to the maternal circulation. Braxton Hicks contractions, the barely noticeable uterine contractions that are present from about the 12th week of pregnancy, aid in maintaining pressure in the intervillous spaces by closing off the uterine veins momentarily with each contraction.

Uterine perfusion, and thus placental circulation, is most efficient when the woman lies on her left side. This position lifts the uterus away from the inferior vena cava, preventing blood from being trapped in the woman's lower extremities. If the woman lies on her back and the weight of the uterus compresses the vena cava, placental circulation can be so sharply reduced that supine hypotension (very low maternal blood pressure and poor uterine circulation) occurs (Knuppel, 2007).

At term, the placental circulatory network has grown so extensively that a placenta weighs 400 to 600 g (1 lb), one-sixth the weight of the baby. If a placenta is smaller than this, it suggests that circulation to the fetus may have been inadequate. A placenta larger than this may also indicate that circulation to the fetus was threatened, because it suggests that the placenta was forced to spread out in an unusual manner to maintain a sufficient blood supply. The fetus of a woman with diabetes may also develop a larger-than-usual placenta from excess fluid collected between cells.

Endocrine Function

Aside from serving as the conduit for oxygen and nutrients for the fetus, the syncytial (outer) layer of the chorionic villi develops into a separate, important hormone-producing system.

Human Chorionic Gonadotropin. The first placental hormone produced, hCG, can be found in maternal blood and urine as early as the first missed menstrual period (shortly after implantation has occurred) through about the 100th day of pregnancy. Because this is the hormone analyzed by pregnancy tests, a false-negative result from a pregnancy test may be obtained before or after this period. The woman's blood serum will be completely negative for hCG within 1 to 2 weeks after birth. Testing for hCG after birth can be used as proof that placental tissue is no longer present.

The purpose of hCG is to act as a fail-safe measure to ensure that the corpus luteum of the ovary continues to produce progesterone and estrogen. This is important because, if the corpus luteum should fail and the level of progesterone fall, the endometrial lining will slough and the pregnancy will be lost. hCG also may play a role in suppressing the maternal immunologic response so that placental tissue is not detected and rejected as a foreign substance. Because the structure of hCG is similar to that of luteinizing hormone of the pituitary gland, if the fetus is male, it exerts an effect on the fetal testes to begin testosterone production. The presence of testosterone causes maturation of the male reproductive tract.

At about the eighth week of pregnancy, the outer layer of cells of the developing placenta begins to produce progesterone, making the corpus luteum, which was producing progesterone, no longer necessary. In coordination with this, the production of hCG, which sustained the corpus luteum, begins to decrease at this point.

Estrogen. Estrogen (primarily estriol) is produced as a second product of the syncytial cells of the placenta. Estrogen contributes to the woman's mammary gland development in preparation for lactation and stimulates uterine growth to accommodate the developing fetus.

Progesterone. Estrogen is often referred to as the "hormone of women"; progesterone as the "hormone of mothers." This is because, although estrogen influences a female appearance, progesterone is necessary to maintain the endometrial lining of the uterus during pregnancy. It is present in serum as early as the fourth week of pregnancy, as a result of the continuation of the corpus luteum. After placental synthesis begins (at about the 12th week), the level of progesterone rises progressively during the remainder of the pregnancy. This hormone also appears to reduce the contractility of the uterus during pregnancy, preventing premature labor. Such reduced contractility is probably produced by a change in electrolytes (notably potassium and calcium), which decreases the contraction potential of the uterus.

Human Placental Lactogen (Human Chorionic Somatomammotropin). hPL is a hormone with both growth-promoting and lactogenic (milk-producing) properties. It is produced by the placenta beginning as early as the sixth week of pregnancy, increasing to a peak level at term. It can be assayed in both maternal serum and urine. It promotes mammary gland (breast) growth in preparation for lactation in the mother. It also serves the important role of regulating maternal glucose, protein, and fat levels so that adequate amounts of these nutrients are always available to the fetus (Taylor & Lebovic, 2007).

Placental Proteins

The placenta also produces several plasma proteins. The function of these has not been well documented, but it is thought that they may contribute to decreasing the immunologic impact of the growing placenta through being part of the complement cascade (Knuppel, 2007).

The Amniotic Membranes

The chorionic villi on the medial surface of the trophoblast (those that are not involved in implantation, because they do not touch the endometrium) gradually thin, leaving the medial surface of the structure smooth (the chorion laeve, or smooth chorion). The smooth chorion eventually becomes the **chorionic membrane,** the outermost fetal membrane. Its purpose is to form the sac that contains the amniotic fluid. A second membrane lining the chorionic membrane, the **amniotic membrane** or amnion, forms beneath the chorion (Fig. 9.4). Early in pregnancy, these membranes become so adherent that they seem as one at term. At birth they can be

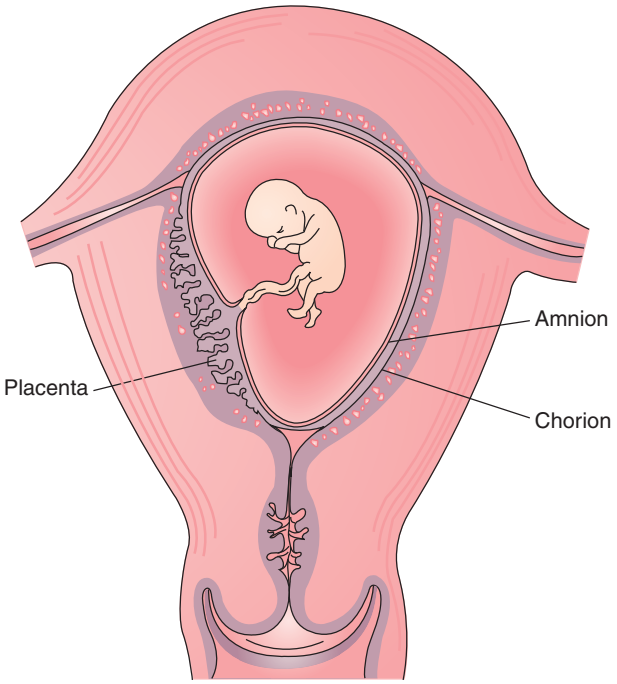

FIGURE 9.4 Membranes, with embryo lying within amniotic sac.

seen covering the fetal surface of the placenta, giving that surface its typically shiny appearance. There is no nerve supply, so when they spontaneously rupture at term or are artificially ruptured, neither woman nor child experiences any pain.

In contrast to the chorionic membrane, the amniotic membrane not only offers support to amniotic fluid but also actually produces the fluid. In addition, it produces a phospholipid that initiates the formation of prostaglandins, which can cause uterine contractions and may be the trigger that initiates labor. Occasionally, fibrous amniotic bands that can constrict an arm or leg of the fetus form in utero. These can close off the blood supply to the distal extremity and cause growth of the extremity to halt at that point (Kumar, Das, & Kumar, 2007).

The Amniotic Fluid

Amniotic fluid is constantly being newly formed and reabsorbed by the amniotic membrane, so it never becomes stagnant. Some of it is absorbed by direct contact with the fetal surface of the placenta. The major method of absorption, however, occurs because the fetus continually swallows the fluid. In the fetal intestine, it is absorbed into the fetal bloodstream. From there, it goes to the umbilical arteries and to the placenta, and it is exchanged across the placenta. At term, the amount of amniotic fluid has increased so much it ranges from 800 to 1200 mL. If for any reason the fetus is unable to swallow (esophageal atresia or anencephaly are the two most common reasons), excessive amniotic fluid, or **hydramnios** (more than 2000 mL in total, or pockets of fluid larger than 8 cm on ultrasound), will result. Hydramnios also tends to occur in women with diabetes, because hyperglycemia causes excessive fluid shifts into the amniotic space (Bush & Pernoll, 2007). Early in fetal life, as soon as the fetal kidneys become active, fetal urine adds to the quantity of the amniotic fluid. A disturbance of kidney function may cause **oligohydramnios,** or a reduction in the amount of amniotic fluid (less than 300 mL in total, or no pocket on ultrasound larger than 1 cm) (Knuppel, 2007).

The most important purpose of amniotic fluid is to shield the fetus against pressure or a blow to the mother's abdomen. Because liquid changes temperature more slowly than air, it also protects the fetus from changes in temperature. As yet another function, it aids in muscular development, because it allows the fetus freedom to move. Finally, it protects the umbilical cord from pressure, protecting the fetal oxygen supply.

Even if the amniotic membranes rupture before birth and the bulk of amniotic fluid is lost, some will always surround the fetus in utero, because new fluid is constantly formed. Amniotic fluid is slightly alkaline, with a pH of about 7.2. Checking the pH of the fluid at the time of rupture helps to differentiate it from urine, which is acidic (pH 5.0–5.5).

The Umbilical Cord

The **umbilical cord** is formed from the fetal membranes (amnion and chorion) and provides a circulatory pathway that connects the embryo to the chorionic villi of the placenta. Its function is to transport oxygen and nutrients to the fetus from the placenta and to return waste products from the fetus to the placenta. It is about 53 cm (21 in) in length at term and about 2 cm (¾ in) thick. The bulk of the cord is a gelatinous mucopolysaccharide called Wharton's jelly, which gives the cord body and prevents pressure on the vein and arteries that pass through it. The outer surface is covered with amniotic membrane.

An umbilical cord contains only one vein (carrying blood from the placental villi to the fetus) but two arteries (carrying blood from the fetus back to the placental villi). The number of veins and arteries in the cord is always assessed and recorded at birth because about 1% to 5% of infants are born with a cord that contains only a single vein and artery. From 15% to 20% of these infants are found to have accompanying chromosomal disorders or congenital anomalies, particularly of the kidney and heart (Lubusky et al., 2007).

The rate of blood flow through an umbilical cord is rapid (350 mL/min at term). The adequacy of blood flow (blood velocity) through the cord, as well as that of both systolic and diastolic cord pressure, can be determined by ultrasound examination during pregnancy. Blood can be withdrawn from the umbilical vein or transfused into the vein during intrauterine life for fetal assessment or treatment (termed percutaneous umbilical blood sampling [PUBS]).

Because the rate of blood flow through the cord is so rapid, it is unlikely that a cord will twist or knot enough to interfere with the fetal oxygen supply. In about 20% of all births, a loose loop of cord is found around the fetal neck (nuchal cord) at birth. If this loop of cord is removed before the newborn's shoulders are born, so that there is no traction on it, the oxygen supply to the fetus remains unimpaired (Jackson, Melvin, & Downe, 2007).

The walls of the umbilical cord arteries are lined with smooth muscle. Constriction of these muscles after birth contributes to hemostasis and helps prevent hemorrhage of the newborn through the cord. Because the umbilical cord contains no nerve supply, it can be cut at birth without discomfort to either the child or woman.

✔Checkpoint Question 9.2

Liz Calhorn is worried that her baby will be born with a congenital heart disease. What assessment of a fetus at birth is important to help detect congenital heart defects?

a. Assessing whether the Wharton jelly of the cord has a pH higher than 7.2.
b. Assessing whether the umbilical cord has two arteries and one vein.
c. Measuring the length of the cord to be certain that it is longer than 3 feet.
d. Determining that the umbilical cord is not stained green or yellow.

ORIGIN AND DEVELOPMENT OF ORGAN SYSTEMS

Following the moment of fertilization, the zygote, and later the embryo and fetus, continues with active growth.

Stem Cells

During the first 4 days of life, zygote cells are termed *totipotent stem cells,* or cells that are so undifferentiated they have the potential to form a complete human being. In another 4 days, as the structure implants and becomes an embryo, cells begin to show differentiation and lose their ability to become any body cell. Instead, they are now slated to become specific body cells, such as nerve, brain, or skin cells, and are termed *pluripotent stem cells*. In yet another few days, the cells grow so specific that they are termed multipotent or are so specific that they have set a sure course toward the body organ they will create.

If the nucleus is removed from an oocyte and the nucleus of an adult cell is transferred into the oocyte, an embryo has the potential to grow into an infant who is identical to the adult donor (reproductive cloning). If its pluripotent stem cells are removed and allowed to grow in the laboratory, these have the potential to be able to supply a type of body cell needed by the adult donor (therapeutic cloning). Stem cell research has revealed that if stem cells such as these are implanted into an adult with a condition such as spinal cord injury, diabetes, or a blood disorder, they can replace the adult's damaged cells (Firpo & Kikyo, 2007). The majority of embryos used for research today are extra embryos that were removed from the mother's body as part of the process of in vitro fertilization but were not used (see Chapter 8). As exciting as this area of research is, it also carries ethical and costly considerations; for example, if stem cell therapy becomes possible on a large scale, how will enough embryos be available unless they are grown just for this purpose? The ability of researchers to derive stem cells from adult skin cells or menstrual blood should help relieve this concern (Goldman, 2007).

Zygote Growth

From the beginning of fetal growth, development proceeds in a **cephalocaudal** (head-to-tail) direction; that is, head development occurs first and is followed by development of the middle and, finally, the lower body parts. This pattern of development continues after birth as shown by the way infants are able to lift up their heads approximately 1 year before they are able to walk. As a fetus grows, body organ systems develop from specific tissue layers called germ layers.

Primary Germ Layers

At the time of implantation, a blastocyst already has differentiated to a point at which two separate cavities appear in the inner structure: (1) a large one, the amniotic cavity, which is lined with a distinctive layer of cells, the *ectoderm*, and (2) a smaller cavity, the yolk sac, which is lined with *entoderm* cells (see Fig. 9.1).

In chicks, the yolk sac serves as a supply of nourishment for the embryo throughout its development. In humans, the yolk sac appears to supply nourishment only until implantation. After that, its main purpose is to provide a source of red blood cells until the embryo's hematopoietic system is mature enough to perform this function (at about the 12th week of intrauterine life). The yolk sac then atrophies and remains only as a thin white streak discernible in the cord at birth.

Between the amniotic cavity and the yolk sac, a third layer of primary cells, the *mesoderm*, forms. The embryo will begin to develop at the point where the three cell layers (ectoderm, entoderm, and mesoderm) meet, called the embryonic shield. Each of these germ layers of primary tissue

TABLE 9.3 ✻ Origin of Body Tissue

Germ Layer	Body Portions Formed
Ectoderm	Central nervous system (brain and spinal cord)
	Peripheral nervous system
	Skin, hair, and nails
	Sebaceous glands
	Sense organs
	Mucous membranes of the anus, mouth, and nose
	Tooth enamel
	Mammary glands
Mesoderm	Supporting structures of the body (connective tissue, bones, cartilage, muscle, ligaments, and tendons)
	Dentin of teeth
	Upper portion of the urinary system (kidneys and ureters)
	Reproductive system
	Heart
	Circulatory system
	Blood cells
	Lymph vessels
Entoderm	Lining of pericardial, pleura, and peritoneal cavities
	Lining of the gastrointestinal tract, respiratory tract, tonsils, parathyroid, thyroid, thymus glands
	Lower urinary system (bladder and urethra)

develops into specific body systems (Table 9.3). Knowing which structures arise from each germ layer is important, because coexisting congenital defects found in newborns usually arise from the same layer. For example, a fistula between the trachea and the esophagus (both of which arise from the entoderm) is a common birth anomaly. Heart and kidney defects (which both arise from the mesoderm) are also commonly seen together. In contrast, it is rare to see a newborn with a malformation of the heart (arises from the mesoderm) and a malformation of the lower urinary tract (arises from the entoderm). One reason rubella infection is so serious in pregnancy is because this virus is capable of infecting all three germ layers, or causing congenital anomalies in a myriad of body systems.

Knowing the origins of body structures helps to explain why certain screening procedures are ordered for newborns with congenital malformations. A radiographic examination of the kidney, for example, may be ordered for a child born with a heart defect. A child with a malformation of the urinary tract is often investigated for reproductive abnormalities as well.

All organ systems are complete, at least in a rudimentary form, at 8 weeks' gestation (the end of the embryonic period). During this early time of **organogenesis** (organ formation), the growing structure is most vulnerable to invasion by teratogens (any factor that adversely affects the fertilized ovum, embryo, or fetus, such as cigarette smoking) (Box 9.2). Figure 9.5 illustrates the most critical periods of fetal growth when it is most important for women to minimize their exposure to teratogens (Box 9.3). The effect of individual teratogens is discussed in Chapter 12.

BOX 9.2 ✻ Focus on Evidence-Based Practice

Should a woman who wants to stop cigarette smoking during pregnancy use a nicotine patch?

Every year, a large number of fetuses are exposed to smoking during pregnancy which results in decreased birth weight, fetal morbidity and, perhaps, attention-deficit/hyperactivity disorder (ADHD). Use of nicotine replacement therapy (NRT) or nicotine patches is often considered as an option to help withdrawal from cigarettes.

To see if a nicotine patch could cause fetal harm, the researcher completed a critical review of the literature and, from this, concluded:

1. Maternal smoking causes low birth weight and nicotine seems to play a significant role in reducing fetal weight.
2. Maternal smoking is a risk factor for ADHD, but a causal link between nicotine and hyperactivity is not well established. It is unclear if NRT would have similar long-term effects in children. More research is needed in this area.

Would the results of this literature review influence which nonsmoking method you would advise that pregnant women choose?

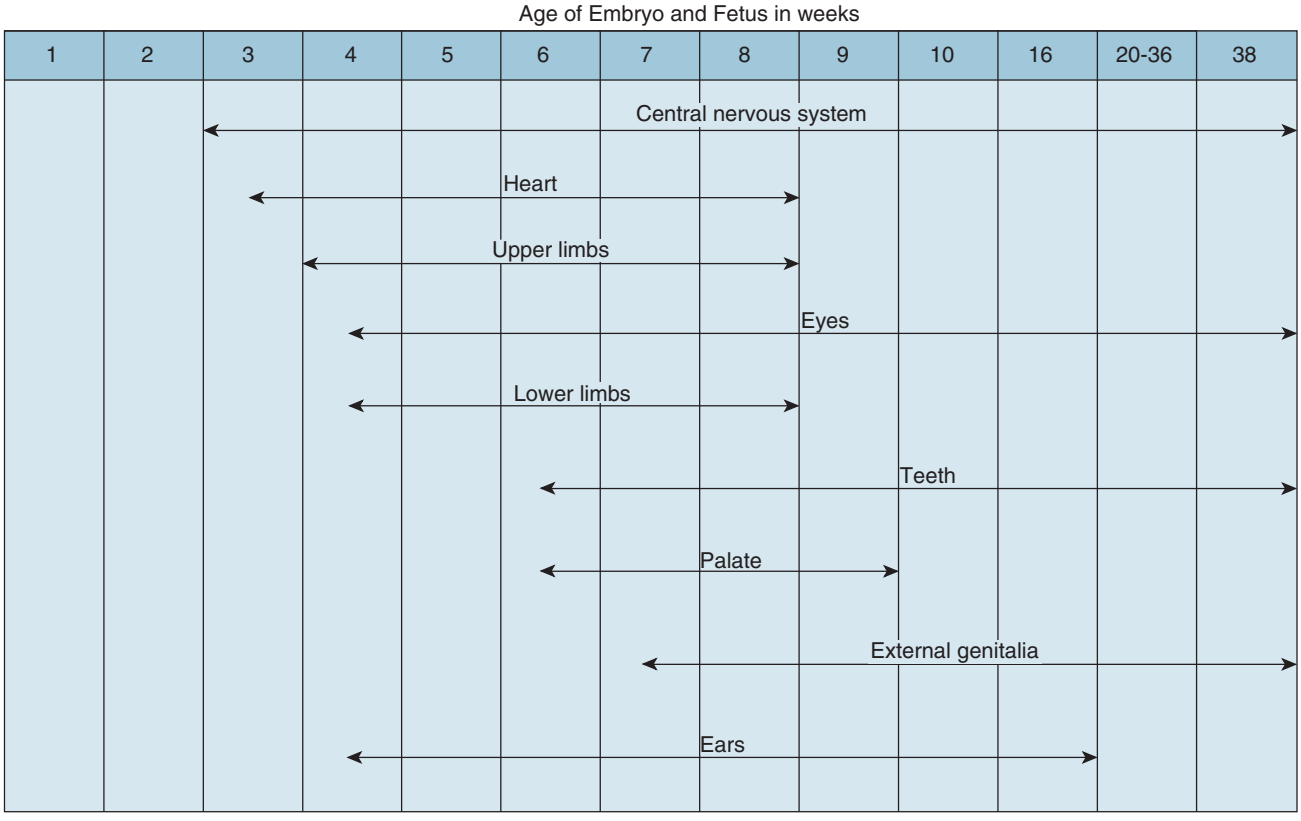

FIGURE 9.5 Critical periods of fetal growth.

BOX 9.3 ✻ Focus on Family Teaching

Teratogens at Work

Q. Liz Calhom tells you, "I have to work. How can I guard against fetal teratogens at work?"

A. Here are some helpful tips:

- Ask your employer for a statement on hazardous substances at your work site; discuss your need to avoid these substances during pregnancy.
- Ask your employer to maintain a smoke-free site if that is not already a rule.
- Avoid any room, such as a coffee room, where smokers gather.
- Refrain from drinking alcohol, a frequent accompaniment to work lunches or social functions; ask for nonalcoholic drinks to be available at such events.

Cardiovascular System

The cardiovascular system is one of the first systems to become functional in intrauterine life. Simple blood cells joined to the walls of the yolk sac progress to become a network of blood vessels and a single heart tube, which forms as early as the 16th day of life and beats as early as the 24th day. The septum that divides the heart into chambers develops during the sixth or seventh week. Heart valves begin to develop in the seventh week. The heartbeat may be heard with a Doppler instrument as early as the 10th to 12th week of pregnancy. An electrocardiogram (ECG) may be recorded on a fetus as early as the 11th week, although the accuracy of such ECGs is in doubt until about the 20th week of pregnancy, when conduction is more regulated.

The heart rate of a fetus is affected by oxygen level, activity, and circulating blood volume, just as in adult life. After the 28th week of pregnancy, when the sympathetic nervous system has matured, the heart rate begins to show a baseline variability of about 5 beats per minute on a fetal heart rate rhythm strip.

Fetal Circulation

As early as the third week of intrauterine life, fetal blood begins to exchange nutrients with the maternal circulation across the chorionic villi. Fetal circulation (Fig. 9.6) differs from extrauterine circulation because the fetus derives oxygen and excretes carbon dioxide not from gas exchange in the lung but from gas exchange in the placenta.

Blood arriving at the fetus from the placenta is highly oxygenated. This blood enters the fetus through the umbilical vein (called a vein even though it carries oxygenated blood, because the direction of the blood is toward the fetal heart). Specialized structures present in the fetus then shunt blood flow to first supply the most important organs of the body: the brain, liver, heart, and kidneys. Blood flows from the umbilical vein to the *ductus venosus*, an accessory vessel that directs oxygenated blood directly to the fetal liver. Blood then empties into the fetal inferior vena cava so oxygenated blood is directed to the right side of the heart. Because there is no need for the bulk of blood to pass through the lungs, it is shunted, as it enters the right atrium, into the left atrium through an opening in the atrial septum, called the **foramen ovale.** From the left atrium, it follows the course of adult circulation into the left ventricle and into the aorta.

A small amount of blood that returns to the heart via the vena cava does leave the right atrium via the adult circulatory route—that is, through the tricuspid valve into the right ventricle, and then into the pulmonary artery and lungs to service the lung tissue. However, the larger portion of even this blood is shunted away from the lungs through an additional structure, the *ductus arteriosus*, directly into the descending aorta.

Most of the blood flow from the descending aorta is transported by the umbilical arteries (called arteries, even though they are now transporting deoxygenated blood, because they are carrying blood away from the fetal heart) back through the umbilical cord to the placental villi, where new oxygen exchange takes place.

The blood oxygen saturation level of the fetus is about 80% of a newborn's saturation level. The rapid fetal heart rate during pregnancy (120–160 beats per minute) is necessary to supply oxygen to cells, because the red blood cells are never fully saturated. Despite this low blood oxygen saturation level, carbon dioxide does not accumulate in the fetal system because it rapidly diffuses into maternal blood across a favorable placental pressure gradient.

Fetal Hemoglobin

Fetal hemoglobin differs from adult hemoglobin in several ways. It has a different composition (two alpha and two gamma chains, compared with two alpha and two beta chains of adult hemoglobin). It is also more concentrated and has greater oxygen affinity, two features that increase its efficiency. So much hemoglobin is present at birth that a newborn's hemoglobin level is about 17.1 g/100 mL, compared with an adult normal level of 11 g/100 mL; a newborn's hematocrit is about 53%, compared with an adult normal level of 45%.

The change from fetal to adult hemoglobin levels begins before birth and accelerates after birth. The major blood dyscrasias, such as sickle cell anemia, tend to be defects of the beta hemoglobin chain. That is why clinical symptoms do not become apparent until the bulk of fetal hemoglobin has matured to adult hemoglobin composition, at about 6 months of age (Rees, 2007).

Respiratory System

At the third week of intrauterine life, the respiratory and digestive tracts exist as a single tube. Like all body tubes, initially this forms as a solid structure, which then canalizes (hollows out). By the end of the fourth week, a septum begins to divide the esophagus from the trachea. At the same time, lung buds appear on the trachea.

Until the seventh week of life, the diaphragm does not completely divide the thoracic cavity from the abdomen. This causes lung buds to extend down into the abdomen, reentering the chest only as the chest's longitudinal dimension increases and the diaphragm becomes complete (at the end of the seventh week). If the diaphragm fails to close completely, the stomach, spleen, liver, or intestines may be pulled up into the thoracic cavity. This causes the child to be born with a diaphragmatic hernia or with intestine present in the chest, compromising the lungs and perhaps displacing the heart (Moyer et al., 2009).

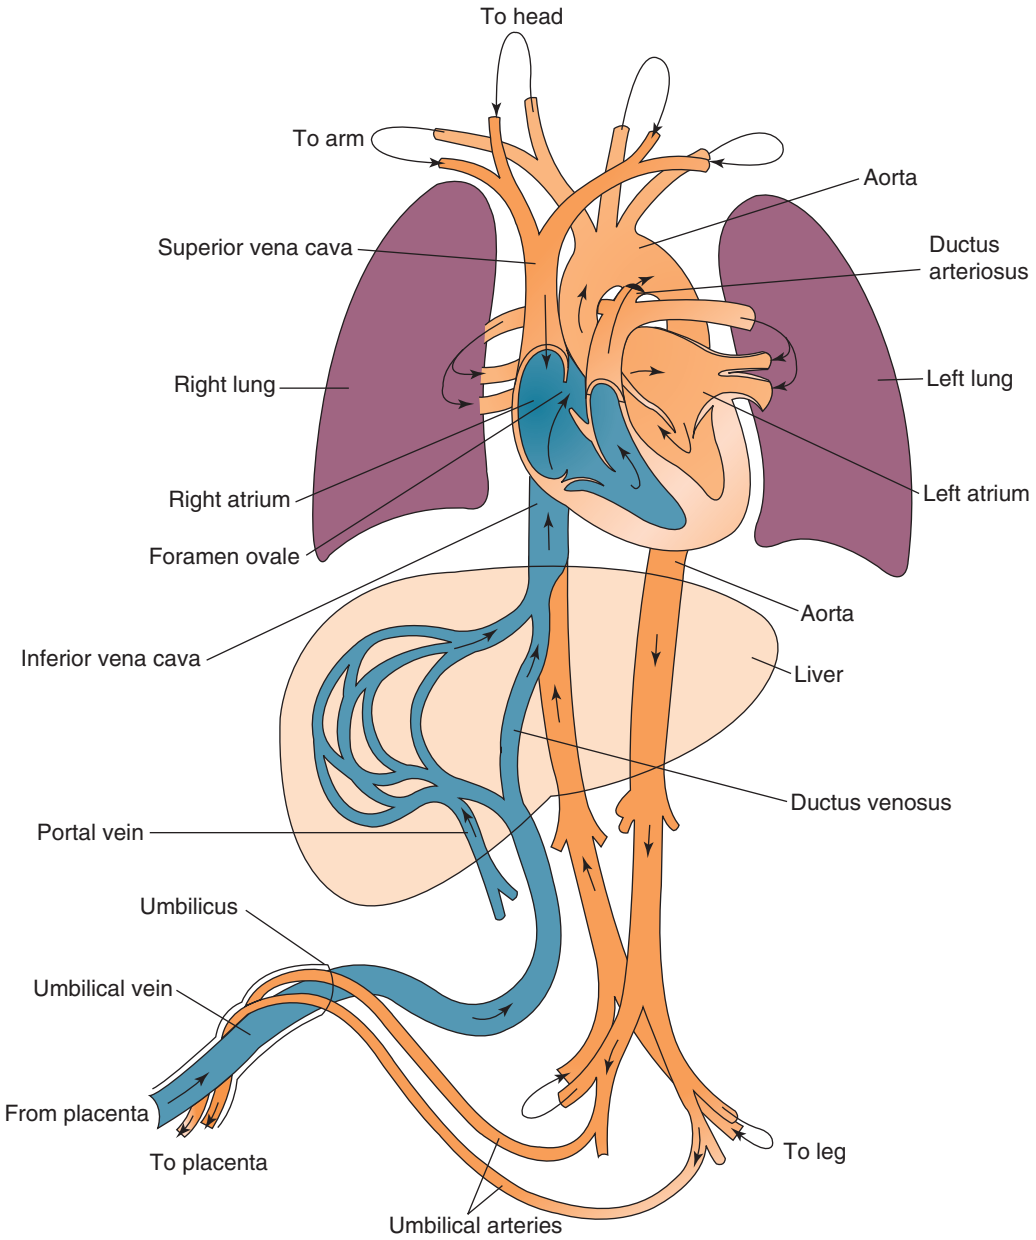

FIGURE 9.6 Fetal circulation.

Other important respiratory developmental milestones include:

- Alveoli and capillaries begin to form between the 24th and 28th weeks. Both capillary and alveoli development must be complete before gas exchange can occur in the fetal lungs.
- Spontaneous respiratory practice movements begin as early as 3 months' gestation and continue throughout pregnancy.
- Specific lung fluid with a low surface tension and low viscosity forms in alveoli to aid in expansion of the alveoli at birth; it is rapidly absorbed after birth.
- **Surfactant,** a phospholipid substance, is formed and excreted by the alveolar cells at about the 24th week of pregnancy. This decreases alveolar surface tension on expiration, preventing alveolar collapse and improving the infant's ability to maintain respirations in the outside environment (Soll, 2009).

Surfactant has two components: lecithin (L) and sphingomyelin (S). Early in the formation of surfactant, sphingomyelin is the chief component. At about 35 weeks, there is a surge in the production of lecithin, which then becomes the chief component by a ratio of 2:1. As a fetus practices breathing movements, surfactant mixes with amniotic fluid. Analysis of the L/S ratio regarding whether lecithin or sphingomyelin is the dominant component by amniocentesis technique is a primary test of fetal maturity. Respiratory distress syndrome, a severe breathing disorder, can develop if there is lack of surfactant or it has not changed to its mature form at birth (see Chapter 26). Any interference with the blood supply to the

fetus, such as occurs with placental insufficiency from hypertension, appears to enhance surfactant development. This type of stress probably causes this by increasing steroid levels in the fetus. Although there is little evidence-based information available to document why the phenomenon occurs, synthetically increasing steroid levels in the fetus (the administration of betamethasone to the mother) can hurry alveolar maturation and surfactant production (Roberts & Dalziel, 2009).

✔ Checkpoint Question 9.3

Liz Calhorn asks you why her doctor is so concerned about whether her fetus is producing surfactant. Your best answer would be:

a. Surfactant keeps lungs from collapsing on expiration and so aids newborn breathing.
b. Surfactant is produced by the fetal liver, so its presence reveals liver maturity.
c. Surfactant is the precursor to IgM antibody production, so it prevents infection.
d. Surfactant reveals mature kidney function, as it is produced by kidney glomeruli.

Nervous System

Like the circulatory system, the nervous system begins to develop extremely early in pregnancy. During the third and fourth weeks of intrauterine life, possibly before the woman even realizes she is pregnant, active formation of the nervous system and sense organs has already begun.

- A neural plate (a thickened portion of the ectoderm) is apparent by the third week of gestation. The top portion differentiates into the neural tube, which will form the central nervous system (brain and spinal cord), and the neural crest, which will develop into the peripheral nervous system.
- All parts of the brain (cerebrum, cerebellum, pons, and medulla oblongata) form in utero, although none are completely mature at birth. Growth proceeds rapidly during the first year and continues at high levels until 5 or 6 years of age.
- The eye and inner ear develop as projections of the original neural tube.
- By 24 weeks, the ear is capable of responding to sound; the eyes exhibit a pupillary reaction, indicating that sight is present.
- Brain waves can be detected on an electroencephalogram (EEG) by the eighth week.

The neurologic system seems particularly prone to insult during the early weeks of the embryonic period. Spinal cord disorders such as meningocele (herniation of the meninges) may occur because of lack of folic acid (contained in green leafy vegetables and pregnancy vitamins) (Lumley et al., 2009). All during pregnancy and at birth, the system is vulnerable to damage from anoxia.

Endocrine System

As soon as endocrine organs mature in intrauterine life, function begins.

- The fetal adrenal glands supply a precursor necessary for estrogen synthesis by the placenta.
- The fetal pancreas produces insulin needed by the fetus (insulin is one of the few substances that does not cross the placenta from the mother to the fetus).
- The thyroid and parathyroid glands play vital roles in fetal metabolic function and calcium balance.

Digestive System

The digestive tract separates from the respiratory tract at about the fourth week of intrauterine life and, after that, begins to grow extremely rapidly. Initially solid, the tract canalizes (hollows out) to become patent. Later, the endothelial cells of the gastrointestinal tract proliferate extensively, occluding the lumen once more, and the tract must canalize again. Atresia (blockage) or stenosis (narrowing) can develop if either the first or second canalization does not occur. The proliferation of cells shed in the second recanalization forms the basis for meconium (see below).

Because of this rapid intestinal growth, by the sixth week of intrauterine life, the intestine becomes too large to be contained by the abdomen. A portion of the intestine, guided by the vitelline membrane (a part of the yolk sac), is pushed into the base of the umbilical cord, where it remains until about the 10th week, when the abdominal cavity has grown large enough to accommodate the intestinal mass again. As the intestine returns to the abdominal cavity at this point, it must rotate 180 degrees. Failure to do so can result in inadequate mesentery attachments, possibly leading to volvulus of the intestine in the newborn. If any intestine remains outside the abdomen in the base of the cord, a congenital anomaly, termed *omphalocele*, develops. A similar defect, *gastroschisis*, occurs when the original midline fusion that occurred at the early cell stage is incomplete (Thilo et al., 2008). If the vitelline duct does not atrophy after return of the intestines, a Meckel's diverticulum (a pouch of intestinal tissue) can result (Hol & Kuipers, 2007).

Meconium, a collection of cellular wastes, bile, fats, mucoproteins, mucopolysaccharides, and portions of the vernix caseosa, the lubricating substance that forms on the fetal skin, accumulates in the intestines as early as the 16th week. Meconium is sticky in consistency and appears black or dark green (obtaining its color from bile pigment).

The gastrointestinal tract is sterile before birth. Because vitamin K is synthesized by the action of bacteria in the intestines, vitamin K levels are low in the newborn. Sucking and swallowing reflexes are not mature until the fetus is at about 32 weeks' gestation or weighs 1500 g.

The ability of the gastrointestinal tract to secrete enzymes essential to carbohydrate and protein digestion is mature at 36 weeks. However, amylase, an enzyme found in saliva that is necessary for digestion of complex starches, is not mature until 3 months after birth. Many newborns have not yet developed lipase, an enzyme needed for fat digestion.

The liver is active throughout gestation, functioning as a filter between the incoming blood and the fetal circulation and as a deposit site for fetal stores such as iron and glycogen, but is still immature at birth. This can possibly lead to hypoglycemia and hyperbilirubinemia, two serious problems, in the first 24 hours after birth. The liver does not prevent recreational drugs or alcohol ingested by the mother from entering the fetal circulation.

Musculoskeletal System

During the first 2 weeks of fetal life, cartilage prototypes provide position and support. Ossification of this cartilage into bone begins at about the 12th week. Ossification continues all through fetal life and actually until adulthood. Carpals, tarsals, and sternal bones generally do not ossify until birth is imminent. A fetus can be seen to move on an ultrasound as early as the 11th week, although the woman usually does not feel this movement (*quickening*) until almost 20 weeks of gestation.

Reproductive System

A child's sex is determined at the moment of conception by a spermatozoon carrying an X or a Y chromosome and can be ascertained as early as 8 weeks by chromosomal analysis. At about the sixth week of life, the gonads (ovaries or testes) form. If testes form, testosterone is secreted, apparently influencing the sexually neutral genital duct to form other male organs (maturity of the wolffian, or mesonephric, duct). In the absence of testosterone secretion, female organs will form (maturation of the müllerian, or paramesonephric, duct). This is an important phenomenon, because if a woman should take an androgen or an androgen-like substance during this stage of pregnancy, a child who is chromosomally female could appear more male than female at birth. If deficient testosterone is secreted by the testes, both the müllerian (female) duct and the male (wolffian) duct could develop (pseudo-hermaphroditism, or intersex).

The testes first form in the abdominal cavity and do not descend into the scrotal sac until the 34th to 38th week. Because of this, many male preterm infants are born with undescended testes. These children need follow-up care to be certain that their testes do descend when they reach what would have been the 34th to 38th week of gestational age, because testicular descent does not occur as readily in extrauterine life as it would in utero. Surgery is necessary as undescended testes are associated with poor sperm production and testicular cancer (Zeitler et al., 2008).

Urinary System

Although rudimentary kidneys are present as early as the end of the fourth week of intrauterine life, the presence of kidneys does not appear to be essential for life before birth because the placenta clears the fetus of waste products. Urine is formed by the 12th week and is excreted into the amniotic fluid by the 16th week of gestation. At term, fetal urine is being excreted at the rate of 500 mL/day. An amount of amniotic fluid that is less than normal (oligohydramnios) suggests that fetal kidneys are not secreting adequate urine (Lanni & Loveless, 2007).

The complex structure of the kidneys is gradually developed during intrauterine life and continues for months afterward. The loop of Henle, for example, is not fully differentiated until the child is born. Glomerular filtration and concentration of urine in the newborn are not efficient, because the kidney function is still not mature at birth.

Early in the embryonic stage of urinary system development, the bladder extends as high as the umbilical region. On rare occasions, an open lumen between the urinary bladder and the umbilicus fails to close. Termed a *patent urachus*, this is discovered at birth by the persistent drainage of a clear, acid-pH fluid (urine) from the umbilicus.

Integumentary System

The skin of a fetus appears thin and almost translucent until subcutaneous fat begins to be deposited at about 36 weeks. Skin is covered by soft downy hairs (lanugo) that serve as insulation to preserve warmth in utero and a cream cheese–like substance, vernix caseosa, which is important for lubrication and for keeping the skin from macerating in utero.

Immune System

Immunoglobulin G (IgG) maternal antibodies cross the placenta into the fetus as early as the 20th week and certainly by the 24th week of intrauterine life to give a fetus temporary passive immunity against diseases for which the mother has antibodies. These often include poliomyelitis, rubella (German measles), rubeola (regular measles), diphtheria, tetanus, infectious parotitis (mumps), hepatitis B, and pertussis (whooping cough). Little or no immunity to the herpes virus (the virus of chickenpox, cold sores, and genital herpes) is transferred to the fetus, so the average newborn is potentially susceptible to these diseases. The recommended immunization for teenagers against the virus should reduce the incidence of this in newborns.

Infants born before antibody transfer has taken place have no natural immunity and need more than the usual protection against infectious disease in the newborn period. The level of these acquired passive IgG immunoglobulins peaks at birth and then decreases over the next 8 months as the infant builds up his or her own stores of IgG, as well as IgA and IgM. Because the passive immunity received by the newborn has already declined substantially by about 2 months, immunization against diphtheria, tetanus, pertussis, poliomyelitis, rotovirus, *Haemophilus influenzae,* and pneumococcus is typically started at this time. Passive antibodies to measles have been demonstrated to last for longer than 1 year. Consequently, the immunization for measles is not given until an extrauterine age of 12 months.

A fetus is capable of active antibody production late in pregnancy. Generally this is not necessary, however, because antibodies are manufactured only after stimulation by an invading antigen, and antigens rarely invade the intrauterine space. However, infants whose mothers have had an infection such as rubella during pregnancy typically have active IgM antibodies to rubella in their blood serum at birth. Because IgA and IgM antibodies cannot cross the placenta, their presence in a newborn is proof that the fetus has been exposed to a disease.

Milestones of Fetal Growth and Development

When fetal milestones occur can be confusing, because the life of the fetus is typically measured from the time of ovulation or fertilization (ovulation age), but the length of a pregnancy is more commonly measured from the first day of the last menstrual period (gestational age). Because ovulation and fertilization take place about 2 weeks after the last menstrual period, the ovulation age of the fetus is

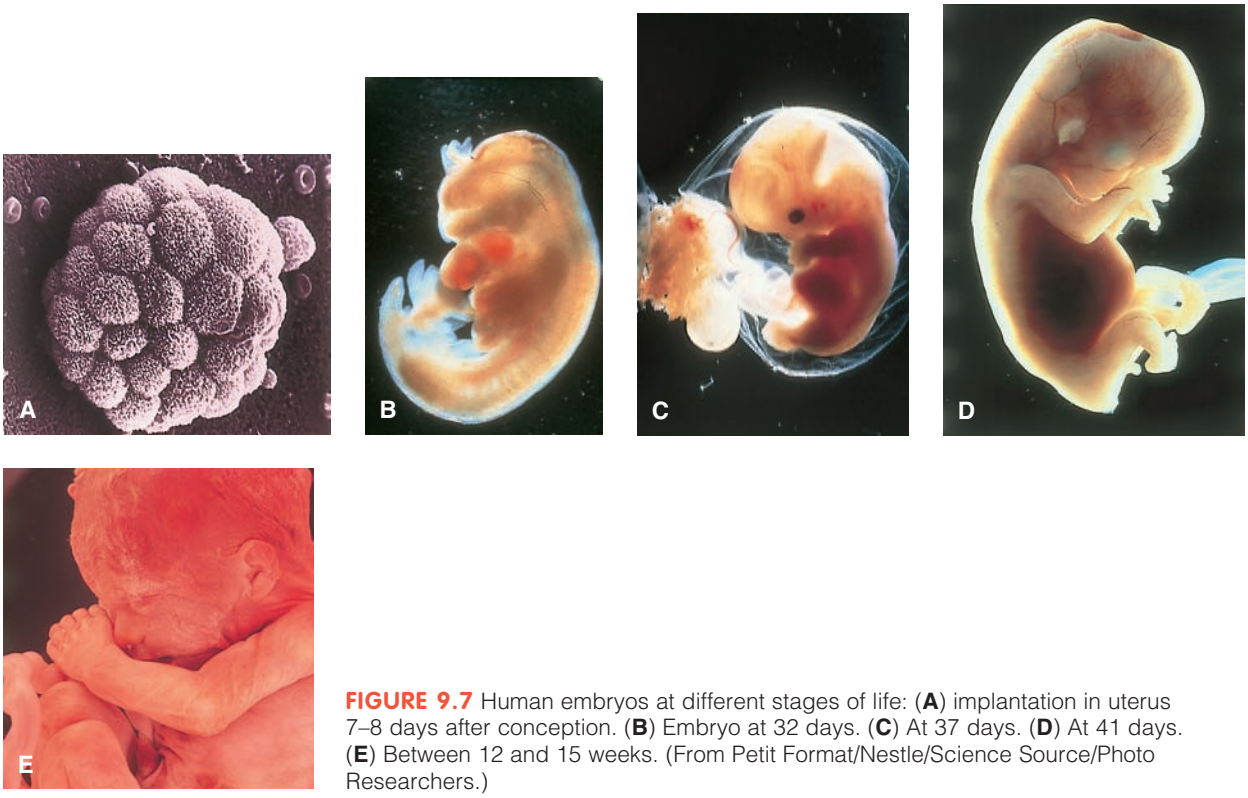

FIGURE 9.7 Human embryos at different stages of life: (**A**) implantation in uterus 7–8 days after conception. (**B**) Embryo at 32 days. (**C**) At 37 days. (**D**) At 41 days. (**E**) Between 12 and 15 weeks. (From Petit Format/Nestle/Science Source/Photo Researchers.)

always 2 weeks less than the length of the pregnancy or the gestational age.

Both ovulation and gestational age are typically reported in lunar months (4-week periods) or in trimesters (3-month periods) rather than in weeks. In lunar months, a pregnancy is 10 months (40 weeks, or 280 days) long; a fetus grows in utero 9.5 lunar months or three full trimesters (38 weeks, or 266 days).

The following discussion of fetal developmental milestones is based on gestational weeks, because it is helpful when talking to expectant parents to be able to correlate fetal development with the way they measure pregnancy—from the first day of the last menstrual period. Figure 9.7 illustrates the comparative size and appearance of human embryos and fetuses at different stages.

End of 4th Gestational Week

At the end of the fourth week of gestation, the human embryo is a group of rapidly growing cells but does not yet resemble a human being.

- Length: 0.75–1 cm
- Weight: 400 mg
- The spinal cord is formed and fused at the midpoint.
- Lateral wings that will form the body are folded forward to fuse at the midline.
- The head folds forward and becomes prominent, representing about one-third of the entire structure.
- The back is bent so that the head almost touches the tip of the tail.
- The rudimentary heart appears as a prominent bulge on the anterior surface.
- Arms and legs are budlike structures.
- Rudimentary eyes, ears, and nose are discernible.

End of 8th Gestational Week

- Length: 2.5 cm (1 in)
- Weight: 20 g
- Organogenesis is complete.
- The heart, with a septum and valves, is beating rhythmically.
- Facial features are definitely discernible.
- Arms and legs have developed.
- External genitalia are forming, but sex is not yet distinguishable by simple observation.
- The primitive tail is regressing.
- The abdomen bulges forward because the fetal intestine is growing so rapidly.
- An ultrasound shows a gestational sac, diagnostic of pregnancy (Fig. 9.8).

End of 12th Gestational Week (First Trimester)

- Length: 7–8 cm
- Weight: 45 g
- Nail beds are forming on fingers and toes.
- Spontaneous movements are possible, although they are usually too faint to be felt by the mother.
- Some reflexes, such as the Babinski reflex, are present.
- Bone ossification centers begin to form.
- Tooth buds are present.
- Sex is distinguishable by outward appearance.
- Urine secretion begins but may not yet be evident in amniotic fluid.
- The heartbeat is audible through Doppler technology.

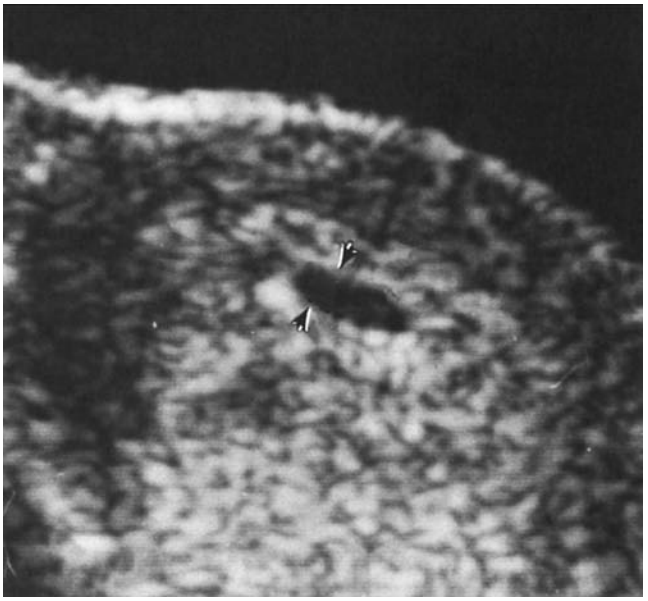

FIGURE 9.8 An ultrasound showing the characteristic circle diagnostic of pregnancy (the gestational sac). (From Benson, C. B., et al. [1988]. *Atlas of obstetrical ultrasound.* Philadelphia: JB Lippincott.)

End of 16th Gestational Week

- Length: 10–17 cm
- Weight: 55–120 g
- Fetal heart sounds are audible by an ordinary stethoscope.
- Lanugo is well formed.
- Liver and pancreas are functioning.
- Fetus actively swallows amniotic fluid, demonstrating an intact but uncoordinated swallowing reflex; urine is present in amniotic fluid.
- Sex can be determined by ultrasound.

End of 20th Gestational Week

- Length: 25 cm
- Weight: 223 g
- Spontaneous fetal movements can be sensed by the mother.
- Antibody production is possible.
- The hair forms on the head, extending to include eyebrows.
- Meconium is present in the upper intestine.
- Brown fat, a special fat that will aid in temperature regulation at birth, begins to be formed behind the kidneys, sternum, and posterior neck.
- Vernix caseosa begins to form and cover the skin.
- Passive antibody transfer from mother to fetus begins.
- Definite sleeping and activity patterns are distinguishable (the fetus has developed biorhythms that will guide sleep/wake patterns throughout life).

End of 24th Gestational Week (Second Trimester)

- Length: 28–36 cm
- Weight: 550 g
- Meconium is present as far as the rectum.
- Active production of lung surfactant begins.
- Eyebrows and eyelashes become well defined.
- Eyelids, previously fused since the 12th week, now open.
- Pupils are capable of reacting to light.
- When fetuses reach 24 weeks, or 601 g, they have achieved a practical low-end **age of viability** (earliest age at which fetuses could survive if born at that time), if they are cared for after birth in a modern intensive care facility.
- Hearing can be demonstrated by response to sudden sound.

End of 28th Gestational Week

- Length: 35–38 cm
- Weight: 1200 g
- Lung alveoli begin to mature, and surfactant can be demonstrated in amniotic fluid.
- Testes begin to descend into the scrotal sac from the lower abdominal cavity.
- The blood vessels of the retina are formed but thin and extremely susceptible to damage from high oxygen concentrations (an important consideration when caring for preterm infants who need oxygen).

End of 32nd Gestational Week

- Length: 38–43 cm
- Weight: 1600 g
- Subcutaneous fat begins to be deposited (the former stringy, "little old man" appearance is lost).
- Fetus responds by movement to sounds outside the mother's body.
- Active Moro reflex is present.
- Iron stores, which provide iron for the time during which the neonate will ingest only milk after birth, are beginning to be developed.
- Fingernails grow to reach the end of fingertips.

End of 36th Gestational Week

- Length: 42–48 cm
- Weight: 1800–2700 g (5–6 lb)
- Body stores of glycogen, iron, carbohydrate, and calcium are deposited.
- Additional amounts of subcutaneous fat are deposited.
- Sole of the foot has only one or two crisscross creases, compared with the full crisscross pattern that will be evident at term.
- Amount of lanugo begins to diminish.
- Most babies turn into a vertex (head down) presentation during this month.

End of 40th Gestational Week (Third Trimester)

- Length: 48–52 cm (crown to rump, 35–37 cm)
- Weight: 3000 g (7–7.5 lb)
- Fetus kicks actively, hard enough to cause the mother considerable discomfort.
- Fetal hemoglobin begins its conversion to adult hemoglobin. The conversion is so rapid that, at birth, about 20% of hemoglobin will be adult in character.
- Vernix caseosa is fully formed.
- Fingernails extend over the fingertips.
- Creases on the soles of the feet cover at least two thirds of the surface.

In primiparas (women having their first baby), the fetus often sinks into the birth canal during the last 2 weeks, giving the mother a feeling that the load she is carrying is less. This event, termed *lightening*, is a fetal announcement that the third trimester of pregnancy has ended and birth is at hand.

Determination of Estimated Birth Date

It is impossible to predict the day an infant will be born with a high degree of accuracy. Traditionally, this date was referred to as the estimated date of confinement (EDC). Because women are no longer "confined" after childbirth, the abbreviation EDB **(estimated date of birth)** or EDD (estimated date of delivery) is more commonly used today.

Fewer than 5% of pregnancies end exactly 280 days from the last menstrual period or exactly on this date; fewer than half end within 1 week of the 280th day.

If fertilization occurred early in a menstrual cycle, the pregnancy will probably end "early"; if ovulation and fertilization occurred later in the cycle, the pregnancy will end "late." Because of these normal variations, a pregnancy ending 2 weeks before or 2 weeks after the calculated EDB is considered well within the normal limit (38–42 weeks). Gestational age wheels or birth date calculators that can be used to predict a birth date are available, but calculation by Nagele's rule is the standard method used to predict the length of a pregnancy (Box 9.4).

What if... Liz Calhorn, the young woman you met at the beginning of the chapter, first came to your prenatal clinic on August 5 and told you that she had her last menstrual period on March 13 to March 18? What would be her estimated date of birth (EDB)?

ASSESSMENT OF FETAL GROWTH AND DEVELOPMENT

Fetal growth and development can be compromised if a fetus has a metabolic or chromosomal disorder that interferes with normal growth, if the supporting structures such as the placenta or cord do not form normally, or if environmental influences such as cigarette smoking (the nicotine in cigarettes causes fetal growth restriction) or alcohol consumption (alcohol causes severe cognitive challenge) interfere with fetal growth. Much information regarding whether a fetus is growing and is healthy can be gathered through a variety of assessment techniques. Nursing responsibilities for these assessment procedures include seeing that a signed consent form has been obtained as needed, scheduling the procedure, explaining the procedure to the woman and her support person including what the procedure will entail and any potential risks, preparing a woman physically and psychologically, providing support during the procedure, assessing both fetal and maternal responses to the procedure, providing any necessary follow-up care, and managing equipment and specimens (see Focus on Nursing Care Planning Box 9.5).

Consent to perform a procedure is necessary if the procedure poses any risk to the mother or fetus that would not otherwise be present.

BOX 9.4 ✻ Nagele's Rule

To calculate the date of birth by this rule, count backward 3 calendar months from the first day of a woman's last menstrual period and add 7 days. For example, if the last menstrual period began May 15, you would count back 3 months (April 15, March 15, February 15) and add 7 days, to arrive at a date of birth of February 22.

Health History

Like all assessments, fetal assessment begins with a health history. Ask specifically about nutritional intake, because, if a woman is not eating a well-balanced diet, she may not be taking in sufficient nutrients for fetal growth. Be certain to also ask about personal habits such as cigarette smoking, recreational drug use, and exercise, because all of these influence glucose/insulin balance and fetal growth. Most women actively protect a fetus growing inside them. Asking if the woman has had any accidents or experienced intimate partner abuse helps reveal whether the fetus could have suffered any trauma (intimate partner abuse tends to increase during pregnancy because of the stress a pregnancy can create) (Records, 2007).

Estimating Fetal Growth

McDonald's rule, a symphysis-fundal height measurement, although not documented to be thoroughly reliable, is an easy method of determining during midpregnancy that a fetus is growing in utero. Typically, the distance from the uterine fundus to the symphysis pubis in centimeters is equal to the week of gestation between the 20th and 31st weeks of pregnancy. Make the measurement from the notch of the symphysis pubis to over the top of the uterine fundus as a woman lies supine (Fig. 9.9). McDonald's rule becomes inaccurate during the third trimester of pregnancy because the fetus is growing more in weight than in height during this time. Until then, a fundal height much greater than this standard suggests multiple pregnancy, a miscalculated due date, a large-for-gestational-age infant, hydramnios (increased amniotic fluid volume), or possibly even hydatidiform mole (see Chapter 21). A fundal measurement much less than this suggests that the fetus is failing to thrive (intrauterine growth restriction), the pregnancy length was miscalculated, or an anomaly, such as anencephaly, has developed.

Determining and recording that the fundus has reached typical milestone measurements, such as over the symphysis pubis at 12 weeks, at the umbilicus at 20 weeks, and at the xiphoid process at 36 weeks, are also helpful.

Assessing Fetal Well-being

Several actions or procedures are helpful in detecting and documenting that the fetus is not only growing but apparently healthy.

BOX 9.5 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Woman Undergoing Fetal Studies

Liz Calhorn, an 18-year-old woman, thinks she is 24 weeks' pregnant. Today, at a clinic visit, she tells you she felt her fetus move for the first time. She states, "Feeling the baby move made me realize for the first time there's someone inside me, you know what I mean? It made me know it's time I started being more careful with what I do."

Family Assessment ✻ Client lives in one-bedroom apartment; supports self with typing position at insurance agency. States, "My parents would help out if I begged them, but I'm not going to do that." Boyfriend (father of fetus) is supportive, but couple has no plans to marry. Client states, "I'm not ready for commitment."

Client Assessment ✻ Client smokes a pack of cigarettes a day. Twice during the pregnancy (at the 4th and 10th week), she drank beer at summer picnics. Takes aspirin, 10 g, for almost-daily sinus headaches. No spotting or falls since last menstrual period. No recreational drugs.

Nutrition: Breakfast: None, to help control her weight.
Lunch: A hotdog and salad. One diet cola.
Dinner: Macaroni and cheese; applesauce. One cup coffee.
Snack: ½ bag potato chips and cream-cheese dip

Physical examination: Fundal height is 20 cm. Fetal heart tones by Doppler at 160/min. Has been advised to have an ultrasound done to assess for fetal growth and to date pregnancy.

Nursing Diagnosis ✻ Risk for altered fetal growth related to inadequate nutrition, alcohol and nicotine consumption

Outcome Criteria ✻ Client consents to ultrasound for fetal growth assessment; reports lessened alcohol and cigarette consumption at next visit.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Ask patient to recount a "typical day" to reveal any actions possibly detrimental to fetal growth.	Discuss common actions that are unsafe during pregnancy, such as smoking and drinking alcohol.	Knowing what constitutes unsafe practices during pregnancy is a woman's best safeguard against fetal harm.	Client states that she now knows and will avoid unsafe actions during pregnancy.
		Consultations		
Physician/nurse	Determine whether ultrasound department has appointments free in coming week.	Schedule ultrasound 1 week in advance with ultrasound department.	Client believes she is 24 weeks pregnant. Fundal height, recent fetal movements correspond more closely to 20 weeks.	Client reports for scheduled ultrasound in 1 week.
		Procedures/Medications		
Nurse	Assess use of over-the-counter and complementary therapies.	Discuss with client inadvisability of taking aspirin during pregnancy; suggest she take acetaminophen (Tylenol) instead.	Acetylsalicylic acid (aspirin) can lead to bleeding or prolonged pregnancy.	Client reports at next prenatal visit that she takes acetaminophen for pain during pregnancy.
		Nutrition		
Nurse/ nutritionist	Ask client for a 24-hour recall nutrition history.	Discuss the advisability of eating breakfast while pregnant to help avoid hypoglycemia in fetus.	Knowing what constitutes unsafe practices during pregnancy is a woman's best safeguard against fetal harm.	Client reports at prenatal visits that she eats breakfast before leaving for work in the morning.

		Nutrition		
Nutritionist	Assess and analyze the 24-hour recall history.	Discuss advantages of good pregnancy nutrition with client and define healthy pregnancy nutrition.	Client needs to improve total nutrition, especially intake of protein sources, to better support pregnancy.	Client meets with clinic nutritionist to discuss better nutrition pattern. Reports improved protein sources in diet.
		Patient/Family Education		
Nurse	Determine whether client understands that ultrasound is not x-ray, so is not harmful to fetus.	Instruct client about preparation for ultrasound (drink fluid; avoid emptying bladder).	A well-prepared client is more apt to result in an effective procedure and a satisfied client.	Client will describe accurate preparations for procedure. Receives printed instructions for ambulatory ultrasound.
		Spiritual/Psychosocial/Emotional Needs		
Nurse/ physician	Assess the extent of factors, such as alcohol and cigarette use, that could have led to intrauterine growth restriction.	Review the possibility with client that her pregnancy dating may be wrong, because fundal height is below normal. Alternate cause could be fetal growth restriction.	Understanding contributors to fetal health is necessary for women to make informed choices during pregnancy.	Client states that she understands the discrepancy in fundal height and weeks' gestation following explanation.
		Discharge Planning		
Nurse/ physician	Perform complete assessment to help ensure continuity of care with other services.	Mark chart as high-risk client for intrauterine growth restriction. Stress importance of continuing prenatal care.	Documenting risk factors helps to safeguard the fetus.	The patient chart documents high-risk status. Client continues prenatal care.

Fetal Movement

Fetal movement that can be felt by the mother (quickening) occurs at approximately 18 to 20 weeks of pregnancy and peaks in intensity at 28 to 38 weeks. A healthy fetus moves with a degree of consistency, or at least 10 times a day. In contrast, a fetus not receiving enough nutrients because of placental insufficiency has greatly decreased movements. Based on this, asking a woman to observe and record the number of movements the fetus is making offers a gross assessment of fetal well-being (Chang & Blakemore, 2007).

FIGURE 9.9 Measuring fundal height from the superior aspect of the pubis to the fundal crest. The tape is pressed flat against the abdomen for the measurement.

Because of variations in movements among normal, healthy fetuses, as well as variations in different health care providers' level of confidence in the technique, a variety of protocols have been developed by different institutions. One popular way to approach this assessment is to ask the woman to lie in a left recumbent position after a meal and record how many fetal movements she feels over the next hour (the Sandovsky method). In this position, a fetus normally moves a minimum of twice every 10 minutes or an average of 10–12 times an hour. If less than 10 movements occur within an hour, the woman repeats the test for the next hour. She should call her health care provider if she feels fewer than 10 movements (half the normal number) during the chosen 2 hours. Another protocol is "Count-to-Ten" (the Cardiff method). For this, a woman records the time interval it takes for her to feel 10 fetal movements. Usually, this occurs within 60 minutes. Make sure to assure a woman that fetal movements do vary, especially in relation to sleep cycles

of the fetus, her activity, and the time since she last ate. Otherwise, she can become unduly worried that her fetus may be in jeopardy when the fetus is just having an inactive time.

What if... You give instructions to Liz Calhorn, the woman described at the beginning of the chapter, to count fetal movements for 1 hour two times a day after meals and she tells you that she snacks all day long rather than eats at regular times? Would you modify your instructions? Which is more important—that she count movements after meals or that she does it two times a day?

Fetal Heart Rate

Fetal hearts beat at 120 to 160 beats per minute throughout pregnancy. Fetal heart sounds can be heard and counted as early as the 10th to 11th week of pregnancy by the use of an ultrasonic Doppler technique (Fig. 9.10).

Rhythm Strip Testing. The term "rhythm strip testing" means assessment of the fetal heart rate for whether a good baseline rate and a degree of variability are present. For this, help a woman into a semi-Fowler's position (either in a comfortable lounge chair or on an examining table or bed with an elevated backrest) to prevent her uterus from compressing the vena cava and causing supine hypotension syndrome during the test. Attach an external fetal heart rate monitor abdominally (Fig. 9.11A). Record the fetal heart rate for 20 minutes.

The baseline reading refers to the average rate of the fetal heartbeat per minute. Variability refers to small changes in rate that occur if the fetal parasympathetic and sympathetic nervous systems are receiving adequate oxygen and nutrients. It is categorized as *absent* (none apparent); *minimal* (extremely small fluctuations); *moderate* (amplitude range of 6–25 beats per minute); and *marked* (amplitude range over 25 beats per minute) (Macones et al., 2008). In the rhythm strip in Figure 9.11B, for example, the baseline (average) of the fetal heartbeat is 130 beats per minute, although over the recorded period, it varies from 120 to 150 beats per minute.

Because the average fetus moves about twice every 10 minutes, and movement causes the heart rate to increase, there will typically be two or more instances of fetal heart rate acceleration in a 20-minute rhythm strip.

Rhythm strip testing requires a woman to remain in a fairly fixed position for 20 minutes. Keep her well informed of the purpose of the test, how it is interpreted, and the meaning of results after the test. The more she understands about the process, the better she can cooperate to make it successful.

FIGURE 9.10 Measuring fetal heart rate with a Doppler transducer, which detects and broadcasts the fetal heart rate to the parent-to-be as well as to the nurse. (© Barbara Proud.)

Nonstress Testing. A **nonstress test** measures the response of the fetal heart rate to fetal movement. Position a woman and attach both a fetal heart rate and a uterine contraction monitor. Instruct a woman to push a button attached to the monitor (similar to a call bell) whenever she feels the fetus move. This will create a dark mark on the paper tracing at these times.

When the fetus moves, the fetal heart rate should increase about 15 beats per minute and remain elevated for 15 seconds. It should decrease to its average rate again as the fetus quiets (see Fig. 9.11C). If no increase in beats per minute is noticeable on fetal movement, poor oxygen perfusion of the fetus is suggested.

A nonstress test usually is done for 10 to 20 minutes. The test is said to be reactive if two accelerations of fetal heart rate (by 15 beats or more) lasting for 15 seconds occur after movement within the chosen time period. The test is nonreactive if no accelerations occur with the fetal movements. The results also can be interpreted as nonreactive if no fetal movement occurs or if there is low short-term fetal heart rate variability (less than 6 beats per minute) throughout the testing period (Chang & Blakemore, 2007).

If a 20-minute period passes without any fetal movement, it may mean only that the fetus is sleeping. Other reasons for lessened variability are maternal smoking, drug use, or hypoglycemia. If you give the woman an oral carbohydrate snack, such as orange juice, it can cause her blood glucose level to increase enough to cause fetal movement. The fetus also may be stimulated by a loud sound (discussed later) to cause movement.

Because both rhythm strip and nonstress testing are noninvasive procedures and cause no risk to either mother or fetus, they can be used as screening procedures in all pregnancies. They can be done at home daily as part of a home monitoring program for the woman who is having a complication of pregnancy.

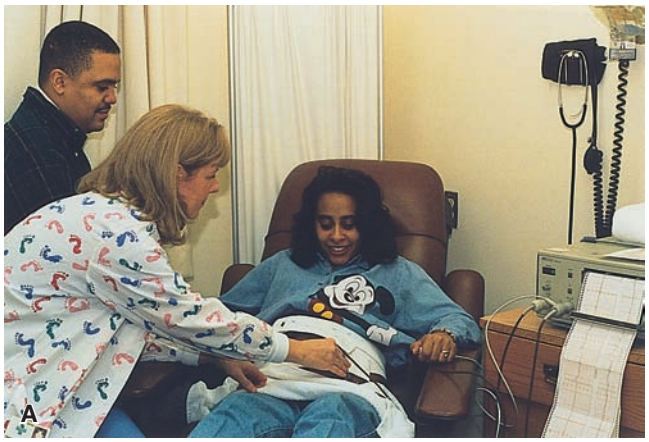
If a nonstress test is nonreactive, additional fetal assessment, such as a contraction stress test or a biophysical profile test, will be scheduled.

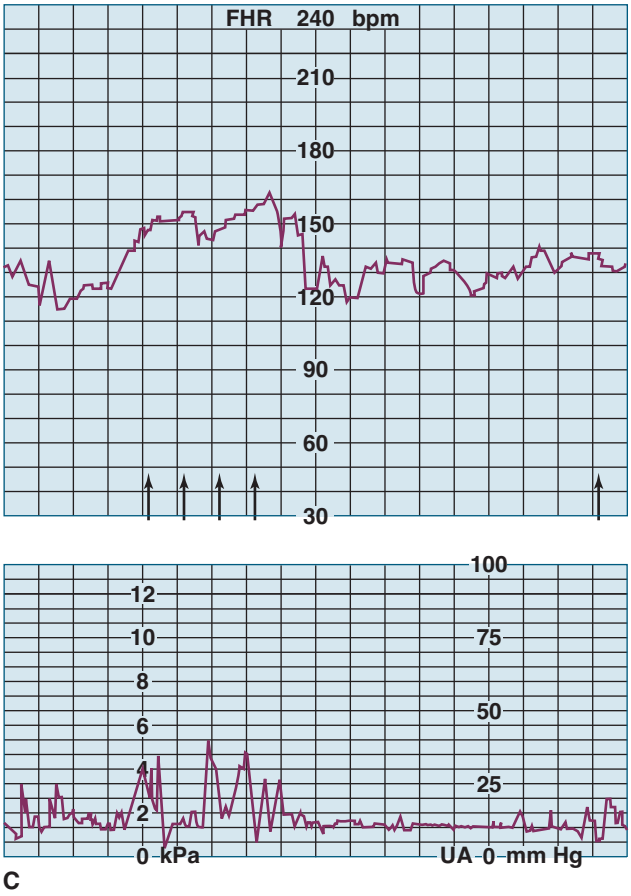
Vibroacoustic Stimulation. For acoustic (sound) stimulation, a specially designed acoustic stimulator is applied to the mother's abdomen to produce a sharp sound of approximately 80 decibels at a frequency of 80 Hz, startling and waking the fetus (Chang & Blakemore, 2007).

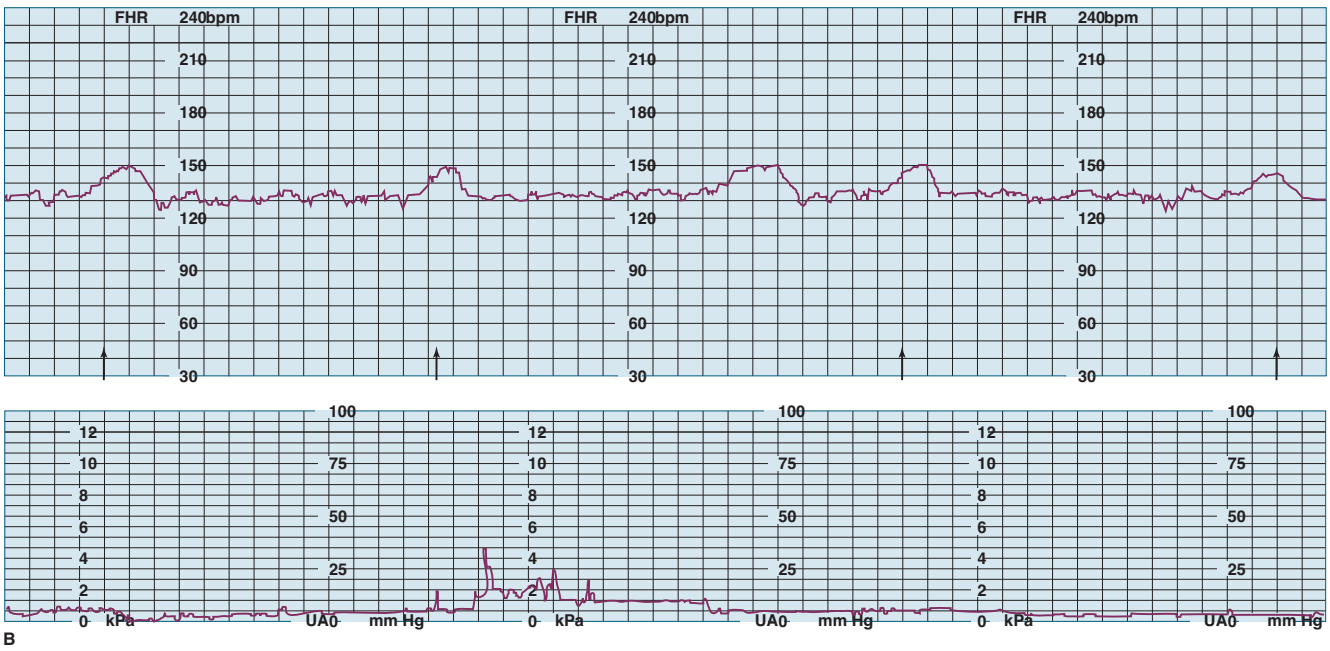
During a standard nonstress test, if a spontaneous acceleration has not occurred within 5 minutes, apply a single 1- to 2-second sound stimulation to the lower abdomen. This can be repeated again at the end of 10 minutes if no further spontaneous movement occurs, so that two movements within the 20-minute window can be evaluated.

Contraction Stress Testing. With contraction stress testing, the fetal heart rate is analyzed in conjunction with contractions. When this test was first developed, contractions were initiated

FIGURE 9.11 Rhythm strip and nonstress testing of fetal heart rate. (**A**) The woman sits in a comfortable chair to avoid supine hypotension. Both a uterine contraction monitor and fetal heart rate monitor are in place on her abdomen. (Photoraph by Melissa Olson, with permission of Chestnut Hill Hospital, Philadelphia, PA.) (**B**) A rhythm strip. The upper strip signifies heart rate; the lower strip indicates uterine activity. *Arrows* signal fetal movement. (**C**) Baseline fetal heart rate is 130–132. This strip shows fetal heart rate acceleration in response to fetal movement, shown by *arrows*. (Photograph by Melissa Olson, with permission of Chestnut Hill Hospital, Philadelphia, PA.)







by the intravenous infusion of oxytocin. However, once started, contractions begun this way were sometimes difficult to stop and led to preterm labor. For this reason, a source of oxytocin for contraction stress testing currently is achieved by nipple stimulation. Gentle stimulation of the nipples releases oxytocin in the same way as happens with breastfeeding.

With external uterine contraction and fetal heart rate monitors in place, the baseline fetal heart rate is obtained. Next, the woman rolls a nipple between her finger and thumb until uterine contractions begin, which are recorded by a uterine monitor. Three contractions with a duration of 40 seconds or longer must be present in a 10-minute window

before the test can be interpreted. The test is negative (normal) if no fetal heart rate decelerations are present with contractions. It is positive (abnormal) if 50% or more of contractions cause a late deceleration (a dip in fetal heart rate that occurs toward the end of a contraction and continues after the contraction) (Chang & Blakemore, 2007). See Chapter 15 for further discussion of fetal heart rate monitoring as this is also measured with labor contractions.

Nonstress tests and contraction stress tests are compared in Table 9.4. After a contraction stress test, encourage a woman to remain in the health care facility for about 30 minutes, to be certain that contractions have quieted and preterm labor is not a risk.

Ultrasonography

Ultrasonography, which measures the response of sound waves against solid objects, is a much-used tool in modern obstetrics, although the recommendations for its use are being questioned because of unproven benefits in the face of added expense (Neilson, 2009). It can be used to:

- Diagnose pregnancy as early as 6 weeks' gestation
- Confirm the presence, size, and location of the placenta and amniotic fluid
- Establish that a fetus is growing and has no gross anomalies, such as hydrocephalus, anencephaly, or spinal cord, heart, kidney, and bladder defects
- Establish sex if a penis is revealed
- Establish the presentation and position of the fetus
- Predict maturity by measurement of the biparietal diameter of the head

Ultrasonography can also be used to discover complications of pregnancy, such as the presence of an intrauterine device, hydramnios or oligohydramnios, ectopic pregnancy, missed miscarriage, abdominal pregnancy, placenta previa, premature separation of the placenta, coexisting uterine tumors, multiple pregnancy, or genetic disorders such as Down syndrome. Fetal anomalies such as neural tube disorders, diaphragmatic hernia, or urethral stenosis also can be diagnosed. Fetal death can be revealed by a lack of heartbeat and respiratory movement. After birth, an ultrasound may be used to detect a retained placenta or poor uterine involution in the new mother.

For an ultrasound, intermittent sound waves of high frequency (above the audible range) are projected toward the uterus by a transducer placed on the abdomen or in the vagina. The sound frequencies that bounce back can be displayed on an oscilloscope screen as a visual image. The frequencies returning from tissues of various thicknesses and properties present distinct appearances. A permanent record, such as a video or photograph, can be made of the scan.

The intricacy of the image obtained depends on the type or mode of process used. B-mode scanning allows patterns to merge and form a still picture, similar to a black-and-white snapshot (called gray-scale imaging). Real-time mode involves the use of multiple waves that allow the screen picture to move. On this type of ultrasound, the fetal heart can be seen to move, and even movement of the extremities, such as bringing a hand to the mouth to suck a thumb, can be seen. A parent who is in doubt that her fetus is well or whole can be greatly reassured by viewing a real-time ultrasound image.

Before an ultrasound examination, be sure that a woman has received a good explanation of what will happen and reassurance that the process does not involve x-rays (Box 9.6). This means it is also safe for the father of the child to remain in the room during the test.

For the sound waves to reflect best and the uterus to be held stable, it is helpful if the woman has a full bladder at the time of the procedure. To ensure this, have her drink a full glass of water every 15 minutes beginning 90 minutes before the procedure and not void until after the procedure.

Help the woman up to an examining table and drape her for modesty, but with her abdomen exposed. To prevent supine hypotension syndrome, place a towel under her right buttock to tip her body slightly so that the uterus will roll away from the vena cava. A gel is then applied to her abdomen to improve the contact of the transducer. Be certain that the gel is at room temperature or even slightly warmer, or it can cause uncomfortable uterine cramping. The transducer is then applied to her abdomen and moved both horizontally and vertically until the uterus and its contents are fully scanned (Fig. 9.12). Ultrasonography also may be performed using an intravaginal technique although this is not necessary for routine testing.

Although the long-term effects of ultrasound are not yet known, the technique appears to be safe for both mother and fetus and involves no discomfort for the fetus. Usually, the only

TABLE 9.4 ✻ Comparison of Nonstress and Contraction Tests

Assessment	Nonstress	Contraction
What is measured	Response of fetal heart rate in relation to fetal movements	Response of fetal heart rate in relation to uterine contractions produced by nipple stimulation
Normal findings	Two or more accelerations of fetal heart rate of 15 beats/min lasting 15 sec or longer following fetal movements in a 20-min period	No late decelerations with contractions
Safety considerations	Woman should not lie supine to prevent supine hypotension syndrome	In addition to preventing supine hypotension syndrome, observe woman for 30 min afterward to see that contractions are quiet and preterm labor does not begin

BOX 9.6 ✻ Focus on Communication

Liz Calhorn is scheduled for an ultrasound.

Less Effective Communication

Nurse: Do you have any questions about what will happen, Liz?
Liz: I guess. I can't decide if I want to know my baby's sex or not.
Nurse: Most people do these days. It helps them plan better.
Liz: I think I'd rather be surprised. I know I don't want a boy.
Nurse: If it were me, I'd want to know. How else do you know what color clothes to buy?
Liz: Okay, tell me what the ultrasound shows.

More Effective Communication

Nurse: Do you have any questions about what will happen, Liz?
Liz: I guess. I can't decide if I want to know my baby's sex or not.
Nurse: That's an individual decision. What things are you thinking about?
Liz: I think I'd rather be surprised. I know I don't want a boy.
Nurse: Tell me about that. Why is that?
Liz: A guy got me into this trouble. I don't need another one around the house.
Nurse: Let's talk about what it will mean if you should have a boy.

Becoming so engrossed in sharing her personal feelings, the nurse in the first example forgot to determine the exact information that the client wanted. Taking the time to discover what the client wanted, as was done in the second example, revealed that the sex of the child was only a small part of what the mother was afraid to learn.

discomfort for the woman is that the contact lubricant may be messy and she may experience a strong desire to void before the scan is completed. Taking home a photograph of the ultrasound image can enhance bonding because it is proof that the pregnancy exists and the fetus appears well. As desirable as it is, however, caution women against having ultrasound images done just for the purpose of having "keepsake" photographs, because commercial firms offering these services are not well regulated so their equipment could be outdated and unsafe.

✔ Checkpoint Question 9.4

Liz Calhorn is scheduled to have an ultrasound examination. What instruction would you give her before her examination?

a. "Void immediately before the procedure to reduce your bladder size."
b. "The intravenous fluid infused to dilate your uterus does not hurt the fetus."
c. "You will need to drink at least 3 glasses of fluid before the procedure."
d. "You can have medicine for pain for any contractions caused by the test."

FIGURE 9.12 An ultrasound being recorded. Notice the mother's interest in being able to see her baby's first photograph.

Biparietal Diameter. Ultrasonography may be used to predict fetal maturity by measuring the biparietal diameter (side-to-side measurement) of the fetal head. In 80% of pregnancies in which the biparietal diameter of the fetal head is 8.5 cm or greater, it can be predicted that the infant will weigh more than 2500 g (5.5 lb) or is at a fetal age of 40 weeks. Figure 9.13 is an ultrasound showing the biparietal diameter of a fetus at 24 weeks.

Two other measurements commonly made by ultrasound to predict maturity are head circumference (34.5 cm indicates a 40-week fetus) and femoral length.

Doppler Umbilical Velocimetry. Doppler ultrasonography measures the velocity at which red blood cells in the uterine and fetal vessels travel. Assessment of the blood flow through uterine blood vessels is helpful to determine the vascular resistance present in women with diabetes or hypertension of pregnancy and whether resultant placental insufficiency is occurring. Because it will limit the number of nutrients that can reach the fetus, decreased velocity is an important predictor of poor neonatal outcome (Valcamonico et al., 2007).

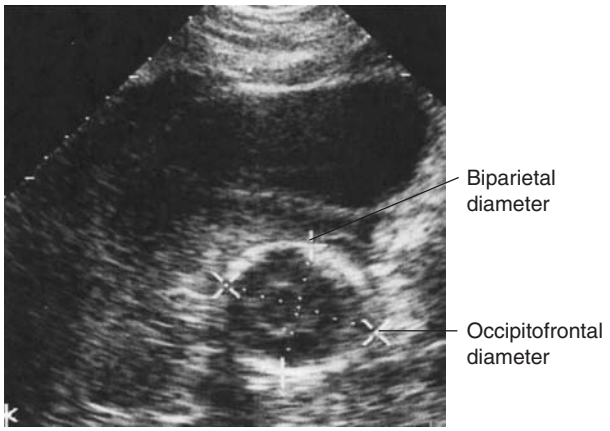


FIGURE 9.13 An ultrasound at 24 weeks' gestation showing measurement of the biparietal diameter. (Courtesy of the Department of Medical Photography, Children's Hospital, Buffalo, NY.)

Placental Grading. Based particularly on the amount of calcium deposits in the base of the placenta, placentas can be graded by ultrasound as 0 (a placenta 12–24 weeks), 1 (30–32 weeks), 2 (36 weeks), and 3 (38 weeks). Because fetal lungs are apt to be mature at 38 weeks, a grade 3 placenta suggests that the fetus is mature.

Amniotic Fluid Volume Assessment. The amount of amniotic fluid present is yet another way to estimate fetal health because a portion of the fluid is formed by fetal kidney output. If a fetus is becoming stressed in utero so that circulatory and kidney functions are failing, urine output and, consequently, the volume of amniotic fluid also will decrease. A decrease in amniotic fluid volume puts the fetus at risk for compression of the umbilical cord and interference with nutrition.

For gestations of less than 20 weeks, the uterus is hypothetically divided along the midpoint (the linea nigra on the woman's abdomen) into two vertical halves. The vertical diameter of the largest pocket of amniotic fluid present on each side is measured in centimeters. The amniotic volume index (AFI) or total is the sum of the two measurements. For gestations of 20 weeks or more, the uterus is divided into four quadrants, using the linea nigra again as the vertical dividing line and the level of the umbilicus as the horizontal dividing line. The vertical diameter of the largest pocket of fluid in each quadrant is obtained, and the four values are then added to produce the amniotic fluid index. The average index is approximately 12–15 cm between 28 and 40 weeks. An index greater than 20–24 cm indicates hydramnios (excessive fluid, perhaps caused by inability of the fetus to swallow); an index less than 5–6 cm indicates oligohydramnios (decreased amniotic fluid, perhaps caused by poor perfusion and kidney failure).

Electrocardiography

Fetal ECGs may be recorded as early as the 11th week of pregnancy. The ECG is inaccurate before the 20th week, however, because until this time fetal electrical conduction is so weak that it is easily masked by the mother's ECG tracing. It is rarely used unless a specific heart anomaly is suspected.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) also may be used to assess the fetus. Because the technique apparently causes no harmful effects to the fetus or woman (although extensive long-term testing is not yet available), MRI has the potential to replace or complement ultrasonography as a fetal assessment technique (Laifer-Narin et al,, 2007). It may be most helpful in diagnosing complications such as ectopic pregnancy or trophoblastic disease (see Chapter 21), because later in a pregnancy fetal movement (unless the fetus is sedated) can obscure the findings.

Maternal Serum Alpha-Fetoprotein

AFP is a substance produced by the fetal liver that is present in both amniotic fluid and maternal serum. The level is abnormally high in maternal serum (MSAFP) if the fetus has an open spinal or abdominal defect such as spina bifida or omphalocele, because the open defect allows more AFP to enter the mother's circulation. Although the reason is unclear, the level is low if the fetus has a chromosomal defect such as Down syndrome. MSAFP levels begin to rise at 11 weeks' gestation and then steadily increase until term. Traditionally assessed at the 15th week of pregnancy, between 85% and 90% of neural tube defects and 80% of Down syndrome babies can be detected by this method (Crombleholme, 2009).

Triple Screening

Triple screening, or analysis of three indicators (MSAFP, unconjugated estriol, and hCG), may be performed in place of simple AFP testing to yield even more reliable results. As with the measurement of MSAFP, it requires only a simple venipuncture of the mother.

Chorionic Villi Sampling

Chorionic villi sampling (CVS) is a biopsy and chromosomal analysis of chorionic villi that is done at 10–12 weeks of pregnancy. This procedure is discussed in Chapter 7. Coelocentesis (transvaginal aspiration of fluid from the extraembryonic cavity) is an alternative method to remove cells for fetal analysis.

Amniocentesis

Amniocentesis (from the Greek *amnion* for "sac" and *kentesis* for "puncture") is the aspiration of amniotic fluid from the pregnant uterus for examination. The procedure can be done in a physician's office or in an ambulatory clinic. It is typically scheduled between the 14th and 16th weeks of pregnancy to allow for a generous amount of amniotic fluid to be present. The technique can be used again near term to test for fetal maturity.

Amniocentesis is a technically easy procedure, but it can be frightening to a woman. Because it involves penetration of the integrity of the amniotic sac, there also are risks to the fetus, although the incidence of these is low (less than 0.5%). Fetal complications range from hemorrhage from penetration of the placenta, infection of the amniotic fluid, and puncture of the fetus. If it leads to irritation of the uterus, it can initiate premature labor (Alfirevic, 2009).

In preparation for amniocentesis, ask the woman to void (to reduce the size of the bladder and prevent an inadvertent puncture). Place her in a supine position on an examining table and drape her appropriately, exposing only her abdomen. Place a folded towel under her right buttock to tip her body slightly to the left and move the uterus off the vena cava, to prevent supine hypotension syndrome. Attach fetal heart rate and uterine contraction monitors. Take her blood pressure and measure the fetal heart rate for baseline levels.

An ultrasound is then done to determine the position of the fetus and the location of a pocket of amniotic fluid and the placenta. The abdomen is then washed with an antiseptic solution, and a local anesthetic is injected. Caution the woman that she may feel a sensation of pressure as the needle used for aspiration, a 3- or 4-in, 20- to 22-gauge spinal needle, is introduced. Do not suggest that she take a deep breath and hold it as a distraction against discomfort: this lowers the diaphragm against the uterus and shifts intrauterine contents.

The needle is inserted until it reaches the amniotic cavity and a pool of amniotic fluid, carefully avoiding the fetus and placenta (Fig. 9.14). A syringe is attached, and about 15 mL of amniotic fluid is withdrawn. The needle is then removed, and the woman rests quietly for about 30 minutes. During the procedure and for the 30 minutes afterward, observe the fetal heart rate monitor to be certain the rate remains within normal values and observe the uterine contraction monitor to be sure that no contractions are occurring.

If the woman has Rh-negative blood, Rho(D) immune globulin (RhIG; RhoGAM) is administered after the procedure to prevent fetal isoimmunization. This is to ensure that maternal antibodies will not form against any placental red blood cells that might have accidentally been released during the procedure.

Amniotic fluid is analyzed for:

- **Alpha-Fetoprotein (AFP).** If the fetus has an open body defect, such as anencephaly, myelomeningocele, or omphalocele, increased levels of AFP will be present in the amniotic fluid because of leakage of AFP into the fluid. The level will be decreased in the amniotic fluid of fetuses with chromosomal defects such as Down syndrome. Acetylcholinesterase is another compound that can be obtained from amniotic fluid in high levels if a neural tube defect is present.

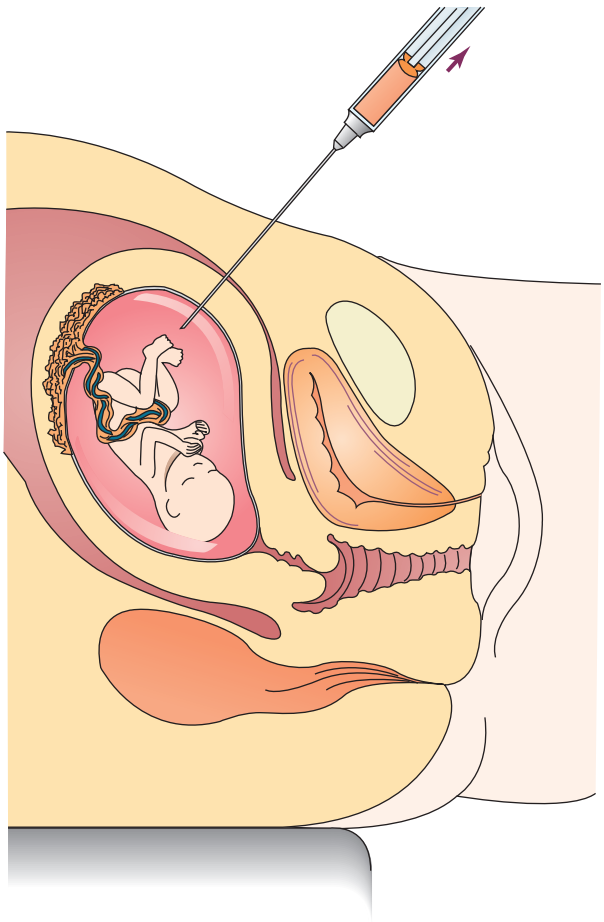

FIGURE 9.14 Amniocentesis. A pocket of amniotic fluid is located by ultrasound. A small amount of fluid is removed by needle aspiration.

- **Bilirubin Determination.** The presence of bilirubin may be analyzed if a blood incompatibility is suspected. If bilirubin is going to be analyzed, the specimen must be free of blood or a false-positive reading will occur.
- **Chromosome Analysis.** A few fetal skin cells are always present in amniotic fluid. These cells may be cultured and stained for karyotyping for genetic analysis. Examples of genetic diseases that can be detected by prenatal amniocentesis and their significance to health are discussed in Chapter 7.
- **Color.** Normal amniotic fluid is the color of water; late in pregnancy, it may have a slightly yellow tinge. A strong yellow color suggests a blood incompatibility (the yellow results from the presence of bilirubin released with the hemolysis of red blood cells). A green color suggests meconium staining, a phenomenon associated with fetal distress.
- **Fetal Fibronectin.** Fibronectin is a glycoprotein that plays a part in helping the placenta attach to the uterine decidua. Early in pregnancy, it can be assessed in the woman's cervical mucus, but the amount then fades until, after 20 weeks of pregnancy, it is no longer present in cervical mucus. As labor approaches and cervical dilatation begins, it can be found again in cervical or vaginal fluid. Damage to fetal membranes from cervical dilatation releases a great deal of the substance, so detection of fibronectin in either the amniotic fluid or in the mother's vagina can serve as an announcement that preterm labor may be beginning.
- **Inborn Errors of Metabolism.** Some inherited diseases that are caused by inborn errors of metabolism can be detected by amniocentesis. For a condition to be identified, an errant enzyme must be present in the amniotic fluid as early as the time of the procedure. Examples of illnesses that can be detected in this way are cystinosis and maple syrup urine disease (amino acid disorders).
- **Lecithin/Sphingomyelin Ratio.** Lecithin and sphingomyelin are the protein components of the lung enzyme surfactant that the alveoli begin to form at the 22nd to 24th weeks of pregnancy. After amniocentesis, the L/S ratio may be determined quickly by a shake test (if bubbles appear in the amniotic fluid after shaking, the ratio is mature) or sent for laboratory analysis. An L/S ratio of 2:1 is traditionally accepted as lung maturity. Infants of mothers with severe diabetes may have false-mature readings of lecithin because the stress to the infant in utero tends to mature lecithin pathways early. This means that fetal values must be considered in light of the presence of maternal diabetes, or the infant may be born with mature lung function but be immature overall (fragile giants) causing them to not do well in postnatal life. Some laboratories interpret a ratio of 2.5:1 or 3:1 as a mature indicator in infants of women with diabetes.
- **Phosphatidyl Glycerol and Desaturated Phosphatidylcholine.** These are additional compounds, in addition to lecithin and sphingomyelin, found in surfactant. Pathways for these compounds mature at 35–36 weeks. Because they are present only with mature lung function, if they are present in the sample of amniotic fluid obtained by amniocentesis, it can be predicted with even greater confidence that respiratory distress syndrome is not likely to occur.

Percutaneous Umbilical Blood Sampling

PUBS (also called cordocentesis or funicentesis) is the aspiration of blood from the umbilical vein for analysis. After the umbilical cord is located by ultrasound, a thin needle is inserted by amniocentesis technique into the uterus and is guided by ultrasound until it pierces the umbilical vein. A sample of blood is then removed for blood studies, such as a complete blood count, direct Coombs' test, blood gases, and karyotyping. To ensure that the blood obtained is fetal blood, it is submitted to a Kleihauer-Betke test which measures the difference between adult and fetal blood. If the test reveals that a fetus is anemic, blood may be transfused using this same technique. Because the umbilical vein continues to ooze for a moment after the procedure, fetal blood could enter the maternal circulation after the procedure, so RhIG is given to Rh-negative women to prevent sensitization. The fetus is monitored by a nonstress test before and after the procedure to be certain that uterine contractions are not present and by ultrasound to see that no bleeding is evident. This procedure carries little additional risk to the fetus or woman over amniocentesis and can yield information not available by any other means, especially about blood dyscrasias.

Amnioscopy

Amnioscopy is the visual inspection of the amniotic fluid through the cervix and membranes with an amnioscope (a small fetoscope). The main use of the technique is to detect meconium staining. It carries some risk of membrane rupture.

Fetoscopy

Fetoscopy, in which the fetus is visualized by inspection through a fetoscope (an extremely narrow, hollow tube inserted by amniocentesis technique), can be helpful to assess fetal well-being (Lopriore et al., 2007). If a photograph is taken through the fetoscope, it can document a problem or reassure parents that their infant is perfectly formed. The procedure is used to:

- Confirm the intactness of the spinal column
- Obtain biopsy samples of fetal tissue and fetal blood samples
- Perform elemental surgery, such as inserting a polyethylene shunt into the fetal ventricles to relieve hydrocephalus or anteriorly into the fetal bladder to relieve a stenosed urethra

The earliest time in pregnancy that fetoscopy can be performed is about the 16th or 17th week. For the procedure, the mother is prepared and draped as for amniocentesis. A local anesthetic is injected into the abdominal skin. The fetoscope is then inserted through a minor abdominal incision. If the fetus is very active, meperidine (Demerol) may be administered to the woman to help sedate the fetus to avoid fetal injury by the scope and to allow better observation.

Fetoscopy carries a small risk of premature labor. Amnionitis (infection of the amniotic fluid) may occur. To avoid this, the woman may be prescribed 10 days of antibiotic therapy after the procedure. The number of procedures performed by fetoscopy is limited because of the manipulation involved and the ethical quandary of the mother's autonomy being compromised by fetal needs if further procedures are necessary (e.g., asking the mother to undergo general anesthesia so that the fetus can have surgery).

Biophysical Profile

A biophysical profile combines five parameters (fetal reactivity, fetal breathing movements, fetal body movement, fetal tone, and amniotic fluid volume) into one assessment. The fetal heart and breathing record measure short-term central nervous system function; the amniotic fluid volume helps measure long-term adequacy of placental function. The scoring for a complete profile is shown in Table 9.5. With use of this system, each item has the potential for scoring a 2, so 10 would be the highest score possible. A biophysical profile is more accurate in predicting fetal well-being than any single assessment (Lalor, et al, 2009). Because the scoring system is similar to that of the Apgar score determined at birth on infants, it is popularly called a fetal Apgar.

Biophysical profiles may be done as often as daily during a high-risk pregnancy. If the fetus score on a complete profile is 8–10, the fetus is considered to be doing well. A score of 6 is considered suspicious; a score of 4 denotes a fetus probably in jeopardy. For simplicity, some centers use only two assessments (amniotic fluid index and a nonstress test) for assessment. Referred to as a modified biophysical profile, this predicts short-term viability by the nonstress test and long-term viability by the AFI. A healthy fetus should show a reactive nonstress test and an AFI range between 5 and 25 cm (Chang & Blakemore, 2007). Nurses play a

TABLE 9.5 ✻ Biophysical Profile Scoring

Assessment	Instrument	Criteria for a Score of 2
Fetal breathing	Ultrasound	At least one episode of 30 sec of sustained fetal breathing movements within 30 min of observation
Fetal movement	Ultrasound	At least three separate episodes of fetal limb or trunk movement within a 30-min observation
Fetal tone	Ultrasound	The fetus must extend and then flex the extremities or spine at least once in 30 min
Amniotic fluid volume	Ultrasound	A range of amniotic fluid between 5 and 25 cm must be present
Fetal heart reactivity	Nonstress test	Two or more fetal heart rate accelerations of at least 15 beats/min above baseline and of 15 sec duration occur with fetal movement over a 20-min time period

large role in obtaining the information for both a modified and a full biophysical profile by obtaining either the nonstress test or the ultrasound reading.

✔Checkpoint Question 9.5

Liz Calhorn is scheduled to have an amniocentesis to test for fetal maturity. What instruction would you give her before this procedure?

a. "Void immediately before the procedure to reduce your bladder size."
b. "The x-ray used to reveal your fetus's position has no long-term effects."
c. "The intravenous fluid infused to dilate your uterus does not hurt the fetus."
d. "Your fetus will have less amniotic fluid for the remainder of your pregnancy."

Key Points for Review

- The union of a single sperm and egg (fertilization) signals the beginning of pregnancy.
- The fertilized ovum (zygote) travels by way of a fallopian tube to the uterus, where implantation takes place in about 8 days.
- From implantation to 5 to 8 weeks, the growing structure is called an embryo. The period after 8 weeks until birth is the fetal period.
- Growth of the umbilical cord, amniotic fluid, and amniotic membranes proceeds in concert with fetal growth. The placenta produces several important hormones: estrogen, progesterone, human placental lactogen, and human chorionic gonadotropin.
- Various methods to assess fetal growth and development include fundal height, fetal movement, fetal heart tones, ultrasonography, magnetic resonance imaging, maternal serum alpha-fetoprotein, amniocentesis, percutaneous umbilical blood sampling, amnioscopy, and fetoscopy.
- A biophysical profile is a combination of fetal assessments that predicts fetal well-being better than measuring single parameters.

CRITICAL THINKING EXERCISES

1. Liz Calhorn, whom you met at the beginning of the chapter, has stated that her feelings have changed since she felt her baby move. Would you modify your health teaching with her because of this statement?
2. When Liz is scheduled for an ultrasound examination at 20 weeks' gestation, she tells you she does not want to know the sex of her fetus. Why do some women want to know this, whereas some do not? Is there an advantage to knowing or not knowing?
3. Late in pregnancy, Liz is scheduled for weekly nonstress tests. She invariably comes late for these tests because they are "time-consuming and boring." How could you make such tests more appealing to help increase her cooperation?
4. Examine the National Health Goals related to fetal growth and assessment. Most government-sponsored money for nursing research is allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would advance evidence-based practice in relation to Liz Calhorn or her family?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX types of questions related to fetal growth. Confirm your answers are correct by reading the rationales.

Chapter 10

Psychological and Physiologic Changes of Pregnancy

KEY TERMS

- ballottement
- Braxton Hicks contractions
- Chadwick's sign
- couvade syndrome
- diastasis
- Goodell's sign
- Hegar's sign
- lightening
- linia nigra
- melasma
- Montgomery's tubercles
- multipara
- operculum
- polyuria
- primigravida
- quickening
- striae gravidarum

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe common psychological and physiologic changes that occur with pregnancy and the relationship of the changes to pregnancy diagnosis.
2. Identify National Health Goals related to preconception counseling and prenatal care that nurses can help the nation achieve.
3. Use critical thinking to analyze how the physiologic and psychological changes of pregnancy affect family functioning, and develop ways to make nursing care more family-centered.
4. Assess a woman for the psychological and physiologic changes that occur with pregnancy.
5. Formulate nursing diagnoses related to the psychological and physiologic changes of pregnancy.
6. Identify expected outcomes for a family's psychological and physical adaptation to pregnancy.
7. Plan nursing care related to the changes and diagnosis of pregnancy, such as helping a woman plan to arrange for adequate rest.
8. Implement nursing care, such as health teaching related to the expected changes of pregnancy.
9. Evaluate outcome criteria for the achievement and effectiveness of care.
10. Identify areas of nursing care related to the psychological and physiologic changes of pregnancy that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of the psychological and physiologic changes of pregnancy with nursing process to achieve quality maternal and child health nursing care.

Lauren Maxwell is a part-time model who has come to your clinic for her first prenatal visit. She tells you she missed her period 4 weeks ago and immediately took a home pregnancy test. She's excited that it was positive, because she and her husband have been trying for several months to get pregnant. She is also anxious. "I know there's no turning back now, but I wonder what this will do to my career," she tells you. She adds that her husband, John, doesn't seem a bit scared. "I don't know if that's a good thing or not," she confides. She's also worried about being a good parent. "I'd die," she says, "if I turned into the same kind of parent as my parents."

In addition to the positive home pregnancy test, Lauren presents with amenorrhea, breast tenderness, fatigue, and morning sickness. She is interested in knowing when she will begin to look pregnant and what she can do for the morning sickness.

Previous chapters discussed the anatomy and physiology of women. This chapter adds information about the physical and psychological changes that occur in both a woman and her partner during pregnancy. Knowing such information can help you protect the health of both women and their fetus for the next 9 months.

What psychological development tasks of pregnancy will Lauren need to complete? What suggestions could you make to ease her worry about being a good parent?

BOX 10.1 * Focus on National Health Goals

Several National Health Goals speak to the physiologic and psychological changes of pregnancy or the care necessary because of these changes:

- Increase abstinence from alcohol, cigarettes, and illicit drugs among pregnant women from baselines of 87%, 90%, and 96% to 95%, 99%, and 100%.
- Reduce maternal deaths from a baseline of 9.9 per 100,000 live births to a target of 4.5 per 100,000.
- Increase the proportion of pregnant women who receive early and adequate prenatal care from a baseline of 74% to a target of 90% (http://www.nih.gov).

Nurses can help the nation achieve these objectives by being certain that women receive counseling in nutrition and safer sex practices before pregnancy so they can enter intended pregnancies in good health. Nursing research to identify the best way to reach women with preconception counseling and effective ways to stop smoking cigarettes are important steps that would help women enter pregnancy in optimum health.

Clients are often interested in learning more about the physical or psychological changes that pregnancy brings, because these changes verify the reality and mark the progress of pregnancy.

Physiologic changes of pregnancy occur gradually but eventually affect all of a woman's organ systems. They are changes that are necessary to allow a woman to be able to provide oxygen and nutrients for her growing fetus as well as extra nutrients for her own increased metabolism during the pregnancy. They also ready her body for labor and birth and for lactation (breastfeeding) once the baby is born. Because the physiologic changes that occur with pregnancy are extensive, women are usually happy to learn that they are also temporary. When pregnancy ends, a woman's body will return virtually to its prepregnant state.

Psychological changes of pregnancy occur in response not only to the physiologic alterations that are happening but also to the increased responsibility associated with welcoming a new and completely dependent person into a family. National Health Goals relevant to these changes of pregnancy are shown in Box 10.1.

Despite the magnitude of some of these changes, they are all extensions of normal physiology and psychology. This makes pregnancy represent a time of wellness, not of illness. A major responsibility of health care personnel caring for pregnant women and their families is to help the family maintain a state of wellness throughout the pregnancy and into early parenthood (Crombleholme, 2009).

Nursing Process Overview

For Healthy Adaptation to Pregnancy

Assessment

Ideally, assessment for pregnancy begins before the pregnancy with preconception counseling. During a preconception assessment, evaluate a woman's overall health status, nutritional intake (e.g., sufficient intake of folic acid and protein), and lifestyle (e.g., drinking and smoking habits); identify any potential problems (e.g., potential for ectopic pregnancy because of tubal scarring); and identify a woman's understanding and expectations of conception, pregnancy, and parenthood.

In early pregnancy, be certain that you establish a trusting relationship with a woman so she will see you as a person who is capable of counseling her and helping her solve problems, and in whom she is willing to confide as she is about to undergo what could be a stressful 9 month time period. Continue to assess a woman's health and nutritional status, as well as the well-being of her fetus, throughout pregnancy. Document a woman's physiologic adaptations and the family's psychological adaptations to pregnancy, noting any abnormal findings. Physical findings are gained through the health history, physical assessment, and laboratory tests. Assessment in psychological areas is obtained primarily through interviewing and should include societal, cultural, family, and personal influences on a woman's adaptation to pregnancy.

Nursing Diagnosis

Examples of nursing diagnoses involving the changes that occur with pregnancy are:

- Anxiety related to unexpected pregnancy
- Altered breathing pattern related to respiratory system changes of pregnancy
- Disturbed body image related to weight gain with pregnancy
- Deficient knowledge related to normal changes of pregnancy
- Imbalanced nutrition, less than body requirements, related to early morning nausea

Outcome Identification and Planning

Although a woman may have read pamphlets or talked to her friends about the physiologic changes of pregnancy, she is often surprised to see these changes occurring in herself. She may say, "I knew I'd be tired, but I never guessed it would be this bad," or "I've read about dark pigment forming on my abdomen, but is it normal for it to be this dark? Will this go away?"

Planning nursing care in connection with the physiologic and psychological changes of pregnancy should involve a plan to review these types of concerns with a woman as well as a plan to ask about the individual responses she is experiencing. Reliable web sites to help women learn more about prenatal care are

- The March of Dimes (http://www.marchofdimes.com)
- The Department of Health and Human Services (http://Women'sHealth.gov)
- The National Institutes of Health (http://Medlineplus/prenatalcare.html)

Implementation

The changes of pregnancy may appear insignificant if taken one by one, but together they add up to major changes.

Most women of childbearing age have a mental picture of themselves or a good idea of how they will look in a dress before they try it on in a store. They participate in sports or other activities that conform to that self-image. Then, in 9 months, a woman gains 25 to 30 lb and her figure changes so drastically that none of her prepregnancy clothes fit any longer and bicycling is difficult because of her poor balance. At the beginning of pregnancy, she may feel constantly nauseated. Toward the end, the extra weight and the strain of waiting may make her feel tired and short of breath. Endocrine changes can make her feel moody and quick to cry. She may never have been concerned with her health before; now, every month (and toward the end of pregnancy, every week), she reports to a health care provider for a prenatal checkup. She may worry that she will never lose all the weight she has gained, that the stretch marks on her abdomen will remain forever, and that she will always be as tired or as nauseated as she feels during various stages of her pregnancy.

Help women during their prenatal visits to voice their concerns about the changes happening to them so any worry brought on by these does not compound an already potentially stressful situation for them. Women may need suggestions on exercise and nutrition to follow during pregnancy. For many women, a prenatal visit is the first time they have seen a health care provider since childhood. Nursing interventions during these visits can be instrumental in not only guiding a woman safely through a pregnancy but also connecting her back with ongoing health care.

Outcome Evaluation

Evaluation should determine whether a woman has really "heard" your teaching in light of the stress of her pregnancy. People under stress do not always comprehend well, so it is not unusual for a woman to pocket away information, thinking, "I'll concentrate on what that means when it happens to me, not now," then, when a particular change has happened, to realize she has forgotten what you said. Evaluation that reveals learning did not take place confirms that pregnancy is a period of stress more often than it reflects the quality of teaching. Examples of outcome criteria you might strive for are:

- Client states she is able to continue her usual lifestyle throughout pregnancy.
- Family members describe ways they have adjusted their lifestyles to accommodate the mother's fatigue.
- Couple states they accept the physiologic changes of pregnancy as normal.

PSYCHOLOGICAL CHANGES OF PREGNANCY

Pregnancy is such a huge change in a woman's life that it brings about more psychological changes than any other life event besides puberty (Rojas, Wood, & Blakemore, 2007). A woman's attitude toward a pregnancy depends a great deal on psychological aspects such as the environment in which she was raised, the messages about pregnancy her family communicated to her as a child, the society and culture in which she lives as an adult, and whether the pregnancy has come at a good time or less than a good time in her life (Darby, 2007).

Social Influences

Until recently, the heavy emphasis on medical management for women during pregnancy conveyed the idea that pregnancy was a 9-month-long illness. The pregnant woman went alone to a physician's office for care; at the time of birth, she was separated from her family and admitted to a hospital. She was hospitalized in seclusion from visitors and even from the new baby for a week afterward.

Today, health care settings view pregnancy as a time of health. Nurses have played an important role in helping bring about this change by convincing agencies that long-standing protocols that separated women from their families are not appropriate. As a result, instead of coming alone for prenatal care, women now bring their families. Instead of being given general anesthetics so they can "sleep through" labor and birth, they participate actively in the experience.

How well a pregnant woman and her partner feel during pregnancy and childbirth is related to their cultural background, their personal experiences, and the experiences of friends and relatives, as well as that taught by childbirth educators, and the current public philosophy of childbirth. People's opinions about adolescent pregnancies, "late in life" pregnancies, or whether women who have sex with women should have children have changed markedly. By informing women about their new health care options and continuing to work with other health care providers to "demedicalize" childbirth, nurses can help make pregnancy and childbirth even more enjoyable for clients and their families.

Cultural Influences

A woman's cultural background may strongly influence how active a role she wants to take in her pregnancy, because certain beliefs and taboos may place restrictions on her behavior and activities (Andrews & Boyle, 2007). To learn about the beliefs of a particular woman and her partner, ask at prenatal visits if there is anything they believe should or should not be done to make the pregnancy successful and keep the baby healthy. Supporting these beliefs shows respect for the individuality of a woman and her knowledge of good health.

Before evidence-based practice was available to scientifically disprove or prove happenings in pregnancy, every culture circulated explanations about what people thought caused complications of pregnancy, and because these myths are well engrained in cultures, they persist. For example, beliefs that lifting your arms over your head will cause the cord to twist, or that watching a lunar eclipse will cause birth deformities, are typical of this type of myth. Listen to such "tall tales" to show respect for the person's beliefs, but encourage a woman to also respect that physiologically these types of action could not affect a fetus.

Family Influences

The family in which a woman was raised can be influential to her beliefs about pregnancy because it is part of her

cultural environment. If she and her siblings were loved and seen as the pleasant outcome of a happy marriage, she is more likely to have a positive attitude toward her pregnancy than if she and her siblings were seen as intruders or were blamed for the breakup of a marriage. No matter how often a woman is told that pregnancy is natural and simple, she will not be overjoyed to find herself pregnant if all she has heard are stories about excruciating pain and endless suffering in labor. If her mother constantly reminded her, "If you hadn't come along, I could have gone to college" or "I could have had a career," the daughter may view pregnancy as a disaster.

"People love as they have been loved" is said so often it has become a cliché. It is highly relevant, however, to whether pregnancy and childbirth are viewed in a positive or a negative light. If a woman has difficulty loving others because she did not receive love as a child, she may worry that she will have difficulty loving and accepting the fetus growing within her. To mother her baby well, she should be able to feel a pleasurable anticipation at the prospect of not only having a baby but also raising a child. Becoming a mother is a second adjustment above and beyond being pregnant. It follows that a woman who views mothering as a positive activity is more likely to be pleased when she becomes pregnant than is one who devalues mothering. Women with disabilities may have specific concerns. They will need careful assessment regarding their feelings about having a baby along with assessment of special adjustments to make during their pregnancy (Smeltzer, 2007).

Individual Influences

A woman's ability to cope with or adapt to stress plays a major role in how she will resolve conflict and adapt to the new life contingencies that are coming. This ability to adapt—to being a mother without needing mothering, to loving a child as well as a husband, to becoming a mother of each new child—depends on her basic temperament. Whether she adapts to new situations quickly or slowly, faces them with intensity or maintains a low-key approach, or whether she has had experiences coping with change and stress will determine her adaptation (Box 10.2).

The extent to which a woman feels secure in her relationship with the people around her, especially the father of her child, is usually also important to her acceptance of a pregnancy. Acceptance is usually easier if she has confidence in the stability of her relationship with the child's father and knows that he will be there to give her emotional support. Worrying whether her partner may soon disappear, leaving her alone to raise a child, may make her re-examine whether her pregnancy is a wise life step.

A woman who thinks of brides as young but mothers as old may believe pregnancy will rob her of her youth. If she thinks children are sticky-fingered and time-consuming, she may view the pregnancy as taking away her freedom. If she has heard that pregnancy will permanently stretch her abdomen and breasts, her concern may be that she will lose her looks. She may also feel that pregnancy will rob her financially and ruin her chances of job promotion. These are real feelings and must be taken seriously when counseling pregnant women. Such concerns cannot be shrugged off with simple clichés ("One door closes, another one opens") or with repression ("You shouldn't think that way; you'll love having a baby in the house"). A woman needs an opportunity to express these feelings to a supportive person (Savage et al., 2007). Women who do not have a supportive partner often look to health care providers during pregnancy to fill the role of an attentive listener.

Whether a father-to-be is able to accept the pregnancy and the coming child depends on the same factors that affect a woman: cultural background, past experience, and relationship with family members. If he was raised to believe that men should not show their emotions, he may not be able to say easily, "I want this baby" or "I'm glad" when his partner tells him of the positive pregnancy diagnosis. He may not be able to say such things as, "It's great to feel it kick."

Although men may be inarticulate in these ways, they may be able to convey such emotions by a touch or a caress, one reason men's presence is always desirable at a prenatal visit and certainly in a birthing room. Their partner will know that a hand on hers is as meaningful an expression of emotion as a spoken word.

BOX 10.2 ✻ Focus on Evidence-Based Practice

Can guided imagery help reduce both maternal and fetal stress?

Pregnancy can be a stress-filled time because of the added responsibility that a coming child will bring. At the same time, finding time to relax can be difficult for busy women. Researchers, who were interested in whether teaching a pregnant woman to truly relax by using guided imagery could have an effect on her fetus as well as provide additional relaxation for her, recorded fetal responses to induced maternal relaxation during the 32nd week of pregnancy for 100 women. Changes documented in the fetus over an 18-minute relaxation time period were decreased fetal heart rate, increased fetal heart rate variability, and lower umbilical and uterine artery resistance. The researchers concluded that induced relaxation effects can be noted in the fetus. Such effects as creating reduced artery resistance could help improve fetal circulation for a compromised fetus.

Could you use the above results to help a pregnant woman plan to take deliberate time every day to rest and relax?

Source: DiPietro, J. A., et al. (2008). Fetal responses to induced maternal relaxation during pregnancy. *Biological Psychology, 77*(1), 11–19.

THE PSYCHOLOGICAL TASKS OF PREGNANCY

During the 9 months of pregnancy, a woman and her partner run a gamut of emotions ranging from the surprise at finding out the woman is pregnant (or wishing she were not), the pleasure and acceptance of the fact as they begin to

identify with the coming child, the worry for themselves and the child, as well as the acute impatience near the end of pregnancy (Table 10.1). Once the child is born, a woman and her partner may feel surprise again that the pregnancy is over and that the mother has really given birth.

From a physiologic standpoint, it is fortunate that a pregnancy is 9 months long, because this gives the fetus time to mature and be prepared for life outside the protective uterine environment. From a psychological standpoint, this period is also fortunate for the family because it gives them time to prepare emotionally as well. How well a woman adjusts to the potential stress of pregnancy can affect her relationship with the child and may even influence whether she is able to carry the pregnancy to term (Box 10.3). These psychological changes are frequently termed "guaranteeing safe passage" for the fetus.

First Trimester: Accepting the Pregnancy

The first task of a woman and partner during the first trimester is to accept the reality of the pregnancy.

The Woman

Most cultures structure their celebrations around important life events—coming of age, marriages, birthdays, and deaths.

TABLE 10.1 ✻ Common Psychosocial Changes That Occur With Pregnancy

Psychosocial Change	Description
First Trimester	
Task: Accepting the pregnancy	Woman and partner both spend time recovering from shock of learning they are pregnant and concentrate on what it feels like to be pregnant. A common reaction is ambivalence, or feeling both pleased and not pleased about the pregnancy.
Second Trimester	
Task: Accepting the baby	Woman and partner move through emotions such as narcissism and introversion as they concentrate on what it will feel like to be a parent. Role-playing and increased dreaming are common.
Third Trimester	
Task: Preparing for the baby and end of pregnancy	Woman and partner prepare clothing and sleeping arrangements for the baby but also grow impatient with pregnancy as they ready themselves for birth.

BOX 10.3 ✻ Focus on Communication

You have seen Lauren Maxwell in your prenatal clinic every month for the last 3 months. At visits, she answers questions but rarely volunteers any information. You'd like her to talk more about how she feels about her pregnancy and her plans for the new baby.

Less Effective Communication

Nurse: Good morning, Lauren. How are you today?
Lauren: Tired.
Nurse: So am I. Working full-time isn't fun, is it? Do you have any problems?
Lauren: No.
Nurse: That's good. Saves me writing. Have you felt the baby move yet?
Lauren: Yes.
Nurse: That must be so exciting. I can't wait until I have my first child and can feel that. Have you started plans for the baby? A crib? Clothing?
Lauren: No.
Nurse: There's a big sale at the mall starting Saturday. My girlfriend and I are both going.

More Effective Communication

Nurse: Good morning. Lauren. How are you today?
Lauren: Tired.
Nurse: Tell me about that.
Lauren: I am so tired by noon every day that I can barely get my work done. I should never have gotten pregnant.
Nurse: You're so tired you can barely get your work done?
Lauren: No one in our financial situation should be having a baby.

Some people are naturally shy and are not interested in casual conversations at health care visits. Others are not talkative because they are not aware that health care providers are interested in them as individuals. In the first example, the nurse actually cuts off conversation because she is so busy talking about her own needs and expectations that the client does not want to compete. Focusing on the client's concerns, as in the second example, allows a woman to feel the health care provider's concern and interest in helping her solve her problem.

These all have rituals to help individuals take a step forward or accept the coming change in their lives. A diagnosis of pregnancy is a similar rite of passage. This aura of initiation into one of the large mysteries of life gives special meaning to the health care visit in which the diagnosis of pregnancy is confirmed, making it more than an ordinary visit to a health care facility. Receiving confirmation of pregnancy, at her health care provider's office, makes the mother feel "more pregnant."

The availability of reproductive planning measures today, in theory, would seem to prevent the diagnosis of pregnancy from being a surprise. In reality, as many as 50% of pregnancies are still unintended, unwanted, or mistimed (Centers

for Disease Control and Prevention [CDC], 2009) because no woman can be absolutely confident in advance that she will be able to conceive until it happens. Every pregnancy is a surprise to some extent, either because a woman had not planned on becoming pregnant or because she had been looking forward to being pregnant but the reality of it happening came too quickly. If pregnancy announced itself with more reliable signs than a missed period, slight breast tenderness, or vague nausea and tiredness, women could become more certain how they feel about being pregnant sooner. Home pregnancy test kits have helped women in this regard by confirming pregnancy as early as the first missed menstrual period. Until it is verified by a home test or a health care visit, however, the uncertainty of the symptoms makes pregnancy only a vague theoretical possibility that leaves room for denial. As almost all drugs cross the placenta and many can cause fetal harm, the earlier that a woman realizes that she is pregnant, the sooner she can safeguard fetal health by discontinuing all drugs not specifically prescribed or approved by her physician or nurse-midwife (Cunningham et al., 2008).

Often women immediately experience something less than pleasure and closer to disappointment or anxiety at the news that they are pregnant or a feeling of ambivalence. Ambivalence toward pregnancy does not mean that positive feelings counteract negative feelings so the woman is left feeling nothing toward her pregnancy. Instead, it refers to the interwoven feelings of wanting and not wanting that can exist at high levels. When talking to pregnant women, emphasize that this ambivalence is normal. Otherwise, if a poor outcome should result, a woman may recall her ambivalence and feel guilty.

Fortunately, most women are able to change their attitude toward the pregnancy by the time they feel the child move inside them. Some health care plans provide for a routine ultrasound at 4 months of pregnancy. Seeing a beating heart or a fetal outline on the monitor screen during an ultrasound can be a major step in promoting acceptance (Matsui & Gardiner, 2007).

The Partner

Once partners were forgotten persons in the childbearing process. Unwed fathers, in particular, were dismissed as not interested in the pregnancy or a woman's health. A female partner to a woman was completely ignored. Today, it is recognized that all partners are important and should be encouraged to play an emotional role in the pregnancy. This means that, as a woman adapts to pregnancy, her partner may go through some of the same psychological changes.

For partners, accepting the pregnancy means not only accepting the certainty of the pregnancy and the reality of the child to come but also accepting the woman in her changed state. A partner should try to give a woman emotional support while she is learning to accept the reality of pregnancy, and she should reciprocate when the partner begins to go through the process.

Like women, partners' feelings regarding the pregnancy vary. Often partners are proud and happy about the pregnancy, facilitating acceptance of it. However, partners may experience some feelings that make this task more difficult as it is not unusual for a partner to feel both overwhelmed with what the loss of the woman's salary will mean to the family if she means to quit work and a feeling close to jealousy of the growing baby, who, although not yet physically apparent, seems to be taking up a great deal of the woman's time and thought.

Partners also experience ambivalence, sometimes more so than pregnant women. The feeling of ambivalence can be compounded if partners are afraid to voice their concerns. This happens if they do not want to intensify the pregnant woman's anxieties by appearing anxious themselves. Partners may also feel ambivalent if they are not well prepared for parenthood or have had little experience with children. Often it is harder for partners to resolve their feelings of ambivalence, because they do not personally experience the changes of pregnancy and may not have as strong a support network. To help partners resolve some ambivalence, provide an outlet for them to discuss concerns, and offer parenting information at prenatal visits.

An unwed father may have a great deal of difficulty accepting a pregnancy unless he is actively involved in prenatal care. He tries to picture himself as a father but then realizes that if he does not marry his partner, he may never play a full father role to this child, so the image disappears again. Because the unwed father can relate to the fact that he fathered the child, however, he may feel a deep sense of loss if a woman decides to have an abortion or if the baby is born less than perfect. In addition, he may not have anyone to turn to for support because no one recognizes his loss.

✔ Checkpoint Question 10.1

Lauren sometimes feels ambivalent about being pregnant. What is the psychological task you'd like to see her complete during the first trimester of pregnancy?

a. Explain why morning sickness occurs.
b. Accept the fact that she's pregnant.
c. Accept the fact she's having a baby.
d. Choose a name for her baby.

Second Trimester: Accepting the Baby

As soon as fetal movements can be felt, psychological responses of both partners are apt to change.

The Woman

During the second trimester, the psychological task of a woman is to accept that she is having a baby, a second step from accepting the pregnancy. This change usually happens at **quickening,** or the first moment a woman feels fetal movement. Until a woman experiences for herself this proof of the child's existence, she may think of the life inside her as an integral part of herself rather than as a separate entity. She knows it is there; she eats to meet its needs and takes special vitamins to help it grow, but it seems more like just another part of her body. With quickening, however, the fetus assumes a separate identity. She begins to imagine how she will feel at the birth, when the physician or midwife announces, "It's a boy!" or "It's a girl!" She begins to imagine herself as a mother, perhaps teaching her child the alphabet or how to ride a bicycle. This anticipatory role-playing is an important activity for midpregnancy. It leads her to a larger concept of her condition and helps her realize that not only is she pregnant but also there is a child inside her.

Women often use the term "it" to refer to the child inside them. This does not mean that they have not yet accepted the pregnancy or still consider the baby an inanimate object. Some women believe that referring to the child as "she" or "he" will bring bad luck or disappointment if the child is of the opposite sex. Although an ultrasound can reveal the sex of the child, some women choose not to know because they fear being misled by an inaccurate ultrasound reading or they simply wish to be surprised about the sex of their child at birth.

Most women can pinpoint a moment during each pregnancy when they knew definitely that they wanted their child. For a woman who carefully planned the pregnancy, this moment of awareness may occur as soon as she recovers from the surprise of learning she has actually conceived. For others, it may come when she announces the news to her parents and hears them express their joy or when she sees a look of pride on her partner's face. It might be the moment of quickening, when she realizes that the fetus inside her is not passive but is an active being. Shopping for baby clothes for the first time, setting up the crib, seeing a blurry outline on an ultrasound screen: any of these small actions may suddenly make the coming baby seem real and desired (Fig. 10.1).

On the other hand, accepting the baby as a welcome family addition might not come until labor has begun or after several hours of labor. It might even be the moment a woman first hears her baby's cry or first touches or feeds her newborn. If a woman has a complication of pregnancy, is having financial difficulties, or lacks emotional support, it could take several weeks after the baby is born for her to accept her new reality and come to terms with motherhood. The emotional and physical upheavals brought about by the hormonal changes of pregnancy are so tremendous that they can lead to not only poor acceptance of the child but also postpartum depression or, in rare instances, psychosis (Westdahl et al., 2007).

A good way to measure the level of a woman's acceptance of the coming baby is to measure how well she follows prenatal instructions. Until a woman views the growing structure inside her as something desired, it may be difficult for her to substitute a high-protein food for her favorite coffee drink. After all, watching herself gain weight may be the most certain proof she has that she is pregnant.

FIGURE 10.1 A growing abdomen and fluttering fetal movements help to make a pregnancy a reality. (© Barbara Proud.)

The Partner

As a woman begins to actively prepare for the coming baby, a partner may feel as if he is left standing in the wings, waiting to be asked to take part in the event. To compensate for this feeling, a partner may become overly absorbed in his work, striving to produce something concrete on the job or to earn enough money to demonstrate that he, too, is capable of creating something. This preoccupation with work may limit the amount of time a partner spends with his family, just when the pregnant woman most needs emotional support.

Some men may have difficulty enjoying the pregnancy because they have been misinformed about sexuality, pregnancy, and women's health. A man might believe, for example, that breastfeeding will make his wife's breasts no longer attractive and so will advise against it. He may believe that childbirth will stretch his wife's vagina so much that sexual relations will no longer be enjoyable and so will advocate for a cesarean birth. Such a man needs education to correct misinformation. Many men comment that the information they receive about childbirth and pregnancy is too concerned with their partner or the child and not enough with how they feel to be relevant to them.

Third Trimester: Preparing for Parenthood

During the third trimester, couples usually begin "nest-building" activities, such as planning the infant's sleeping arrangements, buying clothes, choosing a name for the infant, and "ensuring safe passage" by learning about birth. These preparations are evidence that women are completing the third trimester task of pregnancy or preparing for parenthood.

Couples at this point are interested in attending prenatal classes or preparation for childbirth classes. It is helpful to ask a couple what specifically they are doing to get ready for birth to see if they are interested in taking such a class and to document how well prepared they will be for the baby's arrival.

Certain external life contingencies may slow the mental work of pregnancy on the part of a woman or her partner (Box 10.4). During prenatal visits, ask such questions as, "How does your partner feel about you being pregnant?" or "Has anything changed in your home life since you last came to the clinic?" to reveal if any situation that could interfere with bonding is present. It is unrealistic to believe that one health care professional has all the solutions to the problems that couples reveal when asked these questions. A multidisciplinary approach (e.g., referral to the nutritionist, nurse practitioner, or social services) is often necessary to help solve some of these multifaceted problems.

It is helpful for most couples to attend childbirth education classes or classes on preparing for parenthood as attending these classes can help a couple accept the pregnancy, expose them to other parents as role models, and provide practical information about pregnancy and childcare. It is best if these classes are conducted in small groups so they can meet the individual needs of couples (see Chapter 14 for

BOX 10.4 ✻ Events That Could Contribute to Difficulty Accepting a Pregnancy

- Learning that the pregnancy is a multiple one
- Learning that the fetus has a developmental abnormality
- Pregnancy less than 1 year after a previous one
- Relocation during pregnancy (involves a need to find new support people)
- Moving away from the family or back to the family for economic reasons
- Role reversal (a previously supporting person who becomes dependent, or vice versa)
- Job loss
- Marital infidelity
- Illness in self, husband, or a relative
- Loss of a significant other
- Complications of pregnancy such as severe hypertension
- Having friends or relatives who have had children born with health disorders
- Series of devaluing experiences (e.g., failure in school or work)
- History of previous miscarriages, fertility problems, traumatic births
- Previous fetal or neonatal loss
- History of rape, incest, or domestic violence

more information on childbirth education classes and planning for parenthood).

Reworking Developmental Tasks

Yet another task of pregnancy is working through previous life experiences. Needs and wishes that have been repressed for years may surface to be studied and reworked, often to an extreme extent.

Primary among these life experiences is a woman's relationship with her parents, particularly her mother. For the first time in her life, she finds she can empathize with her mother and the way her mother used to worry when she came home later than expected. The pregnant woman has already begun to worry about her child, to the point that she wonders if something is wrong when she feels no movement for a few hours, even though she is only 5 months into the pregnancy. She may find that her own mother becomes more important to her, and a new, more equal relationship often develops.

For a woman to work through past fears and conflicts of this kind, she needs to think about them when she is alone as well as to discuss them with others. She may throw out comments to her partner, friends, or health care personnel to test their reactions to these thoughts. A typical opening statement is, "I really hated my mother when I was a kid." If the response to this remark is a therapeutic, open-ended one (e.g., "You hated her?"), a woman may feel able to reveal the intensity of her conflict with her mother and how she cannot bear to think of the child inside her feeling that way about her. Teenagers who are pregnant need to resolve the conflict of being both a child and a mother. Unless these feelings are resolved, they can continue to have a negative view about becoming a mother.

Fear of being separated from family or dying are common childhood fears that can be revived during pregnancy. A clue that might signal a woman's distress over this could be, "Am I ever going to make it through this?" This expression might mean simply that she is tired of her backache, but it also might be a plea for reassurance that she will survive this event in her life.

A woman needs to have confidence in those who provide health care for her during pregnancy, so that she can express some of these disturbing thoughts and work through them. As a rule, a woman who is comfortable seeking information experiences less anxiety than one who feels unable to do this.

A pregnant woman's partner needs to do the same reworking of old values and forgotten developmental tasks. A man may rethink his relationship with his father to understand better what kind of father he will be. Some men may have had emotionally distant fathers and wish to be more emotionally available to their own children. These men have to reconcile feelings toward their fathers and learn a new pattern of behavior.

Role-Playing and Fantasizing

Another step in preparing for parenthood is role-playing, or fantasizing about what it will be like to be a parent. Just as a child learns what to do by following her mother as she sets a table or balances her checkbook, a pregnant woman begins to spend time with other pregnant women or mothers of young children to learn how to be a mother. She is drawn into a world of talk about babies and pregnancy with these women. A pregnant woman may offer to babysit for a neighbor or relative so she can "practice" caring for a new baby. As a part of the role-playing process, women's dreams tend to focus on the pregnancy and concerns about keeping herself and her coming child safe.

Although role-playing may be difficult for a pregnant teen who has not yet made the transition to adulthood, it is important in helping her become a mother. If the only role models she has are other girls her age, who typically are not interested in the commitment to mothering—or if her role model is her own mother, who might be unable to cope with problems such as poverty, too many children, or an ineffectual husband—a worry is that the young girl will assume the same role. Try to locate good role models (in classes for mothers, at the health care agency, or from a social agency) for adolescents so they can find a good maternal role to copy and integrate into their own behavior.

The father-to-be also has role-playing to do during pregnancy. He has to imagine himself as the father of a boy or as the father of a girl. A first-time father may have to change his view of himself from being a carefree individual to being a significant member of a family unit. If he already is a father, he has to cast aside a father-of-one identity to accept a father-of-two image, and so forth. Many fathers want or need to take on the role of nurturer but have had little or no experience caring for newborns or infants. Newborn care classes provided before or after the birth can help fathers grow comfortable with this role.

Other support persons who will have an active role in raising the child (e.g., grandparents, close friends) also have to

work out their roles in regard to the pregnancy and impending parenthood. This may be particularly difficult, because the roles for these support persons may not be clearly defined, and no role model may be apparent.

Emotional Responses to Pregnancy

Because of all the tasks that need to be worked through during a pregnancy, emotional responses can vary greatly. Common reactions include grief, narcissism, introversion or extroversion, body image and boundary concerns, couvade syndrome (somatic experiences of father during pregnancy simulating those of the pregnant mother), stress, mood swings, and changes in sexual desire. It is helpful to caution a pregnant woman and her partner about common changes they may expect. Otherwise, they can misinterpret the woman's mood swings, decreased sexual interest, introversion, or narcissism not as changes of pregnancy but as a loss of interest in their relationship.

Grief

The thought that grief could be associated with such a positive process as childbirth seems at first incongruent. But before a woman can take on a mothering role, she has to give up or alter her present roles. She will never be a daughter in exactly the same way again. She will never be as irresponsible and carefree as she is now again. She will not even sleep soundly for the next 18 years. She must incorporate her new role as a mother into her other roles as a daughter, wife, or friend. Her partner must incorporate a new role as a father into his other roles of son, husband, or friend.

Narcissism

Self-centeredness (narcissism) is generally an early reaction to pregnancy. A woman who previously was barely conscious of her body, who dressed in the morning with little thought about what to wear, who was unconcerned about her posture or her weight, suddenly begins to concentrate on these aspects of her life. She dresses so her pregnancy will or will not show, making dressing a time-consuming, mirror-studying procedure. She makes a ceremony out of fixing her meals. She may lose interest in her job or community events because the work seems alien to the more important events taking place in her body, events that constantly remind her a new round of life is beginning.

Narcissism may be manifested by a change in activity. A woman may stop playing tennis, for example, even though her physician tells her it will do no harm in moderation. She may criticize her husband's driving, although it never bothered her before. She does these things to unconsciously protect her body and her baby. Men may demonstrate the same behavior by reducing risky activities such as mountain biking, trying to ensure that they will be present to raise their child.

This need of a woman to protect her body has implications for nursing care. It means she may regard unnecessary nudity as a threat to her body (be sure to drape properly for pelvic and abdominal examinations). She may resent casual remarks such as, "Oh my, you've gained weight" (a threat to her appearance) or, "You don't like milk?" (a threat to her judgment).

There is a tendency to organize health instructions during pregnancy around the baby: "Be sure and keep this appointment. You want to have a healthy baby." "You really ought to eat more protein for the baby's sake." This approach may be particularly inappropriate early in pregnancy, before the fetus stirs and before a woman is convinced not only that she is pregnant but also that there is a baby inside her. At early stages, a woman may be much more interested in doing things for herself because it is her body, her tiredness, and her well-being that will be directly affected ("Eat protein because it keeps your fingernails from breaking" or "Protein will give you more energy").

Introversion Versus Extroversion

Introversion, or turning inward to concentrate on oneself and one's body, is a common finding during pregnancy. Some women, however, react in an entirely opposite fashion and become more extroverted. They become more active, appear healthier than ever before and are more outgoing. This tends to occur in women who are finding unexpected fulfillment in pregnancy, perhaps who had seriously doubted that they would be lucky enough or fertile enough to conceive. Such a woman regards her expanding abdomen as proof she is equal to her sisters. Although such a woman may become more varied in her interests during pregnancy, she may be puzzling to those around her who previously regarded her as quiet and self-contained.

Body Image and Boundary

Body image (the way your body appears to yourself) and body boundary (a zone of separation you perceive between yourself and objects or other people) change during pregnancy as a woman begins to envision herself as a mother. In addition to being a daughter or wife, she begins to see herself becoming "bigger" in many different ways. This change in body image is part of the basis for narcissism and introversion. Changes in concept of body boundaries leads to a firmer distinction between objects, yet at the same time her body boundary is perceived as extremely vulnerable, as if her body were delicate and easily harmed. This change in boundary perception is so startling that pregnant women may walk far away from an object such as a table to avoid bumping against it.

Stress

Because pregnancy brings with it such a major role change, it can cause extreme stress in a woman. This stress of pregnancy, like any stress, can make it difficult for a woman to make decisions, be as aware of her surroundings as usual, or maintain time management with her usual degree of skill. Determining whether the twinges she feels in her back are beginning labor contractions or just backache and whether she should call her primary care provider are difficult decisions to make for someone who is stressed. This may cause people who were dependent on a woman before pregnancy to feel neglected, because now that she is pregnant she seems to have strength only for herself. If a woman was in an abusive relationship before the pregnancy, the increased stress of pregnancy is apt to cause even more abuse. Asking whether intimate partner abuse has ever occurred in the past to help predict if it could occur during pregnancy is an important part of prenatal interviewing (Casanueva & Martin, 2007).

To help families keep their perspective for the full length of a pregnancy, remind them that any decrease in the ability to function that happens to a pregnant woman is a reaction to the stress of pregnancy, not the pregnancy itself. Many nonpregnant women and men function at work under just as much stress because of marital discord or a loved one's illness or death and have just as much difficulty with making decisions. Pregnancy may actually be less stressful than those situations because of its predictable 9-month outcome.

A woman with fewer support people around her almost automatically has more difficulty adjusting to and accepting a pregnancy and a new child than do women who have more support. A woman who begins a pregnancy with a strong support person and then loses that person through trauma, illness, separation, or divorce needs special attention in regard to loneliness and depression. Evaluate her carefully regarding how she is managing and give her extra support because her feeling of loss is likely to be extremely acute. A loss of this kind has the potential to interfere not only with her own health but also with parent–child bonding.

Knowing that she has supportive health care providers she can call on when needed is the one thing that may make this pregnancy tolerable.

✔ Checkpoint Question 10.2

Lauren Maxwell is aware that she's been showing some narcissistic tendencies since becoming pregnant. Which of her actions best describes narcissism?

a. She feels pulled in multiple directions.
b. Her thoughts tend to be mainly about herself.
c. She feels a need to sleep a lot more than usual.
d. She often feels "numb" or as if she's taken a narcotic.

Couvade Syndrome

Many men experience physical symptoms such as nausea, vomiting, and backache to the same degree or even more intensely than their partners during a pregnancy. These symptoms apparently result from stress, anxiety, and empathy for the pregnant woman. This is common enough that it has been given a name: **couvade syndrome.** The more the partner is involved in or attuned to the changes of the pregnancy, the more symptoms a woman's partner may experience. As a woman's abdomen begins to grow, the partner may perceive himself as growing larger, too, as if he is experiencing changing boundaries the same as his partner. For the most part, these are healthy happenings and require psychological attention only if the man becomes emotionally stressed or delusional (Brennan et al., 2007).

What If ... You were working and found yourself doing twice your normal work because a male coworker whose wife is 5 months' pregnant calls in sick at least 3 days a week because of "nausea"? Could you assume that this symptom is part of couvade syndrome?

Emotional Lability

Mood changes occur frequently in a pregnant woman, partly as a manifestation of narcissism (her feelings are easily hurt by remarks that would have been laughed off before) and partly because of hormonal changes, particularly the sustained increase in estrogen and progesterone. Mood swings may be so common that they make a woman's reaction to her family and to health care routines unpredictable. What she finds acceptable one week she may find intolerable the next. She may cry over her children's bad table manners at one meal and find the situation amusing and even charming at the next. Women and their partners and families need to be cautioned that such mood swings occur, beginning with early pregnancy, so that they can accept them as part of pregnancy (Box 10.5).

BOX 10.5 ✻ Focus on Family Teaching

Mood Swings During Pregnancy

Q. Lauren Maxwell tells you she has noticed extreme mood swings since she has been pregnant. She asks you how she can reduce them.

A. Try these measures:

- Avoid fatigue, because when you are tired, your normal defenses are most likely to be down.
- Reduce your level of stress by setting priorities. Ask yourself if everything you are doing really needs to be done.
- Do not let little problems grow into big ones; attack them when they first occur.
- Try to view situations from other people's perspective. They are not as involved in your pregnancy as you are. Things that do not seem important to you may be important to them.
- Let others know you are aware that you are having trouble with emotions since you became pregnant. Your family and friends will be more than willing to help you through this time if they realize that your shifting emotions are of concern to you.

Changes in Sexual Desire

Most women report that their sexual desire changes, at least to some degree, during pregnancy. Women who formerly were worried about becoming pregnant may truly enjoy sexual relations for the first time during pregnancy. Others might feel a loss of desire because of their estrogen increase, or they might unconsciously view sexual relations as a threat to the fetus they must protect. Some may worry that having sexual relations could bring on early labor.

During the first trimester, most women report a decrease in libido because of the nausea, fatigue, and breast tenderness that accompany early pregnancy. During the second trimester, as blood flow to the pelvic area increases to supply the placenta, libido, and sexual enjoyment rise markedly. During the third trimester, sexual desire may remain high, or it may decrease because of difficulty finding a comfortable position and increasing abdominal size. When a couple knows early in pregnancy that such changes may occur, they can be interpreted in the correct light (i.e., as a difference, not as loss of interest in the sexual partner). Suggestions for helping women and their partners adjust to these circumstances are discussed in Chapter 12.

Changes in the Expectant Family

Most parents are aware that their older children need preparation when a new baby is on the way; however, knowing that preparation is needed and being prepared to do this are two different things. For this reason, some couples appreciate suggestions from health care personnel regarding how this task can be accomplished.

Both preschool and school-age children may need to be reassured periodically during pregnancy that a new baby will be an addition to the family and will not replace them in their parents' affection. Preparing a child for the birth of a sibling is discussed in Chapters 14 and 31.

THE DIAGNOSIS OF PREGNANCY

The medical diagnosis of pregnancy serves to date when the birth will occur and also helps predict the existence of a high-risk status. If a pregnancy was planned, the diagnosis produces a feeling of intense fulfillment and achievement. If it was not planned or not desired, it can result in an equally extreme crisis state.

From the day the pregnancy is confirmed, most women try to eat a more nutritious diet, give up cigarette smoking and alcohol ingestion, and stop taking nonessential medications. Because a woman may not take these measures before confirmation of her pregnancy, this makes early confirmation of pregnancy important. If a woman does not wish to continue the pregnancy, early diagnosis is also imperative: therapeutic termination of pregnancy always should be carried out at the earliest stage possible for the safest outcome.

If a sexually active woman is scheduled for diagnostic testing that includes a pelvic x-ray study such as an intravenous pyelogram for kidney disease, you might suggest that she first have a rapid serum pregnancy test to rule out pregnancy as a possibility, to avoid exposing a fetus to radiation.

Most women who come to a health care facility for a diagnosis of pregnancy have already guessed that they are pregnant based on a multitude of subjective signs. Most have already used a home pregnancy test to confirm the pregnancy for themselves.

Pregnancy is officially diagnosed on the basis of the symptoms reported by the woman and the signs elicited by a health care provider. These signs and symptoms are traditionally divided into three classifications: presumptive or subjective, probable or objective, and positive or documented (Table 10.2).

Presumptive (Subjective) Signs of Pregnancy

Presumptive signs of pregnancy are those that are least indicative of pregnancy; taken as single entities, they could easily indicate other conditions (Rojas, Wood, & Blakemore, 2007). These findings, discussed in connection with the body system in which they occur, are experienced by the woman but cannot be documented by an examiner (Box 10.6).

Probable Signs of Pregnancy

In contrast to presumptive signs, probable signs of pregnancy are objective so can be documented by an examiner. Although they are more reliable than presumptive signs, they still are not positive or true diagnostic findings (Box 10.7). They are also discussed in connection with the body system in which they occur.

Laboratory Tests

The commonly used laboratory tests for pregnancy are based on detecting the presence of human chorionic gonadotropin (hCG), a hormone created by the chorionic villi of the placenta, in the urine or blood serum of the pregnant woman. Because all laboratory tests for pregnancy are accurate in diagnosing pregnancy only 95% to 98% of the time, positive results from these tests are considered probable rather than positive signs.

These tests are performed by radioimmunoassay (RIA), enzyme-linked immunosorbent assay (ELISA), or radioreceptor assay (RRA) techniques. For these tests, hCG is measured in international units. In the nonpregnant woman, no units are detectable because there are no trophoblast cells producing hCG. In the pregnant woman, trace amounts of hCG appear in the serum as early as 24 to 48 hours after implantation. They reach a measurable level (about 50 mIU/mL) 7 to 9 days after conception. Levels peak at about 100 mIU/mL between the 60th and 80th day of gestation. After that point, the concentration of hCG declines again so that, at term, it is barely detectable in serum or urine.

Urine, formerly used extensively for pregnancy testing, is now used only rarely in health care settings, because blood serum tests give earlier results. Urine tests still form the basis of home pregnancy tests.

Home Pregnancy Tests

Several kits for pregnancy testing based on immunologic reactions are available over the counter. These tests have a high degree of accuracy (about 97%) if the instructions are followed exactly. They are convenient to use, because waiting for a health care appointment to have a pregnancy confirmed can be an anxious, stressful time for many women. For this type of test, a woman dips a reagent strip into her stream of urine. A color change on the strip denotes pregnancy. Home tests can detect as little as 35 mIU/mL of hCG. They take 3 to 5 minutes to perform. Most manufacturers suggest that women wait until the day of the missed menstrual period to test. Advise any woman who thinks she might be pregnant but gets a negative result from a home pregnancy test to repeat the test 1 week later if she is still experiencing amenorrhea. If symptoms persist after two tests, she needs to see a health care provider as she might have a condition such as an ovarian tumor causing the amenorrhea and needs appropriate diagnosis for this condition.

Women taking psychotropic drugs (e.g., antianxiety agents) may have false-positive results on pregnancy tests. Women taking oral contraceptives also may have false-positive results; for such a test to be accurate, oral contraceptives should have been discontinued 5 days before the test. Women who have proteinuria, are postmenopausal, or have hyperthyroid disease also may show false-positive results.

In the past, one of the chief reasons women sought early prenatal care was to obtain an official diagnosis of pregnancy. Now that women can diagnose their pregnancies at home by means of a test kit, they may not seek prenatal care until something seems to be wrong with the pregnancy or until

TABLE 10.2 ✻ Presumptive, Probable, and Positive Signs of Pregnancy

Time From Implantation (Weeks)	Presumptive Finding	Probable Finding	Positive Finding	Description
1		Serum laboratory tests		Tests of blood serum reveal the presence of human chorionic gonadotropin hormone.
2	Breast changes			Feeling of tenderness, fullness, or tingling; enlargement and darkening of areola
2	Nausea, vomiting			Nausea or vomiting on arising
2	Amenorrhea			Absence of menstruation
3	Frequent urination			Sense of having to void more often than usual
6		Chadwick's sign		Color change of the vagina from pink to violet
6		Goodell's sign		Softening of the cervix
6		Hegar's sign		Softening of the lower uterine segment
6		Evidence on ultrasound of gestational sac		Characteristic ring is evident.
8			Evidence on ultrasound of fetal outline	Fetal outline can be seen and measured by ultrasound.
10–12			Fetal heart audible	Doppler ultrasound reveals heartbeat.
12	Fatigue			General feeling of tiredness
12	Uterine enlargement			Uterus can be palpated over symphysis pubis.
16		Ballottement		When lower uterine segment is tapped on a bimanual examination, the fetus can be felt to rise against abdominal wall.
18	Quickening			Fetal movement felt by woman
20			Fetal movement felt by examiner	Fetal movement can be palpated through abdomen.
20		Braxton Hicks contractions		Periodic uterine tightening occurs.
20		Fetal outline felt by examiner		Fetal outline can be palpated through abdomen.
24	Linea nigra			Line of dark pigment on the abdomen
24	Melasma			Dark pigment on face
24	Striae gravidarum			Red streaks on abdomen

they are so far along they feel they should do something about arranging medical coverage for the birth. Caution women that early and regular prenatal care is important to safeguard the pregnancy outcome. After a positive pregnancy test, the first step should be to arrange for prenatal care (Bernstein & Weinstein, 2007).

Positive Signs of Pregnancy

There are only three documented or positive signs of pregnancy:

- Demonstration of a fetal heart separate from the mother's
- Fetal movements felt by an examiner
- Visualization of the fetus by ultrasound

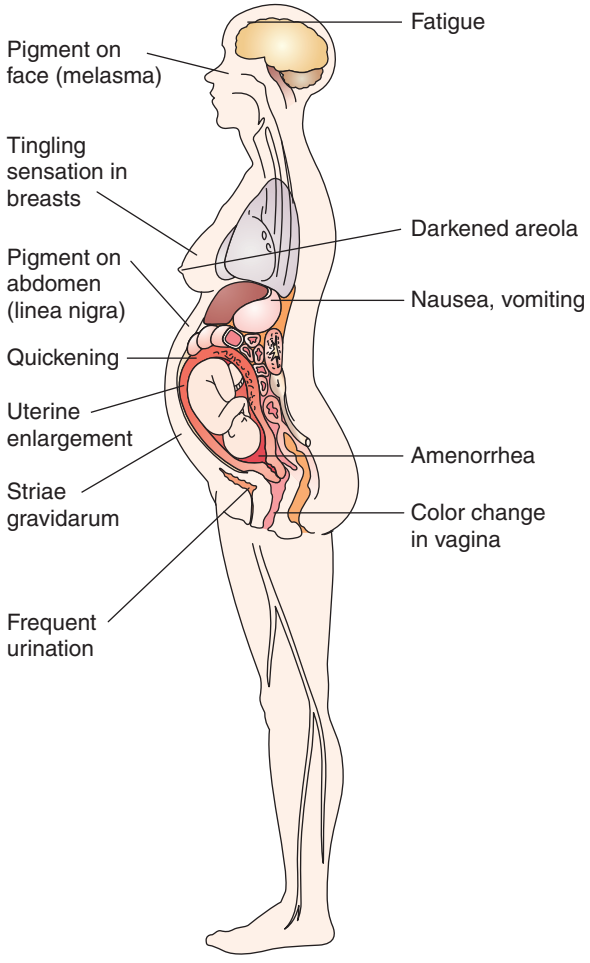
Demonstration of a Fetal Heart Separate From the Mother's Heart

The fetal heart can be shown to be beating on ultrasound as early as the sixth to seventh week of pregnancy. Ultrasonic monitoring systems that convert ultrasonic frequencies to audible frequencies (Doppler technique) can detect fetal heart sounds as early as the 10th to 12th week of gestation. Echocardiography can demonstrate a heartbeat as early as 5 weeks.

Although the fetal heart has been beating since the 24th day after conception, it is audible by auscultation of the abdomen with an ordinary stethoscope only at about 18 to 20 weeks of pregnancy. Fetal heart sounds are difficult to hear if a woman's abdomen has a great deal of subcutaneous fat or if

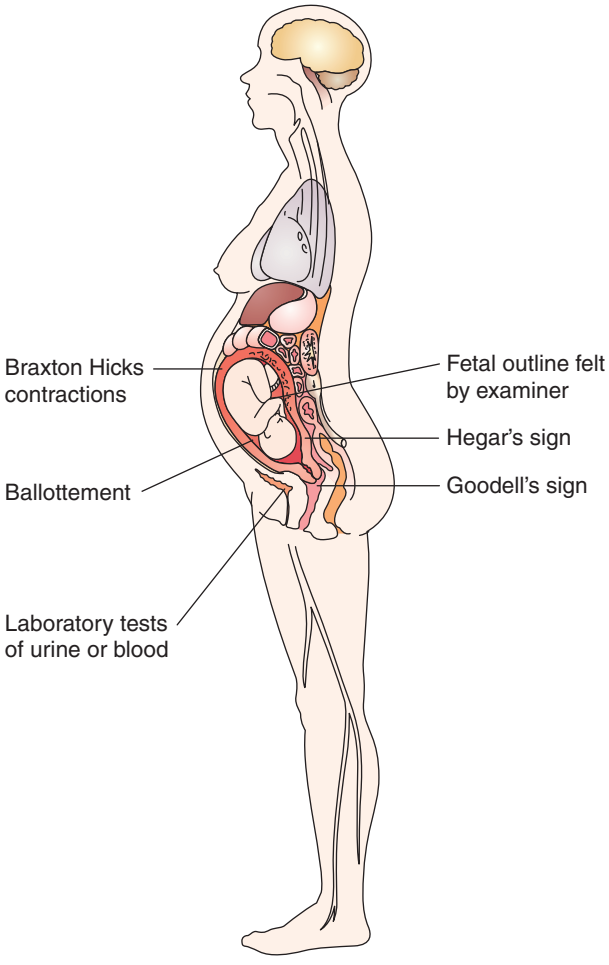
Box 10.6 Assessment

Assessing the Client for Presumptive Signs of Pregnancy



Box 10.7 Assessment

Assessing the Client for Probable Signs of Pregnancy



a larger than normal amount of amniotic fluid is present (hydramnios). They are heard best when the position of the fetus is determined by palpation and the stethoscope is placed over the area of the fetus's back. The fetal heart rate usually ranges between 120 and 160 beats per minute.

Fetal Movements Felt by an Examiner

Fetal movements may be felt by a woman as early as 16 to 20 weeks of pregnancy. Those felt by an objective examiner are considered much more reliable because a woman could mistake the movement of gas through her intestines for fetal movement. Fetal movements can be felt by an examiner at the 20th to 24th week of pregnancy unless a woman is extremely obese.

Visualization of Fetus by Ultrasound

High-frequency sound waves projected toward a woman's abdomen are useful in diagnosing pregnancy. If a woman is pregnant, a characteristic ring, indicating the gestational sac, will be revealed on an oscilloscope screen as early as the fourth to sixth week of pregnancy. This method also gives information about the site of implantation and whether a multiple pregnancy exists. By the eighth week, a fetal outline can be seen so clearly within the sac that the crown-to-rump length can be measured to establish the gestational age of the pregnancy. Seeing the fetal outline on an ultrasound is clear proof for a couple that a woman is pregnant if they had any doubt up to that point.

✔ Checkpoint Question 10.3

Lauren Maxwell used a urine pregnancy test but was surprised to learn that a positive result is not a sure sign of pregnancy. She asks you what would be a positive sign. Your best answer would be:

a. She is having consistent uterine growth.
b. She feels the fetus move especially after meals.
c. hCG can be found in her bloodstream.
d. The fetal heart can be seen on ultrasound.

PHYSIOLOGIC CHANGES OF PREGNANCY

Physiologic changes that occur during pregnancy can be categorized as local (confined to the reproductive organs) or systemic (affecting the entire body). Both symptoms (subjective findings) and signs (objective findings) of the physiologic changes of pregnancy are used to diagnose and mark the progress of pregnancy. Table 10.3 summarizes the physiologic changes that occur in body organs or systems during a typical 40-week pregnancy.

Reproductive System Changes

Reproductive tract changes are those involving the uterus, ovaries, vagina, and breasts.

Uterine Changes

The most obvious alteration in a woman's body during pregnancy is the increase in the size of the uterus to accommodate the growing fetus. Over the 10 lunar months of pregnancy, the uterus increases in length, depth, width, weight, wall thickness, and volume.

- Length increases from approximately 6.5 to 32 cm.
- Depth increases from 2.5 to 22 cm.
- Width expands from 4 to 24 cm.
- Weight increases from 50 to 1000 g.
- Early in pregnancy, the uterine wall thickens from about 1 cm to about 2 cm; toward the end of pregnancy, the wall thins to become supple and only about 0.5 cm thick.
- The volume of the uterus increases from about 2 mL to more than 1000 mL. The uterus can hold a 7-lb (3175-g) fetus plus 1000 mL of amniotic fluid for a total of about 4000 g at term.

This great uterine growth is due partly to formation of a few new muscle fibers in the uterine myometrium but principally to the stretching of existing muscle fibers: by the end of pregnancy, muscle fibers in the uterus have become two to seven times longer than they were before pregnancy. The uterus is able to withstand this stretching of its muscle fibers because of the formation of extra fibroelastic tissue between fibers, which binds them closely together. Because uterine fibers simply stretch during pregnancy and are not newly built, the uterus is able to return to its prepregnant state at the end of the pregnancy with little difficulty and almost no destruction of tissue (Kahn & Koos, 2007).

A woman becomes aware of her growing uterus early in pregnancy; by the end of the 12th week, the uterus is large enough to be palpated as a firm globe under the abdominal wall, just above the symphysis pubis. An important factor to assess regarding uterine growth is its constant, steady, predictable increase in size. By the 20th or 22nd week of pregnancy, for example, it should reach the level of the umbilicus. By the 36th week, it should touch the xiphoid process and can make breathing difficult. About 2 weeks before term (the 38th week) for a **primigravida,** a woman in her first pregnancy, the fetal head settles into the pelvis to prepare for birth, and the uterus returns to the height it was at 36 weeks. This event is termed **lightening,** because a woman's breathing is so much easier it seems to lighten a woman's load. When lightening will occur is not predictable in a **multipara** (a woman who has had one or more children). In these women, it may not occur until labor begins.

Changes in fundal height during pregnancy are shown in Figure 10.2. Uterine height is measured from the top of the symphysis pubis to over the top of the uterine fundus (Neilson, 2009). Because a uterine tumor could mimic this steady growth, uterine growth is only a presumptive sign of pregnancy.

The exact shape of the expanding uterus is influenced by the position of the fetus inside. The fundus of the uterus

TABLE 10.3 ✻ Timetable for Physiologic Changes of Pregnancy

Location of Change	1st Trimester	2nd Trimester	3rd Trimester
Circulatory system	Blood volume increasing Pseudoanemia	Blood pressure slightly decreased	Blood pressure returns to prepregnancy levels
	Clotting factors increasing		
Ovary	Corpus luteum active	Corpus luteum fading	
Uterus	Increased growth	Placenta forming estrogen and progesterone	
Cervix	Softening progressive		"Ripe"
Vagina	White discharge present		Increasing
Musculoskeletal system		Progressive cartilage softening Lordosis increasing	
Pigmentation		Progressively increasing	
Kidney	Maternal glomerular filtration rate increasing Aldosterone increased, retaining sodium and fluid	Glycosuria	
Gastrointestinal system		Slowed peristalsis	
Thyroid	Increased metabolic rate		

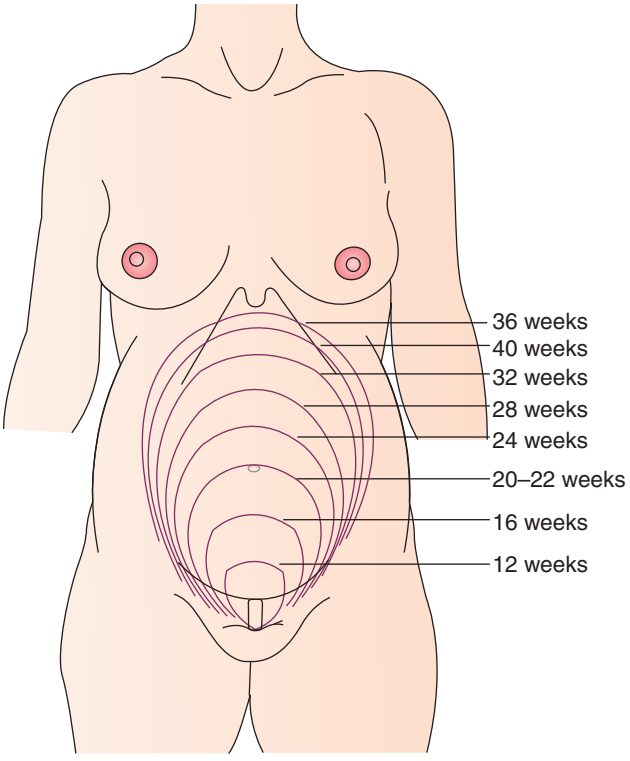


FIGURE 10.2 Fundus height at various weeks of pregnancy.

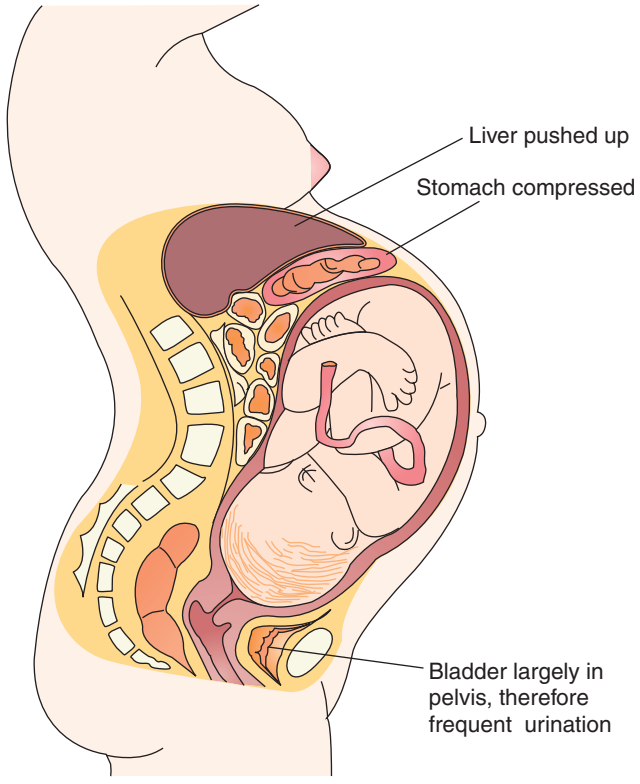

FIGURE 10.3 Crowding of abdominal contents late in pregnancy.

usually remains in the midline during pregnancy, although it may be pushed slightly to the right side because of the larger bulk of the sigmoid colon on the left. As the uterus increases in size, it pushes the intestines to the sides of the abdomen, elevates the diaphragm and liver, compresses the stomach, and puts pressure on the bladder. A woman may worry that there will not be enough room inside her abdomen for this increase in size. You can assure her that the abdominal contents will shift readily to accommodate uterine enlargement (Fig. 10.3).

Uterine blood flow increases during pregnancy as the placenta grows and requires more and more blood for perfusion. Doppler ultrasonography has shown that, before pregnancy, uterine blood flow is 15 to 20 mL/min. By the end of pregnancy, it expands to as much as 500 to 750 mL/min, with 75% of that volume going to the placenta. Measuring that placenta blood volume and velocity is increasing this way is one of the most important gauges of fetal health (Gonzalez et al., 2007).

Toward the end of pregnancy, one-sixth of a woman's blood supply is circulating through the uterus at any given time; therefore, uterine bleeding in pregnancy is always potentially serious because it could result in a major blood loss. Caution women that vaginal blood loss, which suggests uterine bleeding, could pose a major health risk. They should always contact their health care practitioner if such bleeding occurs.

A bimanual examination (one finger of an examiner is placed in the vagina, the other hand on the abdomen) can demonstrate that, with pregnancy, the uterus feels more anteflexed, larger, and softer to the touch than usual. At about the sixth week of pregnancy (at the time of the second missed menstrual period), the lower uterine segment just above the cervix becomes so soft that when it is compressed between examining fingers on bimanual examination, the wall cannot be felt or feels as thin as tissue paper. This extreme softening of the lower uterine segment is known as **Hegar's sign** (Fig. 10.4). It is a probable sign of pregnancy (Rojas, Wood, & Blakemore, 2007).

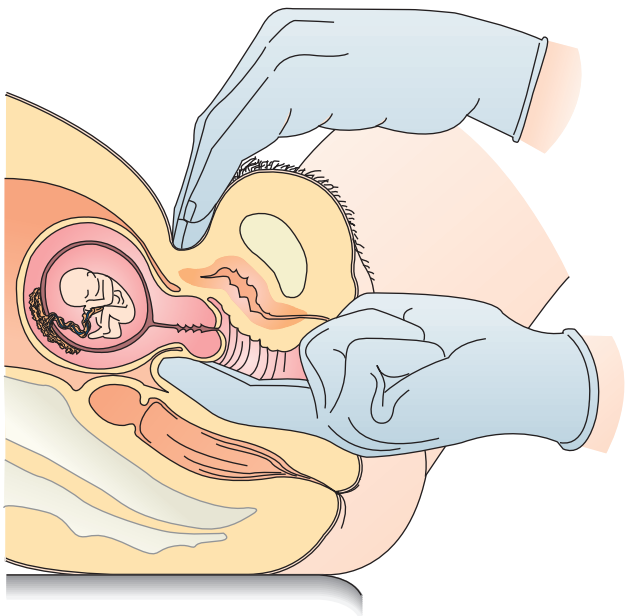

FIGURE 10.4 Examining for Hegar's sign. If the sign is present, the wall of the uterus is softer than usual.

During the 16th to 20th week of pregnancy, when the fetus is still small in relation to the amount of amniotic fluid present, **ballottement** (from the French word *balloter,* meaning "to toss about") may be demonstrated. On bimanual examination, if the lower uterine segment is tapped sharply by the lower hand, the fetus can be felt to bounce or rise in the amniotic fluid up against the top examining hand. Although this phenomenon is interesting, it also may be simulated by a uterine tumor, and therefore it is no more than a probable sign of pregnancy. Between the 20th and 24th week of pregnancy, the uterine wall has become thinned to such a degree that a fetal outline within the uterus may be palpated by a skilled examiner. Because a tumor with calcium deposits could simulate a fetal outline, palpation of a uterine mass, like other uterine assessments, does not constitute a sure confirmation of pregnancy.

Uterine contractions begin early in pregnancy, at least by the 12th week, and are present throughout the rest of pregnancy, becoming stronger and harder as the pregnancy advances. They may be felt by a woman as waves of hardness or tightening across her abdomen. An examining hand may be able to feel a contraction as well, and an electronic monitor will be able to measure the frequency and length of such contractions. These "practice" contractions, termed **Braxton Hicks contractions,** serve as warm-up exercises for labor and also increase placental perfusion. They may become so strong and noticeable in the last month of pregnancy that they are mistaken for labor contractions (false labor). They can be differentiated from true labor contractions on internal examination because they do not cause cervical dilation (Bernstein & Weinstein, 2007). Although these contractions are always present with pregnancy, they also could accompany any growing uterine mass; so, like ballottement, they are no more than a probable sign of pregnancy.

Amenorrhea

Amenorrhea (absence of menstruation) occurs with pregnancy because of the suppression of follicle-stimulating hormone (FSH) by rising estrogen levels. In a healthy woman who has menstruated previously, the absence of menstruation strongly suggests that impregnation has occurred. Amenorrhea, however, also heralds the onset of menopause or could result from delayed menstruation because of unrelated reasons, such as uterine infection, worry (perhaps over becoming pregnant), a chronic illness such as severe anemia, or stress. It occurs in athletes who train strenuously, especially in long-distance runners whose percentage of body fat drops below a critical point. Amenorrhea is, therefore, only a presumptive sign of pregnancy.

Cervical Changes

In response to the increased level of circulating estrogen from the placenta during pregnancy, the cervix of the uterus becomes more vascular and edematous. Increased fluid between cells causes it to soften in consistency, and increased vascularity causes it to darken from a pale pink to a violet hue. The glands of the endocervix undergo both hypertrophy and hyperplasia as they increase in number and distend with mucus. A tenacious coating of mucus fills the cervical canal. This mucous plug, called the **operculum,** acts to seal out bacteria during pregnancy and therefore helps prevent infection in the fetus and membranes.

Softening of the cervix in pregnancy **(Goodell's sign)** is marked. The consistency of a nonpregnant cervix may be compared with that of the nose, whereas the consistency of a pregnant cervix more closely resembles that of an earlobe. This softening is so marked it is rated as a probable diagnostic sign of pregnancy. Just before labor, the cervix becomes so soft that it takes on the consistency of butter or is said to be "ripe" for birth (Kahn & Koos, 2007).

Vaginal Changes

Under the influence of estrogen, the vaginal epithelium and underlying tissue become hypertrophic and enriched with glycogen; structures loosen from their connective tissue attachments in preparation for great distention at birth. This increase in the activity of the epithelial cells results in a white vaginal discharge throughout pregnancy (a presumptive sign).

An increase in the vascularity of the vagina, beginning early in pregnancy, parallels the vascular changes in the uterus. The resulting increase in circulation changes the color of the vaginal walls from the normal light pink to a deep violet **(Chadwick's sign),** a probable sign of pregnancy.

Vaginal secretions during pregnancy fall from a pH of greater than 7 (an alkaline pH) to 4 or 5 (an acid pH). This occurs because of the action of *Lactobacillus acidophilus,* bacteria that grow freely in the increased glycogen environment and by so doing increase the lactic acid content of secretions. This changing acid content helps to make the vagina resistant to bacterial invasion for the length of the pregnancy. This change in pH also, unfortunately, favors the growth of *Candida albicans,* a species of yeast-like fungi. A candidal infection is manifested by an itching, burning sensation in addition to a cream cheese–like discharge. A nonpregnant woman needs medication for such an infection to relieve discomfort. A pregnant woman needs medication not only to relieve discomfort but also to prevent transmission of the infection to the newborn as it passes through the birth canal at term. Candidal infection in the newborn is termed *thrush* or *oral monilia.* Therapy for this infection is discussed in Chapter 43.

Ovarian Changes

Ovulation stops with pregnancy because of the active feedback mechanism of estrogen and progesterone produced by the corpus luteum early in pregnancy and by the placenta later in pregnancy. This feedback causes the pituitary gland to halt production of FSH and luteinizing hormone (LH). Without stimulation from FSH and LH, ovulation does not occur.

The corpus luteum that was created after the ovulation that led to the pregnancy continues to increase in size on the surface of the ovary until about the 16th week of pregnancy, by which time the placenta takes over as the chief provider of progesterone and estrogen. The corpus luteum, no longer essential for the continuation of the pregnancy, regresses in size and appears white and fibrous on the surface of the ovary (a corpus albicans).

✔ Checkpoint Question 10.4

Lauren Maxwell's doctor told her she had a positive Chadwick's sign. She asks you what this means, and you tell her that:

a. Her abdomen is soft and tender.
b. Her uterus has tipped forward.
c. Her cervical mucus is clear but sticky.
d. Her vagina has darkened in color.

Changes in the Breasts

Subtle changes in the breasts may be one of the first physiologic changes of pregnancy a woman notices (at about 6 weeks) (Fig. 10.5). She may experience a feeling of fullness, tingling, or tenderness in her breasts because of the increased stimulation of breast tissue by the high estrogen level in her body. As the pregnancy progresses, breast size increases because of hyperplasia of the mammary alveoli and fat deposits. The areola of the nipple darkens, and its diameter increases from about 3.5 cm (1.5 in) to 5 or 7.5 cm (2 or 3 in). There is additional darkening of the skin surrounding the areola in some women, forming a secondary areola. As vascularity of the breasts increases, blue veins may become prominent over the surface of the breasts. The sebaceous glands of the areola **(Montgomery's tubercles)** enlarge and become protuberant. The secretions from these glands are what keeps the nipple supple and helps to prevent nipples from cracking and drying during lactation.

Early in pregnancy, the breasts begin readying themselves for the secretion of milk. By the 16th week, colostrum, the thin, watery, high-protein fluid that is the precursor of breast milk, can be expelled from the nipples. Talking to women during pregnancy about breast changes and breastfeeding for their infant's health can be the trigger that alerts them to the importance of breastfeeding (Mattar et al., 2007).

Systemic Changes

Although the physiologic changes first noticed by a woman are apt to be those of the reproductive system and breasts, changes are occuring in almost all body systems.

Integumentary System

As the uterus increases in size, the abdominal wall must stretch to accommodate it. This stretching (plus possibly increased adrenal cortex activity) can cause rupture and atrophy of small segments of the connective layer of the skin. This leads to pink or reddish streaks **(striae gravidarum)** appearing on the sides of the abdominal wall and sometimes on the thighs (Fig. 10.6). During the weeks after birth, striae gravidarum lighten to a silvery-white color (striae albicantes or atrophicae), and, although permanent, they become barely noticeable.

Occasionally, the abdominal wall has difficulty stretching enough to accommodate the growing fetus, causing the rectus muscles to actually separate, a condition known as **diastasis.**

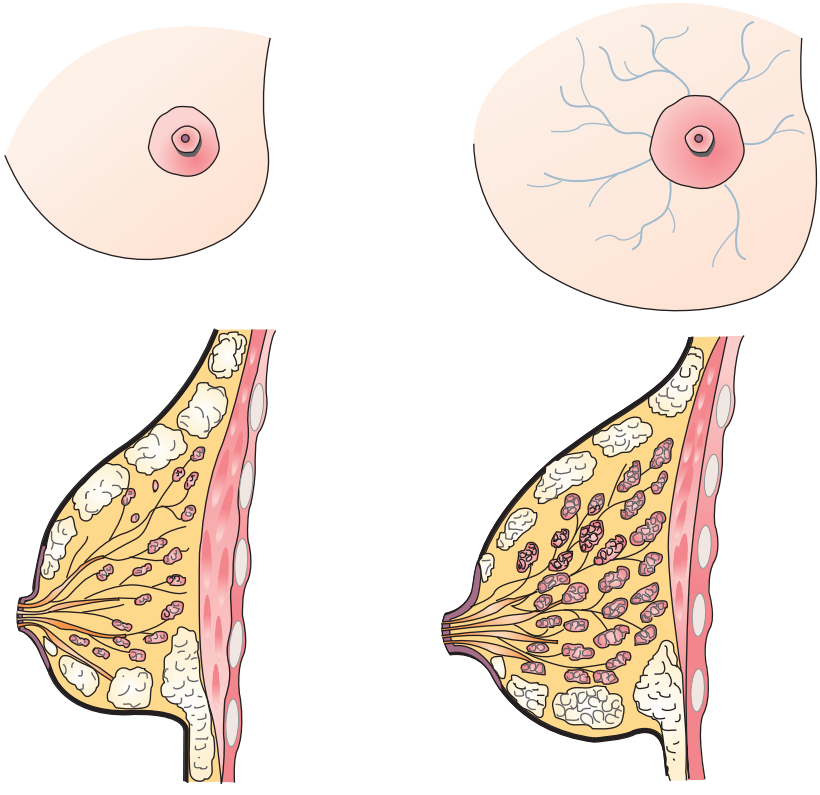

FIGURE 10.5 Comparison of breasts from nonpregnant and pregnant women.

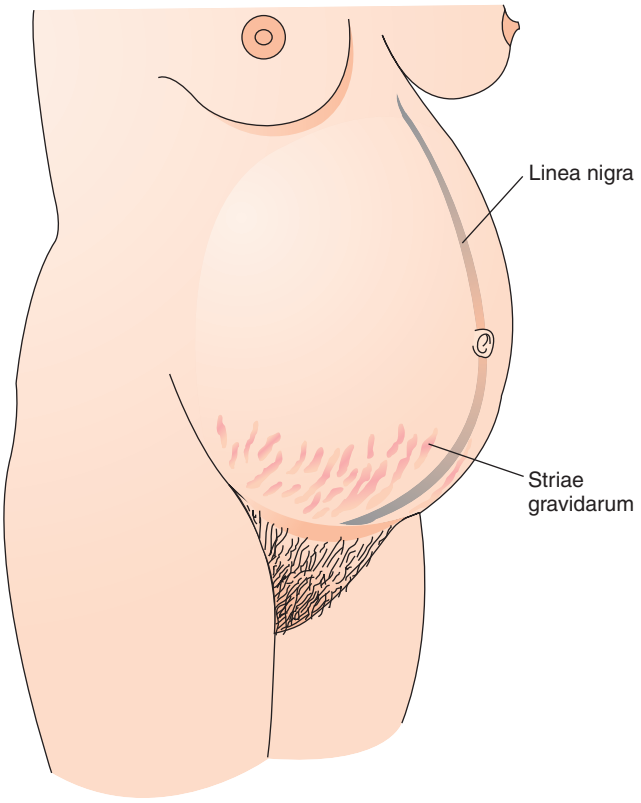

FIGURE 10.6 Skin changes in pregnancy: striae gravidarum and linea nigra.

If this happens, it will appear after pregnancy as a bluish groove at the site of separation.

The umbilicus is stretched by pregnancy to such an extent that by the 28th week, its depression becomes obliterated and smooth because it has been pushed so far outward. In most women, it may appear as if it has turned inside out, protruding as a round bump at the center of the abdominal wall.

Extra pigmentation generally appears on the abdominal wall. A narrow, brown line **(linea nigra)** may form, running from the umbilicus to the symphysis pubis and separating the abdomen into right and left hemispheres (see Fig. 10.6). Darkened areas may appear on the face as well, particularly on the cheeks and across the nose. This is known as **melasma** (chloasma), or the "mask of pregnancy." These increases in pigmentation are caused by melanocyte-stimulating hormone, which is secreted by the pituitary. With the decrease in the level of the hormone after pregnancy, these areas lighten and again disappear.

Vascular spiders or telangiectases (small, fiery-red branching spots) are sometimes seen on the skin of pregnant women, particularly on the thighs. These probably result from the increased level of estrogen in the body. They may fade but not completely disappear after pregnancy. The activity of sweat glands increases throughout the body during pregnancy. Women notice this as an increase in perspiration. Palmar erythema (redness and itching) may occur on the hands from the increased estrogen level. Fewer hairs on the head enter a resting phase because of overall increased metabolism, so scalp hair growth is increased.

Respiratory System

A local change that often occurs in the respiratory system is marked congestion, or "stuffiness," of the nasopharynx, a response to increased estrogen levels. Women may worry that this stuffiness indicates an allergy or a cold. Not realizing that it is happening because they are pregnant, some women take over-the-counter cold medications or antihistamines in an effort to relieve the congestion. Some continue to take the medication after pregnancy is confirmed, not mentioning they are taking this medication to health care providers because they think the stuffiness is a separate problem and not related to the pregnancy. Ask all women at prenatal visits if they are taking any kind of medicine or if they have noticed nasal stuffiness to detect this possibility.

As the uterus enlarges during pregnancy, a great deal of pressure is put on the diaphragm and, ultimately, on the lungs. This can displace the diaphragm by as much as 4 cm upward. This crowding of the chest cavity causes an acute sensation of shortness of breath late in pregnancy, until lightening relieves the pressure.

Even with all this crowding, a woman's vital capacity (the maximum volume exhaled after a maximum inspiration) does not decrease during pregnancy because, although the lungs are crowded in the vertical dimension, they can still expand horizontally. Residual volume (the amount of air remaining in the lungs after expiration) is decreased up to 20% by the pressure of the diaphragm. Tidal volume (the volume of air inspired) is increased up to 40% as a woman draws in extra volume to increase the effectiveness of air exchange. Total oxygen consumption increases by as much as 20%.

The increased level of progesterone during pregnancy appears to set a new level in the hypothalamus for acceptable blood carbon dioxide levels (P_{CO_2}), because, during pregnancy, a woman's body tends to maintain a P_{CO_2} at closer to 32 mm Hg than the normal 40 mm Hg. This low P_{CO_2} level causes a favorable CO_2 gradient at the placenta (the fetal CO_2 level is higher than that in the mother, allowing CO_2 to cross readily from the fetus to the mother).

To keep the mother's pH level from becoming acid because of the load of CO_2 being shifted to her by the fetus, increased ventilation (mild hyperventilation) to blow off excess CO_2 begins early in pregnancy. At full term, a woman's total ventilation capacity may have risen by as much as 40%. This increased ventilation may become so extreme that a woman develops a respiratory alkalosis or exhales more than the usual CO_2. To compensate, kidneys excrete plasma bicarbonate in urine. This results in increased urination or **polyuria,** an early sign of pregnancy. With greater urine output, both additional sodium and additional water are lost.

The slight increase in pH in serum because of the changed expiratory effort is advantageous because it slightly increases the binding capacity of maternal hemoglobin and thereby raises the oxygen content of maternal blood (P_{O_2}), from a normal level of about 92 mm Hg to about 106 mm Hg early in pregnancy. This is advantageous to fetal growth because it allows good placental exchange.

The cumulative effect of these respiratory changes is often experienced by a woman as chronic shortness of breath. Although her breathing rate is more rapid than usual (18–20 breaths per minute), this is normal for pregnancy.

The total respiratory changes and the compensating mechanisms that occur in the respiratory system can be described as

TABLE 10.4 ✻ Respiratory Changes During Pregnancy

Variable	Change
Vital capacity	No change
Tidal volume	Increased by 30% to 40%
Respiratory rate	Increased by 1–2/min
Residual volume	Decreased by 20%
Plasma Pco_2	Decreased to about 27–32 mm Hg
Plasma pH	Increased to 7.40–7.45
Plasma Po_2	Increased to 104–108 mm Hg
Respiratory minute volume	Increased by 40%
Expiratory reserve	Decreased by 20%

a chronic respiratory alkalosis fully compensated by a chronic metabolic acidosis. Changes in respiratory function during pregnancy are summarized in Table 10.4.

Temperature

Early in pregnancy, body temperature increases slightly because of the secretion of progesterone from the corpus luteum (the temperature, which increased at ovulation, remains elevated). As the placenta takes over the function of the corpus luteum at about 16 weeks, the temperature usually decreases to normal.

Some women may mistakenly assume that this slight rise in temperature (99.6° F orally), associated with pregnancy-related nasal congestion, is a sure sign of a cold, and may think they need medication. Explaining the reason for these changes allows a woman to accept them without worrying.

Cardiovascular System

Changes in the circulatory system are extremely significant to the health of the fetus, because they are necessary for adequate placental and fetal circulation. Table 10.5 summarizes these changes.

Blood Volume. To provide for an adequate exchange of nutrients in the placenta and to provide adequate blood to compensate for blood loss at birth, the total circulatory blood volume of a woman's body increases by at least 30% (and possibly as much as 50%) during pregnancy. Blood loss at a normal vaginal birth is about 300 to 400 mL; blood loss from a cesarean birth can be as high as 800 to 1000 mL. The increase in blood volume occurs gradually, beginning at the end of the first trimester. It peaks at about the 28th to the 32nd week and then continues at this high level throughout the third trimester. Because the plasma volume increases faster than red blood cell production, the concentration of hemoglobin and erythrocytes may decline, giving a woman a pseudoanemia early in pregnancy. A woman's body compensates for this change by producing more red blood cells, creating near- normal levels of red blood cells again by the second trimester.

Iron, Folic Acid, and Vitamin Needs. Almost all women need some iron supplementation during pregnancy because of a variety of factors. The fetus requires a total of about 350 to 400 mg of iron to grow. The increases in the mother's circulatory red blood cell mass require an additional 400 mg of iron. This is a total increased need of about 800 mg. Because the average woman's store of iron is less than this amount (about 500 mg), and because iron absorption may be impaired during pregnancy as a result of decreased gastric acidity (iron is absorbed best from an acid medium), additional iron is often prescribed during pregnancy to prevent a true anemia.

Either a hemoglobin concentration of less than 11 g/100 mL or a hematocrit value below 33% in the first or third trimester of pregnancy or a hemoglobin concentration of less than 10.5 g/dL (hematocrit <32%) in the second trimester is considered true anemia, for which iron therapy above normal supplementation is advocated (Arnett & Greenspoon, 2007). Caution women that, like all drugs, a prescribed dose of iron is good for them. Taking excess iron pills over this prescribed amount can cause stomach irritation and possibly iron accumulation in body cells (Pena-Rosas & Viteri, 2009). (See Chapter 20 for additional information on anemia in pregnancy.) The need for folic acid increases even more during pregnancy. If the intake of folic acid is not great enough, megalohemoglobinemia (large, nonfunctioning red blood cells) will result. Inadequate folic acid levels have also been linked to an increased risk for neural tube disorders in fetuses (Lumley et al., 2009).

TABLE 10.5 ✻ Changes in the Cardiovascular System During Pregnancy

Assessment Factor	Prepregnancy	Pregnancy
Cardiac output		25% to 50% increase
Heart rate (bpm)	70–80	80–90
Plasma volume (mL)	2600	3600
Blood volume (mL)	4000	5250
Red blood cell mass (mm^3)	4.2 million	4.65 million
Leukocytes (mm^3)	7000	20,500
Total protein (g/dL)	7.0	5.5–6.0
Fibrinogen (mg/dL)	300	450
Blood pressure		Decreases in second trimester, at prepregnancy level in third trimester

Encourage women to eat foods that are high in folic acid (e.g., spinach, asparagus, legumes) both during the prepregnancy period and during pregnancy. Prenatal vitamins that contain folic acid are routinely prescribed. Unexpectantly, an association between multivitamin supplementation during pregnancy and reduced cancers in children, such as neuroblastoma, leukemia, and brain tumors, can be documented (Goh et al., 2007).

Heart. To handle the increase in blood volume in the circulatory system, a woman's cardiac output increases significantly, by 25% to 50%; the heart rate increases by 10 beats per minute. Like the circulating volume increase, the bulk of the cardiac work increase occurs during the second trimester, with a small increase in the third trimester. An average woman is unaware of the significant circulatory system changes that are occurring inside her to supply adequate blood to the placenta. However, this rise in circulating load has implications for a woman with cardiac disease. Although an average woman's heart is able to adjust to these changes readily, a woman whose heart has difficulty handling her normal circulating load can be overwhelmed by the requirements placed on it when she is pregnant.

Because the diaphragm is pushed upward by the growing uterus late in pregnancy, the heart is shifted to a more transverse position in the chest cavity, a position that may make it appear enlarged on x-ray examination. Some women have audible functional (innocent) heart murmurs during pregnancy, probably because of the altered heart position.

Palpitations of the heart are not uncommon during pregnancy, particularly on quick motion. You can caution women not to feel frightened if palpitations do occur. Palpitations in the early months of pregnancy are probably caused by sympathetic nervous system stimulation; in later months, they may result from increased thoracic pressure caused by the pressure of the uterus against the diaphragm.

Blood Pressure. Despite the hypervolemia of pregnancy, the blood pressure does not normally rise because the increased heart action takes care of the greater amount of circulating blood. Average blood pressures for adult women are shown in Appendix G.

In most women, blood pressure actually decreases slightly during the second trimester because the peripheral resistance to circulation is lowered as the placenta expands rapidly. During the third trimester, the blood pressure rises again to first-trimester levels (Fig. 10.7).

Peripheral Blood Flow. During the third trimester of pregnancy, blood flow to the lower extremities is impaired by the pressure of the expanding uterus on veins and arteries. This resistance to blood flow in the venous system can lead to edema and varicosities of the vulva, rectum, and legs.

Supine Hypotension Syndrome. When a pregnant woman lies supine, the weight of the growing uterus presses the vena cava against the vertebrae, obstructing blood flow from the lower extremities. This causes a decrease in blood return to the heart and, consequently, decreased cardiac output and hypotension (Fig. 10.8). A woman experiences this hypotension as lightheadedness, faintness, and palpitations (Bernstein & Weinstein, 2007).The condition is potentially dangerous because it can cause fetal hypoxia.

FIGURE 10.7 Blood pressure determination is an important assessment during pregnancy; normally, blood pressure does not elevate during pregnancy.

Supine hypotension syndrome can easily be corrected by having a woman turn onto her side (preferably the left side), so that blood flow through the vena cava increases again. To lessen the possibility of occurrence of this phenomenon, women develop an increase in collateral blood circulation during pregnancy. Teach women always to rest on the left side rather than the back, because even with additional collateral circulation, a supine position tends to lead to hypotension.

Blood Constitution. The level of circulating fibrinogen, a constituent of the blood that is necessary for clotting, increases as much as 50% during pregnancy, probably because of the increased level of estrogen. Other clotting factors, such as factors VII, VIII, IX, and X, and the platelet count also increase. These increases are a safeguard against major bleeding should the placenta be dislodged and the uterine arteries or veins be opened. Total white blood cell count rises slightly, both as a protective mechanism and as a reflection of a woman's increased total blood volume (up to about 20,000 cells/mm^3). The total protein level of blood decreases, perhaps indicating the amount of protein being used by the fetus. Because the circulating system has a lower total protein load and hypervolemia, fluid readily leaves the blood for institial tissue vessels to equalize osmotic and hydrostatic pressure. This causes the common ankle and foot edema of pregnancy (not to be confused with nondependent or generalized edema, which is a symptom of pregnancy-induced hypertension).

Blood lipids increase by one third, and the cholesterol serum level increases by 90% to 100%. These increases provide a ready supply of available energy for the fetus.

Gastrointestinal System

At least 50% of women experience some nausea and vomiting early in pregnancy. This is one of the first sensations a woman may experience with pregnancy (sometimes it is noticed even before the first missed menstrual period). It is most apparent early in the morning, on rising, or if a woman becomes fa-

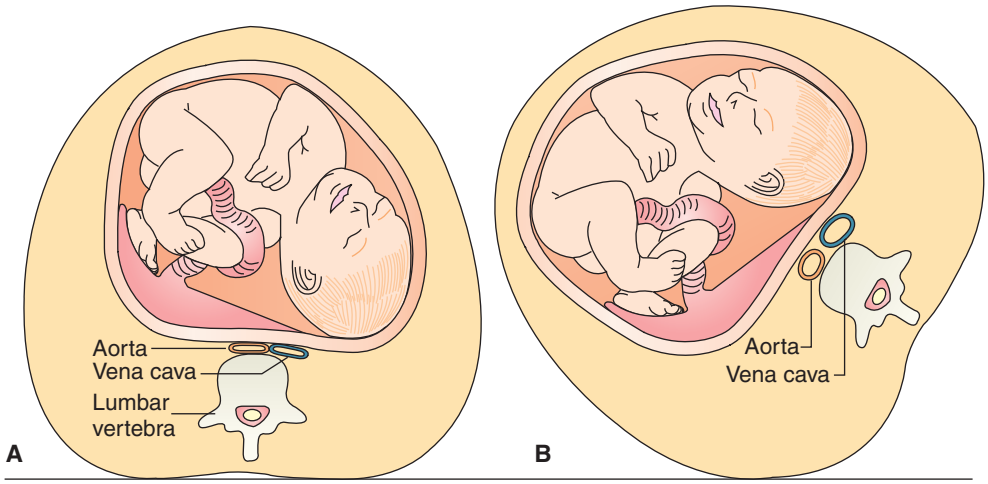

FIGURE 10.8 Supine hypotension can occur if a pregnant woman lies on her back. (**A**) The weight of the uterus compresses the vena cava, trapping blood in the lower extremities. (**B**) If a woman turns on her side, pressure is lifted off of the vena cava.

tigued during the day. It is more frequent in women who smoke cigarettes. Known as morning sickness, nausea and vomiting begin to be noticed at the same time levels of hCG and progesterone begin to rise so these may contribute to its cause. It may occur as a systemic reaction to increased estrogen levels or decreased glucose levels, because glucose is being used in such great quantities by the growing fetus (see Focus on Nursing Care Planning Box 10.8). Many alternative or complementary methods to help reduce nausea with pregnancy are available such as acupuncture or wrist bands, or drinking ginger or peppermint tea. These are discussed in Chapter 13.

This common feeling of nausea usually subsides after the first 3 months, after which time a woman may have a voracious appetite. Although the acidity of stomach secretions decreases during pregnancy, heartburn may result from reflux of stomach contents into the esophagus, caused by upward displacement of the stomach by the uterus, and a relaxed cardioesophageal sphincter, caused by the action of relaxin, an enzyme produced by the ovary. Interventions for heartburn are also discussed in Chapter 13.

As the uterus increases in size, it pushes the stomach and intestines toward the back and sides of the abdomen. At about the midpoint of pregnancy, this pressure may be sufficient to slow intestinal peristalsis and the emptying time of the stomach, leading to increased heartburn, constipation, and flatulence. Relaxin may contribute to decreased gastric motility; this natural slowing can be helpful, because the blood supply may be reduced to the gastrointestinal tract (i.e., blood is drawn to the uterus). Progesterone also has an effect on smooth muscle, such as that in the intestine, making the gastrointestinal tract less active.

Women with chronic gastric reflux usually find their condition improved during pregnancy because the acidity of the stomach is decreased. Because of the gradual slowing of the gastrointestinal tract, decreased emptying of bile from the gallbladder may result. This can lead to reabsorption of bilirubin into the maternal bloodstream, giving rise to a symptom of generalized itching (subclinical jaundice). A woman who has had gallstones may have an increased tendency to stone formation during pregnancy as a result of the increased plasma cholesterol level and additional cholesterol incorporated in bile. Pressure from the uterus on veins returning from the lower extremities can lead to hemorrhoids.

Some pregnant women notice hypertrophy at their gumlines and bleeding of gingival tissue when they brush their teeth. There may be increased saliva formation (hyperptyalism), probably as a local response to increased levels of estrogen. This is an annoying but not serious problem. A lower than normal pH of saliva may lead to increased tooth decay if tooth brushing is not done conscientiously. This can be a problem for homeless women or any other women who do not have frequent access to a place to brush their teeth (Agueda et al., 2008).

What if... Lauren Maxwell, the woman you met at the beginning of this chapter, asks you what to do for morning sickness and fatigue. What if you discovered she was homeless? Would your advice for her be any different?

Urinary System

Like other systems, the urinary system undergoes many physiologic changes during pregnancy. These include alterations in fluid retention and renal, ureter, and bladder function. Changes in the urinary system are summarized in Table 10.6. These changes result from:

- Effects of high estrogen and progesterone levels
- Compression of the bladder and ureters by the growing uterus
- Increased blood volume
- Postural influences

Fluid Retention. To provide sufficient fluid volume for effective placental exchange, total body water increases to 7.5 L; this requires the body to increase its sodium reabsorption in

BOX 10.8 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Woman Experiencing a First Pregnancy

Lauren Maxwell is a part-time model who has come to your clinic for her first prenatal visit. She tells you she missed her period 4 weeks ago and immediately took a home pregnancy test. She's excited that it was positive, because she and her husband have been trying for several months to get pregnant. She adds that her husband, John, doesn't seem a bit scared: "I don't know if that's a good thing or not," she confides. She's also worried about being a good parent: "I'd die," she says, "if I turned into the same kind of parent as my parents."

Family Assessment ✻ The Maxwells have been married for 3½ years. They live in student housing next to the university campus. Husband, John, works as a chef in nearby Italian restaurant. Client, Lauren, works part-time as a model while she attends cooking school. Finances are listed as "tight" but "okay."

Client Assessment ✻ Lauren presents with amenorrhea, breast tenderness, fatigue, and morning sickness. She is interested in when she will begin to look pregnant and what she can do for the morning sickness (she has eaten almost nothing for 2 days).

Nursing Diagnosis ✻ Altered nutrition pattern related to nausea of early pregnancy
Anxiety related to pregnancy and becoming a parent

Outcome Criteria ✻ Client states that she is able to eat at least one full meal a day even in light of nausea; names two complementary therapies she is using to decrease nausea; states that she is managing anxiety by self-help measures, with support from significant others.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Determine whether client is able to carry out usual activities (attending work, school, keeping house) by obtaining a health history.	Work with client to see if modifications (reducing work responsibilities, giving more home responsibility to husband) will help alleviate symptoms.	Documenting whether client can complete normal activities helps to document extent of concerns. Nausea can interfere greatly with cooking school.	Client reports that she is able to attend school and work part-time as long into pregnancy as she desires.
		Consultations		
Nurse	Assess if client needs additional suggestions from team expert for dealing with nausea.	Consult with nutritionist if nausea still interferes with eating by 1 week's time.	Nausea in early pregnancy can become extreme if not recognized as potentially serious in early pregnancy.	Client meets with nutritionist if she still describes incapacitating nausea at 1 week telephone follow-up.
		Procedures/Medications		
Physician/ nurse midwife	Assess whether client would like to try a complementary therapy, such as ginger before meals.	Review pros and cons of any alternative therapy chosen by client.	Many alternative therapies are effective at reducing symptoms of nausea during pregnancy.	Client states she is using at least one alternative therapy by 1 week follow-up telephone call.
		Nutrition		
Nurse/team nutritionist	Ask client to list 24-hour recall nutrition history.	Examine 24-hour recall history and analyze for nutrition deficits. Make suggestions for better intake.	Documenting the problem best identifies its extent.	Client gives 24-hour recall history and helps determine any nutritional deficits and possible solutions.

Nurse	Assess whether client feels that anxiety or worry over gaining weight is adding to her nausea.	Discuss with client that anxiety can add to nausea; weight gained during pregnancy can be lost after pregnancy.	Identifying the cause of anxiety is the first step in determining how to best relieve it. Gaining weight means she will lose modeling assignments.	Client states that she recognizes anxiety is normal for her situation. No longer anxious about pregnancy weight gain.
		Patient/Family Education		
Nurse	Determine whether client is aware that nausea and anxiety are both common concerns during pregnancy.	Provide clinic pamphlet, *So You're Pregnant,* to client and discuss early symptoms of pregnancy. Discuss with client how she normally manages anxiety. Offer suggestions as necessary.	Recognizing that a symptom is normal helps client to accept discomfort. Mild anxiety responds to many self-help measures, such as meditation or quiet reflection.	Client reports at 1-week follow-up telephone call that she recognizes nausea as part of early pregnancy. Client reports that she is managing anxiety by suggested self-help measures.
		Psychosocial/Spiritual/Emotional Needs		
Nurse	Determine whether client feels it would be helpful for nurse to meet with husband.	If desired, schedule a time to meet with husband to explain early pregnancy symptoms.	Significant others may be unable to give support if they are not well informed.	Client asks for help as needed by 1-week follow-up telephone call.
Nurse	Assess if client is concerned that differences in husband's and her feelings toward pregnancy will interfere with their relationship.	Urge client to discuss pregnancy fears with husband.	Differences in reactions to pregnancy can potentially interfere with degree of support from significant other.	Client says she has discussed her fears with her husband and will continue to do so as pregnancy progresses.
		Discharge Planning		
Nurse	Assess if client has any further questions before she leaves the clinic.	Meet with client after physical examination to be certain all her questions have been answered.	Unanswered questions can lead to increased anxiety over coming weeks.	Client confirms that her questions have been answered; has telephone number for clinic if further concerns arise.

TABLE 10.6 ✻ Urinary Tract Changes During Pregnancy

Variable	Change
Glomerular filtration rate	Increased by 50%
Renal plasma flow	Increased by 25% to 80%
Blood urea nitrogen	Decreased by 25%
Plasma creatinine level	Decreased by 25%
Renal threshold for sugar	Decreased to allow slight spillage
Bladder capacity	Increased by 1000 mL
Diameter of ureters	Increased by 25%
Frequency of urination	Increased first trimester, last 2 weeks of pregnancy to 10–12 times/day

the tubules to maintain osmolarity. Under the influence of progesterone, there is an increased response of the angiotensin-renin system in the kidney, which leads to an increase in aldosterone production. Aldosterone aids sodium reabsorption. Progesterone appears to be potassium-sparing, so that even with an increased urine output, potassium levels remain adequate.

Water is retained during pregnancy to aid the increase in blood volume and to serve as a ready source of fluid for the fetus. Because nutrients can pass to the fetus only when dissolved in or carried by fluid, this ready fluid supply is a fetal safeguard.

At one time, pregnant women were administered diuretics to help clear this excess fluid from their system. A sodium-restricted diet was also recommended. Today, it is recognized that these practices are actually harmful, because the increased fluid volume provides physiologic benefits for the fetus. In addition, the excess fluid can serve to replenish the mother's own blood volume, should hemorrhage occur.

Renal Function. During pregnancy, a woman's kidneys must excrete not only the waste products from her body but also those of the growing fetus. Also, her kidneys must be able to excrete additional fluid and manage the demands of increased renal blood flow. The kidneys may increase in size, changing their structure and ultimately affecting their function.

During pregnancy, urinary output gradually increases (by about 60% to 80%). The specific gravity of urine decreases. The glomerular filtration rate (GFR) and renal plasma flow begin to increase in early pregnancy to meet the increased needs of the circulatory system. By the second trimester, both the GFR and the renal plasma flow have increased by 30% to 50%, and they remain at these levels for the duration of the pregnancy. This rise is consistent with that of the circulatory system increase, peaking at about 24 weeks. This efficient GFR level leads to a lowered blood urea nitrogen (BUN) and low creatinine levels in maternal plasma. A BUN of 15 mg/100 mL or higher or a serum creatinine concentration greater than 1 mg/100 mL is considered abnormal and reflects the kidneys' difficulty in handling the increased blood load. The higher GFR leads to increased filtration of glucose into the renal tubules. Because reabsorption of glucose by the tubule cells occurs at a fixed rate, there may be some accidental spilling of glucose into the urine during pregnancy. Lactose, which is being produced by the mammary glands but is not used during pregnancy, will also be spilled into the urine. Although minimal spilling of glucose into the urine may occur this way, the finding of more than a trace of glucose in a routine sample of urine from a pregnant woman is considered abnormal until proved otherwise, because this can be a sign of gestational diabetes (see Chapter 20).

Creatinine clearance has become the standard test for renal function during pregnancy, because creatinine is cleared from the body at a steady rate in relation to GFR. A normal pregnancy value is 90 to 180 mL/min. This is analyzed from a 24-hour urine sample.

Ureter and Bladder Function. A pregnant woman may notice an increase in urinary frequency during the first 3 months of pregnancy, until the uterus rises out of the pelvis and relieves pressure on the bladder. Frequency of urination may return at the end of pregnancy, as lightening occurs and the fetal head exerts renewed pressure on the bladder.

Because of the increased level of progesterone during pregnancy, the ureters increase in diameter and the bladder capacity increases to about 1500 mL. The uterus tends to rise on the right side of the abdomen because it is pushed slightly in that direction by the greater bulk of the sigmoid colon. As a result, pressure on the right ureter may lead to urinary stasis and pyelonephritis if not relieved. Pressure on the urethra may lead to poor bladder emptying and bladder infection. Such infections are potentially dangerous to the pregnant woman, because they can ascend to become kidney infections. They are potentially dangerous to the fetus, because urinary tract infections are associated with preterm labor (Cootauco & Althaus, 2007).

Skeletal System

Calcium and phosphorus needs are increased during pregnancy, because the fetal skeleton must be built. As pregnancy advances, there is a gradual softening of a woman's pelvic ligaments and joints to create pliability and to facilitate passage of the baby through the pelvis at birth. This softening is probably caused by the influence of both the ovarian hormone relaxin and placental progesterone. Excessive mobility of the joints can cause discomfort. A wide separation of the symphysis pubis, as much as 3 to 4 mm by 32 weeks of pregnancy, may occur. This makes women walk with difficulty because of pain.

To change her center of gravity and make ambulation easier, a pregnant woman tends to stand straighter and taller than usual. This stance is sometimes referred to as the "pride of pregnancy." Standing this way, with the shoulders back and the abdomen forward, creates a lordosis (forward curve of the lumbar spine), which may lead to backache (Box 10.9).

Endocrine System

Almost all aspects of the endocrine system increase during pregnancy (Table 10.7).

Placenta. The most striking change in the endocrine system during pregnancy is the addition of the placenta as an endocrine organ that produces large amounts of estrogen, progesterone, hCG, human placental lactogen (hPL), relaxin, and prostaglandins. Estrogen causes breast and uterine enlargement. Palmar erythema during early pregnancy may also be a response to the high circulating estrogen levels. Progesterone has a major role in maintaining the endometrium, inhibiting uterine contractility, and aiding in the development of the breasts for lactation. Relaxin, secreted primarily by the corpus luteum, is responsible for helping to inhibit uterine activity and to soften the cervix and the collagen in joints. Softening of the cervix allows for dilatation at birth; softening of collagen allows for laxness in the lower spine and helps enlarge the birth canal. hCG is secreted by the trophoblast cells of the placenta in early pregnancy. It stimulates progesterone and estrogen synthesis in the ovaries until the placenta can assume this role. hPL, also known as human chorionic somatomammotropin, is also produced by the placenta. It serves as an antagonist to insulin, making insulin less effective, which allows more glucose to become available for fetal growth.

BOX 10.9 ✻ Focus on Family Teaching

Backache During Pregnancy

Q. You notice Lauren Maxwell rubbing her back at a prenatal visit. She asks you how she can keep her backache from becoming worse.

A. Backache is a common symptom of pregnancy because of the strain the extra uterine weight puts on lower vertebrae. It may be serious if

- It is experienced as waves of pain (could be preterm labor).
- There are accompanying urinary symptoms, such as frequency and pain on urination (could be a urinary tract infection).
- The back is tender at the point of backache (could be pyelonephritis or a kidney infection).
- Rest does not relieve it (could be a muscle strain).

Measures to relieve backache in pregnancy are

- Limit the use of high heels, because they add to the natural lordosis of pregnancy.
- Try to rest daily with feet elevated.
- Walk with head high, pelvis straight.
- Pelvic rocking (see Chapter 14) at the end of the day may relieve pain for the night.

In addition to these changes, prostaglandins are found in high concentrations in the female reproductive tract and the decidua during pregnancy. Prostaglandins affect smooth muscle contractility to such an extent they may be the trigger that initiates labor at term.

Pituitary Gland. The pituitary gland is affected by pregnancy, because there is a halt in the production of FSH and LH brought on by the high estrogen and progesterone levels of the placenta. There is increased production of growth hormone and melanocyte-stimulating hormone (which causes skin pigment changes). Late in pregnancy, the posterior pituitary begins to produce oxytocin, which will be needed to aid labor. Prolactin production is also begun late in pregnancy, as the breasts prepare for lactation.

Thyroid and Parathyroid Glands. The thyroid gland enlarges in early pregnancy to such an extent that the basal body metabolic rate increases by about 20%. Levels of protein-bound iodine, butanol-extractable iodine, and thyroxine are all elevated in blood serum. If a sufficient supply of iodine is not present during pregnancy, goiter (thyroid hypertrophy) can occur as the gland intensifies its productive effort.

These thyroid changes, along with emotional lability, tachycardia, palpitations, and increased perspiration, may lead to a mistaken diagnosis of hyperthyroidism if pregnancy has not been determined.

The parathyroid glands, which are necessary for the metabolism of calcium, also increase in size during pregnancy. Because calcium is important for fetal growth, the hypertrophy is probably necessary to satisfy the increased requirement of this.

TABLE 10.7 ✻ Endocrine Gland Changes and Effects During Pregnancy

Gland	Change	Effect
Thyroid gland	Slight enlargement	Increased basal metabolism rate
	Increased thyroid hormone production	Increased oxygen consumption
Parathyroid gland	Slight enlargement	Better utilization of calcium and vitamin D
	Increased parathyroid hormone production	
Pancreas	Early in pregnancy, decreased insulin production because of heavy fetal demand for glucose	Additional glucose is available for fetal growth
	After first trimester, increased insulin production because of insulin antagonist properties of estrogen, progesterone, and human placental lactogen	
Pituitary gland	FSH and LH decrease	Anovulation
	Prolactin increases	Breasts prepared for lactation
	Melanocyte-stimulating hormone increases	Increased skin pigment
	Human growth hormone increases	Aids fetal growth
Placenta	Estrogen and progesterone produced	Uterine and breast enlargement, fat deposits
		Increased blood coagulation, sodium and water retention
	Relaxin increased	Softening of cervix and collagen of joints
	Human placental lactogen	Increases glucose available for fetus
		Decreases utilization of protein for energy, increasing availability for fetal growth

Adrenal Glands. Adrenal gland activity increases in pregnancy as increased levels of corticosteroids and aldosterone are produced. It is assumed that these increased levels aid in suppressing an inflammatory reaction or help reduce the possibility of a woman's body rejecting the foreign protein of the fetus, the same as it would a foreign-tissue transplant. They also help to regulate glucose metabolism in a woman. The increased level of aldosterone aids in promoting sodium reabsorption and maintaining osmolarity in the amount of fluid retained. This indirectly helps to safeguard the blood volume and to provide adequate perfusion pressure across the placenta.

Pancreas. The pancreas increases production of insulin in response to the higher levels of glucocorticoid produced by the adrenal glands. Insulin is less effective than normal, however, because estrogen, progesterone, and hPL are all antagonists to insulin. Therefore, a woman who is diabetic and taking insulin before pregnancy will need more insulin during pregnancy. A woman who is prediabetic may develop overt diabetes for the first time during pregnancy. Overall, the effect of diminishing the action of insulin is beneficial because it ensures a ready supply of glucose for fetal growth.

The glucose level of a fetus is about 30 mg/100 mL lower than the maternal glucose level. To prevent fetal hypoglycemia, with resultant cell destruction or lack of fetal growth, the maternal glucose level is usually at a higher than normal level during pregnancy. Several fail-safe physiologic measures are initiated to achieve this.

As mentioned, although the pancreas secretes an increased level of insulin throughout pregnancy, it appears to be not as effective. With insulin that is less effective, fat stores of a woman are utilized, as well as available glucose. This maintains maternal glucose levels at a fairly steady level despite long intervals between meals or days of increased activity. To ensure against hypoglycemia, a pregnant woman should keep her diet high in calories and should never go longer than 12 hours between meals. Because the rapidly developing fetus uses so much glucose in early pregnancy, a fasting blood glucose level at this time is usually low (80–85 mg/100 mL).

Immune System

Immunologic competency during pregnancy apparently decreases, probably to prevent a woman's body from rejecting the fetus as if it were a transplanted organ. Immunoglobulin G (IgG) production is particularly decreased, which can make a woman more prone to infection during pregnancy. A simultaneous increase in the white blood cell count may help to counteract the decrease in IgG response.

✔ Checkpoint Question 10.5

Lauren Maxwell overheard her doctor say that insulin is not as effective during pregnancy as usual. How would you explain how decreased insulin effectiveness safeguards the fetus?

a. Decreased effectiveness prevents the fetus from being hypoglycemic.
b. If insulin is ineffective, it cannot cross the placenta and harm the fetus.
c. The lessened action prevents the fetus from gaining too much weight.
d. The mother, not the fetus, is guarded by this decreased insulin action.

Key Points for Review

- The ability of a woman to accept her pregnancy depends on social, cultural, family, and individual influences.
- The psychological tasks of pregnancy are centered on ensuring safe passage for the fetus. These consist of, in the first trimester, accepting the pregnancy; in the second trimester, accepting the baby; and in the third trimester, preparing for parenthood.
- Common emotional responses that occur with pregnancy include grief, narcissism, introversion or extroversion, stress, couvade syndrome, body image and boundary confusion, emotional lability, and changes in sexual desire.
- Physiologic changes that occur with pregnancy are both local (uterine, ovarian, and vaginal changes) and systemic (respiratory, cardiovascular, urinary, and skin changes).
- Women may have read about the expected psychological and physiologic changes of pregnancy, but once these changes are actually being experienced, they may find them more intense than anticipated.
- The diagnosis of pregnancy is based on three types of findings: presumptive (subjective), probable (objective), and positive (documented).
- The positive signs of pregnancy are demonstration of a fetal heartbeat separate from the mother's, fetal movement felt by an examiner, and visualization of the fetus by ultrasound.
- Although a woman may be in a physician's office or prenatal clinic for only an hour, if her pregnancy was confirmed at that visit, she invariably feels "more pregnant" when she leaves. Early diagnosis is important so that a woman can begin to change unhealthy habits or, if she desires, have adequate time to carry out a therapeutic termination of pregnancy.

CRITICAL THINKING EXERCISES

1. Lauren Maxwell, the woman described at the beginning of the chapter, said she is worried about being pregnant because she "would die" if she thought she might be the same type of parent as her parents. Is this type of worry a common reaction to learning about a pregnancy? She says her partner is not worried. Would it be better or worse if he felt the same way? Has she completed the psychological development tasks of pregnancy? What suggestions could you make to help her be a better parent?

2. Lauren used a home test kit to determine that she was pregnant. She then did not schedule a prenatal visit, because the most important reason for going would have been to learn whether she was pregnant, and she already knew that. What argument could you use to convince her that prenatal care is important for more than pregnancy diagnosis?
3. You notice that Lauren's husband (35 years old) does not come with her on prenatal visits. He says this is because doing that is only for "young guys." How would you advise him?
4. Examine the National Health Goal related to early prenatal care. Most government-sponsored money for nursing research is allotted based on National Health Goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to the Maxwell family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX types of questions related to psychological and physiologic changes of pregnancy. Confirm your answers are correct by reading the rationales.

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe the areas of health assessment commonly included in prenatal visits.
2. Identify National Health Goals related to prenatal care that nurses can help the nation achieve.
3. Use critical thinking to analyze ways to ensure that prenatal care is family centered.
4. Assess a pregnant woman's health status and readiness for pregnancy.
5. Formulate nursing diagnoses related to women's health status during pregnancy.
6. Identify expected outcomes to help ensure a safe pregnancy.
7. Plan nursing care such as preparing a woman for a pelvic examination or fundal measurement.
8. Implement nursing care such as establishing a risk score for pregnancy.
9. Evaluate expected outcomes for achievement and effectiveness of care.
10. Identify areas of prenatal care that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of pregnancy health assessment with nursing process to achieve quality maternal and child health care.

Sandra Czerinski is a 29-year-old woman, 12 weeks' pregnant, who comes for a first prenatal visit. She is concerned because she did not realize she was pregnant until a week ago. Because of this, she has been actively dieting (two diet drinks plus one meal of mainly vegetables daily) plus lifting weights at a health club. She has not had a pelvic examination since she was in high school, when she had a vaginal infection. She remembers that examination as being very painful. She is worried she has a urinary tract infection now because she has to "go all the time." She does not want any blood work done because she does not have health insurance.

Previous chapters described normal anatomy and physiology of the reproductive tract and the psychological and physiologic changes that occur during pregnancy. This chapter adds information about care needed during pregnancy to help ensure a healthy outcome for both a woman and her child.

What type of care does Sandra need? Is Sandra a high-risk or low-risk patient?

Prenatal care, essential for ensuring the overall health of newborns and their mothers, is a major strategy for helping to reduce complications of pregnancy such as the number of low-birth-weight babies born yearly (Crombleholme, 2009). It is so important that several National Health Goals speak directly to it (Box 11.1).

Ideally, prenatal care begins during a woman's childhood. It includes balanced nutrition with adequate intake of calcium and vitamin D during childhood to prevent rickets (which can distort pelvic size); adequate immunizations against contagious diseases so a woman has protection against viral diseases such as rubella during pregnancy; and maintenance of an overall healthy lifestyle to ensure the best state of health possible for a woman and her partner when entering pregnancy.

An overall healthy lifestyle includes a positive attitude about sexuality, womanhood, and childbearing. Once a woman becomes sexually active, preparation for a successful pregnancy includes practicing safer sex, regular pelvic examinations, and prompt treatment of any sexually transmitted infection to prevent complications that could lead to subfertility (Katsufrakis & Workowski, 2008). It includes not smoking or using recreational drugs. Acquisition and use of reproductive life planning information can help to ensure that each pregnancy is planned.

Women who maintain a healthy lifestyle this way come to a first prenatal visit prepared to follow health-promotion strategies. For many women this visit is the first time they have been to a health care facility since their routine health maintenance visits of childhood. It also may be the first time they have had an appointment that focuses more on health promotion than on the diagnosis of a disease. A woman may have a specific reason (her agenda) for coming to a first prenatal visit (e.g., to confirm the diagnosis of pregnancy). A prenatal visit encompasses more than this, though. It is also a time for additional health promotion, pregnancy education, and development of a positive pattern of healthy behaviors for the family to use in the future (your agenda). What and how much is needed vary depending on the lifestyle, age, and parity of a woman and her degree of family support (Bernstein & Weinstein, 2007).

Lack of prenatal care is associated with the birth of preterm infants and various complications for a woman such as hypertension of pregnancy (Cootauco & Athaus, 2007).

BOX 11.1 * Focus on National Health Goals

Several National Health Goals speak directly to the importance of prenatal care:

- Increase the proportion of pregnant women who receive early and adequate prenatal care from a baseline of 74% to a target of 90%.
- Increase the proportion of pregnant women who attend a series of prepared childbirth classes from a baseline of 66% to a target of 77%.
- Increase to at least 90% the proportion of all pregnant women who receive prenatal care in the first trimester of pregnancy from a baseline of 83% (http://www.nih.gov).

Nurses can help the nation achieve these goals by educating women and their families about the importance of prenatal care and by making sites of prenatal care receptive to women and families. Additional nursing research to investigate ways to promote prenatal care or to enlarge the scope of nursing involvement in prenatal care could add a lot to helping the nation meet these goals.

Nursing Process Overview

For Prenatal Care

Assessment

The first prenatal visit is a time to establish baseline data relevant to health assessment and health-promotion strategies that will be important at every prenatal visit. This begins with obtaining a health history, including screening for the presence of teratogens (any factor that may adversely affect the fetus) and any concerns a woman may be experiencing. Explaining why specific assessment data are relevant to the pregnancy is important. For instance, when weighing a woman, discussing what routine weight gain she can expect in the coming months and why monitoring weight gain is important supplies information to a woman as well as allowing you to obtain baseline data. Relating assessment information and health-promotion activities this way throughout the pregnancy helps keep a woman and her family well informed and eager to comply with further health care recommendations.

Nursing Diagnosis

Although most women probably have used a home pregnancy kit to find out if they are pregnant, the first prenatal visit officially confirms this, so nursing diagnoses usually focus on the response of a woman and her family to that information. For example:

- Decisional conflict related to desire to be pregnant
- Risk for ineffective coping related to confirmation of unplanned pregnancy

Nursing diagnoses appropriate to prenatal care include:

- Health-seeking behaviors related to guidelines for nutrition and activity during pregnancy
- Deficient knowledge regarding exposure to teratogens during pregnancy
- Risk for injury to fetus related to current lifestyle behaviors

Outcome Identification and Planning

Be certain to reserve sufficient time at prenatal visits so care can be thorough and there is enough time to set realistic goals and expected outcomes with both a woman and her partner, if desired. Make sure that a woman leaving an initial prenatal visit schedules an appointment for a following visit, as this may not occur to a woman who may be extremely excited or overwhelmed by all the new things that are happening to her and her family; establishing a pattern of regular appointments is crucial to

providing effective prenatal care. Although many settings are looking at whether the number of prenatal visits traditionally scheduled is needed during a normal pregnancy, return appointments are usually scheduled every 4 weeks through the 28th week of pregnancy, every 2 weeks through the 36th week, and then every week until birth. Women categorized as high risk are followed more closely.

Reliable Internet sites to use for referral on preconceptual or prenatal care are the National Institute of Health and Human Development (http://www.nichd.nih.gov/health/topics/preconception_care.cfm) and the March of Dimes (http://www.marchofdimes.com).

Implementation

An important nursing intervention at prenatal visits is teaching women and their families about a safe pregnancy lifestyle. It may be helpful to give a woman and her partner pamphlets or books that cover the same topics. Be certain that you have read all the printed material you give families. This helps to ensure that a pamphlet's advice is consistent with what you have said and with the views of a woman's primary care physician or nurse-midwife. A pretty picture on the cover of a pamphlet does not ensure the quality of the advice inside. In addition, reinforce with a woman that she should call, e-mail, or text message the health care setting if she has any problems or questions between visits. Some women may feel reluctant to "bother" a health care provider outside of scheduled visits unless you give them permission to do so.

Outcome Evaluation

Evaluation during prenatal visits should concentrate on a woman's initial progress toward understanding goals of care for pregnancy and assessing outcomes established for specific concerns. Examples of expected outcomes are:

- Couple states they have reached a mutual decision to both stop smoking.
- Client states she feels well informed about the common discomforts of pregnancy and actions to take to relieve them.
- Client lists ways to avoid exposure to teratogens during pregnancy.

HEALTH PROMOTION DURING PREGNANCY

The purposes of prenatal care are to:

- Establish a baseline of present health
- Determine the gestational age of the fetus
- Monitor fetal development and maternal well being
- Identify women at risk for complications
- Minimize the risk of possible complications by anticipating and preventing problems before they occur
- Provide time for education about pregnancy, lactation, and newborn care

If a woman has good health coming into a pregnancy, it helps to ensure a good pregnancy outcome, so care includes both preconceptual and pregnancy timeframes.

The Preconceptual Visit

Ideally, women should schedule an appointment with a physician or nurse-midwife before becoming pregnant to obtain accurate reproductive life planning information, receive reassurance about fertility (as much as can be given based on a health history and a routine physical examination), and detect any problems that may need correction through a thorough health history, and physical and pelvic examinations (Rojas, Wood, & Blakemore, 2007). At this visit, hemoglobin level and blood type (including Rh factor) can be determined; a Papanicolaou (Pap) test can be taken, and minor vaginal infections such as those arising from *Candida* or chlamydia can be corrected to help ensure fertility. A woman can be counseled on the importance of a good protein diet, adequate intake of folic acid and other vitamins, and early prenatal care if she does become pregnant. More often, however, women arriving for their first prenatal visit will not have had a recent health care appointment oriented toward reproduction this way.

Choosing a Health Care Provider for Pregnancy and Childbirth

Once a woman is or suspects that she may be pregnant, her next step is to choose a primary health care provider to care for her throughout the pregnancy and birth. Various options are available, including a prenatal clinic, her health maintenance organization (HMO) or preferred provider (PPO), a certified nurse-midwife, an obstetrician, or a family practitioner. Regardless of the type of health care provider chosen, prenatal care needs to be initiated early and continued throughout pregnancy.

Nurses contribute to the success of prenatal care by listening, counseling, and teaching, three areas of nursing expertise (Box 11.2). Many clinics and group practices provide an initial

BOX 11.2 ✻ Focus on Evidence-Based Practice

Is continuity of care important in a prenatal setting?

In many prenatal settings, women see either one caregiver (usually a midwife) for the majority of their prenatal visits or see a multitude of care providers (midwives, physicians, nurse practitioners). To investigate whether continuity of care with one provider made a difference, researchers reviewed two studies including 1815 women. Women who saw a single care provider for their pregnancy visits were less likely to be admitted to a hospital antenatally. No differences were detected in Apgar scores, low birth weight, and stillbirths or neonatal deaths. They were more likely to be pleased with their antenatal, intrapartum and postnatal care.

Suppose you had the chance to reorganize a prenatal clinic? Would the above study influence the decisions you would make?

Source: Hodnett, E .D. (2009).Continuity of caregivers for care during pregnancy and childbirth. *Cochrane Database of Systematic Reviews, (2009)*(1), (CD000062).

BOX 11.3 ✻ Suggestions for Improving Prenatal Care Services

- Schedule appointments for women within a week after they first call the health care setting. This initial contact can be done through a group orientation session, individually by a health team member or, if risk status warrants, by a physician. Try to schedule further appointments at times convenient for a woman and her support people to encourage attendance.
- Make waiting time educational by providing materials such as pamphlets or videotapes in the waiting room.
- Provide privacy for assessments such as blood pressure and weight.
- Be certain that pregnant women meet health care providers while fully clothed and upright, not exposed or in a lithotomy position on an examining table.
- Encourage women to feel responsible for their health record. If a woman's first language is not English, be sure to record pregnancy information so she can read it.
- Encourage family members and friends to accompany a woman for prenatal care. Allow them to enter the examination room and participate in all aspects of care to the extent they and the woman desire.
- Schedule appointments to provide continuity of care. Be certain that women have a specific person's name as a telephone or e-mail contact for pregnancy-related questions. Without this information, they tend not to call.
- Educate pregnant women about care options and encourage them to participate in making decisions about their care.

educational seminar for women in the early stages of their pregnancy, often led by a nurse or nurse practitioner. Some practices form cohorts of women to meet monthly and discuss their concerns to be certain that women will have support from others all through pregnancy. Box 11.3 summarizes ways that prenatal care can be improved and individualized so that all women can be interested in obtaining it.

HEALTH ASSESSMENT DURING THE FIRST PRENATAL VISIT

The major causes of death during pregnancy today for women are ectopic pregnancy, hypertension, hemorrhage, embolism, infection, and anesthesia-related complications such as intrapartum cardiac arrest (http://www.nih.gov). An important focus of all prenatal visits, therefore, in addition to education about pregnancy, is to screen for danger signs that might reveal any of these conditions (Fig. 11.1).

Screening includes an extensive health history, a complete physical examination, including a pelvic examination, and blood and urine specimens for laboratory work. Manual pelvic measurements can be taken to determine pelvic adequacy.

FIGURE 11.1 Include support people in a prenatal visit so that visits are family centered. Here a husband, wife, and child are included in the initial prenatal interview, making all feel a part of the pregnancy. (© Barbara Proud.)

✔ Checkpoint Question 11.1

Sandra Czerinski feels well so she asks you why she needs to come for prenatal care. The best reason for her to receive regular care is:

a. Discovering allergies can help eliminate early birth.
b. It helps document how many pregnancies occur each year.
c. It provides time for education about pregnancy and birth.
d. It will give her something to look forward to every month.

The Initial Interview

Because initial health history taking is often time-consuming, a woman may be asked to complete some of the forms. Good interviewing technique, however, is important to obtain thorough and meaningful health histories. The rapport established by face-to-face interviewing gives a woman a feeling that she is more than just a client number or chart. It may be as much a reason she returns for follow-up care as her desire to be assured that her pregnancy is progressing normally.

Interviewing expectant women often elicits contradictory information. Women are likely to want to talk about their past health and current pregnancy, so interviewing them should go smoothly and be productive. On the other hand, pregnancy symptoms are subtle, so a woman may not regard certain information as important, providing vague answers instead of specific information to questions about these areas. She may be unaware that she is the only person who knows the answers to several vital questions ("How do you feel about being pregnant?" or "Have you been taking anything for your morning nausea?"). Outside pressures, such as having to report for work or older children coming home from school, can limit the length of an interview. Late in pregnancy, a woman may feel uncomfortable sitting for a long interview.

Interviewing is best accomplished in a private, quiet setting. Trying to talk to a woman in a crowded hallway or a full waiting room is rarely effective. Pregnancy is too private an affair to be discussed under these circumstances.

It is helpful if the person scheduling appointments cautions a woman that a first visit may be lengthy. This prevents a woman from trying to fit the visit in between other errands or from having to terminate the interview because of another appointment.

Be certain to ask what name a woman wants you to use when addressing her in a prenatal setting (Mrs? Miss? Ms? Or her first name?) and make certain that she knows your name and understands your role correctly. If she views you as someone only gathering preliminary data, she will be willing to discuss superficial facts (name, address, telephone number, and the like) but will resist discussing more intimate things (her feelings toward this pregnancy, the difficulty she has reworking old fears or how scared she is about birth).

Components of the Health History

An initial interview serves several purposes:

- Establishing rapport
- Gaining information about a woman's physical and psychosocial health
- Obtaining a basis for anticipatory guidance for the pregnancy

If on subsequent visits a symptom is mentioned, establishing a baseline health picture at the initial pregnancy allows you to be able to verify that it is truly a new symptom and a woman is not just becoming more aware of it. General interviewing techniques are discussed in Chapter 34. Included in the following section are the elements pertinent to a pregnancy history.

Demographic Data

Demographic data usually obtained include name, age, address, telephone number, e-mail address, religion, and health insurance information.

Chief Concern

The chief concern is the reason a woman has come to the health care setting—in this instance, the fact that she is or thinks she is pregnant.

To help confirm pregnancy, inquire about the date of her last menstrual period and whether she has had a pregnancy test or used a home test kit. Elicit information about the signs of early pregnancy, such as nausea, vomiting, breast changes, or fatigue. Ask if she has any discomforts of pregnancy, such as constipation, backache, or frequent urination. Also, ask about any danger signs of pregnancy, such as bleeding, continuous headache, visual disturbances, or swelling of the hands and face.

Document if the pregnancy was planned. If you feel uncomfortable asking directly, using a statement such as, "All pregnancies are a bit of a surprise. Is that how it was with this one?" may help her answer this question. Another way to word such a question would be, "Some couples plan on having children right away; some plan on waiting. How was it with you?" If a woman says the pregnancy was not planned, explore to learn if she has reached a decision about whether to continue with the pregnancy. A question such as, "Some women change their mind about wanting a baby once they realize they are pregnant; some don't. How has it been for you?" is an effective way for obtaining this type of information because it says either option is possible and acceptable as an answer. You just want her to tell you which is happening.

Family Profile

In the past, the social history or family setting history (family profile) was left until the end of a health interview. However, obtaining this information early in an interview can help you get to know a woman earlier, identify important support persons, shape the nature and kind of questions to be asked, and evaluate the possible impact of a woman's culture on care. It also lays a foundation for health teaching as before you can begin to offer a woman any more than stereotyped health care instructions, you need to know her age and that of her sexual partner (additional testing such as genetic screening may be necessary if she is over 35), their educational levels (offers an estimation of the level of teaching you will plan), and occupation (does a woman's work involve heavy lifting, long hours of standing in one position, handling of a toxic substance, actions that may need to be modified during pregnancy?).

Be certain to ask about marital status and support people available as part of the information obtained. As a rule, both married and unmarried women want you to know their married status as they want to alert you if they do not have support people readily available.

Ask enough questions about the size of the apartment or house in which a woman lives so you can talk with her in the coming months about a bedroom or space for a baby's bed. It also is important to know whether the essential rooms are on the ground floor or upstairs in case she is restricted from climbing stairs more than once or twice a day during the last part of pregnancy or after birth.

Adaptation to pregnancy is highly individualized. A change in status from independence to dependence because of stopping work, chronic illness at home, the death or loss of a significant person during pregnancy, geographic moves, financial hardship, and lack of support people are examples of situations that can hinder a woman's ability to accept her pregnancy and child. No one in the health care setting will be aware of these potentially harmful situations unless questions of this kind about family profile are asked.

History of Past Illnesses

Questions about a woman's past medical history are an important part of an interview because a past condition can become active during or immediately following pregnancy. Representative diseases that pose potential difficulty during pregnancy include kidney disease, heart disease (coarctation of the aorta and heart valve problems from rheumatic fever cause problems most often), hypertension, sexually transmitted infections (including hepatitis B and human immunodeficiency virus [HIV]), diabetes, thyroid disease, recurrent seizures, gallbladder disease, urinary tract infections, varicosities, phenylketonuria, tuberculosis, and asthma. It is important to find out whether a woman had childhood diseases such as chickenpox (varicella), mumps (epidemic parotitis), measles (rubeola), German measles (rubella), or poliomyelitis and whether she has had immunizations against these. Ask also about HPV (human papillomavirus) vaccine as many women are not yet aware there is a vaccine for this.

The vaccine has the potential to prevent not only HPV infections but the development of cervical cancer (Tanner & Alexander, 2007).

From the information obtained about common infectious diseases and immunizations, you can estimate the degree of antibody protection a woman has against these diseases if she is exposed to them during her pregnancy. While pregnant, she can be immunized against influenza and against poliomyelitis with the Salk (killed virus) vaccine. However, she cannot be immunized against the other diseases because the vaccines against these contain live viruses, as does the oral Sabin poliomyelitis vaccine. Live virus vaccines could be harmful to the fetus if the virus crossed the placenta (Fiore et al., 2007).

Ask also about any allergies, including any drug sensitivities. Although not well proven, encouraging women with allergies of any magnitude to breastfeed rather than bottle-feed may help avoid milk or protein allergy in their infants (Akobeng & Heller, 2007). Any past surgical procedures are also important to know about because adhesions resulting from past abdominal surgery such as appendicitis could interfere with uterine growth.

What if... Sandra Czerinski tells you she has no idea what childhood diseases or immunizations she has had. How would you suggest that she obtain this information?

History of Family Illnesses

A family history documents illnesses that occur frequently in the family and so can help identify potential problems in a woman during pregnancy or in her infant at birth. Ask specifically about cardiovascular and renal disease, cognitive impairment, blood disorders, or any known genetically inherited diseases or congenital anomalies (Dorigo, Martinez-Maza, & Berek, 2007).

Day History/Social Profile

Information about a woman's current nutrition, elimination, sleep, recreation, and interpersonal interactions can be elicited best by asking a woman to describe a typical day of her life. If any of this information is not reported spontaneously as she describes her day, ask for additional details.

Nutrition is an important part of a day history, particularly in light of the number of young adults with eating disorders today. A "24-hour recall" is helpful to obtain accurate nutrition information, because by doing this, a woman tells you what she actually ate, not what she should have eaten (Box 11.4).

Ask about the type, amount, and frequency of exercise to determine a woman's routine pattern and whether it will be consistent with a recommended level for pregnancy as this varies greatly among women (Chasan-Taber et al., 2007). If a woman hikes or camps, for example, this type of exercise is good for her but also can put her at risk for exposure to Lyme disease. Ask if she knows about precautions to prevent this (Chapter 43). Ask also about hobbies. Certain hobbies, such as working with lead-based glazes and ceramics, might not be wise to continue during pregnancy because lead is teratogenic.

BOX 11.4 ✻ Focus on Communication

Sandra Czerinski has come to her obstetrician's office for a first prenatal visit.

Less Effective Communication

Nurse: Tell me what a typical day is like for you.
Ms. Czerinski: I don't usually have typical ones. Or very interesting ones.
Nurse: What about yesterday? Could you describe that to me?
Ms. Czerinski: Okay. I was up at 7:00, was at work by 9:00. A friend picked me up after work and we celebrated his birthday. I was back home and in bed by 10:00. That's pretty much the day.
Nurse: You're right. It doesn't sound too interesting. Next, let me ask you about your family medical history.

More Effective Communication

Nurse: Tell me what a typical day is like for you.
Ms. Czerinski: I don't usually have typical ones. Or very interesting ones.
Nurse: What about yesterday? Could you describe that to me?
Ms. Czerinski: Okay. I was up at 7:00, was at work by 9:00. A friend picked me up after work and we celebrated his birthday. I was back home and in bed by 10:00. That's pretty much the day.
Nurse: What did you have for breakfast?
Ms. Czerinski: Nothing. I was too rushed to eat.
Nurse: Dinner?
Ms. Czerinski: We went to a bar to celebrate. Cheese blintzes, I think. And beer. A lot of beer.

Most people are not aware how much information can be revealed by a day history, so they give only a scant description of their day. Asking additional questions to make them elaborate on various parts often reveals poor nutrition, poor exercise, or risky pregnancy patterns.

As many as 12% of women of childbearing age either smoke cigarettes or are routinely exposed to passive smoke (Venugopalan et al., 2007). As many as 50% of woman drink alcohol (Donnelly et al., 2008). Because smoke, whether first-hand or second-hand, has been shown to be harmful to fetal growth, obtain information about a woman and her family's smoking habits. Excessive alcohol intake can not only lead to poor nutrition but can be directly responsible for fetal alcohol syndrome and preterm birth so also record the amount of alcohol a woman consumes (Pollard, 2007). If a woman answers vaguely about how much she smokes or drinks ("I drink socially" or "I only smoke occasionally"), determine exactly what she means by "socially" or "occasionally" so you can more accurately evaluate the frequency of these events.

Pregnant women, especially adolescents, are at an increased risk for intimate partner abuse (Barlow et al., 2007). Ask enough questions to be certain a woman is not involved in an abusive partnership by questions such as "Have you ever been hurt by someone?" or "Are you afraid of anyone?"

A medication history is also important to obtain. Ask whether a woman takes any medications, prescribed or over-the-counter, because their effect on a growing fetus will have to be evaluated. For example, isotretinoin (Accutane), a vitamin A preparation taken for acne, is associated with spontaneous miscarriage and congenital anomalies (Karch, 2009). Many women use herbal supplements to relieve the nausea of early pregnancy (Evans, 2007), so also ask about any herbal preparations that a woman might be using as even seemingly innocent alternative therapies such as these could be detrimental during pregnancy if they could stimulate uterine contractions or in any other way interfere with fetal health.

Be sure to include the use of recreational drugs, such as marijuana or cocaine, as these also can be deleterious to fetal growth (Pollard, 2007). Include intravenous drug use because of the increased risk for exposure to HIV or hepatitis B that this causes. Although this type of information is not usually readily revealed, most women will answer these questions honestly during pregnancy because they are concerned about protecting the health of their fetus.

Gynecologic History

In the past, most women had children early in their childbearing years, so the number of reproductive tract or women's health problems, such as breast disease, that they had experienced before pregnancy were few. Today, however, women often delay conception of their first child past 30 years of age. That makes it not unusual today to discover a woman who has had a reproductive tract or breast problem. Table 11.1 lists common gynecologic illnesses and their possible significance in pregnancy.

A woman's past experience with her reproductive system may have some influence on how well she accepts a pregnancy so obtain information about her age of menarche (first menstrual period) and how well she was prepared for it as a normal part of life. Ask about her usual cycle, including the interval, duration, amount of menstrual flow, and any discomfort she feels. Ascertain if she has discomfort with periods, including when the discomfort occurs, how long it lasts, and what she does to relieve it. If she describes menstrual cramps as "horrible" and wonders "how I live through them some months," anticipate the need for additional counseling to help her prepare for labor. Some women with severe dysmenorrhea are looking forward to pregnancy as it will mean 9 months without discomfort. Anticipate their need for counseling in the postpartum period about active ways to relieve their menstrual discomfort when their periods resume (see Chapter 47). Also ask if a woman does a monthly perineal self-examination to inspect for lesions or ulcers. Breast self-examination is no longer thought to yield sufficient reliable information to be continued as a self-care routine (Kosters & Gotzsche, 2009), but women should be alerted to continue health care provider exams and begin to have mammograms when they reach 40 years of age (Ruhl, 2007).

Ask about past surgery on the reproductive tract. For example, if a woman has had tubal surgery following an ectopic pregnancy, her statistical risk of another tubal pregnancy is increased because of the tubal scarring present. If she has had uterine surgery, a cesarean birth may be necessary because her uterus may not be able to expand and contract as efficiently as usual because of the surgical scar. If she has undergone frequent dilatation and curettage of the uterus, her cervix may be weakened or unable to remain closed for 9 months. This could lead to premature birth unless she has a surgical procedure (cerclage) for this (see Chapter 21).

Ask also about what reproductive planning methods, if any, have been used. Occasionally, a woman may become pregnant with an intrauterine device (IUD) in place. If this occurs, it will be removed to prevent infection during pregnancy. Another woman, not realizing she is pregnant, may continue to take an oral contraceptive for some time into her pregnancy. Document whether such use occurred, because some evidence suggests that estrogen can harm fetal growth. Be certain to include a sexual history, including the number of sexual partners and use of safer sex practices, to establish a woman's risk for contracting a sexually transmitted infection during pregnancy.

As part of any woman's gynecologic history, assess for the possibility of stress incontinence (incontinence of urine on laughing, coughing, deep inspiration, jogging, or running). With these actions, the diaphragm descends, increasing abdominal pressure, which increases bladder tension and causes emptying. Stress incontinence occurs from lack of strength in the perineal muscles and bladder supports. Commonly, this weakness has occurred from difficult births, the birth of large infants, grand multiparity, and instrumented births. During pregnancy, stress incontinence can become intensified from the increasing abdominal pressure. Some women accept this incontinence as a normal consequence of childbearing and may not report it unless asked.

Women can relieve stress incontinence to some degree by strengthening the perineal muscles with the use of Kegel exercises (periodic tightening of the perineal muscles; see Chapter 12). Surgical correction to increase support to the bladder neck also could be performed following the pregnancy.

Obstetric History

Do not assume that the current pregnancy is a woman's first pregnancy simply because she is very young or says she has only recently been married. She may have had an adolescent pregnancy or this could be a second marriage. For each previous pregnancy, document the child's sex and the place and date of birth. Review the pregnancy briefly for:

- Was it planned?
- Did she have any complications, such as vaginal spotting, swelling of her hands or feet, falls, or surgery?
- Did she take any medication? If so, what and why?
- Did she receive prenatal care? If so, when did she start?
- What was the duration of the pregnancy?
- What was the duration of labor?
- Was labor what she expected? Worse? Better?
- What was the type of birth? Vaginal or cesarean? Vertex or breech? In a hospital or at home?
- What type of anesthesia, if any, was used?
- Did she have perineal stitches following birth?
- Did she have any complications, such as excessive bleeding or infection following the birth?
- What was the infant's birth weight and sex?
- What was the condition of the infant at birth? Did the infant cry right away?
- What was the infant's Apgar score? (Most mothers know this.)
- Was any special care needed for the baby, such as suctioning, oxygen, or an incubator?

TABLE 11.1 ✻ Common Gynecologic Disorders

Disorder	Possible Symptoms	Significance and Suggested Therapy
Vulva		
Cysts of Skene or Bartholin glands	Asymptomatic swelling at the sides of the urinary meatus or vestibule	Such cysts are surgically incised to prevent blockage of gland duct.
Condylomata acuminata	Cauliflower-like lesion on vulva	This lesion tends to occur in women with chronic vaginitis. Caused by the epidermatrophic virus that causes common warts. Removed by cryocautery or knife excision.
Lichen sclerosus	Whitish papules on the vulva; asymptomatic	There is no need for removal; the area is biopsied because leukoplakia, a potentially cancerous condition, has an almost identical appearance.
Leukoplakia	Thick, gray, patchy epithelium that cracks; possibly a premalignant state that infects easily, accompanied by itching and pain	Therapy involves hydrocortisone and frequent return visits to health care personnel (every 6 months) for observation to detect any changes suggestive of carcinoma.
Carcinoma of the vulva	A shallow vulvar ulcer that does not heal	Vulvar cancer occurs most often in postmenopausal women; represents only 3% to 4% of all reproductive tract cancers in women. Therapy is vulvectomy—vagina is left intact, and sexual relations and pregnancy, with cesarean birth to prevent tearing of fibrotic vulvar tissue, may be possible.
Vagina and Cervix		
Adenosis	Asymptomatic vaginal cysts with columnar rather than squamous epithelium present on vaginal walls	This condition is caused by diethylstilbestrol (DES) administration while in utero. Has the potential for becoming malignant (clear cell adenocarcinoma). If adenosis is present, an examination two or three times a year with a Pap test and Lugol's staining is necessary, and a woman should not use estrogen sources such as oral contraceptives. If adenocarcinoma occurs, local destruction of atypical cells can be achieved by excision, cautery, or cryosurgery. This condition is rarely seen today because DES is no longer prescribed during pregnancy.
Cervical polyp	Red, vascular, protruding pedunculated tissue that bleeds readily with trauma	A polyp may be discovered because of vaginal spotting on coitus, tampon insertion, or vaginal examination. Removed vaginally by excision. Often associated with chronic cervical inflammation.
Cervicitis (erosion)	Reddened cervical tissue with whitish exudate	Douching with a vinegar solution aids healing. May be treated with cryosurgery if extensive.
Nabothian cyst	Clear shining circles on cervix from blocked gland ducts	No therapy is necessary.
Cervical carcinoma	Postcoital spotting, unexplained vaginal discharge or spotting between menstrual periods	Cervical cancer is the most frequent type of reproductive tract malignancy; risk factors include coitus with multiple partners or uncircumcised males, herpes simplex 2 infections, or DES use during pregnancy. Diagnosed by Pap test or colposcopy. Therapy is conization, radiation, or surgical excision. Pregnancy is possible following cervical carcinoma; cesarean birth may be necessary because of fibrotic cervical tissue. Can be prevented by HPV vaccine.
Ovaries		
Endometrial cyst	Chocolate-brown cyst on tender enlarged ovary; may cause acute pain if rupture occurs	Endometriosis is the cause; occurs in women aged 20 to 40 years. Therapy is surgical excision; ovary may or may not be removed depending on extent of cyst.
Follicular cyst	Amenorrhea and possibly dyspareunia; ovary tender and enlarged	Cysts typically regress after 1 or 2 months; low-dose oral contraceptive may be prescribed for 6 to 12 weeks to suppress ovarian activity; estrogen may be continued for 6 months.

(continued)

TABLE 11.1 ✻ Common Gynecologic Disorders (continued)

Disorder	Possible Symptoms	Significance and Suggested Therapy
Polycystic ovary syndrome	A syndrome of chronic follicular cysts, anovulation, insulin resistance, and excess testosterone production leading to perimenopausal onset of hirsutism, obesity, subfertility, and elevated triglycerides.	Excess testosterone by ovaries leads to inhibition of FSH and anovulation. Weight loss, reduction in triglycerides and cholesterol, and clomiphene citrate therapy to induce ovulation are used as therapy.
Corpus luteum cyst	Delayed menstrual flow followed by prolonged bleeding; ovary enlarged and tender	A corpus luteum persists rather than atrophies. Most regress in about 2 months; a low-dose oral contraceptive may be prescribed for 6 weeks to suppress ovarian activity.
Dermoid cyst	Asymptomatic; ovary enlarged on examination	Cyst originates from embryonic tissue; may contain hair, cartilage, and fat. Most common ovarian tumor of childhood; also occurs at 30 to 50 years. Therapy is surgical resection.
Serous cystadenoma	Bilateral; asymptomatic except for signs of pelvic pressure	This is the most common type of ovarian cyst; high malignancy rate of 20% to 30%. Therapy is surgical resection.
Carcinoma	Asymptomatic; intermenstrual bleeding	Ovarian cancer originates in epithelial tissue most often in women over 50 years of age. Tendency can be inherited; environmental contamination such as use of talcum powder may play a role in development. Therapy is hysterectomy and salpingo-oophorectomy.
Uterus		
Endometrial polyp	Intermenstrual bleeding	Polyp is removed by dilatation and curettage.
Leiomyomas (fibroids)	Asymptomatic or with increased menstrual flow	Muscle and fibrous connective tissue form in response to estrogen stimulation. May increase in size during pregnancy; may cause interference with cervical dilatation and result in postpartal hemorrhage. Stress to the myometrium by uterine contractions may be the original cause of formation. Therapy is surgical resection (myomectomy) or hysterectomy if childbearing is complete.
Endometrial carcinoma	Vaginal bleeding between menstrual periods	Diagnosis is by endometrial washing, not Pap test. Therapy is hysterectomy.
Uterine prolapse	Vaginal pressure and low back pain	The uterus has descended into the vagina because of overstretching of uterine supports and trauma to the levator ani muscle. Occurs most often in women who had insufficient prenatal care, birth of a large infant, a prolonged second stage of labor, bearing-down efforts or extraction of a baby before full dilatation, instrument birth, and poor healing of perineal tissue postpartally. Therapy is surgery to repair uterine supports or placement of a pessary, a plastic uterine support. Women with pessaries in place need to return for a pelvic examination every 3 months to have the pessary removed, cleaned, and replaced and the vagina inspected; otherwise, vaginal infection or erosion of the vaginal walls can result.

- Was the baby discharged from the health care setting with her?
- What is the child's present state of health?
- How was the pregnancy overall for her?

Ask about any previous miscarriages or therapeutic abortions and whether she had any complications during or following these. If a woman's blood type is Rh negative, ask if she received Rh immune globulin (RhIG [RhoGAM]) after miscarriages or abortions or previous births so you will know whether Rh sensitization could have occurred. Ask if she has ever had a blood transfusion to establish possible risk of hepatitis B or HIV exposure or Rh sensitization from a blood transfusion.

After a history of previous pregnancies is obtained, determine a woman's status with respect to the number of times

TABLE 11.2 ✻ Terms Related to Pregnancy Status

Term	Definition
Para	Number of pregnancies that have reached viability, regardless of whether the infants were born alive
Gravida	Woman who is or has been pregnant
Primigravida	Woman who is pregnant for the first time
Primipara	Woman who has given birth to one child past age of viability
Multigravida	Woman who has been pregnant previously
Multipara	Woman who has carried two or more pregnancies to viability
Nulligravida	Woman who has never been and is not currently pregnant

she has been pregnant, including the present pregnancy (*gravida*), and the number of children above the age of viability she has previously borne (*para*). Table 11.2 explains these terms. For example, a woman who has had two previous pregnancies, has given birth to two term children, and is again pregnant is gravida 3, para 2. A woman who has had two miscarriages at 12 weeks (under the age of viability) and is again pregnant is a gravida 3, para 0.

A more comprehensive system for classifying pregnancy status (GTPAL or GTPALM) provides greater detail on a woman's pregnancy history. By this system, the gravida classification remains the same, but para classification is broken down into:

T: Number of full-term infants born (infants born at 37 weeks or after)
P: Number of preterm infants born (infants born before 37 weeks)
A: Number of spontaneous miscarriages or therapeutic abortions
L: Number of living children
M: Multiple pregnancies

Using this system, a woman in the first example above would be gravida 3, para 2002 (GTPAL) or 320020 (GTPALM). A multigestation pregnancy is considered as one para. For example, a woman who had term twins, then one preterm infant, and is now pregnant again would be a gravida 3, para 21031 (GTPALM).

A pregnant woman who had the following past history—a boy born at 39 weeks' gestation, now alive and well; a girl born at 40 weeks' gestation, now alive and well; a girl born at 33 weeks' gestation, now alive and well—would have her pregnancy information summarized as follows: gravida 4; para 21030 (GTPALM).

Review of Systems

A review of systems completes the subjective information. Use a systematic approach, such as head to toe, and explain what you will be doing by an explanation such as, "I'm going to start at the top of your head and go through to your toes, asking about body parts or systems and any diseases that you may have had." A review of systems helps women recall concerns they forgot to mention earlier, such as a urinary tract infection, a disease that can influence the outcome of pregnancy and so would be important to your history taking.

The following body systems and questions about conditions constitute the minimum information to be addressed in a review of systems for a first prenatal visit:

- *Head:* Headache? Head injury? Seizures? Dizziness? Fainting?
- *Eyes:* Vision? Glasses needed? Diplopia or double vision? Infection? Glaucoma? Cataract? Pain? Recent changes?
- *Ears:* Infection? Discharge? Earache? Hearing loss? Tinnitus? Vertigo?
- *Nose:* Epistaxis (nose bleeds)? Discharge? How many colds a year? Allergies? Postnasal drainage? Sinus pain?
- *Mouth and pharynx:* Dentures? Condition of teeth? Toothaches? Any bleeding of gums? Hoarseness? Difficulty in swallowing? Tonsillectomy? Last dental exam?
- *Neck:* Stiffness? Masses?
- *Breasts:* Lumps? Secretion? Pain? Tenderness?
- *Respiratory system:* Cough? Wheezing? Asthma? Shortness of breath? Pain? Serious chest illness, such as tuberculosis or pneumonia?
- *Cardiovascular system:* History of heart murmur? History of heart disease such as rheumatic fever or Kawasaki disease? Hypertension? Any pain? Palpitations? Anemia? Does she know her blood pressure? Has she ever had a blood transfusion?
- *Gastrointestinal system:* What was her prepregnancy weight? Vomiting? Diarrhea? Constipation? Change in bowel habits? Rectal pruritus? Hemorrhoids? Pain? Ulcer? Gallbladder disease? Hepatitis? Appendicitis?
- *Genitourinary system:* Urinary tract infection? Hematuria? Frequent urination? Sexually transmitted infection? Pelvic inflammatory disease? Hepatitis B? HIV? Was subfertility a concern? Did she have a problem getting pregnant?
- *Extremities:* Varicose veins? Pain or stiffness of joints? Any fractures or dislocations?
- *Skin:* Any rashes? Acne? Psoriasis?

Conclusion

End an interview by asking if there is something you have not covered that a woman wants to discuss. This gives her one more chance to ask any questions she has about this new life experience.

Support Person's Role

Both partners and young children accompany women for prenatal care. Some women bring a female friend or their mother as their best support person. If family members are present, should they be included in an initial interview? As a whole, interviewing is most effective if it is a one-to-one interaction. A woman may be unwilling to mention certain concerns when her family is present for fear of worrying them. A husband may not be the father of her child, for example, and she would be unable to voice

BOX 11.5 ✻ Focus on Family Teaching

Suggestions for Encouraging Partner Participation in Prenatal Visits

Q. Sandra Czerinski asks you, "What can I do to make sure that my boyfriend feels involved with prenatal care?"

A. Here are some suggestions for encouraging your partner's participation:

- Ask for appointments to be scheduled at a time that is convenient for both of you.
- Be certain that your partner reserves enough time so the visit does not become more of an inconvenience than an enjoyable event. A prenatal visit can be lengthy.
- Ask your partner to accompany you into the examining room at visits so you can share progress or decisions.
- Be certain that your partner listens to the fetal heart at visits as soon as it can be heard.
- If an ultrasound is scheduled, ask your partner to view it with you (it is an exciting moment for both of you to see your fetus moving).

her concern over this or alert you to the possibility she is worried about blood incompatibility because another man is the father.

If childbearing is to be a family affair, however, it is important to determine a partner's degree of acceptance of the pregnancy and of assuming a new parenting role. Including siblings in a prenatal visit provides them with an opportunity to involve them with the pregnancy planning and coming baby from the very beginning. Interviewing a woman alone and then inviting the support person and family to join her while you talk about pregnancy symptoms with them as a family is an effective solution. In addition, providing some private interview time with a partner allows the partner to express any concerns or worries. The main areas you should investigate with a partner include current health, feelings and concerns about the pregnancy, and knowledge of pregnancy and childbirth. If a woman wishes, a partner can accompany her during the physical examination. After confirmation of pregnancy, a partner should be included when health care information is given (Box 11.5).

✔ Checkpoint Question 11.2

Why is it important to ask Sandra about past surgery in a pregnancy health history?

a. To test both her recent and long-term memory.
b. Adhesions from surgery could limit uterine growth.
c. To assess whether she could be allergic to any medication.
d. To determine if she has effective health insurance.

Physical Examination

The next step in health assessment is a physical examination. Ask a woman to void for a clean-catch urine specimen before the examination as this can reduce bladder size and make the pelvic examination more comfortable and allow easier identification of pelvic organs, as well as providing a urine specimen for laboratory testing. The urine specimen is sent to the laboratory for evaluation of bacteria, protein, glucose, and ketones, or these can be immediately tested by dipstick analysis. If you are not already familiar with this, Box 11.6 provides instructions on how to obtain a clean-catch urine sample.

A physical examination at a first prenatal visit typically includes inspection of major body systems, with emphasis on the changes that occur with pregnancy or that could signal a developing problem. General techniques of physical examination are discussed in Chapter 34.

Baseline Height/Weight and Vital Sign Measurement

Measure a woman's weight and height at a first prenatal visit to establish a baseline for future comparison. Record this assessment with her prepregnancy weight, if available, to determine how much weight she has already gained or lost (Fig. 11.2). When weighing, be certain to convey an air of "weight gain is healthy" so a woman feels comfortable gaining 30 to 35 lb during pregnancy (many adolescents need to gain 40 lb to ensure a healthy fetus).

Measure vital signs, including blood pressure, respiratory rate, and pulse rate, as well for a baseline level. A sudden increase in blood pressure, the same as a sudden weight gain, is a danger sign of hypertension of pregnancy. A sudden increase in pulse or respirations can suggest bleeding. If close monitoring of vital signs will be necessary during pregnancy, a support person or a woman herself can be taught the techniques of taking and recording these so a woman can continue assessing these at home.

FIGURE 11.2 A woman weighs in at a prenatal visit. Pregnant women may need reassurance that gaining weight aids fetal growth. (© Barbara Proud.)

Box 11.6 Nursing Procedure ✻ Obtaining a clean-catch urine specimen

Purpose: Helping a woman obtain a clean-catch urine specimen

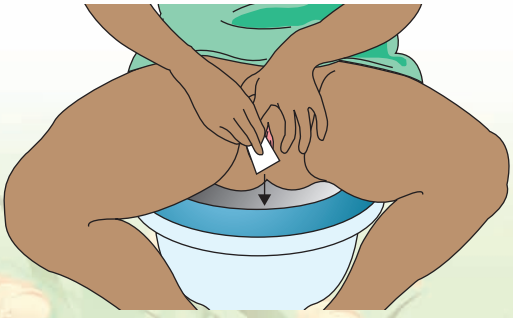
Procedure

1. Ask the woman to wash her hands.

2. Have the woman open the commercial clean-catch urine specimen kit and moisten the cotton balls with the antiseptic solution or open the prepared antiseptic wipes.

3. a. Ask the woman to sit on the commode and separate her labia with her nondominant hand.

b. Tell her to cleanse the perineum, washing from front to back, using a cotton ball or wipe for only one stroke, then discard it.



Principle

1. Handwashing helps prevent the spread of microorganisms.

2. Preparation enhances efficiency and decreases the possibility of contamination during the procedure.

3. Cleansing helps prevent microorganisms from entering the urine specimen. Cleansing from front to back prevents bringing rectal contamination forward and prevents transmission of microorganisms.

Box 11.6 Nursing Procedure ✻ Obtaining a clean-catch urine specimen (continued)

Procedure	Principle
4. Advise the woman to avoid touching the inside of the container or cap.	**4.** Careful handling of equipment prevents contamination.
5. Ask her to begin urinating, allowing the first urine to flow into the toilet. Then tell her to hold the container under the urine stream to obtain the specimen, removing the container after approximately 10 to 20 mL has been obtained. Once obtained, advise the client to remove the container, release her hand from her labia, and finish voiding into the toilet.	**5.** The first flow of urine washes microorganisms and debris from the urinary meatus. Collecting the specimen midstream helps ensure that a sterile specimen is obtained.
	
6. Tell the woman to cap the specimen container, wash her hands, and bring it to you. Encourage her to report any pain on urination.	**6.** Capping the container prevents inadvertent spilling and possible contamination of the specimen. Pain on urination is a symptom of urinary tract infection.

Assessment of Systems

General Appearance and Mental Status. Physical examination always begins with an inspection of general appearance to form an overall impression of a woman's health and well-being. General appearance is important because the manner in which people dress, the way they speak, and the body posture they assume all suggest how they feel about themselves. Not all women are happy about being pregnant. Closely inspect for signs such as careless hygiene, unwashed hair, inappropriate or soiled clothing, and sad facial expression that may suggest fatigue or depression about their diagnosis.

If a woman has any bandages or other dressings in place, be sure to remove and replace them because they could hide an important finding such as a malignant melanoma or skin cancer, which are increasing problems in young adults because of excessive sun exposure (Edwards, 2007).

A second increasing problem that bandages could be concealing and one receiving increased recognition is intimate partner abuse, a condition that not only is dangerous to a woman but also may lead to early pregnancy loss (Records, 2007). Ask when and how any skin abnormality, such as an ecchymotic area, occurred. Most marks from battering occur on the face, the ulnar surfaces of the forearms (from a woman raising her arms to defend herself), the abdomen or buttocks (from being kicked), or the upper arms (from being grabbed and held forcefully). Noting the color of ecchymotic spots helps to date when they occurred. Such marks typically progress through purple to yellow changes as they age.

Head and Scalp. Examine a woman's head for symmetry, normal contour, and tenderness and the hair for presence, distribution, thickness, excessive dryness or oiliness, cleanliness, or the use of hair dye (hair dye may be carcinogenic over an extended period of time). Look for **chloasma** (extra pigment on the face that occurs from melanocyte-stimulating hormone), which may accompany pregnancy. Hair growth speeds up during pregnancy as a result of the overall increased metabolic rate, and women may comment they have noticed this. Dryness or sparseness of hair suggests poor nutrition. Lack of cleanliness may suggest fatigue, reflecting that a woman has not felt well enough to wash it recently. Urge women during pregnancy to let some other task go and save energy for self-care so they can continue to feel good about their appearance. Dandruff shampoos may be used during pregnancy because they are not absorbed.

Eyes. Edema of the eyelids combined with a swollen optic disk (identified on ophthalmoscopic examination) suggests edema from pregnancy-induced hypertension, a potentially dangerous condition in pregnancy. On interview, women

with pregnancy-induced hypertension also usually report spots before their eyes or diplopia (double vision). Teach pregnant women to recognize symptoms of changing vision as a potential danger sign of pregnancy that should be reported as soon as possible. If they do close desk work, caution them to take a break every hour so they do not confuse sensations of eyestrain with actual danger signs.

Nose. The increased level of estrogen associated with pregnancy may cause nasal congestion or the appearance of swollen nasal membranes. Even topical medicines such as nose drops or nasal sprays used to reduce this are absorbed to some degree. Advise a woman to avoid these during pregnancy without her physician's or nurse-midwife's knowledge and consent.

Ears. The nasal stuffiness that accompanies pregnancy may lead to blocked eustachian tubes and therefore a feeling of "fullness" in the ears or dampening of sound during early pregnancy. Usually this disappears as the body adjusts to the new estrogen level. Normal hearing level and normal tympanic landmarks should be present.

Sinuses. Sinuses should feel nontender. Establishing that tenderness over sinuses does not exist helps to evaluate that a woman's report of headache during pregnancy (a danger sign until ruled otherwise) is probably not sinus related.

Mouth, Teeth, and Throat. Gingival (gum) hypertrophy may result from estrogen stimulation during pregnancy. The gums become slightly swollen and tender to the touch, but not reddened. Pregnant women are prone to vitamin deficiency because of the rapid growth of the fetus. Assess carefully for cracked corners of the mouth, which would reveal vitamin A deficiency. Assess carefully for pinpoint lesions with an erythematous base on the lips; these suggest a herpes infection (a herpes lesion on the gumline is more often a shallow ulcer). Because newborns are susceptible to herpes infection, lesions present at birth may necessitate limiting a woman's contact with her newborn.

Teach all women not to neglect good dental hygiene or yearly dental visits while pregnant. They should maintain thorough toothbrushing (some stop thorough brushing because they notice slightly blood-tinged saliva because of gingival hypertrophy).

If many dental caries are obvious, a woman should be referred to a dentist or dental clinic. Carious teeth are a source of infection and should be treated before abscesses develop and cause more serious problems. Contrary to what many women believe, dental radiographs can be taken during pregnancy as long as a woman reminds her dentist she is pregnant and is given a lead apron to shield her abdomen. Urge her to obtain permission from her primary care provider before consenting to extensive dental work requiring anesthesia.

Neck. Slight thyroid hypertrophy may occur with pregnancy because the overall metabolic rate is increased. Suggest that all women eat a serving of seafood at least once weekly to supply enough iodine for the accompanying increased thyroxine production (eating fish more often than 3 times a week is contraindicated, however, because of potentially high mercury content) (Sunderland, 2007). Encourage a woman who uses iodized salt to continue using this during pregnancy. Without this precaution, some women will view iodine as an unnecessary additive and discontinue using it.

Lymph Nodes. No palpable lymph nodes should be present; however, because pregnant women may develop an increased number of upper respiratory infections because of reduced immunologic resistance, one or two pea-sized cervical lymph nodes may be palpable. If a woman has a tooth abscess from bacterial growth under hypertrophied gingival tissue (periodontal disease), submaxillary lymph nodes will be palpable.

Breasts. Breast changes may be one of the first things women notice in pregnancy:

- Areolae darken.
- Secondary areolae develop.
- Montgomery tubercles (sebaceous glands in the areolae) become prominent.
- Overall breast size increases.
- Breast consistency firms.
- Blue streaking of veins becomes prominent.
- Colostrum may be expelled as early as the 16th week of pregnancy.
- Any supernumerary nipple also may become darker and enlarge in size.

Benign breast lesions that might be discovered on physical examination are discussed in Chapter 47.

Heart. Heart rate typically ranges from 70 to 80 beats per minute in pregnant women, and no accessory sounds or murmurs should be present. Occasionally, a woman may develop an innocent (functional) heart murmur during pregnancy because of her increased vascular volume. If this occurs, she needs further evaluation to ensure that it is only a physiologic change of pregnancy and not a previously undetected heart condition. Many women notice occasional palpitations (heart skipping a beat) during pregnancy, especially when lying supine. Teach pregnant women always to rest or sleep on their side (left side is best) to help avoid this problem.

Lungs. Assess respiratory rate and rhythm. Although lung tissue assumes a more horizontal position during pregnancy, vital capacity is not reduced. Late in pregnancy, diaphragmatic excursion (diaphragm movement) is lessened because the diaphragm cannot descend as fully as usual because of the distended uterus. This causes women to feel short of breath.

Back. The lumbar curve in many pregnant women is accentuated on standing so that they can maintain body posture in the face of increasing abdominal size. This response can cause considerable back pain during pregnancy. Assess a woman's spine for any abnormal curve that would suggest scoliosis. Young women with scoliosis may need a referral to their orthopedist during pregnancy to be certain that the extra abdominal pressure is not worsening the scoliosis.

Rectum. Assess the rectum closely for hemorrhoidal tissue, which commonly occurs from uterine pressure on pelvic

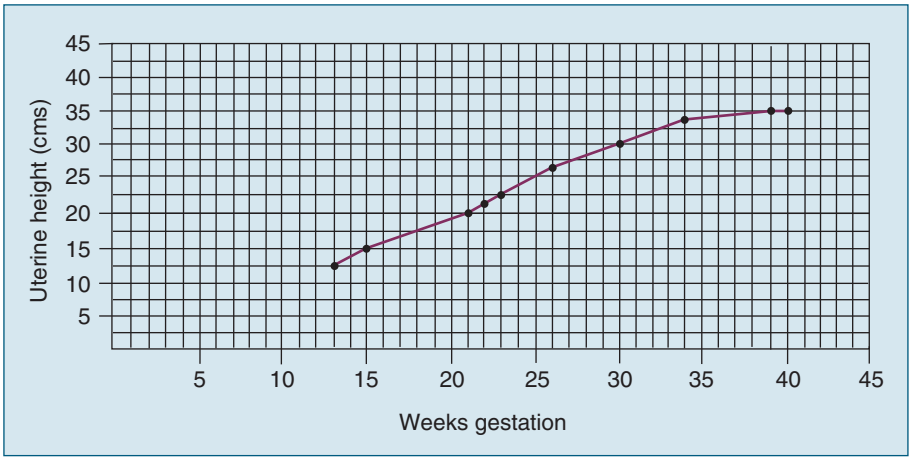


FIGURE 11.3 Plotting uterine height on a uterine height graph at prenatal visits (typically after 12 weeks' gestation) helps to monitor whether fundal height is increasing.

veins. Hemorrhoids can be very uncomfortable for women and worrisome if they are not assured that hemorrhoids are a normal discomfort of pregnancy and will fade afterward.

Extremities and Skin. Many women develop palmar erythema or itching early in pregnancy from a high estrogen level and perhaps subclinical jaundice (jaundice that is not yet apparent by a color change) from reabsorbed bilirubin because of slowed intestinal peristalsis. Assess the lower extremities carefully for varicosities, filling time of the toenails (which should be under 5 seconds), and the presence of edema caused by impaired venous return from the lower extremities. Any edema more than ankle swelling may be a danger sign of pregnancy.

Assess the gait of pregnant women to see that they are keeping their pelvis tucked under the weight of their abdomen. This position prevents them from developing muscle strains from abnormal abdominal muscle tension. Many pregnant women develop a "waddling" gait late in pregnancy from relaxation of the symphysis pubis. This relaxation may cause pain if the cartilage at the joint becomes so unstable that it moves on walking.

Measurement of Fundal Height and Fetal Heart Sounds

At about 12 to 14 weeks of pregnancy, the uterus becomes palpable as a firm globular sphere over the symphysis pubis. It reaches the umbilicus at 20 to 22 weeks and the xiphoid process at 36 weeks, and then often returns to about 4 cm below the xiphoid because of "lightening" at 40 weeks. If a woman is past 12 weeks of a pregnancy, palpate the fundus location, measure the fundal height (from the notch above the symphysis pubis to the superior aspect of the uterine fundus), and plot the height on a graph such as the one shown in Figure 11.3. Plotting uterine growth at each visit this way can help detect any unusual variation in fetal growth. If an abnormality is detected, further investigation with ultrasound can be done to determine the cause of the unusual increase or decrease in growth.

Auscultate for fetal heart sounds (120 to 160 beats per minute). These can be heard at 10 to 12 weeks if a Doppler technique is used but not until 18 to 20 weeks if a regular stethoscope is used. Palpate for fetal outline and position after the 28th week as a further estimation of fetal size and growth.

✔ Checkpoint Question 11.3

Sandra reports that the palms of her hands are always itchy. You notice scratches on them when you do a physical examination. What is the most likely cause of this finding during pregnancy?

a. She must be unduly anxious about her pregnancy.
b. She has an allergy to her fetus and will probably abort.
c. Her weight gain has stretched the skin over her hands.
d. This is a common reaction to increasing estrogen levels.

Pelvic Examination and Estimating Pelvic Size

The pelvis is a bony ring formed by four united bones: the two innominate (flaring hip) bones, which form the anterior and lateral portion of the ring, and the coccyx and sacrum, which form the posterior aspect (Fig. 11.4). It serves both to support and protect the pelvic organs.

Each innominate bone is divided into three parts: *ilium, ischium,* and *pubis*. The ilium forms the upper and lateral portion. The flaring superior border forms the prominence of the hip (the crest of the ilium). The ischium is the inferior portion. At the lowest portion of the ischium are two projections: the ischial tuberosities or the part of the bone on which a person sits. These projections are important markers used to determine lower pelvic width. The ischial spines are small projections that extend from the lateral aspects of the pelvis into the pelvic cavity. The level of the ischial spines marks the midplane or midpoint of the pelvis. This marker is used to assess the level to which the fetus has descended into the birth canal during labor.

The pubis is the anterior portion of the innominate bone. The symphysis pubis is the junction of the innominate bones at the front of the pelvis. The sacrum forms the upper posterior portion of the pelvic ring. There is a marked anterior projection of this bone at the point where it touches the lower lumbar vertebrae (the sacral prominence). This is a landmark to identify when securing pelvic measurements.

The coccyx, just below the sacrum, is composed of five very small bones fused together. Although it is stiff, there is a

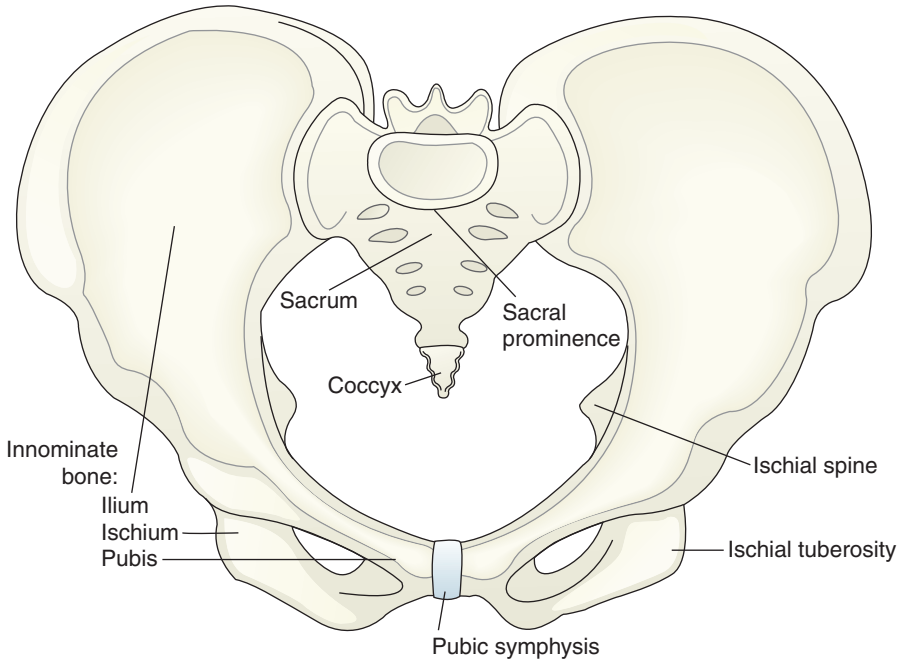

FIGURE 11.4 Structure of the pelvis.

degree of movement possible in the joint between the sacrum and the coccyx (the sacrococcygeal joint). This movement is important because it permits the coccyx to be pressed backward, allowing more room for the fetal head as it passes through the bony pelvic ring at birth.

For obstetric purposes, the pelvis is further divided into the false pelvis (the superior half) and the true pelvis (the inferior half) (Fig. 11.5). The false pelvis supports the uterus during the late months of pregnancy and aids in directing the fetus into the true pelvis for birth. The false pelvis is divided from the true pelvis only by an imaginary line, the linea terminalis. This imaginary line is drawn from the sacral prominence at the back of the pelvis to the superior aspect of the symphysis pubis at the front of the pelvis. The area above the line is the false pelvis and that below it is the true pelvis.

Other important terms in relation to the pelvis are the inlet, the pelvic cavity, and the outlet. The inlet is the entrance to the true pelvis, or the upper ring of bone through which the fetus must pass to be born vaginally. It is at the level of the linea terminalis or is marked by the sacral prominence in the back, the ilium on the sides, and the superior aspect of the symphysis pubis in the front. If you looked down at the pelvic inlet, the passageway would appear heart shaped because of the jutting sacral prominence. It is wider transversely (sideways) than in the anteroposterior dimension.

The outlet is the inferior portion of the pelvis, or that portion bounded in the back by the coccyx, on the sides by the ischial tuberosities, and in the front by the inferior aspect of the symphysis pubis. In contrast to the inlet of the pelvis, the greatest diameter of the outlet is its anteroposterior diameter.

The pelvic cavity is the space between the inlet and the outlet. This space is not a straight but a curved passage that slows and controls the speed of birth and therefore reduces sudden pressure changes in the fetal head, helping prevent ruptured cerebral arteries. The snugness of the cavity compresses the chest of the fetus as he or she passes through, helping to expel lung fluid and mucus and thereby better prepare the lungs for good aeration at birth.

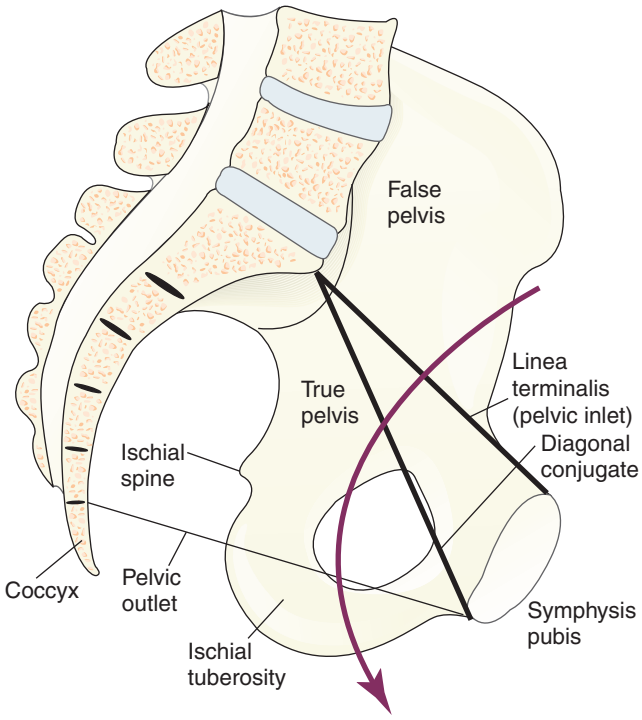

FIGURE 11.5 True and false pelvis. Portion above linea terminalis is false pelvis; portion below is true pelvis. *Arrow* shows "stovepipe" curve that the fetus must follow to be born.

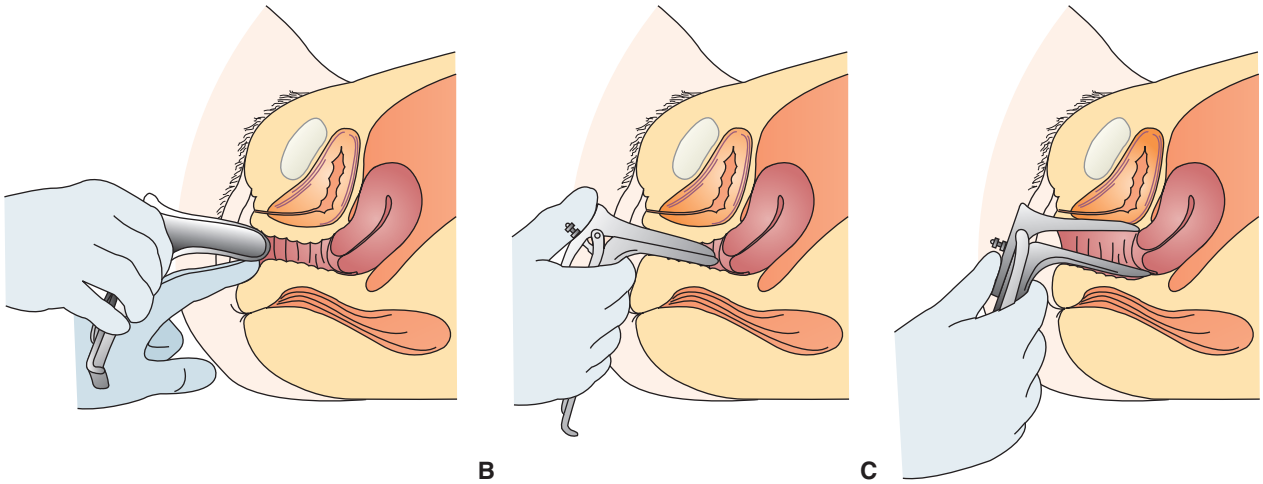

FIGURE 11.6 Insertion of a vaginal speculum. (**A**) Blades held obliquely on entering the vagina. (**B**) Blades rotated to horizontal position as they pass the introitus. (**C**) Blades separated by depressing thumbpiece and elevating handle. The position of the blades is maintained by adjusting a thumbscrew.

For a baby to be born vaginally, he or she must be able to pass through the inlet, the cavity, and the outlet of the pelvic bone. This is not a problem for the average fetus; it may be a problem if the mother is a young adolescent girl who has not yet achieved full pelvic growth (girls younger than 14 years are most prone to this difficulty) or a woman who has had a pelvic injury (e.g., from an automobile accident).

Pelvic Examination. A pelvic examination reveals information on the health of both internal and external reproductive organs. Equipment required is a **speculum** (a metal or plastic instrument with movable flat blades; Fig. 11.6), a spatula for cervical scraping, a clean examining glove, lubricant, a glass slide or liquid collection device for the Pap smear, a culture tube, two or three sterile cotton-tipped applicators or cytobrushes for obtaining cervical cultures, a good examining light, and a stool at correct sitting height.

Pelvic examinations have the reputation of being painful and causing a loss of modesty. If this is a first pregnancy, it may be the first time a woman has ever had this type of examination. Having heard stories about how painful these examinations are may cause her to tense just thinking about it. When pelvic muscles are tight and tense, however, not only does the examination become painful but also an examiner has difficulty assessing the status of pelvic organs.

Allow a woman the opportunity to talk with the person performing the examination while sitting up, before being placed in a **lithotomy position** (on her back with her thighs flexed and her feet resting in the examining table stirrups) (Fig. 11.7) as this can enhance her sense of self-esteem and control if she meets her examiner first while upright rather than in a lithotomy position. Many women want their support person to remain with them at the head of the table during the examination. In addition, it is customary, especially on an initial visit, for a nurse or a nursing assistant to be in the room with a woman for a pelvic examination to offer additional support. This is true whether the examiner is male or female.

Before a pelvic examination, ask a woman to void to reduce her bladder size and then lie in a lithotomy position (see Fig. 11.7). Make sure her buttocks extend slightly beyond the end of the examining table. Place a pillow under her head to help her relax her abdominal muscles.

Properly drape her with a draw sheet over her abdomen that extends over her legs. Be sure pregnant women remain in a lithotomy position for as short a time as possible to help prevent thromboembolism and supine hypotension syndrome or a sudden drop in blood pressure (Rojas, Wood, & Blakemore, 2007).

Recognizing what are the steps included in a pelvic examination helps you to be able to assist with the procedure. When serving as a support person, remember to remain at the head of the table so you can hold a woman's hand or put a hand on her shoulder if she needs the support of physical contact. Give explanations of what is happening or what the examiner is doing as needed. Conversation with the examiner over her head is not helpful. Suggesting that a woman breathe in and out (not hold her breath as she is likely to do) is another technique to help her relax (holding her breath pushes the diaphragm down and makes the pelvic organs tense and unyielding).

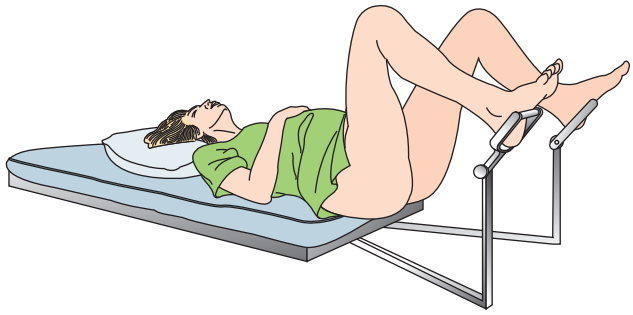

FIGURE 11.7 A lithotomy position used for a pelvic examination. Help position a woman with her buttocks just over the edge of the table. Drape appropriately for modesty.

If desired, a woman may watch the pelvic examination with an overhead mirror or a mirror held by herself or the examiner. Seeing vaginal cervical pathology can help her to understand any kind of problem present and the interventions necessary to improve it. If not already doing so, sexually active women should be taught how to do a monthly perineal examination (holding a mirror) so they can detect perineal lesions such as herpes simplex 2 viral infections so observing their perineum during a pelvic examination is good practice for this.

What if. . . The foot of an examining table in a clinic faces the room door, leaving women to feel exposed if someone should walk in unexpectedly? This saves an examiner steps, but is this the best position for the table?

External Genitalia. A pelvic examination begins with inspection of the external genitalia. Any signs of inflammation, irritation, or infection, such as redness, ulcerations, or vaginal discharge, are noted.

A herpes simplex 2 virus infection appears as clustered, pinpoint vesicles on an erythematous (reddened) base on the vulva. These feel painful when touched or irritated. It is important to detect these during pregnancy as the presence of herpes lesions on the vulva or vagina at the time of birth may necessitate cesarean birth to prevent exposing the fetus to the virus during passage through the birth canal. Note in the record the presence of a herpes infection so a woman receives future follow-up care with cytologic (Pap) smears as there is an association between herpes simplex 2 infections and the development of cervical cancer (American College of Obstetricians and Gynecologists [ACOG], 2007).

Next, the Skene glands that empty into the urethra and the Bartholin glands that empty into the distal vagina are palpated between the vaginal finger and the thumb of the same hand. If a discharge is produced from any of these gland ducts (Skene or Bartholin), a culture is obtained. Infection here could be caused by something as simple as streptococci; often it is gonorrhea.

Problems with vaginal muscle wall support, such as a rectocele (a forward pouching of the rectum into the posterior vaginal wall because of loss of posterior vaginal muscular support) or a cystocele (a pouching of the bladder into the anterior vaginal wall, caused by loss of anterior vaginal muscular support), are also evaluated. To reveal these, while the labia are gently separated to allow a view of the vaginal walls, a woman is asked to bear down as if she were moving her bowels.

Internal Genitalia. To view the cervix, the vagina must be opened with a speculum. When helping prepare for an examination, do not apply any lubricant other than warm water on speculum blades because even a water-soluble lubricant might interfere with the interpretation of the Pap smear that will be taken. Use warm water rather than cold water to warm the blades so a woman does not contract her vaginal muscles when she feels the cold instrument.

A speculum is introduced with the blades in a closed position and directed toward the posterior rather than the anterior vaginal wall because the posterior wall is less sensitive (see Fig. 11.6A). A speculum enters most readily if it is inserted at an oblique angle (the crease of the blades directed to a 4 or 8 o'clock position), then rotated to a horizontal position when fully inserted (the crease of the blades pointing to a 3 or 9 o'clock position) (see Fig. 11.6B). When fully inserted and rotated to a horizontal position, the blades are opened so the cervix is visible and are secured in the open position by tightening the thumb screw at the side (see Fig. 11.6C).

With the speculum in place, the cervix can be inspected for position. Normally it is centered on the vagina; a retroverted uterus has a cervix positioned anteriorly, and an anteverted uterus has its cervix positioned posteriorly. The cervix color (a nonpregnant cervix is light pink; in pregnancy it changes to almost purple) and any lesions, ulcerations, discharge, or otherwise abnormal appearance are documented.

In a nulligravida (a woman who is not or never has been pregnant), the cervical os is round and small. In a woman who has had a previous pregnancy with a vaginal birth, the cervical os has much more of a slitlike appearance. If a woman had a cervical tear during a previous birth, the cervical os may appear as a transverse crease the width of the cervix or a typical starlike (stellate) formation (Fig. 11.8A3). If a cervical infection is present, a mucus discharge may be present. With infection, the epithelium of the cervical canal often enlarges and spreads onto the area surrounding the os, giving the cervix a reddened appearance (**erosion**). This area bleeds readily if it is touched (Fig. 11.8B3).

Trichomoniasis, a protozoal infection, generally causes signs of redness; a profuse, whitish, bubbly discharge; and petechial spots on the vaginal walls. Candidal (*Monilia*) infection typically presents with thick, white vaginal patches that may bleed if scraped away. A gonorrhea infection presents with a thick, greenish-yellow discharge and extreme inflammation. Chlamydia infection, in contrast, shows few symptoms except slight cervical redness.

Carcinoma of the cervix appears as an irregular, granular growth at the os. Cervical polyps (red, soft, pedunculated benign protrusions) also are occasionally seen at the os.

Pap Smear. A Pap smear is taken for early detection and diagnosis of precancerous and cancerous conditions of the uterine cervix, vulva, or vagina; the test also reveals inflammatory and infectious diseases (MacKay, 2009). Although only an endocervical smear (one from inside the cervix) may be taken to be plated for a Pap test in some centers, in others three

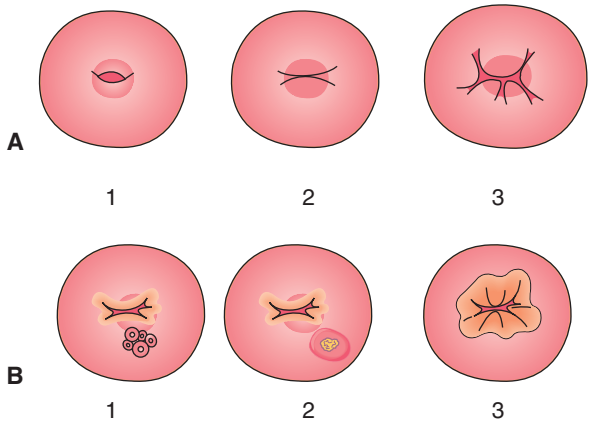

FIGURE 11.8 (**A**) Appearances of the cervix. (1) Nulligravida cervix. (2) Cervix after childbirth. (3) "Stellate" cervix seen after mild cervical tearing. (**B**) Possible cervical lesions. (1) Herpes simplex 2. (2) Chancre of syphilis. (3) Erosion or infection.

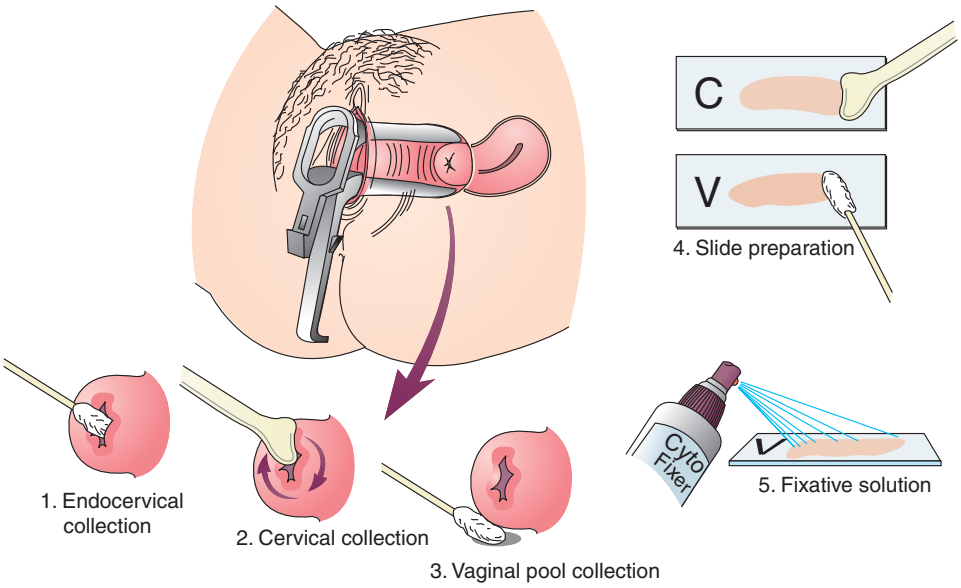

FIGURE 11.9 Obtaining a traditional Pap smear. (**1**) Specimen taken from endocervix. (**2**) Specimen taken from cervix. (**3**) Specimen taken from vaginal pool.

separate specimens—one from the endocervix, one from the cervical os, and one from the posterior vaginal fornix—are obtained (Fig. 11.9). In addition, a cervicogram (a photograph of the cervix) may be taken. Cervicograms serve as complements to Pap smears as a weapon for detecting cervical cancer and documenting that lesions from infections are healing.

To obtain an endocervical specimen for a Pap smear, a sterile cotton applicator, wet with saline, is inserted through the speculum into the os of the cervix and gently rotated, first clockwise, then counterclockwise (see Fig. 11.9[1]). It is then removed without touching the sides of the vagina. The specimen is then gently painted onto a glass slide. The slide is sprayed with a fixative to preserve the cells. Use of cytobrushes for pregnant women is not recommended, because they can cause cervical bleeding because of increased cervical softening.

To take a cervical os specimen, the uneven end of a spatula is inserted through the speculum and pressed on the os of the cervix and rotated to scrape cells in a circle around the os (see Fig. 11.9[2]). After removal, the spatula is then smeared onto a slide and the slide is sprayed with fixative.

For the specimen from the posterior vaginal fornix, a cotton-tipped applicator or the opposite end of the spatula blade is placed at the posterior fornix just below the cervix (the vaginal pool; see Fig. 11.9[3]). The applicator or spatula is rolled gently to pick up secretions collected there. After careful removal, the specimen is painted onto a third slide and sprayed with fixative. Many Pap smears are read by computer today, an advance that has made the collection of specimens slightly different. If a ThinPrep Pap smear is being taken, a small broomlike collection device is inserted into the endocervical canal deep enough to allow the short bristles to contact the endocervix, and it is rotated in a clockwise direction five times. The device is then rinsed off in a special collection vial filled with a fixative solution; the vial is then capped, labeled, and sent to the laboratory (Fig. 11.10).

The classification of Pap smears is constantly being revised as the meaning of abnormal cells is further defined (MacKay, 2009). The Bethesda classification of Pap smears is shown in Table 11.3. Be certain if discussing these reports with women that they do not overinterpret the results. The first category means only normal cells were found. The second category means cells are inflamed probably because infection is present (a woman needs to be treated and re-examined in about 3 months). At the next level (LSIL), cells are moderately suspicious for malignancy. The HSIL category identifies that precancerous cells are present. This level requires a colposcopy examination for further evaluation. Only the last category is indicative that squamous cell carcinoma is present. Therapy at this level will include colposcopy, biopsy, and removal of the affected cells, usually by conization.

Women who engage in anal intercourse may have an anal swab taken as well as vaginal swabs to detect anal squamous neoplasms. The technique for plating anal Pap smears is the same as that for vaginal specimens (a cytobrush is used). Caution the patient that she may have slight rectal bleeding following this procedure.

Many women ask how often repeat Pap smears are necessary. The American Cancer Society recommends women begin to have Pap smears when they turn 21 or 3 years after becoming sexually active (whichever occurs first). After age 30, they then can be done as infrequently as every 2 to 3 years.

FIGURE 11.10 For liquid Pap tests, the collecting instrument is placed in a commercial vial and capped rather than being smeared onto a slide.

TABLE 11.3 ✻ Interpretation of Pap Smears (CIN and Bethesda Systems)

Source: MacKay, H. T. (2009). Gynecology. In S. J. McPhee, et al. (Eds.). *Current medical diagnosis and treatment.* Columbus, OH: McGraw-Hill.

Women who should have them done more frequently are those who have multiple sexual partners, who have a history of human papillomavirus (HPV) infection, who smoke cigarettes, or who were active sexually before age 21. Screening as infrequently as every 3 years could miss pathology in these women.

Vaginal Inspection. Before the vaginal speculum is removed, a culture for gonorrhea, human papillomavirus (HPV), chlamydia, trichomoniasis, or group B streptococci may be taken. After gently swabbing the cervix using a cotton-tipped applicator, the specimen obtained is then plated onto a medium to allow for growth. Treatment to eliminate organisms such as these during pregnancy helps to guard fetal and newborn health (Gulmezoglu, 2007).

A speculum must be unlocked and partially closed before removal; otherwise, pain from excessive stretching could occur. If the speculum is kept partially open as it is removed, however, it should not cause pain, and the sides of the vagina can be inspected as it is withdrawn. In a nonpregnant woman, vaginal walls are light pink; pregnancy turns them dark blue to purple. Any areas of inflammation, ulceration, lesions, or discharge should be noted.

Examination of Pelvic Organs. Following the speculum examination, a bimanual (two-handed) examination is performed to assess the position, contour, consistency, and tenderness of pelvic organs (Fig. 11.11). The index and middle fingers of one gloved hand are lubricated and inserted into the vagina so the walls of the vagina can be palpated for abnormalities. The other hand is then placed on a woman's abdomen and pressed downward toward the hand still in the vagina until the uterus can be felt between them. If a uterus is extremely retroverted, it may not be palpable abdominally. Next, the right and left ovaries are identified by the same method. Ovaries are normally slightly tender, so the pressure caused by palpation may cause a woman some discomfort.

Abnormalities that can be noted by bimanual examination include ovarian cysts, enlarged fallopian tubes (perhaps from pelvic inflammatory disease), and an enlarged uterus (see Table 11.1). An early sign of pregnancy (Hegar's sign) is elicited on bimanual examination as well (see Fig. 10.4).

Rectovaginal Examination. After a bimanual pelvic examination, the hand is withdrawn from the vagina. The index finger is reinserted into the vagina and the middle finger into the rectum. By palpating the tissue between the examining fingers in this way, it is possible to assess the strength and irregularity of the posterior vaginal wall. This maneuver may be slightly uncomfortable for a woman because of the rectal pressure involved. Some examiners use a clean pair of gloves before they perform a vaginal-rectal examination so they will not spread an

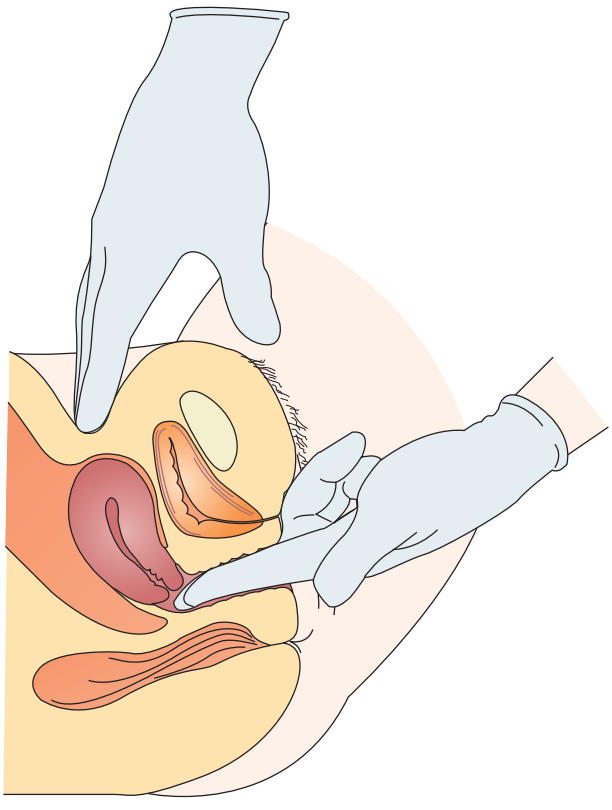

FIGURE 11.11 A bimanual examination to determine uterine size.

infection from the vagina to the rectum. After the rectal examination, if it is necessary to re-examine the vagina for any reason, the glove must be changed to avoid contaminating the vagina with fecal material.

After completing the examination, any excess lubricant is wiped away from the vaginal and rectal openings. It is important to wipe front to back to prevent bringing rectal contamination forward to the vaginal introitus.

✔ Checkpoint Question 11.4

Sandra has not had a pelvic examination since she was in high school. What advice would you give her to help her relax during her first prenatal pelvic examination?

a. Have her take a deep breath and hold it during the examination.
b. Tell her to bear down slightly as the speculum is inserted.
c. Singing out loud helps, because it pushes down the diaphragm.
d. She should breathe slowly and evenly during the examination.

Estimating Pelvic Size. It is impossible to predict from the outward appearance of a woman whether her pelvic ring will be adequate for a fetus to pass through its center. Some women look as if they have a wide pelvis but, in reality, have only wide iliac crests and a normal or even smaller-than-normal internal ring. Other women appear as if their pelvis will be small because the iliac crests are nonflaring, but the internal pelvis, the part that must be sufficiently large for childbirth, is of average size, allowing them to give birth vaginally without difficulty. Differences in pelvic contour and development occur mainly because of hereditary factors, but disease (e.g., rickets, now rarely seen in the United States but still a concern in undeveloped countries, may cause contraction of the pelvis) or injury (inadequate repair following an accident) also may play a role.

If on an initial prenatal visit, the primary care provider establishes that a woman is pregnant, and if she has never given birth vaginally before, pelvic measurements may be taken. Some care providers prefer to take these measurements later in pregnancy, when a woman's pelvic muscles are more relaxed, making measurement easier. Estimation of pelvic adequacy must be done at least by the 24th week of pregnancy, because by this time there is danger that the fetal head will reach a size that will interfere with safe passage and birth if the pelvic measurements are small. If a routine ultrasound is scheduled, estimations of fetal head size may be made by fetal ultrasound.

Once a woman has given birth vaginally, her pelvis has been proven adequate for vaginal birth so it is unnecessary for pelvic measurements to be taken again unless she has an intervening history of trauma to the pelvis.

The types of pelves found in women are categorized into four groups (Fig. 11.12), android, anthropoid, gynecoid, and platypelloid. A *gynecoid,* or "female," pelvis has an inlet that

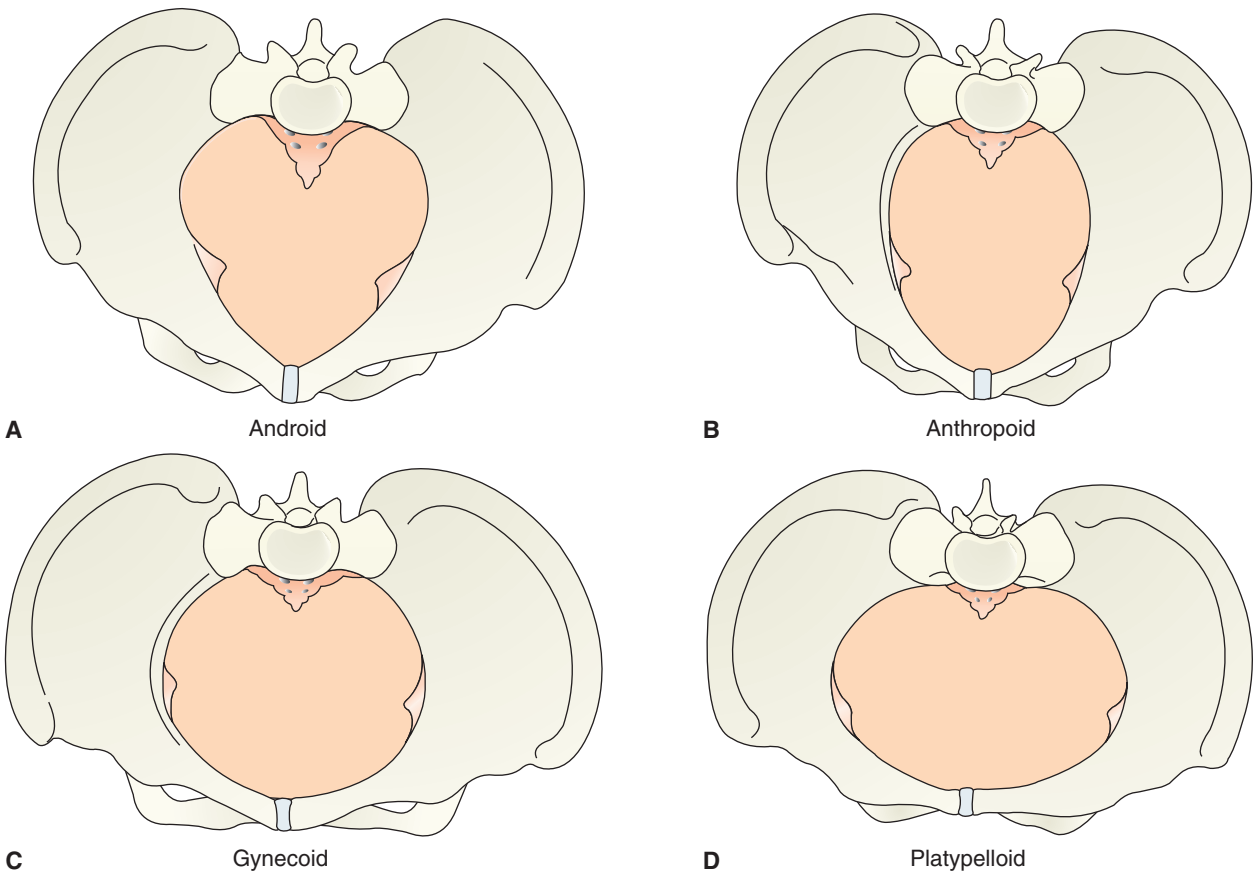

FIGURE 11.12 Types of pelves. (**A**) *Android,* or "male," pelvis. (**B**) *Anthropoid,* or "ape-like," pelvis. (**C**) *Gynecoid,* or "female," pelvis. (**D**) *Platypelloid,* or "flattened," pelvis.

is well rounded forward and backward and a wide pubic arch. This pelvic type is ideal for childbirth. In an *android,* or "male," pelvis, the pubic arch forms an acute angle, making the lower dimensions of the pelvis extremely narrow. A fetus may have difficulty exiting from this type of pelvis. In an *anthropoid,* or "ape-like," pelvis, the transverse diameter is narrow, and the anteroposterior diameter of the inlet is larger than normal. This structure does not accommodate a fetal head as well as a gynecoid pelvis. A *platypelloid,* or "flattened," pelvis has a smoothly curved oval inlet but the anteroposterior diameter is shallow. A fetal head might not be able to rotate to match the curves of the pelvic cavity in this type of pelvis.

Internal pelvic measurements give the actual diameters of the inlet and outlet through which the fetus must pass. The following measurements are made most commonly:

1. The **diagonal conjugate.** This is the distance between the anterior surface of the sacral prominence and the anterior surface of the inferior margin of the symphysis pubis (Fig. 11.13A). The most useful measurement for estimation of pelvic size, it suggests the anteroposterior diameter of the pelvic inlet (the narrower diameter at that level, or the one that is most apt to cause a misfit with the fetal head). The diagonal conjugate is measured while a woman is in a lithotomy position. To measure it, two fingers are introduced vaginally and pressed inward and upward until the middle finger touches the sacral prominence. With the other hand, the part of the examining hand where it touches the symphysis pubis is marked (see Fig. 11.13A). After withdrawing the examining hand, the distance between the tip of the middle finger and the marked point on the glove on that hand is measured by comparing it with a ruler or, for greater accuracy, a pelvimeter. Caution a woman that the measurement may be slightly painful, because she may feel the pressure of the examining finger as it stretches to touch the sacral prominence. If an examiner's hand is small with short fingers, manual pelvic measurements may not be possible, because the fingers may not reach the sacral prominence. If the measurement obtained is more than 12.5 cm, the pelvic inlet is rated as adequate for childbirth (the diameter of the fetal head that must pass that point averages 9 cm in diameter).
2. The **true conjugate** or **conjugate vera** is the measurement between the anterior surface of the sacral prominence and the posterior surface of the inferior margin of the symphysis pubis. This measurement cannot be made directly, but it can be estimated from the measurement made of the diagonal conjugate. To do this, the usual depth of the symphysis pubis (assumed to be 1.5–2 cm) is subtracted from the diagonal conjugate measurement. The distance remaining will be the true conjugate, or the actual diameter of the pelvic inlet through which the fetal head must pass. The average true conjugate diameter is, therefore, 12.5 cm minus 1.5 or 2 cm, or 10.5 to 11 cm.
3. The **ischial tuberosity** diameter. This measurement is the distance between the ischial tuberosities, or the transverse diameter of the outlet (the narrowest diameter at that level, or the one most apt to cause a misfit). It is made at the medial and lowermost aspect of the ischial tuberosities at the level of the anus (see Fig. 11.13B). A pelvimeter is generally used, although the diameter can be measured by a ruler or by comparing it with a known hand span or clenched fist measurement. A diameter of 11 cm is considered adequate because it will allow the diameter of the fetal head, or 9 cm, to pass freely through the outlet.

Laboratory Assessment

Several laboratory studies are included in assessment measures at a first prenatal visit to confirm general health and rule

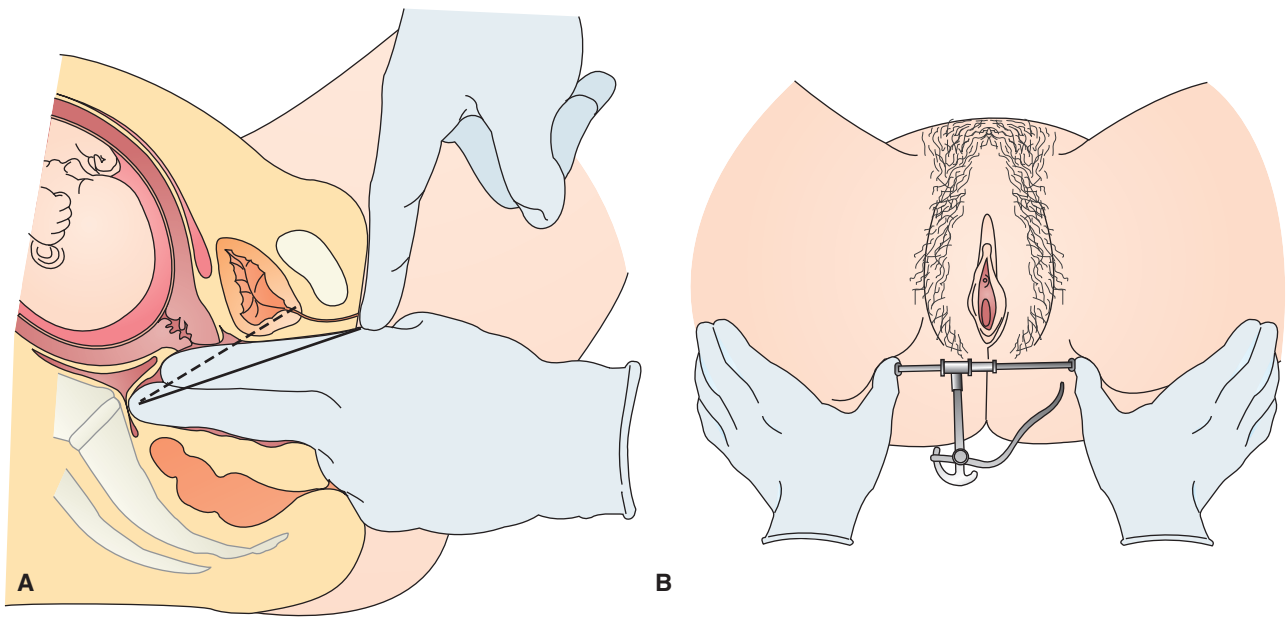

FIGURE 11.13 (**A**) Measurement of diagonal conjugate diameter. *Solid line,* diagonal conjugate; *dotted line,* true conjugate. (**B**) Measurement of ischial tuberosity diameter.

out sexually transmitted infection that could injure the growing fetus. Normal levels for these studies are shown in Appendix F.

Blood Studies

The following blood studies are usually obtained at a first prenatal visit:

1. A **complete blood count,** including hemoglobin or hematocrit and red cell index to determine the presence of anemia, a white blood cell count to determine infection, and a platelet count to estimate clotting ability.
2. A **genetic screen** for common ethnically inherited diseases. African American women, for example, may have a blood sample taken to screen for sickle cell trait or disease and glucose-6-phosphate dehydrogenase (G6PD). Asian and Mediterranean women may have this done for beta-thalassemia; those with Jewish ancestry may have this done for Tay-Sachs disease; and Caucasian women may be tested for cystic fibrosis.
3. A **serologic test for syphilis** (VDRL or rapid plasma reagin test). If syphilis is present, it must be treated early in pregnancy before fetal damage occurs. A blood sample for a serologic test for gonorrhea may be drawn as well.
4. **Blood typing (including Rh factor).** Blood type is documented because blood may have to be made available if a woman has bleeding during pregnancy and to detect the possibility of Rh isoimmunization.
5. **Maternal serum for alpha-fetoprotein (AFP)** (MSAFP). This level will be elevated if a neural tube or abdominal defect is present in the fetus; it may be decreased if a chromosomal anomaly is present. This test is done at 16 to 18 weeks of pregnancy. The level in serum is expressed as "multiples of the mean" (MOM). A normal value is 2.5 MOM. If this is elevated or decreased, an ultrasound or amniocentesis will be ordered to assess for a fetal disorder.
6. An **indirect Coombs' test** (determination if Rh antibodies are present in an Rh-negative woman). This test is generally repeated at 28 weeks of pregnancy. If the titers are not elevated, an Rh-negative woman will receive RhIG (RhoGAM) at 28 weeks of pregnancy and after any procedure that might cause placental bleeding, such as amniocentesis or external version.
7. **Antibody titers for rubella and hepatitis B** (HBsAg). These tests determine whether a woman is protected against rubella if exposure should occur during pregnancy and whether a newborn will have a chance of developing hepatitis B. HBsAg testing may be repeated at about 36 weeks. Antibodies for varicella (chickenpox) may also be assessed. Vaccine against these diseases can then be offered in the postpartum period.
8. **HIV screening.** All women can be asked, and those at high risk for contracting HIV infection should be asked, whether they want to be screened for this disease early in pregnancy (Pratt, 2007). High-risk criteria include women who have used or are using intravenous drugs; have engaged in sex with multiple partners; have had sexual partners who are infected or are at risk because they are bisexual, intravenous drug abusers, or hemophiliacs; or women who received a blood transfusion between 1977 and 1985.

Screening is done by an enzyme-linked immunosorbent assay (ELISA) on a blood sample. If this is positive, the finding is confirmed by a second test (a Western blot). Testing for HIV early in pregnancy allows a woman who is found to be HIV antibody positive the opportunity to begin therapy with zidovudine (AZT), which can decrease the risk of her infant acquiring the virus. It also allows a woman the option of choosing to terminate a pregnancy to avoid giving birth to an infant who has a high risk of HIV infection.

As there is still no cure for HIV infection, some women may choose not to have a blood titer taken because they would rather not know that they have the illness. This is their option. Screening cannot be mandatory in prenatal settings. Because HIV testing is controversial, be certain that the information given about test results is accurate (a high blood antibody titer means the person has been exposed to the virus, not that he or she necessarily is infected) and findings are presented with tact and compassion, with respect for the meaning of the results to a woman. Results of HIV testing are kept confidential; be certain not to report this information to anyone other than the woman.

9. If a woman has a history of previously unexplained fetal loss, has a family history of diabetes, has had babies who were large for gestational age (9 lb or more at term), is obese, or has glycosuria, she will need to be scheduled for a 50-g oral 1-hour **glucose loading** or **tolerance test** toward the end of the first trimester to rule out gestational diabetes. If not, she will have this done routinely at the 24th to 28th week to evaluate insulin-antagonistic effects of placental hormones, which can register a noticeable effect at this time. Unless a problem is developing, the plasma glucose level should not exceed 140 mg/dL at 1 hour (see Chapter 20 for a discussion of diabetes in pregnancy).

Urinalysis

A urinalysis is performed to test for proteinuria, glycosuria, and pyuria. All three of these can be done by means of test strips or microscopic examination of the urine.

Tuberculosis Screening

The incidence of tuberculosis is on the rise, related to the HIV epidemic as more people with lowered immune system function (i.e., those with HIV infection) are contracting tuberculosis and then spreading it to others. In light of this, the physician or nurse-midwife may order a purified protein derivative (PPD) tuberculin test for a woman to screen for tuberculosis. Any woman who has a positive reaction would then require a chest radiograph for further diagnosis.

If a woman has a history of tuberculosis or has received a bacillus Calmette-Guérin (bCG) vaccine for tuberculosis, a tuberculin skin test should not be given because the reaction would be extreme. Although bCG vaccine is not administered in the United States, immigrants from other countries may have received this. To assess a woman's current disease status, a chest radiograph will be ordered instead. A woman is often reluctant to have this done because she knows radiation is harmful to a growing fetus. Assure her that she will be

given a lead apron to cover her abdomen to protect the fetus, exposing only her chest to radiation.

Screening for tuberculosis early in pregnancy is important because it is a chronic and debilitating disease that increases the risk of miscarriage. Further, the change in the shape of the lung tissue as the growing uterus presses on the lung may reactivate old lesions.

Ultrasonography

If the date of the last menstrual period is unknown, a woman will be scheduled for an ultrasound to confirm the pregnancy length and document healthy fetal growth. Be certain that women know an ultrasound done this early in pregnancy will show only the presence of a gestation sac, not a moving, kicking fetus so their expectations of what they will see are realistic (Lalor & Devane, 2007).

Risk Assessment

Table 11.4 summarizes necessary data assessment for a first prenatal visit. After this assessment, findings are analyzed to determine whether a pregnancy is apt to continue with a good outcome or there is some risk that it will end before term or with an unfavorable fetal or maternal outcome (a high-risk pregnancy).

Table 11.5 lists factors that would identify a pregnancy as being at high risk. A woman identified this way will need close observation during pregnancy to see that the pregnancy is progressing well; the infant born of a woman identified this way needs close observation in the neonatal period until it is confirmed that no anomalies exist.

Risk assessment should be updated at each pregnancy visit, as the failure to identify risk potential in pregnancy leads to increased perinatal mortality. See Chapters 20 through 22 for discussion of high-risk pregnancy and its management.

Following a first prenatal visit, a woman needs to continue with prenatal care. Box 11.7 lists components of assessments and care done during continuing prenatal visits.

BOX 11.7 ✻ Assessments and Care for Continuing Prenatal Visits

Mother's Health

Health Interview

Interim history or new personal or family developments since last visit
Review danger signs of pregnancy
Review symptoms of beginning labor

Physical examination

Blood pressure (every visit)
Clean-catch urine for glucose, protein, and leukocytes (every visit)
Blood serum level for alpha-fetoprotein (MSAFP) (16 weeks)
VDRL test for syphilis if possibility of new exposure
Glucose screen (28 weeks)
Glucose challenge (24–28 weeks) if warranted
Anti-Rh titer (28 weeks)
Group B streptococci (GBS) (35–37 weeks)

Fetal Health

Fetal heart rate
Fundal height
Quickening or fetal movement
Ultrasound dating of pregnancy

TABLE 11.4 ✻ Assessments for a First Pregnancy Visit

Health History	
Demographic data	Name, address, age, telephone number, health insurance
Chief concern	Was pregnancy planned? When was last menstrual period? Any exposure to infectious diseases or ingestion of drugs since a woman thinks she has been pregnant?
Family and social profile	What is family composition? Does the woman have a support person? What is her occupation? Source of income? Level of exercise? Hobbies? Recreational drug use? Living conditions? Nutrition? Sleep pattern?
Past medical history	Any abdominal surgery, kidney, heart, hypertension, sexually transmitted infections, diabetes, allergies? What immunizations has she had?
Gynecologic history	When was menarche? What is length and duration of menstrual cycle?
Obstetric history	Any previous pregnancies? When? Type and outcome of birth? Any history of previous miscarriages?
Review of systems	Brief review of all body systems
Physical Examination	
Baseline data	Height, weight, vital signs, fundal height measurements (after 12 weeks), fetal heart sounds
System assessment	Full physical examination to confirm general health
Pelvic examination	General assessment, Pap smear, cultures for chlamydia, gonorrhea, group B streptococci, pelvic measurements
Laboratory Assessment	
Blood	Complete blood count, serologic test for syphilis, blood type and Rh, alpha-fetoprotein, antibody titer against Rh, hepatitis B, rubella, and possibly varicella and HIV
Urinalysis	Clean catch for glucose, protein, ketones, and culture
Tuberculosis	PPD test
Ultrasound	To date pregnancy or confirm fetal health (if date of last menstrual period is unknown)

TABLE 11.5 ✻ Assessments That Might Categorize a Pregnancy as "at Risk"

Obstetric History	History of subfertility or grand multiparity
	Previous premature cervical dilatation
	Existing uterine or cervical anomaly
	Previous preterm labor or preterm birth or cesarean birth
	Previous macrosomic infant
	Two or more spontaneous miscarriages or therapeutic abortions
	Previous hydatidiform mole/ choriocarcinoma
	Previous ectopic pregnancy or stillborn/neonatal death
	Previous multiple gestation
	Previous prolonged labor
	Previous low-birth-weight infant
	Previous midforceps birth
	Last pregnancy less than 1 year previous
	Previous infant with neurologic deficit, birth injury, or congenital anomaly
Medical History	Cardiac or pulmonary disease, chronic hypertension
	Metabolic disease such as diabetes mellitus
	Renal disease, recent urinary tract infection, or bacteriuria
	Gastrointestinal disorders
	Seizure disorders
	Family history of severe inherited disorders
	Surgery during pregnancy
	Emotional disorder or cognitive challenge
	Previous surgeries, particularly involving reproductive organs
	Endocrine disorders such as hypothyroidism
	Hemoglobinopathies
	Sexually transmitted infections
	Reproductive tract anomalies, history of abnormal Pap smear, malignancy
Current Obstetric Status	Inadequate prenatal care
	Intrauterine growth-restricted fetus
	Large-for-gestational-age fetus
	Pregnancy-induced hypertension or pre-eclampsia
	Abnormal fetal surveillance tests
	Polyhydramnios
	Placenta previa
	Abnormal presentation
	Maternal anemia
	Maternal weight gain under 10 lb or weight loss
	Currently over/underweight
	Fetal or placental malformation
	Rh sensitization
	Preterm labor
	Multiple gestation
	Premature rupture of membranes
	Abruptio placentae
	Postdate pregnancy
	Fibroid tumors
	Fetal version
	Cervical cerclage
	Sexually transmitted infection
	Other maternal infection
	Poor immunization status
Psychosocial Factors	Inadequate finances
	Lack of support person
	Adolescent
	Poor nutrition
	More than two children at home; no help
	Lack of acceptance of pregnancy
	Attempt or ideation of suicide
	Inadequate or poor housing
	Father of baby uninvolved
	Minority status
	Dangerous occupation
	Dysfunctional grieving
	Psychiatric history
Demographic Factors	Maternal age under 16 or over 35
	Education less than 11 years
Lifestyle	Cigarette smoking greater than 10 cigarettes a day or living with a person who smokes this much
	Substance abuse
	Long amounts of time spent commuting
	Nonuse of seatbelts
	Alcohol intake
	Heavy lifting or long periods of standing
	Unusual stress
	No in-home smoke detectors

SIGNS INDICATING COMPLICATIONS OF PREGNANCY

Although most signs indicating complications of pregnancy occur toward the end of pregnancy, women need to know what these are from the beginning (see Focus on Nursing Care Planning Box 11.8). When teaching about these signs, assure a pregnant woman you have every reason to believe she is going to have a normal, uncomplicated pregnancy (assuming that is true) as well as no reason to think that she is going to experience any serious problems, but if any danger signs do occur, she should inform her health care provider by telephone or e-mail immediately. Be certain you give her an alternate contact number to call if the health care facility is closed. Emphasize that if one of these danger signs should occur, it serves merely as a signal of the possibility that something may happen, not that something serious has already happened. It is important for her to report it immediately, though, so it can be dealt with before something harmful does occur.

BOX 11.8 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Woman's First Prenatal Visit

Sandra Czerinski is a 29-year-old woman, 12 weeks' pregnant, who comes for a first prenatal visit. She is concerned because she did not realize she was pregnant until a week ago. Because of this, she has been actively dieting (two diet drinks plus one meal of mainly vegetables daily) plus lifting weights at a health club. She has not had a pelvic examination since she was in high school, when she had a vaginal infection. She remembers that examination as being very painful. She is worried she has a urinary tract infection now because she has to "go all the time." She does not want any blood work done because she does not have health insurance.

Family Assessment ✻ Single woman; lives by self in one-bedroom apartment. Works at a laundry. Boyfriend is a roofing salesman; out of town 4 days a week.

Client Assessment ✻ Gravida 1, para 0. Last menstrual period 4 months ago. Had nausea last month but thought that was the "flu."

Menarche at age 11; menstrual cycle every 29 days, 6 days' duration with moderate flow and mild cramps. Past history positive for sinusitis; appendectomy at age 12 years. Smokes about ½ pack per day, "more when I'm stressed at work"; denies alcohol use. "I drink club soda with lime or mineral water."

ROS: Height 5 feet 5 inches; prepregnancy weight 160 lb (BMI: 27.5 or overweight). Slight gingival hyperplasia; breasts full and slightly tender.

Pelvic examination by nurse-midwife: cervical os round, clean, and slightly soft; uterus enlarged and soft; + Chadwick's sign, + Hegar's sign, + Goodell's sign. Uterine height palpable at three fingers over symphysis pubis. Fetal heart rate via Doppler at 152 beats per minute.

Remainder of physical examination within normal limits. Weight today: 177 lb.

Nursing Diagnosis ✻ Health-seeking behaviors related to guidelines for pregnancy

Outcome Criteria ✻ Client states the need to stop smoking; identifies measures she will take to reduce number of cigarettes smoked and states she will no longer try to lose weight. Makes appointment for follow-up visits.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse/nurse-midwife	Assess client's expectations about this pregnancy, including whether she expects to continue to work, continue present lifestyle.	Discuss the effect of pregnancy on her partner and any religious or cultural beliefs that would interfere with her ability to adapt to pregnancy changes.	Assessing expectations is important to assist a woman in identifying areas of need and adaptation necessary for pregnancy to ensure the optimal outcome for the mother, fetus, and partner.	Client describes the likely effect of the pregnancy on herself and partner; identifies areas where she anticipates life changes.
		Consultations		
Nurse-midwife	Fully assess symptoms of urinary frequency to rule out urinary tract infection	Consult with primary care provider about further investigation of urinary tract infection if indicated.	Urinary tract infections are associated with preterm birth.	Primary care physician will document urinary tract infection if signs/symptoms warrant and will prescribe appropriate antibiotic.
		Procedures/Medications		
Nurse-midwife/nurse	Obtain a gynecologic and obstetrics health history.	Perform initial assessment, including vital signs, height and weight measurement, and history and physical examination.	Initial assessment provides a baseline for future comparison and identification of factors that may place a client at risk for pregnancy concerns.	Client receives a thorough initial assessment, to lay a psychological and physiologic foundation of health care information for pregnancy care.

(continued)

BOX 11.8 ✻ Focus on Nursing Care Planning (continued)

Nurse	Obtain usual weight before pregnancy and weight at each visit. Obtain urine and blood specimens.	Monitor weight at every visit. Explain that blood assessment is not done at every visit.	A baseline weight is necessary for future comparison. Adequate weight gain during pregnancy (typically 25 to 30 lb) is necessary for optimal fetal growth and development.	Client's weight is monitored and compared with previous weights at each prenatal visit. Client states she understands importance of initial blood work, urinalysis, and weight gain during pregnancy.
		Nutrition		
Nurse/ nutritionist	Obtain a 24-hour nutrition recall.	Discuss with client her increased nutritional needs during pregnancy. Provide information about including fresh fruits and vegetables, milk products, and high-protein foods, fluid intake, and prenatal vitamin supplementation.	A well-balanced diet with adequate fluid intake and use of prenatal vitamins helps to ensure an optimal environment for fetal growth and development. Dieting is contraindicated during pregnancy.	Client voices an understanding of the increased nutritional needs during pregnancy and describes her plan to provide for these needs. Voices understanding of why she should discontinue dieting.
		Patient/Family Education		
Nurse	Assess if client is interested in decreasing smoking during pregnancy.	Instruct client in the effects of smoking on the fetus. Assist client with methods to reduce and stop, if possible.	Nicotine in cigarettes has been shown to be teratogenic to a fetus.	Client describes the effect on a fetus of smoking during pregnancy and her plan to stop smoking at least until after the birth and, ideally, long term.
Nurse	Assess if client is aware of the danger signs of pregnancy that she will need to report immediately should they occur.	Instruct client about possible danger signs to report immediately. Emphasize that although these signs are important, they do not necessarily mean that something is wrong.	Knowledge of possible danger signs allows for early detection and prompt intervention should it be necessary.	Client and intimate partner list danger signs of pregnancy to report immediately. They acknowledge that these signs suggest, but do not necessarily mean, that the pregnancy is at risk.
		Psychosocial/Spiritual/Emotional Needs		
Nurse	Assess if client has concerns about success of pregnancy.	Assure client that concern during pregnancy is a normal response. Include information about physiologic and psychological changes of pregnancy.	Anxiety can interfere with client's ability to adjust to pregnancy. Reviewing information reinforces understanding of what is to come and helps to alleviate fears and anxieties related to pregnancy.	Client describes any concerns about pregnancy and receives appropriate assurance.
		Discharge Planning		
Nurse	Assess whether client will have any difficulty continuing with prenatal care.	Assist client with setting up appointments for future visits with respect that she has no health insurance.	Assisting with appointment setting helps to ensure adherence.	Client states plan for expected antepartal care visits and affirms her willingness to adhere to the plan.

Vaginal Bleeding

A woman should report vaginal bleeding, no matter how slight, because some of the serious bleeding complications of pregnancy begin with only slight spotting. When talking with a woman, ask her how she discovered the spotting. If she discovered it on toilet paper following a bowel movement, she is probably reporting spotting from hemorrhoids. Until the bleeding is found to be innocent, however, all women with spotting need further evaluation.

Persistent Vomiting

Once- or twice-daily vomiting is not uncommon during the first trimester of pregnancy. However, persistent, frequent vomiting is not normal. Vomiting that continues past the 12th week of pregnancy is also extended vomiting. Persistent or extended vomiting depletes the nutritional supply available to a fetus so is a danger to the pregnancy. (See Chapter 13 for an in-depth discussion of persistent vomiting [hyperemesis gravidarum].)

Chills and Fever

Chills and fever may be symptoms of a relatively benign gastroenteritis, but they also may indicate an intrauterine infection, a potentially serious complication for both a woman and a fetus. Because a woman cannot make a definite determination about the cause of a fever, further evaluation by a health care provider is necessary.

Sudden Escape of Clear Fluid From the Vagina

When a gush of clear fluid is discharged suddenly from the vagina, it means the membranes have ruptured and mother and fetus are now both threatened, because the uterine cavity is no longer sealed against infection. If a fetus is small so the head does not fit snugly into the cervix, the umbilical cord may prolapse following membrane rupture. If the cord is then compressed by the fetal head, oxygenation is compromised and a fetus will be in immediate and grave danger. Alerting a health care provider to any sudden escape of fluid is crucial so a safe and controlled birth can be planned. Occasionally, a woman confuses stress incontinence (involuntary loss of urine on coughing or sneezing or lifting a heavy object) for this. In this situation, vaginal examination typically reveals that the membranes are still intact.

Abdominal or Chest Pain

Abdominal pain at any time is a signal that something is abnormal, so a woman should report it immediately. Some women may think that this is normal because the growing uterus is deflecting their other organs from their usual alignment, but a pregnant uterus normally expands painlessly. Abdominal pain is therefore a sign of some other problem, such as a tubal (ectopic) pregnancy, separation of the placenta, preterm labor, or something unrelated to the pregnancy but perhaps equally as serious, such as appendicitis, ulcer, or pancreatitis. Chest pain may indicate a pulmonary embolus, a complication that can follow thrombophlebitis.

Pregnancy-Induced Hypertension

Pregnancy-induced hypertension (PIH) refers to a potentially severe and even fatal elevation of blood pressure that occurs during pregnancy. Several symptoms signal that PIH is developing:

- Rapid weight gain (over 2 lb per week in the second trimester, 1 lb per week in the third trimester)
- Swelling of the face or fingers
- Flashes of light or dots before the eyes
- Dimness or blurring of vision
- Severe, continuous headache
- Decreased urine output

One by one, these are vague symptoms so a woman may need some help appreciating that they are important to report during pregnancy. Some edema of the ankles during pregnancy is normal, for example, particularly if it occurs after a woman has been on her feet for a long period. Swelling of the hands (ask if she has noticed if her rings are tight) or face (difficulty opening eyes in the morning because of edema of the eyelids), however, indicates edema that is more extensive than usual. Visual disturbances or a continuous headache may signal cerebral edema or acute hypertension. Be certain a woman is not reporting symptoms she had before she became pregnant. If she had the same visual difficulties and headaches before pregnancy as she is reporting now, she may need to see an ophthalmologist rather than her obstetrician for help with the problem. (See Chapter 21 for more on PIH.)

Increase or Decrease in Fetal Movement

Because a fetus normally moves more or less the same amount every day, an unusual increase or decrease in movement suggests that a fetus is responding to a need for oxygen. Be sure to ask a woman about typical fetal movements and whether she has noticed any increase or decrease in this rate. If there has been a change, she is a candidate for further testing and follow-up. Common tests of fetal movement are discussed in Chapter 9.

✔ Checkpoint Question 11.5

You tell Sandra about the danger signs of pregnancy. Which of the following would you tell her to report if it should occur?

a. Her uterus becomes palpable over the symphysis pubis at 12 weeks.
b. Blue veins can be readily observed on both of her breasts.
c. She gains more weight than 2 lb a week beginning at 20 weeks.
d. Her uterus is growing so slowly the growth is not causing any pain.

KEY POINTS FOR REVIEW

- Prenatal care has the potential to reduce the incidence of preterm birth and congenital anomalies and the infant mortality rate.

- The purpose of prenatal care is to establish a baseline of present health, determine the gestational age of the fetus, monitor fetal development, identify women at risk for complications, minimize the risk of possible complications by anticipating and preventing problems before they occur, and provide time for education about pregnancy and possible dangers.
- A first prenatal visit confirms a pregnancy, but it is also a time for important assessments such as a health history, physical examination, and laboratory tests. The physical examination includes measurement of fundal height and assessment of fetal heart sounds if the pregnancy is beyond 12 weeks, a pelvic examination (including a Pap test), and possibly an estimation of pelvic size.
- A first prenatal visit sets the tone for visits to follow. Maintaining a supportive manner is helpful to establish rapport and allow a woman to feel comfortable to return for future care.
- Common pelvic types include gynecoid (well-rounded with a wide pubic arch), anthropoid (narrow), platypelloid (flattened), and android (male or with a sharp pubic arch). A gynecoid pelvis is ideal for childbearing.
- The true conjugate (conjugate vera) is the measurement between the anterior surface of the sacral prominence and the posterior surface of the inferior margin of the symphysis pubis (the anterior-posterior diameter of the pelvic inlet). The average is 10.5 to 11 cm. The ischial tuberosity diameter is the distance between the ischial tuberosities or the transverse diameter of the outlet. The average is 11 cm.
- For a pelvic examination, pregnant women should remain in a lithotomy position for as short a time as possible to help prevent thromboembolism and supine hypotension syndrome.
- Danger signs for women to report during pregnancy are vaginal bleeding, persistent vomiting, chills and fever, escape of fluid from the vagina, abdominal or chest pain, swelling of the face and fingers, vision changes or continuous headache, burning with urination, or a pronounced decrease in fetal movement.
- Remember that a family, not a woman alone, is having a baby, and include family members in procedures and health teaching as desired.

CRITICAL THINKING EXERCISES

1. Sandra Czerinski, whom you met at the beginning of the chapter, was worried about having a pelvic examination. How could you help relieve her concern?
2. Sandra works at a commercial laundry ironing sheets. Is this a job that probably keeps her on her feet for long periods? Is she apt to be exposed to toxic substances at work? Is there a greater opportunity than usual for her to develop upper respiratory infections?
3. Sandra's boyfriend rarely comes with her to prenatal visits. Another woman has a supportive husband who always comes. Would your role be different in these two situations?
4. Examine the National Health Goals related to prenatal care. Most government-sponsored money for nursing research is allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to the Czerinski family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX types of questions related to prenatal care. Confirm your answers are correct by reading the rationales.

Chapter

12 Promoting Fetal and Maternal Health

KEY TERMS

- cytomegalovirus
- fetal alcohol syndrome
- leukorrhea
- Sims' position
- teratogen
- toxoplasmosis

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe health behaviors important for a healthy pregnancy outcome.
2. Identify National Health Goals related to a healthy pregnancy lifestyle that nurses can help the nation achieve.
3. Use critical thinking to analyze ways to promote both individualized and family-centered prenatal care.
4. Assess a woman for healthy practices and concerns during pregnancy.
5. Formulate nursing diagnoses related to a healthy pregnancy.
6. Identify expected outcomes to promote a healthy pregnancy such as encouraging daily exercise.
7. Plan health-promotion strategies to limit exposure to teratogens or reduce the minor discomforts of pregnancy.
8. Implement nursing care to promote positive health practices during pregnancy.
9. Evaluate outcomes for achievement and effectiveness of care.
10. Identify areas of prenatal care that could benefit from additional nursing research or the application of evidence-based practice.
11. Integrate knowledge of health-promotion strategies with the nursing process to achieve quality maternal and child health nursing care.

Julberry Adams, a single woman, is 4 months pregnant when you see her in a prenatal clinic. She works as a curator for an art gallery but has missed work this past week because of nausea. She is worried she will not be able to work past 6 months of her pregnancy because her job involves a great deal of walking. She wonders how she will be able to afford her apartment if she has to quit work. She has already stopped volunteer work teaching children's swimming at the YMCA. She wants to travel to see her sister in St. Louis because her sister is very ill but has heard that pregnant women should not drive over 100 miles. She asks you if marijuana would help reduce her early pregnancy nausea. Previous chapters discussed normal anatomy and physiology and the changes that occur with pregnancy. This chapter adds information about the health teaching that women need during pregnancy to ensure a healthy outcome for themselves and their child.

What additional health teaching does Ms. Adams need?

The health of a fetus and the health of the mother are inextricably linked. Generally, a woman who eats well and takes care of her own health during pregnancy provides a healthy environment for fetal growth and development. However, she may need instructions on exactly what constitutes a healthy lifestyle for herself and her baby. Most women have questions regarding how much extra rest they need, what type of exercise they can continue, and whether all the changes going on in their bodies, some of which bring them daily discomfort, are normal. Therefore, a major role in promoting maternal and fetal health is education. Providing empathic advice about ways to alleviate the minor discomforts of pregnancy, alerting a woman to the danger signs of pregnancy, and keeping abreast of the latest evidence-based practice studies done on maternal exposure to **teratogens** (factors detrimental to fetal health) are all part of this role (Knopik, 2009). Because effective prenatal care is vital to healthy fetal growth, National Health Goals have been established to increase the number of women receiving effective prenatal care (Box 12.1).

Nursing Process Overview

For Health Promotion of a Fetus and Mother

Assessment

A thorough health history, physical evaluation, and initial laboratory data are obtained at the first prenatal visit. Continuing assessment concentrates on screening for any abnormalities in physical or emotional health that might be occurring and for the possibility of teratogens in the pregnant woman's environment. Encourage a pregnant woman to discuss whatever concerns she is having during all visits. Although some of these concerns may represent minor common discomforts associated with normal pregnancy, others may be early indicators of potential problems (Box 12.2). Early problem identification allows you to provide information and guidance on ways to alleviate the discomforts of pregnancy and also allows you to alert a woman's physician or nurse-midwife of your findings as soon as they appear. Early detection and continued monitoring of conditions such as pregnancy-induced hypertension (PIH) and gestational diabetes reduce the risks of their danger.

Unless women bring problems to their health care provider's attention early in pregnancy, they do not have the opportunity to take the necessary measures to prevent further discomfort during or after the pregnancy. Many women do not mention any concerns or discomforts unless specifically asked because they may not be aware of

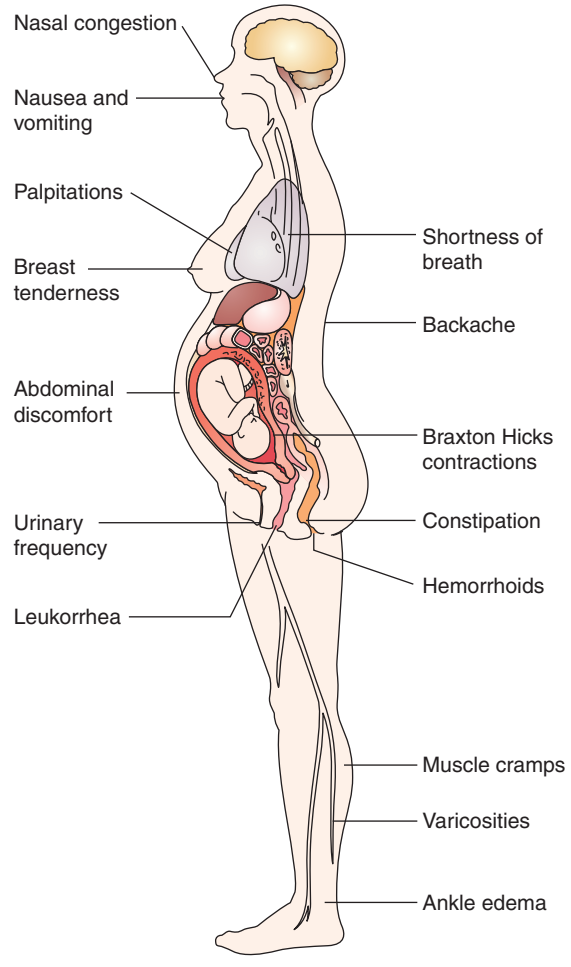
BOX 12.1 ✻ Focus on National Health Goals

Several National Health goals speak to the importance of health promotion during pregnancy.

- Increase the proportion of pregnant women who receive early and adequate prenatal care from a baseline of 74% to a target of 90%.
- Increase to 100% from a baseline of 96% the proportion of pregnant women who abstain from illicit drugs during pregnancy.
- Increase to 99% from a baseline of 87% the proportion of pregnant women who abstain from cigarette smoking during pregnancy.
- Increase to 95% from a baseline of 90% the proportion of pregnant women who abstain from alcohol during pregnancy.
- Increase to 100% from a baseline of 96% the proportion of pregnant women who abstain from binge drinking during pregnancy (http://www.nih.gov).

Because nurses are important members of prenatal health care teams, they play an important role in seeing that services include preconceptual care and that women are aware that early pregnancy care is important. Evidence-based practice and nursing research to answer such questions as what aspects of preconceptual care are most important in reducing pregnancy complications, and what are effective incentives to make women come early for prenatal care, would be important to help the nation meet these goals.

Box 12.2 Assessment
Assessing a Woman for Discomforts of Pregnancy



their significance or are reluctant to take up a busy health care provider's time for these things. For example, women experiencing constipation may not take care of the problem early or well enough to prevent the occurrence of hemorrhoids, which can then become a long-term problem not only throughout the pregnancy but afterward as well.

Nursing Diagnosis

Examples of nursing diagnoses related to health promotion of the pregnant woman and fetus are:

- Health-seeking behaviors related to interest in maintaining optimal health during pregnancy
- Anxiety related to minor discomforts of pregnancy
- Risk for deficient fluid volume related to nausea and vomiting of pregnancy
- Disturbed body image related to change of appearance with pregnancy
- Risk for altered sexuality patterns related to fear of harming fetus during pregnancy
- Disturbed sleep pattern related to frequent need to empty bladder during night
- Risk for fetal injury related to maternal cigarette smoking

Outcome Identification and Planning

When establishing goals and outcomes, be certain that plans are realistic for a woman's situation and family lifestyle. Try to turn long-term goals into more manageable, short-term ones if possible. For example, a goal of reducing smoking during pregnancy may be more realistic than a goal of stopping smoking forever. Eliminating the pressure of making a major permanent lifestyle change can help a woman concentrate her efforts on herself and her fetus over the next several months. Continued reinforcement of her progress could then help her to continue reducing the number of cigarettes smoked or to quit smoking altogether after the baby is born so she can provide a smoke-free environment for her child. Similarly, you cannot set a goal for a woman to be free of the nausea of early pregnancy. The best you can expect to accomplish is to be certain that she maintains good nutrition and adequate weight gain in the face of it. Nor can you do much about the frequency of urination, backache, or fatigue that occur with pregnancy except to help a woman adapt her lifestyle to these symptoms (e.g., encourage her to drink more liquids during the day and less in the early evening; schedule regular rest periods when possible).

Often, helping a woman plan to avoid teratogens is difficult because a total change in lifestyle, such as not smoking, not drinking alcohol, or changing a work environment, may be involved. Fortunately, most women are highly motivated to have a healthy baby. With this level of motivation, planning the best route to achieve a goal becomes the focus rather than educating about the need for goal achievement. Information on specific teratogenic chemicals can be obtained from the National Institute for Occupational Safety and Health (NIOSH) (http://www.cdc.gov/NIOSH). The March of Dimes has a good site for questions about prenatal care in general (http://www.marchofdimes.com).

Implementation

The major intervention associated with health promotion during pregnancy is education. Although the average woman is aware that some discomforts may occur, these discomforts may seem extreme when they are happening to her. Often, adolescent girls are uninformed about the common discomforts of pregnancy because they lack a set of peers with pregnancy experience. Even one who knows that it is normal for breast tenderness to occur during pregnancy may not be sure that the amount of breast tenderness she is having is normal. A woman who had a mental image of herself as someone who would not gain much weight during pregnancy may be very concerned because she is, in fact, gaining a great deal of weight.

It is crucial to all teaching to be certain all women understand that they should double-check with their primary care provider before taking any nonessential medication during pregnancy. Other important interventions include good role modeling, such as not smoking in prenatal settings, and exhibiting a healthy lifestyle through adequate nutrition and exercise.

Cultural beliefs play a large role in how teaching is structured. Teaching can be challenging if a woman has limited English proficiency. Women from cultures that view pregnancy as a wellness state may not seek care because they do not view pregnancy as a time when medical intervention is necessary. Other women may be extremely modest and avoid health visits because they find pelvic examinations difficult, intrusive, and embarrassing. Some women may rely on herbs and folk remedies to manage the common discomforts of pregnancy, so they do not feel a need for medical management. This variety of cultural backgrounds makes individualized assessment and education mandatory.

Implementing prenatal care to meet the needs of all of the different cultures represented in the United States may include furnishing interpreters to aid in communication, providing classes in prenatal health, explaining how health-promotion regimens fit with women's cultural belief systems, and maintaining an attitude of advocacy to help women adjust to a formal health care system.

When planning teaching strategies, a woman's receptiveness to instruction is key. Regardless of how excited and pleased a woman is about being pregnant, she can assimilate only so much information at one particular time. Therefore, be selective about the health information you provide and include those points most relevant to the individual woman. For example, you would want to discuss varicosity prevention more for a woman with a history of varicosities in a former pregnancy than for one who is pregnant for the first time and is very athletic. Keep in mind that the health measures being taught must be maintained for an extended time—40 weeks. To help a woman follow changes this long, choose priorities and make health advice meaningful and individualized.

Remember that a basic tenet of teaching and learning is that learning is enhanced when the information has direct application to that person. This principle means that devising a plan that spaces out health-promotion and health-maintenance information based on the changes associated with early and late pregnancy is most helpful. Teach those measures that are immediately applicable

first; those that have relevance only toward the end of pregnancy can be taught then.

Outcome Evaluation

Evaluation is an ongoing process at prenatal health care visits. Expected outcomes developed with a woman at one prenatal visit need to be assessed at the next. Examples of outcomes are:

- Client states measures she will use to manage the common discomforts of pregnancy.
- Client reports resting for one half-hour twice a day.
- Client verbalizes positive statements about her appearance.
- Client and her partner both state they have stopped smoking.
- Client documents by use of a pedometer that she walks the length of a city block daily.

HEALTH PROMOTION DURING PREGNANCY

Health promotion during pregnancy begins with reviewing aspects of self-care.

Self-Care Needs

Because pregnancy is not an illness, few special care measures other than common sense about self-care are required. Many women, however, have heard different warnings about what they should or should not do during pregnancy, so they may need some help separating fact from fiction so that they can enjoy their pregnancy unhampered by unnecessary restrictions. In no other area of nursing, except possibly infant feeding, does there seem to be as many misconceptions or inappropriate information available to women.

Bathing

At one time, tub baths were restricted during pregnancy because it was feared that bath water would enter the vagina and cervix and contaminate the uterine contents. Further, it was believed that hot water touching the abdomen might initiate labor. Because the vagina normally is in a closed position, however, the danger of tub bath water entering the cervix is minimal. During pregnancy, sweating tends to increase because a woman excretes waste products for herself and a fetus. She also has an increase in vaginal discharge. For these reasons, daily tub baths or showers are now recommended. Women should not soak for long periods in extremely hot water or hot tubs as heat exposure for a lengthy time could lead to hyperthermia in the fetus (Crombleholme, 2009).

As pregnancy advances, a woman may have difficulty maintaining her balance when getting in and out of a bathtub. If so, she should change to showering or sponge bathing for her own safety. If membranes rupture or vaginal bleeding is present, tub baths are contraindicated because then there might be a danger of contamination of uterine contents. During the last month of pregnancy, when the cervix may begin to dilate, some health care providers restrict tub bathing for the same reason.

Breast Care

A few precautions during pregnancy are helpful to prevent breast discomfort (Graham, 2007). A general rule is for a woman to wear a firm, supportive bra with wide straps to spread breast weight across the shoulders. A woman may need to buy a larger bra halfway through pregnancy to accommodate her increasing breast size. If she plans on breastfeeding her newborn, she might choose bras suitable for breastfeeding so she can continue to use them after the baby's birth.

At about the 16th week of pregnancy, colostrum secretion begins in the breasts. The sensation of a fluid discharge from the breasts can be frightening unless a woman is cautioned that this is a possibility. Teach her to wash her breasts with clear tap water (no soap, because that could be drying and cause nipples to crack) daily to remove the colostrum and reduce the risk of infection. Afterward, she should dry her nipples well by patting them with a soft towel.

If colostrum secretion is profuse, a woman may need to place gauze squares or breast pads inside her bra, changing them frequently to maintain dryness. Constant moisture next to the breast nipple can cause nipple excoriation, pain, and fissuring.

Dental Care

Gingival tissue tends to hypertrophy during pregnancy. Unless a pregnant woman brushes her teeth well, pockets of plaque form readily between the enlarged gumline and teeth. In addition to stressing brushing, encourage pregnant women to see their dentists regularly for routine examination and cleaning because 9 months is a long time to be without preventive dental care. Remind women that x-ray examinations are often included as a part of routine dental health. A pregnant woman may want to consider delaying these until after her baby is born. In the few instances when x-ray examinations are necessary for dental health, they can be done safely as long as a woman's abdomen is shielded with a lead apron.

Tooth decay occurs from the action of bacteria on sugar. This action lowers the pH of the mouth, creating an acid medium that leads to etching or destruction of the enamel of teeth. Encourage women to snack on nutritious foods, such as fresh fruits and vegetables (e.g., apples and carrots), to avoid sugar coming in contact with their teeth. If a woman has trouble avoiding sweet snacks such as candy, suggest eating sweet snacks that dissolve easily (like a chocolate bar) rather than one that remains in the mouth a long time (like chewy candy). This helps to minimize the level of sugar in the mouth and long-term contact with teeth.

Perineal Hygiene

Most women have an increased vaginal discharge during pregnancy and may desire to cleanse with a douche. Douching is contraindicated during pregnancy. The force of the irrigating fluid could cause it to enter the cervix and lead to infection. In addition, douching alters the pH of the vagina, leading to an increased risk of bacterial growth (Bernstein & Weinstein, 2007).

Clothing

Women have a multitude of clothing options to wear during a pregnancy. Recommend loose-fitting, comfortable garments.

Caution women to avoid tight-fitting items such as garters, girdles with panty legs, and knee-high stockings during pregnancy. These items impede lower-extremity circulation. Suggest wearing shoes with a moderate to low heel to minimize pelvic tilt and possible backache. Otherwise, the rules are common sense and comfort.

Sexual Activity

Some women are embarrassed to ask questions about sexual relations during pregnancy. However, most women are concerned about whether sexual intercourse should be restricted. Many need information to refute some of the myths about sexual relations in pregnancy that still exist, such as:

- Coitus on the expected date of her period will initiate labor.
- Orgasm will initiate preterm labor, but participating in sexual relations without orgasm will not.
- Coitus during the fertile days of a cycle will cause a second pregnancy or twins.
- Coitus might cause rupture of the membranes.

None of the above are true. Asking a woman at a prenatal visit if she has any questions about sexual activity allows her to voice such concerns (Box 12.3). By dispelling these myths, you allow a woman to feel more comfortable and secure that coitus is not harming her child.

There are a few situations when sexual relations during a pregnancy are contraindicated. Women with a history of spontaneous miscarriage may be advised to avoid coitus during the time of the pregnancy when a previous miscarriage occurred. Women whose membranes have ruptured or who have vaginal spotting should be advised against coitus until examined to prevent possible infection. Advise caution about male oral–female genital contact, because accidental air embolism has been reported from this act during pregnancy or following birth from air entering open or fragile uterine arteries (Truhlar et al., 2007). Otherwise, there are no sexual restrictions during pregnancy.

Early in pregnancy, a woman may experience a decreased desire for coitus resulting from the increased estrogen level in her body. Breast tenderness may limit a usual pattern of sexual arousal. As pelvic congestion increases from the additional uterine blood supply, most women notice increased clitoral sensation. Some women may experience orgasm for the first time during pregnancy because of this increased pelvic congestion. As pregnancy advances and a woman's abdomen increases in size, she and her sexual partner may need to use new positions for intercourse. A side-by-side position or a woman in a superior position may be more comfortable. As vaginal secretions change, a woman may find a water-soluble lubricant helpful. If she begins to experience discomfort from penile penetration, mutual masturbation or female oral–male genital relations might be satisfying to both partners. Caution women with a nonmonogamous sexual partner that the partner needs to use a condom to prevent transmission of a sexually transmitted infection during pregnancy (Katsufrakis & Workowski, 2008). Women may use female condoms throughout pregnancy.

BOX 12.3 ✻ Focus on Communication

Julberry Adams is 4 months pregnant and no longer lives with the father of her baby.

Less Effective Communication

Nurse: Do you have any questions, Mrs. Adams?
Julberry: I'm not Mrs. Adams.
Nurse: I'm sorry, Ms. Adams. Do you have any questions?
Julberry: How long into pregnancy can I have sex?
Nurse: Well, since you're single, you don't really need that kind of advice. Let's talk about exercise and nutrition instead.

More Effective Communication

Nurse: Do you have any questions, Mrs. Adams?
Julberry: I'm not Mrs. Adams.
Nurse: I'm sorry, Ms. Adams. Do you have any questions?
Julberry: How long into pregnancy can I have sex?
Nurse: Basically, as long as you're comfortable and you don't have any complications.
Julberry: Good. My new boyfriend made me promise to ask today.

Health teaching is an art separate from teaching morality. In the first scenario, the nurse cuts off communication by making a judgment to supply only information that the nurse thinks that her client needs. In the second scenario, the nurse actively listens to the client, focuses on her needs and concerns, and supplies the information the client has requested.

✔ Checkpoint Question 12.1

Which statement by Julberry Adams would alert you that she needs more teaching about self-care practices during pregnancy?

a. "I take either a shower or tub bath, because I know both are safe."
b. "I wash my breasts with clear water, not with soap, every day."
c. "I'm glad I don't have to ask my boyfriend to use condoms anymore."
d. "I'm wearing low-heeled shoes to try to avoid backache."

Exercise

Extreme exercise has been associated with lower birth weight but moderate exercise is healthy during pregnancy. It can help prevent circulatory stasis in the lower extremities. It also can offer a general feeling of well-being. For some women, teaching about exercise focuses on helping them realize the need for exercise and urging them to get enough. Others may need to be cautioned to restrict exercise or participation in contact sports.

The average, well-nourished women should exercise during pregnancy a minimum of 3 times weekly for 30 consecutive minutes (Rojas, Wood, & Blakemore, 2007). An exercise program should consist of 5 minutes of warm-up exercises, an active "stimulus" phase of 20 minutes, and then 5 minutes of cool-down exercises. The type of activity chosen depends on a woman's interests. Exercises that involve large muscle groups rhythmically, such as walking, are best. The intensity of the exercise program depends on a woman's cardiopulmonary

fitness. Before she begins any exercise program, make sure a woman has consulted her physician or nurse-midwife. Women who know they have an incompetent cervix or have had cerclage to correct this and women who develop any complication of pregnancy such as bleeding, PIH, preterm rupture of membranes, or preterm labor or whose fetus is growth restricted should check with their primary health care provider before beginning or continuing an exercise program.

Both pregnant and nonpregnant women should exercise at 70% to 85% of their maximum heart rate. The easiest way to calculate this is to subtract a woman's age from 220, then multiply this by 70% or 85%. For example, during exercise a 23-year-old woman should have a pulse range of 137 to 167 (220 minus 23 times 70% and 85%, respectively). For a woman of 35, this target range would be 129 to 157.

Teach women how to assess quickly if they are exercising too strenuously by self-evaluating their ability to continue talking while exercising. If a woman is too short of breath to do this, she is exercising beyond her target heart rate.

In additional to being healthy during pregnancy, a planned exercise program may have long-term benefits such as:

- Lowering cholesterol level
- Reducing risk of osteoporosis
- Increasing energy level
- Maintaining a healthy body weight
- Decreasing risk of heart disease
- Increasing self-esteem and well-being

As a rule, a woman can continue any sport she participated in before pregnancy unless it was one that involved body contact, such as soccer. If a woman is a competent horsewoman, for example, there is little reason for her to discontinue riding until it becomes uncomfortable. Pregnancy is not the time to learn to ride, however, because a beginning rider is at greater risk for being thrown than is an experienced rider. The same principles apply to skiing and bicycling. An accomplished skier or bicyclist may continue the activity in moderation until balance becomes a problem. Pregnancy is not the time to learn to ski or ride a bicycle, however, because the lack of skill could result in many falls.

Walking is the best exercise during pregnancy, and women should be encouraged to take a walk daily unless inclement weather, many levels of stairs, or an unsafe neighborhood are contraindications (Box 12.4). Jogging, in contrast, is questioned because of the strain that the extra weight of pregnancy places on the knees. Late in pregnancy, jogging can cause pelvic pain from relaxed symphysis pubis movement. A high-impact aerobics program is also contraindicated because this can be strenuous on both pelvic and knee joints (Kramer & McDonald, 2007).

Swimming is a good activity for pregnant women and, like bathing, is not contraindicated as long as the membranes are intact. It may help relieve backache during pregnancy (Young & Jewell, 2009). Diving or long-distance swimming or any other activity carried out to a point of extreme fatigue should be avoided. Epidemiologic studies suggest that an elevation of maternal body temperature by 2° C for at least 24 hours can cause a range of developmental defects, but there is little information on thresholds for shorter exposures. Use of hot tubs and saunas after workouts longer than 15 minutes is contraindicated, however, on the chance these could raise the internal fetal temperature. General guidelines for exercise during pregnancy are highlighted in Box 12.5.

BOX 12.4 ✻ Focus on Evidence-Based Practice

Can a telephone call stimulate women to exercise more? All women need to exercise during pregnancy, but doing this may be more difficult for women living in rural than urban areas as they have less access to classes or facilities for exercise. To investigate whether a simple telephone call could motivate rural adults to increase their activity level, nurse researchers divided into two research groups 86 physically inactive adults living in rural communities who stated that they were ready to increase physical activity during the next 6 months. The first group, or study group, received a pedometer and monthly exercise motivational telephone calls over the next 6 months. The second group, or control group, received an equal number of telephone calls but without exercise motivational content. How much physical activity the participants engaged in was measured by self-reports. Results showed that participants in the study group improved in self-efficacy toward exercise but not in the actual amount of physical exercise they undertook.

Would the results of this study be useful when counseling pregnant women about exercise in pregnancy? Does it suggest that motivating women to exercise is not an easily solved problem?

Source: Bennett, J. A., et al. (2008). A telephone-only motivational intervention to increase physical activity in rural adults: a randomized controlled trial. *Nursing Research, 57*(1), 24–32.

Sleep

The optimal condition for body growth occurs when growth hormone secretion is at its highest level—that is, during sleep. This, plus the overall increased metabolic demand of pregnancy, appears to be the physiologic reason that pregnant women need an increased amount of sleep or at least need rest to build new body cells during pregnancy.

Pregnant women rarely have difficulty falling asleep at night because of this increased physiologic need for sleep. If a woman has trouble falling asleep, drinking a glass of warm milk may help. Relaxation exercises (lying quietly, systematically relaxing neck muscles, shoulder muscles, arm muscles, and so on) also may be effective.

Late in pregnancy, a woman often finds herself awakened from sleep at short, frequent intervals by the activity of her fetus. Frequent waking this way leads to loss of rapid eye movement (REM) sleep. This can cause a woman to feel anxious or not well rested, although she has slept her usual number of hours. Pyrosis (heartburn) or dyspnea (shortness of breath) also can cause her to come awake, especially if she has been lying flat. In this instance, sleeping with two pillows or on a couch with an armrest may be helpful.

To obtain enough sleep and rest during pregnancy, most pregnant women need a rest period during the afternoon as well as a full night of sleep. A good resting or sleeping

BOX 12.5 * Focus on Family Teaching

Guidelines for Exercise in Pregnancy

Q. Julberry Adams asks you, "Now that I'm pregnant, can I still do aerobic exercises?"

A. Use the following recommendations as guidelines for exercising while you're pregnant:

1. Perform regular exercise (about three times per week) rather than engaging in intermittent activity.
2. Do not perform vigorous exercise in hot, humid weather or if you have a fever to avoid overexerting yourself or developing hyperthermia.
3. Avoid activities that require jumping, jarring motions, or rapid changes in direction such as jogging, because your joints may be unstable.
4. Exercise on a wooden floor or a tightly carpeted surface to reduce shock to the abdomen or knees and provide a sure footing.
5. To avoid muscle cramping, avoid exercises and motions that involve deep flexion or joint extension, such as stretching with the toes extended.
6. Always start your exercise program by warming up for approximately 5 minutes with activities such as slow walking or stationary cycling with low resistance.
7. End your exercise program with a period of gradually declining activity that includes gentle, stationary stretching. Because of the increased risk of joint injury, do not stretch to the point of maximum resistance.
8. Measure your heart rate at times of peak activity. Talk with your primary care provider about target heart rate and limits, and do not exceed them.
9. When getting up from lying on the floor, do so gradually to prevent dramatic blood pressure changes or stretching of the round ligament that can lead to sharp abdominal pain.
10. Drink liquids liberally before and after exercise to prevent dehydration. If necessary, interrupt your activity to replenish fluids.
11. If you were sedentary before pregnancy, begin your exercise program with physical activity of very low intensity and advance your activity level gradually.
12. Stop any activity and contact your primary care provider if any unusual symptoms appear.
13. Perform strenuous activities for no longer than 20 minutes.
14. To prevent supine hypotension do not exercise in the supine position (lying down flat) after the fourth month of pregnancy.
15. Avoid exercises that employ a Valsalva maneuver (holding your breath, bearing down) because these actions decrease blood supply to the fetus.
16. Make sure your caloric intake is adequate to meet not only the extra energy needs of pregnancy but also those of the exercise performed.

position is a modified **Sims' position,** with the top leg forward (Fig. 12.1). This position puts the weight of the fetus on the bed, not on the woman, and allows good circulation in lower extremities.

Be certain a woman knows to avoid resting on her back, as supine hypotension syndrome (faintness, diaphoresis, and hypotension from the pressure of the expanding uterus on the inferior vena cava) can develop in this position. Also be certain she knows not to rest with her knees sharply bent either when sitting or lying down, because of the increased risk of venous stasis this causes below the knee.

Employment

Changes in public assistance laws that encourage women to seek employment have led to more women working during pregnancy than ever before. Unless a woman's job involves exposure to toxic substances, lifting heavy objects, other kinds of excessive physical strain, long periods of standing or sitting, or having to maintain body balance, there are few reasons a woman cannot continue to work throughout pregnancy (Bonzini, Coggon, & Palmer, 2007). Women who are unable to continue work are protected from loss of employment benefits during pregnancy by federal law (Public Law 95-555). However, this law does not cover women who work for companies with fewer than 15 employees.

According to this law, an employer cannot:

- Deprive women of seniority rights, in pay or promotion, because they take a maternity leave
- Treat women returning from maternity leave as new hires, starting over on the eligibility period for pension and other benefits
- Force pregnant women to leave if they are able to and want to continue working
- Refuse to hire women just because they are pregnant or fire them for the same reason
- Refuse to cover employees' normal pregnancy and birth expenses in the company health plan or pay less for pregnancy than for other medical conditions
- Refuse to pay sick leave or disability benefits to women whose difficult pregnancies keep them off the job

Passed in 1993, the Family and Medical Leave Act, another federal law, guarantees women the right to 12 weeks of unpaid, job-protected leave for the birth of a child, the adoption of or foster placement of a child, when a woman is needed to care for a parent, spouse, or child with a serious

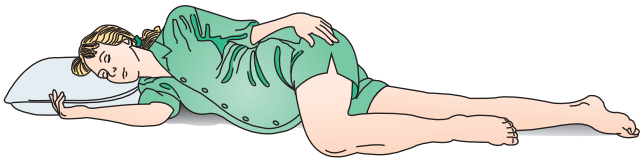


FIGURE 12.1 A modified Sims' position is a good rest position during pregnancy. Notice that the weight of the fetus rests on the bed.

health condition, or because of a serious personal health condition (29 CFR 825.11). Specifically mentioned in this law is any period of incapacity because of pregnancy or for prenatal care. Families need to be educated about this important law because many women are still not aware that they can take time off from work during pregnancy or spend time with a new baby without penalty of losing their job. Additional women may be able to qualify for provisions under the Americans With Disabilities Act.

Some occupations are hazardous during pregnancy and should be discontinued because they bring women into contact with harmful substances. For example, nurses working with anesthetic gases in operating rooms or dental offices are reported to have a higher incidence of spontaneous miscarriage and, possibly, congenital anomalies in children than nurses working in other locales, probably because of exposure to nitrous oxide (National Institute of Occupational Safety and Health, 2007). Nurses working with chemotherapy agents are also at risk. They should wear gloves to protect themselves from exposure to these drugs, which are possibly teratogenic. Ribavirin (Virazole), an antibiotic used to treat respiratory syncytial infections, is also apparently teratogenic if inhaled by health care providers (Karch, 2009).

Other problems that can occur with employment include interference with adequate rest and nutrition. Urge a woman who works outside her home to put her feet up and rest when performing tasks that can be done in that position. Review what she eats at fast-food restaurants or packs for herself to be certain she plans ways to make this type of lunch as nutritious as if she were eating at home.

Remember, most women work to augment or supply the family income, not for fun. Even those who could afford to leave their jobs may not be willing to sacrifice the collegial relationships and sense of fulfillment derived from work, or the lifestyle their income has allowed them to enjoy. Counseling them to reserve periods during the day for rest and to eat a healthy diet is more effective than suggesting they resign from their jobs during pregnancy to get more rest (Box 12.6).

✔ Checkpoint Question 12.2

Julberry Adams describes her typical day to you. What would alert you that she may need further pregnancy advice?

a. "I jog rather than walk to get an increased amount of exercise."
b. "I always go to sleep on my side, not on my back."
c. "I pack a lunch every day so I know I won't eat junk food."
d. "I walk around my desk every hour to help leg circulation."

Travel

Because we live in a mobile society, many women have questions about travel during pregnancy (McGovern, Boyce, & Fischer, 2007). Early in a normal pregnancy, there are no restrictions. If a woman is susceptible to motion sickness, advise her not to take any medication for this unless it is specifically prescribed or approved by her physician or nurse-midwife. Suggest that she use a "sea-sick" wrist or acupuncture band instead. Late in pregnancy, travel plans should take into consideration the possibility of early labor, requiring birth at a strange setting where a woman's obstetric history will be unknown.

BOX 12.6 ✻ Focus on Family Teaching

Guidelines for Pregnant Women Working Outside their Home

Q. Julberry Adams asks you, "Now that I'm pregnant, can I continue to work at the art gallery?"

A. Use the following suggestions as guidelines for safe pregnancy work practices:

- Plan rest periods during your break periods rather than running errands, etc.
- Try to use at least part of your lunch hour to rest. Lie on your left side in a break room if possible. If this is not possible, then rest sitting with your legs elevated.
- If your job involves long periods of standing, think of times you could stop and elevate your legs (working in a low file drawer, reading time in a classroom, etc.).
- Walk around periodically to avoid prolonged standing or sitting in one position if possible; stretch your back periodically to avoid backache.
- Wear support hose to improve venous return to your lower extremities.
- Avoid excessive overtime or working longer than 8-hour shifts.
- Empty your bladder every 2 hours to help prevent bladder infection.
- Get extra rest on weekends or days off.
- Take great caution when working around equipment that requires good balance. Avoid ladders or climbing late in pregnancy, when balance can be a problem.
- Learn your target heart rate for exercise. If your job involves strenuous exercise, stop and rest at the point your target heart rate is exceeded.
- Be sure you are not relying on fast foods for lunch. Take time to pack or purchase nutritious foods.

Regardless of the month of her pregnancy, if a woman plans to spend time at a remote location, such as a campsite, be certain she knows the location of a nearby health care facility should an unexpected complication occur. Caution her not to eat uncooked fruits, vegetables, or meat or drink unpurified water at such sites. If she is going to be away from home for an extended time, she should make arrangements to visit a health care provider in that area so she can keep the schedule of her regular prenatal visits. Encourage her to make these plans far enough in advance so that her records can be copied and sent with her or be forwarded to the interim health care provider with her consent. Also, make sure she has enough of her prescribed vitamin supplement plus adequate prescriptions for refills as necessary.

Advise a woman who is taking a long trip by automobile to plan for frequent rest or stretch periods. Preferably every hour, but at least every 2 hours, she should get out of the car and walk a short distance. This break relieves stiffness and muscle aches and improves lower extremity circulation, helping prevent varicosities, hemorrhoids, and thrombophlebitis.

Pregnant women may drive automobiles as long as they fit comfortably behind the steering wheel. They should use seat belts like everyone else. Occasionally, uterine rupture has

been reported from seat belt use, but overall evidence suggests that seat belts reduce mortality among pregnant women in car accidents, as they do for everyone (Rojas, Wood, and Blakemore, 2007). Both shoulder harnesses and lap belts should be used. The lap belt should be worn as snugly as comfortable so that it fits under the abdominal bulge and across the pelvic bones. The shoulder harness should be snug but comfortable, worn across the shoulder, chest, and upper abdomen. A pad may be placed under the shoulder harness at the neck to avoid chafing (Fig. 12.2).

Pregnancy is also a time for a family to think about transportation safety for the newborn. Purchasing a car seat is an investment that not only is legally required for transporting infants but also helps guarantee their safety. Families who cannot afford to purchase an infant car seat may want to ask friends or relatives about the possibility of borrowing one no longer needed. Many hospitals and local Red Cross chapters provide infant seats on a rental or loan basis for families who may find it difficult to obtain one in other ways. The American Academy of Pediatrics (AAP) recommends that when considering using a preowned car seat, parents should be certain that the car seat was not in a previous crash, has not been recalled, is not too old for use according to the manufacturer's instructions, has no cracks in the frame and no missing parts, and has a label from the manufacturer on the car seat along with instructions for use (AAP, 2009). One easy way to determine if a used car seat has been recalled is to check the web site http://www.odi.nhtsa.dotgov/cars/problems/recalls/childseat.cfm.

FIGURE 12.2 Encourage women to wear seatbelts during pregnancy. The bottom strap should cross beneath the abdomen.

Traveling by plane for women is not contraindicated during pregnancy as long as the plane has a well-pressurized cabin (true of commercial airlines but not of all small private planes) and a woman walks the length of the plane every hour to help prevent thrombophlebitis. Some airlines do not permit women who are more than 7 months pregnant to board; others require written permission from a woman's primary care provider. Advise a woman to investigate these restrictions by calling the airline or a travel agency before making such travel plans.

With businesses becoming global, more women than ever before are asked to travel internationally. Women who travel abroad may need additional immunizations, such as cholera vaccine, for entry into certain countries (McGovern, Boyce, and Fischer, 2007). All live virus vaccines (measles, mumps, rubella, and yellow fever) are contraindicated during pregnancy and should not be administered unless the risk of the disease outweighs the risk to the pregnancy. Before allowing any immunization during pregnancy, a woman should ask her primary care provider to verify it will be safe. Pregnancy does not alter indications for rabies vaccine because without the vaccine, a fatal disease could occur. Tetanus is also treated the same in pregnant women as in others.

What if... Julberry Adams tells you she usually drives to her parents' house for vacation but cannot this year because she no longer fits behind the wheel of her compact car. She asks you if it would be better for her to take the train or fly. How would you respond?

Discomforts of Early Pregnancy: The First Trimester

Early pregnancy symptoms can often cause discomfort in an expectant woman. Providing empathic and sound advice about measures to relieve these discomforts helps promote overall health and well-being. Although these symptoms are classified as minor, they may not seem minor to a woman who wakes up each morning feeling nauseated, wondering if she will ever feel like herself again. Also, each of these symptoms has the potential to lead to problems that are more serious.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Health-seeking behaviors related to learning more about the minor discomforts of early pregnancy such as morning nausea

Outcome Evaluation: Client states she is familiar with early discomforts of pregnancy and will take measures to relieve them such as drinking ginger tea for nausea.

Most women will experience at least one minor discomfort of pregnancy. Because each woman's experience is unique, nursing diagnoses and care must be developed according to each woman's individual needs. Examples of nursing diagnoses that might be

developed for women experiencing the discomforts of early pregnancy are:

- Health-seeking behaviors related to interest in using herbal remedies to relieve discomforts of pregnancy
- Constipation related to reduced peristalsis in pregnancy
- Fatigue related to increased physiologic need for sleep and rest during pregnancy
- Acute pain related to frequent muscle cramps secondary to physiologic changes of pregnancy
- Disturbed sleep pattern related to frequent need to empty bladder during night

Breast Tenderness

Breast tenderness is often one of the first symptoms noticed in early pregnancy; it may be most noticeable on exposure to cold air. For most women, the tenderness is minimal and transient, something they are aware of but not something that overly concerns them. If the tenderness is enough to cause discomfort, encourage a woman to wear a bra with a wide shoulder strap for support and to dress warmly to avoid cold drafts if cold increases symptoms. If actual pain exists, the presence of conditions such as nipple fissures or other explanations for the pain, such as breast abscess, need to be ruled out.

Palmar Erythema

Palmar erythema, or palmar pruritus, occurs in early pregnancy and is probably caused by increased estrogen levels. Constant redness or itching of the palms can make a woman believe she has developed an allergy. Explain that this type of itching in early pregnancy is normal before she spends time and effort trying different soaps or detergents or attempting to implicate certain foods she has eaten. Calamine lotion can be soothing. As soon as a woman's body adjusts to the increased level of estrogen, the erythema and pruritus disappear.

Constipation

As peristalsis slows and the weight of a growing uterus presses against the bowel, constipation can occur (Bernstein & Weinstein, 2007). Discuss preventive measures with a woman early in pregnancy to help her avoid this problem. Encourage her to evacuate her bowels regularly (many women neglect this first simple rule); increase the amount of fiber in her diet by eating raw fruits, bran, and vegetables; and to drink at least eight 8-oz glasses of water daily.

Some women find a prescribed oral iron supplement contributes to constipation. Reinforce the need for this supplement to build fetal iron stores. Help a woman find a method to relieve or prevent constipation other than omitting taking the supplement. Iron supplements are more rapidly absorbed on an empty stomach because iron is absorbed best from an acid medium. Women should take iron with juice rather than dairy products for this same reason.

Women should not use mineral oil to relieve constipation as it can absorb fat-soluble vitamins (A, D, K, and E), vitamins that are necessary for both good fetal and maternal health, and flush them out of the body.

Enemas also should be avoided because their action might initiate labor. Over-the-counter laxatives are also contraindicated, as are all nonessential drugs during pregnancy unless specifically prescribed or sanctioned by a woman's physician or nurse-midwife. If dietary measures and attempts at regular bowel evacuation fail, a stool softener, such as docusate sodium (Colace), or evacuation suppositories, such as glycerin, may be prescribed. Some women have extensive flatulence accompanying constipation. Recommend avoiding gas-forming foods, such as cabbage or beans, to help control this problem.

Nausea, Vomiting, and Pyrosis

At least half of pregnant women experience other gastrointestinal symptoms such as nausea, vomiting, and pyrosis (heartburn). Because these symptoms also interfere with nutrition, they are discussed in Chapter 13.

Fatigue

Fatigue is extremely common in early pregnancy, probably because of increased metabolic requirements. Much of it can be relieved by increasing the amount of rest and sleep. Some women, however, are reluctant to take time out of their day for rest. They know that pregnancy is not an illness, and so they proceed as if nothing is happening to them. Rarely is there justification during a normal pregnancy for women to take extra days off from work because of their condition, but it is also unrealistic to proceed as if nothing is different. Fatigue can increase the amount of morning sickness a woman experiences. If she becomes too tired, she may not eat properly and nutrition can suffer. If she remains on her feet without at least one break during a day, the risk for varicosities and the danger of thromboembolic complications increase.

For all these reasons, ask women at prenatal visits whether they manage to have at least one short rest period every day. A woman who works outside her home at a job that requires her to be on her feet most of the day might use part of her lunch hour to sit with her feet elevated, such as on an adjoining chair (Fig. 12.3). After she returns home from work in the evening, she may need to modify her customary routine from typical activities such as cooking dinner or watching a child's soccer game to resting, then cooking dinner and going to the soccer game, or resting while her partner cooks

FIGURE 12.3 A "feet-up" break during a workday helps prevent ankle edema. (© Caroline Brown, RNC, MS, DEd.)

dinner (part of "we are having a baby at our house" for a partner who does not usually share in household chores). Women who work at sedentary jobs, inside or outside their home, may, in contrast, need to use this time to increase their activity, such as taking a walk or using a treadmill to ensure healthy lower extremity circulation.

Muscle Cramps

Decreased serum calcium levels, increased serum phosphorus levels, and, possibly, interference with circulation commonly cause muscle cramps of the lower extremities during pregnancy. This problem is best relieved if a woman lies on her back momentarily and extends her involved leg while keeping her knee straight and dorsiflexing the foot until the pain disappears (Fig. 12.4).

If a woman is experiencing frequent leg cramps, she may be advised to take magnesium citrate or aluminum hydroxide gel (Amphojel), which binds phosphorus in the intestinal tract and thereby lowers its circulating level. Lowering milk intake to only 1 pint daily and supplementing this with calcium lactate may also help to reduce the phosphorus level. Elevating lower extremities frequently during the day to improve circulation and avoiding full leg extension, such as stretching with the toes pointed, may also be helpful. Typically, muscle cramps are a minor symptom of pregnancy, but the pain is extreme and the intensity of the contraction can be frightening. Always ask at prenatal visits if this is a problem. Otherwise, women may not realize that cramping is pregnancy related and so fail to report it.

Pregnant women also have a higher incidence of "restless leg syndrome" (waking at night because of spontaneous leg movement) than nonpregnant women. This movement can be so annoying and frequent that women have difficulty sleeping (Smith & Tolson, 2008). Mirapex (pramipexole dihydrochloride), a drug frequently recommended for restless leg syndrome, should not be taken during pregnancy.

Hypotension

Supine hypotension is a symptom that occurs when a woman lies on her back and the uterus presses on the vena cava, impairing blood return to her heart. A woman experiences an irregular heart rate and a feeling of apprehension. The method of relieving the problem is simple: if a woman turns or is turned onto her side, pressure is removed from the vena cava, blood flow is restored, and the symptoms quickly fade. To prevent the syndrome, advise pregnant women to always rest or sleep on their side, not their back. If they can only fall asleep on their back, they should insert a small firm pillow under their right hip to cause the weight of their uterus to shift off their vena cava.

If a woman rises suddenly from a lying or sitting position or stands for an extended time in a warm or crowded area, she may faint from the same phenomenon (blood pooling in the pelvic area or lower extremities). Rising slowly and avoiding extended periods of standing prevent this problem. If a woman should feel faint, sitting with her head lowered—the same action as for any person who feels faint—alleviates the problem.

Varicosities

Varicosities, or the development of tortuous leg veins, are common in pregnancy because the weight of the distended uterus puts pressure on the veins returning blood from the lower extremities. This causes pooling of blood and distention of the vessels. The veins become engorged, inflamed, and painful. Although usually confined to the lower extremities, varicosities can extend up to and include the vulva. They occur most frequently in women with a family history of varicose veins and those who have a large fetus or a multiple pregnancy. Urge such women to take active measures to prevent varicosities beginning in early pregnancy; if left until the second trimester, the best they will be able to accomplish is relief of pain from already formed varicosities.

Resting in a Sims' position or on the back with the legs raised against the wall (a small firm pillow under their right hip) or elevated on a footstool for 15 to 20 minutes twice a day is a good precaution (Fig. 12.5). Caution women not to sit with their legs crossed or their knees bent and to avoid constrictive knee-high hose or garters.

Some women, especially those who developed varicosities during a previous pregnancy, may need elastic support stockings such as T.E.D. stockings for relief of varicosities in a second pregnancy. Urge a woman to put on support stockings before she arises in the morning as once she is on her feet, the

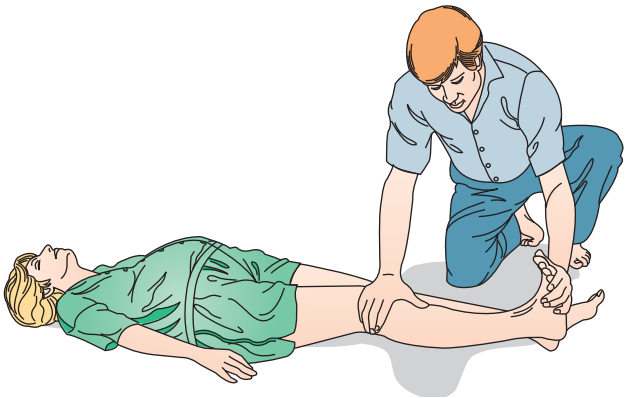

FIGURE 12.4 Relieving a leg cramp in pregnancy. Pressing down on the knee and pressing the toes backward (dorsiflexion) relieves most cramps. Here, a woman's partner helps.

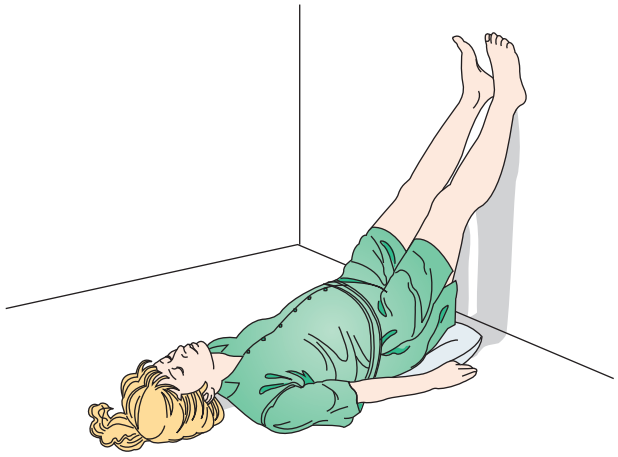

FIGURE 12.5 Position to relieve varicosities. The mother keeps a pad under her right hip to prevent supine hypotensive syndrome.

pooling of blood begins, and the stockings will be less effective. When applied properly, the stockings should reach an area above the point of distention. Be certain that a woman understands the stockings should be labeled "medical support hose." Many pantyhose manufacturers advertise their stockings as giving "firm support," and a woman may assume erroneously this is sufficient for her.

Because it stimulates venous return, exercise is as effective as rest periods for alleviating varicosities. Most women assume they do not need set exercise periods during pregnancy because they work hard at other activities. If they analyze the type of work they do, however, they may realize that a great deal of their work leads to venous stasis of the lower extremities. Women stand in one position to wash dishes, cook dinner, run a copying machine, defend a client in court, process a part on an assembly line, or teach a class. Sitting at a desk for prolonged periods of time with legs dependent also encourages venous stasis. Advise women to break up these long periods of sitting or standing with a "walk break" at least twice a day. As a rule, their families or fellow workers will benefit by accompanying them. Partners, especially, may discover that they, too, walk very little during their workday.

Vitamin C may be helpful in reducing the size of varicosities because it is necessary for the formation of blood vessel collagen and endothelium. Ask at prenatal visits if women include fresh fruit or juice in their diet every day.

Hemorrhoids

Hemorrhoids (varicosities of the rectal veins) occur commonly in pregnancy because of pressure on these veins from the bulk of the growing uterus (Quijano & Abalos, 2009). Daily bowel evacuation to relieve constipation and resting in a modified Sims' position daily are both helpful. At day's end, assuming a knee–chest position (Fig. 12.6) for 10 to 15 minutes is an excellent way to reduce the pressure on rectal veins. A knee–chest position may make a woman feel lightheaded initially. If this happens, she should remain in this position for only a few minutes at first, and then gradually increase the time until she can maintain the position comfortably for about 15 minutes. A stool softener such as docusate sodium (Colace) may be recommended for a woman who already has hemorrhoids. Applying witch hazel or cold compresses to external hemorrhoids can help relieve pain. Replacing hemorrhoids with gentle finger pressure can also be helpful. As with varicosities, think prevention, not just providing help for already established hemorrhoids.

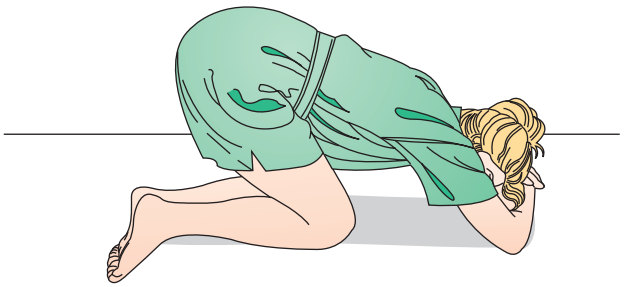

FIGURE 12.6 Knee–chest position. Because the weight of the uterus is shifted forward, this position promotes free flow of urine from the kidneys (preventing urinary tract stasis and infection) and better circulation in the rectal area (preventing hemorrhoids).

✔ Checkpoint Question 12.3

Julberry Adams tells you she is developing painful hemorrhoids. Advice you would give her would be:

a. "Take a tablespoon of mineral oil with each of your meals."
b. "Omit fiber from your diet. This will prevent constipation."
c. "Lie on your stomach daily to drain blood from rectal veins."
d. "Witch hazel pads feel cool against swollen hemorrhoids."

Heart Palpitations

On sudden movement, such as turning over in bed, a pregnant woman may experience a bounding palpitation of the heart. This is probably because of circulatory adjustments necessary to accommodate her increased blood supply during pregnancy. Although only momentary, the sensation can be frightening because the heart seems to skip a beat. It is reassuring for women to know that palpitations are normal and to be expected on occasion. Only if they occur very frequently or continuously or are accompanied by pain are they a concern and should be reported to a physician or nurse midwife. Gradual, slow movements help prevent this from happening so frequently.

Frequent Urination

Frequent urination occurs in early pregnancy because of the pressure of the growing uterus on the anterior bladder. The sensation may last for about 3 months, sometimes beginning as early as the first or second missed menstrual period, disappear in midpregnancy when the uterus rises above the bladder, and return again in late pregnancy as the fetal head presses against the bladder (Fig. 12.7).

When a woman describes frequency of urination, be certain this is the only urinary symptom she is experiencing. Ask her about any burning or pain on urination or whether she has noticed any blood in her urine, signs of urinary tract infection.

Women should not restrict their fluid intake to try to diminish frequency of urination, as fluids are necessary to allow their blood volume to double. Suggesting that a woman reduce the amount of caffeine she is drinking may be helpful. Most importantly, a woman needs to understand that voiding more frequently is a normal phenomenon. Unless a woman is cautioned that the sensation of frequency returns after lightening (the settling of the fetal head into the inlet of the pelvis at pregnancy's end), she may worry at that time that she has a urinary tract infection. Again, unless other symptoms are present, she can be assured this a normal finding.

Occasionally, a woman notices stress incontinence (involuntary loss of urine on coughing or sneezing) during pregnancy. Although this is largely unpreventable, doing Kegel exercises (alternately contracting and relaxing perineal muscles; Box 12.7) helps strengthen urinary control, directly strengthens perineal muscles for birth, and decreases the possibility of stress incontinence (Smith, 2007).

Abdominal Discomfort

Some women experience uncomfortable feelings of abdominal pressure early in pregnancy. Women with a multiple pregnancy may notice this throughout pregnancy. Typically, pregnant women stand with their arms crossed in front of

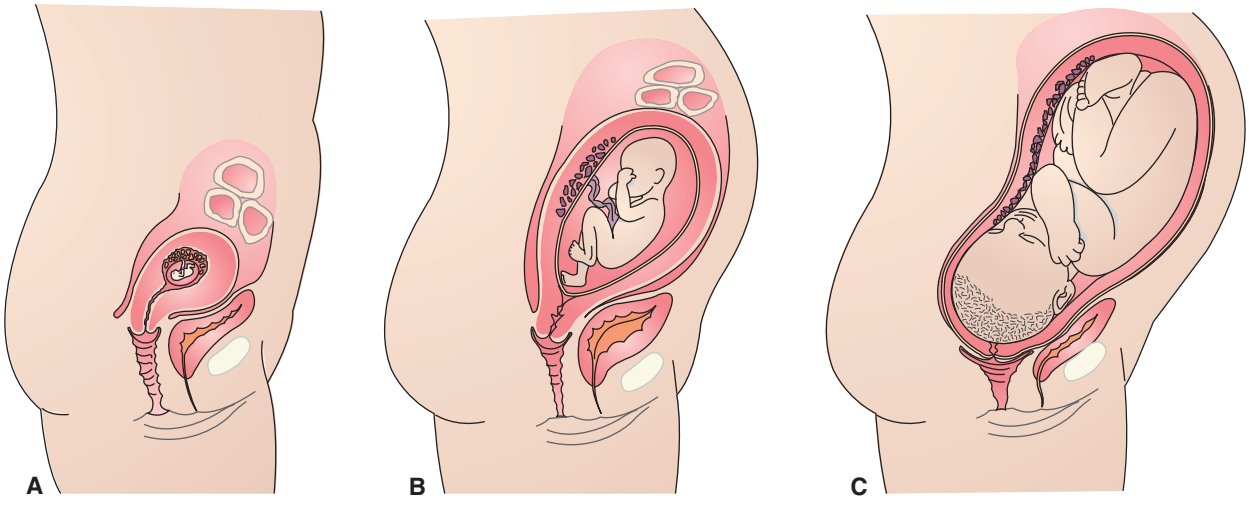

FIGURE 12.7 Bladder changes during pregnancy. (**A**) Early pregnancy: the uterus presses against the bladder, causing frequent urination. (**B**) Middle pregnancy: urinary frequency is relieved. (**C**) Late pregnancy: the uterus is again pressing on the bladder, leading to the recurrence of urinary frequency.

them because the weight of their arms resting on their abdomen relieves this discomfort.

When a woman stands up quickly, she may experience a pulling, sometimes sharp and frightening, pain in the right or left lower abdomen from tension on a round ligament. She can prevent this from happening by always rising slowly from a lying to a sitting, or from a sitting to a standing position.

BOX 12.7 ✻ Kegel Exercises

Kegel exercises are exercises designed to strengthen the pubococcygeal muscles. Each is a separate exercise and should be done about three times a day.

1. Squeeze the muscles surrounding the vagina as if stopping the flow of urine. Hold for 3 seconds. Relax. Repeat this sequence 10 times.
2. Contract and relax the muscles surrounding the vagina as rapidly as possible 10 to 25 times.
3. Imagine that you are sitting in a bathtub of water and squeeze muscles as if sucking water into the vagina. Hold for 3 seconds. Relax. Repeat this action 10 times.
4. Caution: Do not regularly start and stop the flow of urine during urination to try and strengthen muscles as this can lead to incomplete emptying of the bladder.

It may take as long as 6 weeks of exercise before pubococcygeal muscles are strengthened. In addition to strengthening urinary control and preventing stress incontinence, Kegel exercises can lead to increased sexual enjoyment because of the tightened vaginal muscles.

Because round ligament pain may simulate the abrupt pain that occurs with ruptured ectopic pregnancy, a woman's description of the pain must be evaluated carefully.

Leukorrhea

Leukorrhea, a whitish, viscous vaginal discharge or an increase in the amount of normal vaginal secretions, occurs in response to the high estrogen levels and the increased blood supply to the vaginal epithelium and cervix in pregnancy. A daily bath or shower to wash away accumulated secretions and prevent vulvar excoriation usually controls this problem. Wearing cotton underpants and sleeping at night without underwear can be helpful to reduce moisture and possible vulvar excoriation. Some women may need to wear a perineal pad to control the discharge. Caution women not to use tampons because this could lead to stasis of secretions and subsequent infection. Advise women to contact their physician or nurse-midwife if there is a change in the color, odor, or character of this discharge as these suggest infection.

A woman with vulvar pruritus needs evaluation because this strongly indicates infection. Be certain she is describing pruritus-like symptoms and is not describing burning on urination, a sign of an early bladder infection (which also needs therapy, but of a different type). Common vaginal infections such as *Candida* that present with pruritus are discussed in Chapter 47.

Avoiding tight underpants and pantyhose may help prevent vulvar and vaginal infections, particularly yeast infections. Although over-the-counter medications for yeast infections are available, caution women to contact their health care provider rather than self-treat vaginal infections during pregnancy so their health care provider knows infections are occurring.

A woman who is uncomfortable about discussing this part of her body or who associates vaginal infections with poor hygiene or sexually transmitted infection may be reluctant to mention an irritating vaginal discharge. At each prenatal visit, therefore, be sure to ask a woman specifically whether she is experiencing this problem.

What if... Julberry Adams tells you she has urinary frequency. She also reports a white vaginal discharge. How would you go about evaluating whether she is experiencing a normal discomfort of pregnancy or a urinary tract infection?

Discomforts of Middle to Late Pregnancy

At about the 20th to 24th weeks, the midpoint of pregnancy, a woman is usually ready for further health teaching that relates to the new developments that will occur in the latter half of pregnancy. As she starts to view the child within her as a separate person, she becomes interested in discussing and making plans for the signs and symptoms of beginning labor, birth, and the infant's care. The midpoint of a pregnancy is also a good time to describe the new minor symptoms that may occur and to review the precautionary measures to prevent constipation, varicosities, and hemorrhoids, as these increase in intensity late in pregnancy.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Health-seeking behaviors related to learning more about the minor discomforts of late pregnancy such as Braxton Hicks contractions.

Outcome Evaluation: Client states that she feels confident in self-managing the minor discomforts of late pregnancy.

Examples of other possible nursing diagnoses associated with the discomforts of middle to late pregnancy are:

- Acute abdominal pain related to sudden postural change in position
- Anxiety related to shortness of breath resulting from expanding uterine pressure on diaphragm
- Deficient knowledge related to beginning signs of labor
- Pain related to almost constant backache

Backache

As pregnancy advances, a lumbar lordosis develops and postural changes necessary to maintain balance lead to backache. Wearing shoes with low to moderate heels reduces the amount of spinal curvature necessary to maintain an upright posture. Encouraging a woman to walk with her pelvis tilted forward (putting pelvic support under the weight of the fetus) is also helpful. In addition, applying local heat may aid in relieving backache.

To avoid back strain, advise women to squat rather than bend over to pick up objects. Also encourage them always to lift objects by holding them close to the body. For some women, a firmer mattress during this time may be required. Sliding a board under the mattress is a cost-effective alternative for achieving a firmer sleeping surface. Pelvic rocking or tilting, an exercise described in Chapter 14, also helps to prevent and relieve backache.

Backache can be an initial sign of a bladder or kidney infection. Obtaining a detailed account of a woman's symptoms is therefore crucial to ensure that she is describing only backache. Too often, women are observed at a prenatal visit only lying in a lithotomy position on an examining table. Always assess the manner in which a woman walks and what type of shoes she wears as she moves from a waiting room to an examining room to evaluate whether her posture or shoes could be a cause of backache.

Generally, acetaminophen (Tylenol) is considered to be safe and effective for relieving this type of pain during pregnancy. Acupuncture can also be effective (Young & Jewell, 2009). Caution women not to take herbal remedies, muscle relaxants, or analgesics (or any other medication) for back pain without first consulting their physician or nurse-midwife.

Headache

Many women experience headache during pregnancy, apparently from their expanding blood volume, which puts pressure on cerebral arteries. Trying to reduce any possible causative situations, such as eye strain or tension, may lessen the number of headaches they experience. Resting with cold towels on their forehead and taking usual adult doses of acetaminophen usually furnishes adequate relief. Although a few women who have migraine headaches find these worsen during pregnancy, most women notice considerable improvement with this type of headache during pregnancy (see Chapter 49). Caution women that if a headache is unusually intense or continuous, they should report it to their primary care provider. A continuous sharp headache may be a danger sign of high blood pressure during pregnancy.

Dyspnea

As the expanding uterus places pressure on the diaphragm, lung compression and shortness of breath result. A woman will notice this primarily at night if she lies flat. She also will definitely notice it on exertion. To relieve nighttime dyspnea, advise her to sleep with her head and chest elevated so the weight of the uterus falls away from her diaphragm. As pregnancy progresses, she may require two or more pillows to sleep at night to avoid the problem. Caution her to limit her activities during the day to prevent exertional dyspnea. Always question women about this important symptom at prenatal visits to be certain the sensation is not continuous, which describes more than usual involvement.

Ankle Edema

Most women experience some swelling of the ankles and feet during late pregnancy, most noticeably at the end of the day. Women are often first conscious of this when they kick off their shoes to rest and then cannot put them on again comfortably.

As long as proteinuria and hypertension are absent, ankle edema of this nature is a normal occurrence of pregnancy. It is probably caused by general fluid retention and reduced blood circulation in the lower extremities because of uterine pressure. This simple edema can be relieved best by resting in a left side-lying position because this increases the kidney's glomerular filtration rate and also allows good venous return. Sitting for half an hour in the afternoon and again in the evening with the legs elevated is also helpful. Caution women to avoid wearing constricting clothing such as panty girdles

or knee-high stockings because these impede lower extremity circulation and venous return.

Some women need reassurance that ankle edema is normal during pregnancy. Otherwise, they worry that it is a beginning sign of PIH (Menzies et al., 2007). On the other hand, do not dismiss a report of lower extremity edema lightly until you are certain a woman does not exhibit any signs of proteinuria or edema of other, nondependent parts, or has had a sudden increase in weight indicative of PIH.

Braxton Hicks Contractions

Beginning as early as the 8th to 12th week of pregnancy, the uterus periodically contracts and then relaxes again (Cunningham et al., 2008). Early in pregnancy, these sensations, termed *Braxton Hicks contractions,* are not noticeable. By middle or late pregnancy, the contractions become stronger, and a woman who tenses at the sensation may even experience some minimal pain, similar to a hard menstrual cramp. Although these contractions are not a sign of beginning labor, women should inform their primary care provider about them so that they can be evaluated. A rhythmic pattern of even very light but persistent contractions could be a beginning sign of labor.

✔ Checkpoint Question 12.4

Julberry Adams has ankle edema by the end of each day. Which statement by her would reveal that she understands what causes this?

a. "I know this is a beginning complication; I'll call my doctor tonight."
b. "I understand this is from eating too much salt; I'll restrict that more."
c. "I'll rest in a Sims' position to take pressure off lower extremity veins."
d. "I know this is from gaining too much weight. I'll start to diet tomorrow."

PREVENTING FETAL EXPOSURE TO TERATOGENS

A *teratogen* is any factor, chemical or physical, that adversely affects the fertilized ovum, embryo, or fetus. At one time, it was assumed that a fetus in utero was protected from chemical or physical injury by the presence of the amniotic fluid and by the absence of any direct placental exchange between mother and fetus. When infants were born with disorders, it was attributed to the influence of fate, bad luck, or, in some cultures, evil spirits. Today, it is acknowledged that a fetus is extremely vulnerable to environmental injury. Although the causes of many anomalies occurring in utero are still unknown, many specific teratogenic factors have been isolated.

Effects of Teratogens on a Fetus

Several factors influence the amount of damage a teratogen can cause. The strength of the teratogen is one of these. For example, radiation is a known teratogen. In small amounts (everyone is exposed to some radiation every day, such as from sun rays), it causes no damage. However, in large doses (e.g., the amount of radiation necessary to treat cancer of the cervix), serious fetal defects or death can occur.

The timing of the teratogenic insult makes a significant impact on damage done to the fetus.. If a teratogen is introduced before implantation, either the zygote is destroyed or it appears unaffected. If the insult occurs when the main body systems are being formed (in the second to eighth weeks of embryonic life), a fetus is very vulnerable to injury. During the last trimester, the potential for harm again decreases because all the organs of a fetus are formed and are merely maturing. The times when different anatomic areas of a fetus are most likely to be affected by teratogens are shown in Figure 9.5.

Two exceptions to the rule that deformities usually occur in early embryonic life are the effects caused by the organisms of syphilis and toxoplasmosis. These two infections can cause abnormalities in organs that were originally formed normally.

A third factor determining the effects of a teratogen is the teratogen's affinity for specific tissue. Lead and mercury, for example, attack and disable nervous tissue. Thalidomide, a drug once used to relieve nausea in pregnancy, causes limb defects. Tetracycline, a common antibiotic, causes tooth enamel deficiencies and, possibly, long-bone deformities. The rubella virus can affect many organs: the eyes, ears, heart, and brain are the four most commonly attacked.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Health-seeking behaviors related to learning more about teratogens that can affect fetal growth

Outcome Evaluation: Client states that she feels confident in monitoring her environment for the presence of possible teratogens.

Much of the health history information obtained at prenatal visits is taken to help determine if there is a possibility that a woman is being exposed to teratogens during her pregnancy. Examples of nursing diagnoses associated with maternal exposure to teratogens are:

- Health-seeking behavior related to mother's interest in avoiding exposure to substances she could contact at work that would be harmful to a fetus
- Risk for fetal injury related to lack of knowledge about teratogenicity of alcohol, drugs, and cigarettes
- Risk for fetal infection related to maternal transmission of genital herpes

Teratogenic Maternal Infections

Teratogenic maternal infections can involve either sexually transmitted or systemic infections. These organisms that cross the placenta can be viral, bacterial, or protozoan. Most infections important to a healthy pregnancy outcome cause relatively mild, flulike symptoms in a woman but can have much more serious effects on a fetus or newborn. Preventing and predicting fetal injury from infection is complicated because a disease may be subclinical (without any symptoms in the mother) and yet may injure a fetus.

Several diseases that are commonly known to cross the placenta and cause fetal harm are tested for and are described collectively under the umbrella term TORCH, an abbreviation

for *to*xoplasmosis, *r*ubella, *c*ytomegalovirus, and *h*erpes simplex virus. Some laboratories spell the test as TORSCH to show that it includes *s*yphilis. Some sources identify the O with "*o*ther infections," which could include hepatitis B virus (HBV) and human immunodeficiency virus (HIV), illnesses discussed in Chapters 20 and 42. However it is spelled, the TORCH screen is an immunologic survey to determine whether common infections exist in either the pregnant woman (to identify fetal risk factors) or the newborn (to detect if antibodies against the common infectious teratogens are present). Although it is now known that many more than these original four or five maternal infections can cause harm to a fetus or newborn (a chlamydial or streptococcal B infection, for example, can cause pneumonia in the newborn [see Chapter 26]), the TORCH screen is still used extensively as it still provides a quick way to assess the potential risk of common teratogenic infections in pregnant women or newborns. In addition to TORCH screening, ask women if it is all right to screen them for human HIV as you must obtain consent for this test (Pratt, 2007).

Toxoplasmosis

Toxoplasmosis, a protozoan infection, is spread most commonly through contact with uncooked meat, although it may also be contracted through handling cat stool in soil or cat litter (Friars, 2007). A woman experiences almost no symptoms of the disease except for a few days of malaise and posterior cervical lymphadenopathy. Even in light of these mild symptoms, if the infection crosses the placenta, the infant may be born with central nervous system damage, hydrocephalus, microcephaly, intracerebral calcification, and retinal deformities. If the diagnosis is established by serum analysis during pregnancy, therapy with sulfonamides may be prescribed. However, the prevention of fetal deformities is uncertain, and sulfa may lead to increased bilirubin levels in the newborn. Pyrimethamine, an antiprotozoal agent, may also be used. This drug is an antifolic acid drug, so it is administered with caution early in pregnancy to prevent reducing folic acid levels.

As many as 1 in 900 pregnancies may be affected by toxoplasmosis. Prepregnancy serum analysis can be done to identify women who have never had the disease and so are susceptible (about 50% of women). Removing a cat from the home during pregnancy as a means of prevention is not necessary as long as the cat is healthy. On the other hand, taking in a new cat is unwise. Instruct pregnant women to avoid undercooked meat and also not to change a cat litter box or work in soil in an area where cats may defecate to avoid exposure to the disease.

Rubella

The rubella virus usually causes only a mild rash and mild systemic illness in a woman, but the teratogenic effects on a fetus can be devastating (Johnson & Ross, 2007). Fetal damage from maternal infection with rubella (German measles) includes hearing impairment, cognitive and motor challenges, cataracts, cardiac defects (most commonly patent ductus arteriosus and pulmonary stenosis), intrauterine growth restriction (IUGR), thrombocytopenic purpura, and dental and facial clefts, such as cleft lip and palate.

Typically, a rubella titer from a pregnant woman is obtained on the first prenatal visit. A titer greater than 1:8 suggests immunity to rubella. A titer of less than 1:8 suggests that a woman is susceptible to viral invasion. A titer that is greatly increased over a previous reading or is initially extremely high suggests that a recent infection has occurred.

A woman who is not immunized before pregnancy cannot be immunized during pregnancy because the vaccine uses a live virus that would have effects similar to those occurring with a subclinical case of rubella. After a rubella immunization, a woman is advised not to become pregnant for 3 months, until the rubella virus is no longer active. Immediately after a pregnancy, assess whether a woman with low rubella titers would like to be immunized to provide protection against rubella in future pregnancies (Johnson & Ross, 2007).

An increasing concern is women who demonstrate antibodies against rubella yet still become reinfected during pregnancy. Because of this, all pregnant women should avoid contact with children with rashes. Infants who are born to mothers who had rubella during pregnancy may be capable of transmitting the disease for a time after birth. Because of this, an infant may be isolated from other newborns during the newborn period. Be certain a woman is aware that her infant might infect others, including pregnant women. Nurses who care for pregnant women or newborns should receive immunization against rubella to ensure that they neither spread nor contract the disease.

Cytomegalovirus

Cytomegalovirus (CMV), a member of the herpes virus family, is another teratogen that can cause extensive damage to a fetus while causing few symptoms in a woman (Lilleri et al., 2007). It is transmitted from person to person by droplet infection such as occurs with sneezing. If a woman acquires a primary CMV infection during pregnancy and the virus crosses the placenta, the infant may be born severely neurologically challenged (hydrocephalus, microcephaly, spasticity) or with eye damage (optic atrophy, chorioretinitis), hearing impairment, or chronic liver disease. The child's skin may be covered with large petechiae ("blueberry-muffin" lesions). Because a woman has almost no symptoms, she may not be aware that she has contracted an infection. However, diagnosis in the mother or infant can be established by the isolation of CMV antibodies in blood serum. Unfortunately, there is no treatment for the infection even if it presents in the mother with enough symptoms to allow detection. Because there is no treatment or vaccine for the disease, routine screening for CMV during pregnancy is not recommended. Women can help prevent exposure by thorough handwashing before eating and avoiding crowds of young children at daycare or nursery settings.

Like herpes simplex, a primary CMV infection may become latent and then reactivate periodically. These recurrences are not thought to have a teratogenic effect on a fetus, but they can cause infection of a newborn during birth from genital secretions or postpartum from exposure to CMV-infected breast milk. CMV infection contracted at or shortly after birth this way is not associated with serious adverse effects except in babies of very low birth weight (1200 g).

Herpes Simplex Virus (Genital Herpes Infection)

The first time a woman contracts a genital herpes infection, systemic involvement occurs. The virus spreads into the bloodstream (viremia) and crosses the placenta to a fetus posing substantial fetal risk (ACOG, 2007).

If the infection takes place in the first trimester, severe congenital anomalies or spontaneous miscarriage may occur. If the infection occurs during the second or third trimester, there is a high incidence of premature birth, intrauterine growth restriction, and continuing infection of the newborn at birth. Unless recognized and treated, the fetal mortality and morbidity rates are as high as 80% (ACOG, 2007).

If a woman has had herpes simplex virus type 1 infections before the genital herpes invasion or if the genital herpes (type 2) infection is a recurrence, antibodies to the virus in her system prevent spread of the virus to a fetus across the placenta. If genital lesions are present at the time of birth, however, a fetus may contract the virus from direct exposure during birth. For women with a history of genital herpes and existing genital lesions, cesarean birth is often advised to reduce the risk of this route of infection. This awareness of the placental spread of herpes simplex virus has increased the importance of obtaining information about exposure to genital herpes or any painful perineal or vaginal lesions that might indicate this infection at prenatal visits.

Intravenous or oral acyclovir (Zovirax) can be administered to women during pregnancy (Karch, 2009). The primary mechanism for protecting a fetus, however, focuses on disease prevention. Urging women to practice safe sex is important to lessen their exposure to this and other sexually transmitted infections. Advising adolescents to obtain a vaccine against HPV (Gardasil) should lessen the incidence of genital herpes infection in the future.

Other Viral Diseases

It is difficult to demonstrate other viral teratogens, but rubeola (measles), coxsackievirus, infectious parotitis (mumps), varicella (chickenpox), poliomyelitis, influenza, and viral hepatitis all may be teratogenic. Parvovirus B19, the causative agent of erythema infectiosum (also called fifth disease), a common viral disease in school age children, if contracted during pregnancy, can cross the placenta and attack the red blood cells of a fetus. Infection with the virus during early pregnancy is associated with fetal death. If the infection occurs late in pregnancy, the infant may be born with severe anemia and congenital heart disease (Barankin, 2008).

Syphilis. Syphilis, a sexually transmitted infection, is of great concern for the maternal–fetal population despite the availability of accurate screening tests and proven medical treatment, as it is growing in incidence and places a fetus at risk for intrauterine or congenital syphilis (Walker, 2009). Early in pregnancy, when the cytotrophoblast layer of the chorionic villi is still intact, the causative spirochete of syphilis, *Treponema pallidum,* cannot cross the placenta and damage the fetus. When this layer atrophies at about the 16th to 18th week of pregnancy, however, the spirochete then can cross and cause extensive damage. If syphilis is detected and treated with an antibiotic such as benzathine penicillin in the first trimester, a fetus is rarely affected. If left untreated beyond the 18th week of gestation, hearing impairment, cognitive challenge, osteochondritis, and fetal death are possible.

For this reason, serologic screening (by either a VDRL or a rapid plasma reagin test) should be done at a first prenatal visit; the test may then be repeated again close to term (the 8th month) if exposure is a concern. Even when a woman has been treated with appropriate antibiotics, the serum titer remains high for more than 200 days; an increasing titer, however, suggests that reinfection has occurred. In an infant born to a woman with syphilis, the serologic test for syphilis may remain positive for up to 3 months even though the disease was treated during pregnancy.

The newborn with congenital syphilis may have congenital anomalies, extreme rhinitis (sniffles), and a characteristic syphilitic rash, all of which identify the baby as high risk at birth (Chakraborty & Luck, 2007). When the baby's primary teeth come in, they are oddly shaped (Hutchinson teeth). As the infant requires long-term follow-up, medical and nursing care of the newborn with congenital syphilis are discussed in Chapter 47.

Lyme Disease. Lyme disease, a multisystem disease caused by the spirochete *Borrelia burgdorferi,* is spread by the bite of a deer tick. The highest incidence occurs in the summer and early fall. The largest outbreaks of the disease are found on the east coast of the United States (Mullen, 2007). After a tick bite, a typical skin rash, *erythema chronicum migrans* (large, macular lesions with a clear center), develops. Pain in large joints such as the knee may develop. Infection in pregnancy can result in spontaneous miscarriage or severe congenital anomalies.

Women anticipating becoming pregnant or who are pregnant should avoid walking in areas such as wooded or tall grassy areas where they are apt to be bitten by ticks. If hiking in these areas, a woman should not use tick repellents containing diethyltoluamide because this ingredient is teratogenic. Instead, she should wear long, light-colored slacks tucked into her socks to prevent her legs from being exposed. To spread the spirochete, the tick must be present on the body possibly as long as 24 hours. After returning home from an outing, therefore, a woman should inspect her body carefully and immediately remove any ticks found. If she has any symptoms that suggest Lyme disease or knows she has been bitten, she should contact her primary health care provider immediately. Treatment of Lyme disease for pregnant women differs from that for nonpregnant women. The drugs used for nonpregnant adults, tetracycline and doxycycline, cannot be used during pregnancy because they cause tooth discoloration and, possibly, long-bone malformation in a fetus. A course of penicillin will be prescribed to reduce symptoms in the pregnant woman.

Because the symptoms of Lyme disease are chronic but not dramatic (a migratory rash and joint pain), women may not report them at a prenatal visit unless they are educated about their importance and are asked at prenatal visits if such symptoms are present.

Infections That Cause Illness at Birth. Several infections are not teratogenic to a fetus during pregnancy but are harmful if they are present at the time of birth. Gonorrhea, candidiasis, *Chlamydia, Streptococcus* B, and hepatitis B infections are examples of these. Chapters 26 and 43 discuss the effects of these infections on maternal, fetal, and neonatal health.

Potentially Teratogenic Vaccines

Live virus vaccines, such as measles, HPV, mumps, rubella, and poliomyelitis (Sabin type), are contraindicated during pregnancy because they may transmit the viral infection to a fetus (Rojas, Wood, & Blakemore, 2007). Care must be taken

in routine immunization programs to make sure that adolescents about to be vaccinated are not pregnant. Women who work in biologic laboratories where vaccines are manufactured are well advised not to work with live virus products during pregnancy.

Teratogenic Drugs

Many women, assuming that the rule of being cautious with drugs during pregnancy applies only to prescription drugs, take over-the-counter drugs or herbal supplements freely. Although not all drugs cross the placenta (heparin, for example, does not because of its large molecular size), most do. Also, even though most herbs are safe, ginseng, for example, used to improve general well-being, or senna, used to relieve constipation, may not be safe (Der Marderosian & Beutler, 2007).

To identify drugs that are unsafe during pregnancy, the U.S. Food and Drug Administration (FDA) has established five categories of safety (Table 12.1). Always look for a drug's listed category before administering it to a pregnant woman. In addition, two principles always govern drug intake during pregnancy:

- Any drug or herbal supplement, under certain circumstances, may be detrimental to fetal welfare. Therefore, during pregnancy, women should not take any drug or supplement not specifically prescribed or approved by their physician or nurse-midwife.
- A woman of childbearing age and ability should not take any drug other than one prescribed by a physician or nurse-midwife to avoid exposure to a drug should she become pregnant.

The classic example of a teratogenic drug is thalidomide, once liberally prescribed for morning sickness in Europe. Never approved for use in the United States, thalidomide caused amelia or phocomelia (total or partial absence of extremities) in 100% of instances when taken between the 34th and 45th day of pregnancy. Thalidomide is again available as it is effective as an anticancer drug, particularly with patients with multiple myeloma, so women need to be cautioned again about its detrimental fetal effects (Karch, 2009). Minoxidil (Rogaine), a drug taken by both men and women to restore hair growth, is an example of another drug that is documented to cause fetal deformities and could be readily available in a modern home (Shapiro, 2007). Valproic acid, a common drug prescribed for seizures, is yet another example (Duncan, 2007). Other examples of drugs capable of being teratogenic are shown in Box 12.8.

The use of recreational drugs during pregnancy puts a fetus at risk in two ways: the drug may have a direct teratogenic effect, and intravenous drug use risks exposure to diseases such as HIV and hepatitis B (Donnelly et al., 2008).

Narcotics such as meperidine (Demerol) and heroin have long been implicated as causing intrauterine growth restriction (IUGR). The use of marijuana alone apparently does not, although the long-term effects of marijuana during pregnancy are still unstudied. Cocaine, particularly its crack form, is potentially harmful to a fetus because it causes severe vasoconstriction in the mother, compromising placental blood flow and perhaps dislodging the placenta. Its use is associated with spontaneous miscarriage, preterm labor, meconium staining, and IUGR (Rojas, Wood, & Blakemore, 2007). Whether cocaine causes long-term effects in the infant remains controversial (Bernstein & Weinstein, 2007). See Chapter 22 for more information on the potential hazards of cocaine or heroin use during pregnancy.

An area of recreational drug use that needs to be examined is that of inhalant abuse ("huffing"). Substances frequently used as inhalants include gasoline, butane lighter fluid, Freon, glue, and nitrous oxide (NIOSH, 2007). Although the teratogenic properties of inhalants are not well studied, they all carry the possibility of respiratory distress, which could limit the oxygen supply to a fetus. They are used most often by adolescents.

Teratogenicity of Alcohol

Evidence over the years has shown that when women consume a large quantity of alcohol during pregnancy, their babies show a high incidence of congenital deformities and cognitive impairment. It was assumed in the past that these defects were the result of the mother's poor nutritional status (drinking alcohol rather than eating food), not necessarily the direct result of the alcohol. However, alcohol has now been firmly isolated as a direct teratogen. Fetuses cannot remove the breakdown products of alcohol from their body.

TABLE 12.1 ✻ Pregnancy Risk Categories of Drugs

Category	Description	Example
A	Adequate studies in pregnant women have failed to show a risk to the fetus in the first trimester of pregnancy; there is no evidence of risk in later trimesters.	Thyroid hormone
B	Animal studies have not shown an adverse effect on the fetus, but there are no adequate clinical studies in pregnant women.	Insulin
C	Animal studies have shown an adverse effect on the fetus, but there are no adequate studies on humans, or there are no adequate studies in animals or humans. Pregnancy risk is unknown.	Docusate sodium (Colace)
D	There is evidence of risk to the human fetus, but the potential benefits of use in pregnant women may be acceptable despite potential risks.	Lithium citrate
X	Studies in animals or humans show fetal abnormalities, or adverse reaction reports indicate evidence of fetal risk. The risks involved clearly outweigh potential benefits.	Isotretinoin (Accutane)

BOX 12.8 ✻ Focus on Pharmacology

Some Potentially or Positively Teratogenic Drugs

Category	Example	Drug Use	Teratogenic Effect
Alcohol (ethanol)	Wine, whiskey	Social use	Fetal alcohol syndrome
Analgesics	Acetylsalicylic acid (aspirin)	Minor pain relief	Prolonged pregnancy; maternal bleeding
	Nonsteroidal anti-inflammatory drugs (NSAIDs)		Patent ductus arteriosus
Antineoplastics	Methotrexate	Chemotherapy	Multiple anomalies
	Cyclophosphamide (Cytoxan)	Chemotherapy	Multiple anomalies
Androgens	Danazol	Endometriosis	Masculinization of female fetus
Anticonvulsants	Phenytoin (Dilantin)	Seizures	Fetal hydantoin syndrome
	Valproic acid		Neural tube defects
	Carbamazepine		Neural tube defects
	Lamotrigine		Possibly fetal anomalies
Anticoagulants	Warfarin (Coumarin)	Anticoagulation	Fetal bleeding or anomalies
Antidepressants	Imipramine (Tofranil)	Elevate mood	Cardiovascular anomalies
Antidiabetic agents	Chlorpropamide	Lower blood glucose	Neonatal hypoglycemia
Antischizophrenic	Lithium	Schizophrenia	Hydramnios
Antithyroid	Methimazole	Hypothyroidism	Hypothyroidism in fetus
Antibiotics	Ribavirin	Respiratory infection	Multiple anomalies
	Sulfonamides	Infection	Hyperbilirubinemia in newborn
	Tetracycline	Infection	Teeth and bone deformities
Antihelmintics	Lindane	Eradication of lice	Manufacturer recommends limiting exposure to 2 doses
Angiotensin-converting enzyme inhibitors	Enalapril (Vasotec) Captopril (Capoten)	Reduce hypertension	Oligohydramnios
Caffeine	Coffee, soft drinks, chocolate	Social use	Low birth weight
Hypoglycemics	Tolbutamide (Orinase)	Type 2 diabetes	Profound hypoglycemia in newborn
Nicotine	Cigarette smoke	Relaxation	Growth restriction
Radiopharmaceuticals	Iodide-131	Diagnostic studies	May destroy thyroid of fetus
Narcotics	Cocaine	Social pleasure	Dysmorphic and CNS anomalies
	Heroin		Growth restriction; narcotic withdrawal in newborn
Tranquilizers	Benzodiazepine (diazepam)	Reduce anxiety	Growth restriction; CNS dysfunction Hypotonia, respiratory depression
Vaccines (live)	Rubella	Provide immunity	Possible infection in fetus
Vitamin A derivatives	Isotretinoin (Accutane)	Acne	Craniofacial, cardiac, CNS anomalies
	Etretinate (Tegison)	Psoriasis	Craniofacial, cardiac, CNS anomalies

CNS, central nervous system.

The large buildup of this leads to vitamin B deficiency and accompanying neurologic damage.

Women during pregnancy should be screened for alcohol use because an infant born with **fetal alcohol syndrome (FAS)** not only is small for gestational age but can be cognitively challenged (Shankar, Ronis, & Badger, 2007). The infant typically has a characteristic craniofacial deformity including short palpebral fissures, a thin upper lip, and an upturned nose. Because of individual variations in metabolism, it is impossible to define a safe level of alcohol consumption. Women are best advised, therefore, to abstain from alcohol completely. Be certain to ask about binge drinking (consuming more than five alcohol drinks in an evening) as women may refer to this as only "occasional drinking." Refer women with alcohol addiction to an alcohol treatment program as early in pregnancy as possible to help them reduce their alcohol intake (see Focus on Nursing Care Planning Box 12.9).

BOX 12.9 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Pregnant Woman With Threats to Fetal Health

Julberry Adams, a single woman, is 4 months pregnant when you see her in a prenatal clinic. She works as a curator for an art gallery but has missed work this last week because of nausea. She is worried she will not be able to work past 6 months of her pregnancy because her job involves a great deal of walking. She wonders how she will be able to afford her apartment if she has to quit work. She has already stopped volunteer work teaching children's swimming at the YMCA. She wants to travel to see her sister in St. Louis because her sister is very ill but has heard that pregnant women shouldn't drive over 100 miles. She asks you if marijuana would help reduce her early pregnancy nausea.

Family Assessment ✻ Client lives by herself in one-bedroom apartment. Rates finances as "good, unless I have to quit work because of pregnancy." She asks you, "Will I have to have an ultrasound? I'm worried about that."

Client Assessment ✻ Gravida 1, para 0. Unsure of date of last menstrual period, but it was about 11 weeks ago. Uterine height barely above symphysis. Fetal heart rate at 148 beats per minute by Doppler. History of frequent sinus headaches. "I use Sudafed (pseudoephedrine) at least 3 to 4 times a week; sometimes other things." Smokes one half pack of cigarettes "some days." Drinks 2 to 3 glasses of wine per week at art gallery functions. Denies history of marijuana or other recreational drug use.

Nursing Diagnosis ✻ Risk for fetal injury related to knowledge deficit concerning possible fetal exposure to teratogens.

Outcome Evaluation ✻ Client reports a decrease in smoking to less than 10 cigarettes per day or less and no alcohol consumption.
Verbalizes no use of recreational drugs including marijuana.
States she has contacted health care provider about use of sinus medications and is following advice.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Assess what activities client wants to participate in during pregnancy.	Discuss desired activities and any modification necessary for pregnancy with client.	Finding a match between desired activities and possible activities will help with adherence.	Client discusses what activities she intends to continue during pregnancy and ways to modify them as necessary.
Physician/nurse	Assess what work or travel plans entail.	Assure client she can continue work, travel to sister's home.	Reassurance helps clients maintain normal lifestyle.	Client states she will continue work, maintain contact with sister.
		Consultations		
Nurse	Assess what medications client is currently taking.	Consult with client's maternal health care provider about safety of over-the-counter (OTC) medications.	Not all OTC medications are safe during pregnancy.	Client states she will follow recommendations of primary health care provider regarding medications.
		Procedures/Medications		
Physician/ nurse-midwife	Anticipate the need for follow-up ultrasound examination for fetal growth evaluation.	Explain the need for ultrasound exam to assess for fetal growth restriction because of alcohol and cigarette smoking habits.	Teratogen exposure may have slowed fetal growth, which will be revealed by ultrasound exam.	Client states that she is aware of purpose of ultrasound exam and will allow exam to be scheduled.

(continued)

BOX 12.9 ✻ Focus on Nursing Care Planning (continued)

		Nutrition		
Nurse	Assess client's lifestyle to see what beverages she could substitute for alcohol, what measures she could use best for nausea.	Suggest client replace alcohol consumption with caffeine-free beverages.	Alcohol consumption during pregnancy is associated with fetal alcohol syndrome.	Client voices intent to replace alcohol consumption with caffeine-free beverages.
	Assess what measures client could use to decrease nausea.	Suggest measures to combat nausea and vomiting, such as dry crackers, acupuncture band.	Decreasing nausea to increase food intake aids fetal growth and development.	Client suggests measures that appeal to her to reduce nausea and vomiting.
		Patient/Family Education		
Nurse/nurse-midwife	Assess whether client has tried any non-medicinal measures to relieve sinus headaches.	Discuss with client possible non-medicinal measures to assist with sinus headache relief, including saline nasal sprays, humidification, and warm compresses to nasal area.	Complementary comfort measures may provide symptomatic relief without danger to a fetus.	Client describes two complementary therapies she will use to relieve sinus congestion.
		Psychosocial/Spiritual/Emotional Needs		
Nurse/social worker	Discuss with client whether her current support system is reliable.	Help client locate at least one person she can depend on if a pregnancy emergency should arise.	Pregnancy can be a very stressful time for a woman who has an insecure support system.	Client telephones or e-mails the health care facility with questions rather than relying on non-experienced friends for information; names one support person.
		Discharge Planning		
Nurse	Assess extent of cigarette smoking.	Encourage the client to decrease smoking and quit if possible. Offer suggestions to accomplish this goal, including use of sugar-free gums or candies, distraction, and activity. Refer to a smoking-cessation group if appropriate.	Cigarette use during pregnancy can lead to fetal growth restriction. Support and suggestions provide concrete measures to assist client with cutting down and quitting.	Client voices intention to decrease smoking and if possible quit smoking during pregnancy.

Teratogenicity of Cigarettes

Cigarette smoking is associated with infertility in women. Cigarette smoking by a pregnant woman has been shown to cause fetal growth restriction (Lawrence & Haslam, 2007). In addition, a fetus may be at greater risk for being stillborn (Hogberg & Cnattingius, 2007) and, after birth, may be at greater risk than others for sudden infant death syndrome. Low birth weight in infants of smoking mothers results from vasoconstriction of the uterine vessels, an effect of nicotine. This limits the blood supply to a fetus. Another contributory effect may be related to inhaled carbon monoxide. Secondary smoke, or inhaling the smoke of another person's cigarettes, may be as harmful as actually smoking the cigarettes. All prenatal health care settings should be smoke-free environments for this reason.

If a woman cannot stop smoking during pregnancy (and, realistically, many women cannot), reducing the number of cigarettes smoked per day should help diminish adverse effects on a fetus as well as also protect a woman's health from long-term illnesses such as chronic respiratory diseases.

The best way to urge women to discontinue smoking is to educate them about the risks to themselves and their fetus at a first prenatal visit. It may be effective to encourage women to sign a contract with a health care provider to try to stop or to join a smoking-cessation program. Be certain pregnant women know that they should not enter a stop-smoking program that uses drug therapy such as nicotine patches, because the substitute drug may be as harmful to a fetus as smoking (Winzer-Serhan, 2008).

Environmental Teratogens

Teratogens from environmental sources can be as damaging to a fetus as those that are directly or deliberately ingested. Women can be exposed through contact at home or at work sites. For example, washing children's hair with a shampoo such as lindane (Kwell) to remove lice should be limited to two exposures because of potential toxicity (Karch, 2009).

Metal and Chemical Hazards

Pesticides and carbon monoxide such as from automobile exhaust should be avoided as these are examples of chemical teratogens. Arsenic, a byproduct of copper and lead smelting, used in pesticides, paints, and leather processing; formaldehyde, used in paper manufacturing; and mercury, used in the manufacture of electrical apparatuses and found in swordfish and tuna fish, are all teratogens that can be contacted at work sites.

Lead poisoning generally is considered a problem of young children eating lead-based paint chips, but it also can be a fetal hazard (Maloney, 2007). Women may ingest lead by drinking water that travels through old pipes that are leaching lead or by "sniffing" lead-based gasoline. Lead ingestion during pregnancy may lead to a newborn who is cognitively or neurologically challenged (Pavone & Hueppchen, 2007).

Radiation

Rapidly growing cells are extremely vulnerable to destruction by radiation. That makes radiation a potent teratogen to unborn children because of their high proportion of rapidly growing cells. Radiation produces a range of malformations depending on the stage of development of the embryo or fetus and the strength and length of exposure. If the exposure occurs before implantation, the growing zygote apparently is killed. If the zygote is not killed, it survives apparently unharmed. The most damaging time for exposure and subsequent damage is from implantation to 6 weeks after conception (when many women are not yet aware that they are pregnant). The nervous system, brain, and retinal innervation are most affected.

As a rule, therefore, all women of childbearing age should be scheduled for pelvic x-ray examinations only in the first 10 days of a menstrual cycle (when pregnancy is unlikely because ovulation has not yet occurred), except in emergency situations. A serum pregnancy test can be done on all women who have reason to believe they might be pregnant before diagnostic tests involving x-rays are scheduled.

Radiation of the pelvis should be avoided all during pregnancy if possible. It should be undertaken only at term if the data obtained are important for birth and cannot be obtained by any other means. Ultrasound and magnetic resonance imaging have replaced x-ray examination for confirmation of situations such as multiple pregnancy because these do not appear to be teratogenic.

In addition to immediate fetal damage, evidence exists that radiation can have long-lasting effects on the health of a child. There appears to be an increased risk of cancer in children who are exposed to radiation in utero. Exposure of the fetal gonads could lead to a genetic mutation that will not be evident until the next generation (Pavone & Hueppchen, 2007).

If a woman needs nonpelvic radiation during pregnancy (e.g., dental x-ray examinations, an arm or leg x-ray examination after a fall), be certain that she is supplied a lead apron to shield her pelvis during the procedure. Even fluoroscopy, which uses lower radiation doses than regular x-ray photography, can cause fetal deformities and should be avoided during pregnancy—again, except in an emergency. Although still being investigated, long-term use of slight radiation sources, such as a word processor, computer, or cellular phone, does not appear to be teratogenic.

Hyperthermia and Hypothermia

Hyperthermia to a fetus can be detrimental to growth because it interferes with cell metabolism. This can occur from the use of saunas, hot tubs, or tanning beds, from a work environment next to a furnace, such as in welding or steel making, or from a high maternal fever early in pregnancy (4–6 weeks). For this reason, after exercise programs, advise pregnant women not to use hot tubs or saunas. Women who use a hot tub at 40° C should not stay in it for longer than about 10 minutes at one time.

The effect of hypothermia on pregnancy is not well known. Because the uterus is an internal organ, a woman's body temperature would have to be lowered significantly before a great deal of fetal temperature change would result.

Teratogenic Maternal Stress

Many myths exist about the effect of being frightened or surprised while pregnant. For example:

- If a woman sees a mouse during pregnancy, her child will be born with a furry or molelike birthmark.
- Eating strawberries causes strawberry birthmarks.
- Looking at a handicapped child while pregnant will cause a child in utero to be handicapped the same way.

Common sense and awareness of fetal–maternal physiology have dispelled these superstitions. There is some evidence, however, that an emotionally disturbed pregnancy, one filled with anxiety and worry beyond the usual amount, could produce physiologic changes through its effect on the sympathetic division of the autonomic nervous system. The primary changes this could cause include constriction of the peripheral blood vessels (a fight-or-flight syndrome). If the anxiety is prolonged, the constriction of uterine vessels (the uterus is a peripheral organ) could interfere with the blood and nutrient supply to a fetus.

These phenomena are characteristic only of long-term, extreme stress, not of the normal anxiety of pregnancy. Illness or death of one's partner, difficulty with relatives, marital discord, and illness or death of another child are examples of stressful situations that might provoke excessive anxiety.

Helping a woman resolve these complex problems during pregnancy is not easy. If maternal stress is severe, however, securing counseling is as important as ensuring good physical care.

PREPARATION FOR LABOR

At about the midpoint of pregnancy, along with cautioning women about discomforts of pregnancy and possible teratogenic situations, it is time to review the events that signal the beginning of labor so that women will not be surprised by these happenings or dismiss them as something other than what they are.

Lightening

Lightening is the settling of the fetal head into the inlet of the true pelvis. It occurs approximately 2 weeks before labor in primiparas but at unpredictable times in multiparas. A woman notices she is not as short of breath as she was before. Her abdominal contour is definitely changed, and on standing she may experience frequency of urination or sciatic pain (pain across a buttock radiating down her leg) from the lowered fetal position.

Show

Show is the common term used to describe the release of the cervical plug (operculum) that formed during pregnancy. It consists of a mucous, often blood-streaked vaginal discharge and indicates the beginning of cervical dilatation.

Rupture of the Membranes

A sudden gush of clear fluid (amniotic fluid) from the vagina indicates rupture of the membranes. A woman should telephone her primary care provider immediately when this occurs as after rupture of the membranes, there is a danger of cord prolapse and uterine infection.

Excess Energy

Feeling extremely energetic is a sign of labor important for women to recognize. It occurs as part of the body's physiologic preparation for labor. If a woman does not recognize the sensation for what it is, she may use this burst of energy to clean her house or finish paperwork at the office and exhaust herself before labor begins. If she can recognize this symptom as an initial sign of labor, she can conserve her energy in preparation for labor.

Uterine Contractions

For most women, labor begins with contractions. True labor contractions usually start in the back and sweep forward across the abdomen like the tightening of a band. They gradually increase in frequency and intensity. Advise a woman to call her primary care provider when contractions begin to alert health care personnel that she is in labor. Inform her at what point in labor her physician or nurse-midwife wants her to come to the health care facility (such as when contractions are 5 minutes apart). Be certain she knows this is not a hard-and-fast rule, however. If she should become exceptionally anxious, will be home alone, or will have a long drive, she should be given the option of using common sense to determine when to leave home.

✔ Checkpoint Question 12.5

Julberry Adams makes the following statements. Which one is the safest practice?

a. "My brother takes medicine for heartburn; if I get that, I'll just borrow his."
b. "I'm going to get a measles shot; I don't want measles while I'm pregnant."
c. "There are so many medicines for headache, I have to ask my doctor what to take."
d. "I know all over-the-counter medicine is safe; it's why it's over the counter."

Key Points for Review

- Prenatal education is an important part of prenatal care. The more women know about measures they should take during pregnancy to safeguard their health, the more likely it is that they will avoid substances or activities harmful to fetal growth.
- Urge women to find the best way for them to modify their lifestyle for pregnancy. Pregnancy is 9 months long, so modifications must be agreeable to a woman or she will not maintain them over such a long time span.
- Women need to make provisions for rest periods during their day and to be aware of any potential teratogens at a work site, such as exposure to radiation or heavy metals.
- Women who travel should plan for break periods to avoid congestion in their lower extremities. Seat belts should be used when traveling by car.
- Common discomforts of early pregnancy include breast tenderness, constipation, palmar erythema, nausea and vomiting, fatigue, muscle cramps, pain from varicosities or hemorrhoids, heart palpitations, frequency of urination, and leukorrhea. If women know that these symptoms may occur, they will not interpret them as complications.
- Minor discomforts of middle or late pregnancy include backache, dyspnea, ankle edema, and Braxton Hicks contractions. Caution women that contractions could be a sign of labor.
- Women should take active measures to avoid exposure to infectious diseases such as rubella, HIV, cytomegalovirus, herpes simplex virus, syphilis, Lyme disease, and toxoplasmosis during pregnancy.
- Counsel women about the necessity to avoid the use of any drugs or herbal supplements not specifically approved by their physician or nurse-midwife during pregnancy, as well as alcohol and cigarettes.
- It is almost impossible for a woman to modify a behavior, such as smoking, if her support person does not agree to change also. Including the family in care is an important way of helping support persons understand the need for the modification and increasing cooperation.
- Beginning signs of labor for which the pregnant woman should be alert include lightening, show, excess energy, rupture of membranes, and uterine contractions.

CRITICAL THINKING EXERCISES

1. Julberry Adams, the woman you met at the beginning of the chapter, voiced several concerns, including whether she should stop work and whether it would be safe to take a long trip. What advice would you give her regarding these questions?
2. Although Julberry describes a day she says involves a lot of walking, she also has long periods of sitting with almost no exercise. What would be some recommendations you could make to help her prevent blood clots from the sharp bend in her knee while sitting?
3. Julberry is having trouble remembering to take her prenatal vitamin. What are some suggestions you could make to help her remember to take this daily?
4. Examine the National Health Goals related to prenatal care. Most government-sponsored money for nursing research is allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to Julberry and her family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to health promotion in pregnancy. Confirm your answers are correct by reading the rationales.

Chapter

13 Promoting Nutritional Health During Pregnancy

KEY TERMS

- body mass index
- complete protein
- Hawthorne effect
- heartburn (pyrosis)
- hypercholesterolemia
- hyperplasia
- hypertrophy
- incomplete protein
- lactase
- obese
- overweight
- pica
- underweight

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Discuss the recommendations for healthy nutrition during pregnancy.
2. Identify National Health Goals related to nutrition and pregnancy that nurses can help the nation achieve.
3. Use critical thinking to analyze the effects of different life situations on nutrition patterns to create ways nutritional health can be both improved and family centered.
4. Assess a woman for nutritional adequacy during pregnancy.
5. Formulate nursing diagnoses related to nutritional concerns during pregnancy.
6. Develop expected outcomes to assist a pregnant woman achieve optimal nutrition during pregnancy.
7. Plan health teaching strategies such as ways to increase folic acid and calcium intake to promote optimal nutritional intake during pregnancy.
8. Implement nursing care that encourages healthy nutritional practices during pregnancy.
9. Evaluate expected outcomes for achievement and effectiveness of care.
10. Identify areas related to nutrition and pregnancy that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate nutrition knowledge with nursing process to achieve quality maternal and child health nursing care.

Tori Alarino is 4 months pregnant. She works at a fast-food restaurant and eats her breakfast and lunch at the restaurant at work. Her husband works four evenings a week, so she cooks for herself on those evenings. She dislikes milk, so she drinks milkshakes as a source of calcium. She is concerned because she has already gained 23 lb. She craves oranges, eating six to eight of them a day. She tells you, "I thought pregnant women always craved pickles and ice cream. What's wrong with me?"

Previous chapters described normal anatomy and physiology, the changes associated with pregnancy, and common discomforts and danger signs of pregnancy. This chapter adds information about prenatal nutrition, an important aspect to help ensure a healthy outcome for both a woman and her child. Inadequate nutrition during pregnancy can affect not only fetal health but the child's health for years to come.

What nutritional counseling does Ms. Alarino need?

Although adequate nutrition during pregnancy cannot guarantee a good pregnancy outcome, it does make an important contribution. Both the nutritional state that a woman brings into pregnancy and her nutrition during pregnancy have a direct bearing on her health and on fetal growth and development. A poor diet, such as one deficient in folic acid, for example, is associated with birth anomalies such as neural tube defects.

Early in pregnancy, fetal growth occurs largely by an increase in the number of cells formed **(hyperplasia);** late in pregnancy it occurs mainly by enlargement of existing cells **(hypertrophy).** A fetus deprived of adequate nutrition early in pregnancy can be small for gestational age because of an inadequate number of cells in the body. Later on, although the number of cells may be normal, restricted growth can occur because cells cannot grow to their full potential. To ensure that early pregnancy deficiencies do not occur, encourage women of childbearing age to follow a healthy nutrition plan before pregnancy (preconceptual care) that specifically supplies adequate folic acid (400 μg/day). Otherwise, in the time before a woman recognizes that she is pregnant (about 6 weeks), her poor diet and lack of important nutrient stores could seriously impair fetal growth (Fowles & Murphey, 2009). Good nutrition during pregnancy is so important that the subject is addressed in National Health Goals (Box 13.1).

BOX 13.1 ✻ Focus on National Health Goals

Several National Health Goals speak to nutrition in pregnancy. These are:

- Reduce iron deficiency among young children and females of childbearing age from a baseline of 11% to 7%.
- Reduce anemia among low-income pregnant females in their third trimester of pregnancy from a baseline of 29% to a target of 20%.
- Increase the proportion of pregnancies begun with an optimum folic acid level from a baseline of 21% to a target of 80%.
- Increase the proportion of women who achieve a recommended weight gain during their pregnancies (http://www.nih.gov).

Nurses can help the nation achieve these goals by stressing the importance of balanced nutrition for all people so women enter pregnancy with adequate nutritional stores. They can help pregnant women plan ways to ingest adequate iron daily and to remember to take their prenatal vitamin (which contains an iron and folic acid supplement) daily. Nursing research on such topics as what are effective methods to help people remember to take daily medications, what are the best methods for women who cannot drink milk to obtain adequate calcium during pregnancy, and what are the ways to urge women to eat high-protein, not empty-carbohydrate foods, could add important information in this area of care.

Nursing Process Overview

For Promoting Nutritional Health in a Pregnant Woman

Assessment

Assessment begins with a woman's preconceptual nutrition patterns. From this assessment, determine whether a client is eating healthy food sources as represented by the food pyramid (Fig. 13.1; see also Appendix K) and evaluate any cultural, environmental, or social lifestyles that could affect eating habits. A 24-hour recall history is the best way to secure necessary information, confirm well-balanced nutrition, and identify areas for teaching and learning.

Nursing Diagnosis

Nursing diagnoses related to nutritional status of the pregnant woman consider the desired health and growth of both the fetus and the woman. Both a woman who is eating large amounts of nutritionally inferior food and a woman who has a problem eating because of fatigue or nausea and vomiting may be at risk for the same problem: fetal growth restriction. Being sensitive to a woman's concern about maintaining her own appearance in light of her need to gain sufficient weight helps her keep a healthy perspective on "eating for two." Examples of nursing diagnoses are:

- Imbalanced nutrition, less than body requirements, related to increased physiologic needs
- Imbalanced nutrition, less than body requirements, related to nausea every morning
- Health-seeking behaviors related to determining best food choices in pregnancy
- Imbalanced nutrition, more than body requirements, related to chronic poor eating habits
- Deficient knowledge related to need for increased intake of nutrients and calories during pregnancy

Outcome Identification and Planning

In large health centers, nutritionists are available to meet with women prenatally and help them plan nutrition during pregnancy. In other settings, a nutritionist may be available only for women with special needs, so the responsibility for nutrition advice falls directly on nurses. When helping a woman set expected outcomes for improving nutritional patterns, be certain to consider all the cultural and lifestyle factors that give different meanings to food. Because food is an expensive commodity, consider financial resources as well. Teaching about long-term outcomes such as building iron stores or bone mass is as important as short term goals to eat better for this week. Eating more nutritious foods for a week will probably not make a radical change. However, continuing a healthy eating pattern throughout the pregnancy (and maintaining it throughout life) will bring about important changes and help prepare the woman for feeding her family nutritionally for the years to come. Interesting web sites for pregnant woman to consult about nutrition are the Department of Health and Human Services Women's Health Care site (http://womenshealth.gov/pregnancy/pregnancy/eat.cfm) or the Department of Agriculture MyPyramid site (http://www.mypyramid.gov). Women who need financial or nutritional counseling can

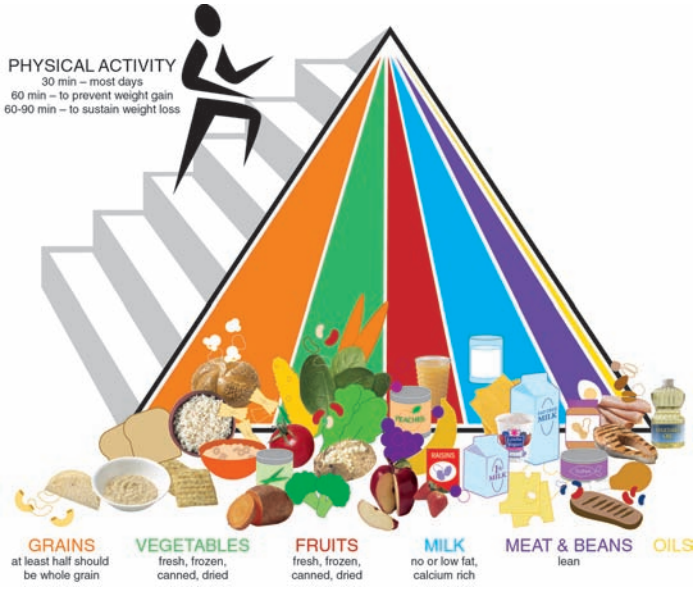

FIGURE 13.1 The food pyramid. (From the Department of Agriculture. [2008]. *Food guide pyramid: a guide to daily food choices*. Washington, DC: Author.)

be referred to the Women, Infants and Children Special Supplemental Food Program (WIC) (http://www.fns.usda.gov/wic).

Implementation

As everyone who has tried to change a nutritional pattern knows, this can be a lonely and seemingly unrewarding endeavor as results occur slowly. Begin by emphasizing the physiologic basis for nutritional needs in pregnancy (a woman is building a whole new person). Based on this, explain what nutritional deficits you have identified, and then show the woman how to change her nutritional pattern to improve this situation. Pregnant women are usually highly motivated to adopt healthy behaviors for the sake of their baby's health, although they still need support and encouragement because this can involve a major life change, such as eating a different lunch than everyone around them is eating; getting up 15 minutes earlier in the morning to prepare breakfast rather than just dashing to work with only coffee; or resisting having a soft drink with dinner and drinking orange juice or milk instead. Asking women to list what foods they eat daily and to bring in a chart to show you at a prenatal visit is an effective motivating technique. In research studies, this is called a **Hawthorne effect,** in which people who are being watched do better than those who are not. With this system, the average woman will eat better than she usually does, so her list looks better when she presents it. As soon as she realizes that these better eating patterns are making her feel better, hopefully, she will continue them indefinitely.

Outcome Evaluation

When evaluating whether a woman's nutritional pattern has been improved, rely on the most important assessments: weight, energy level, general appearance, bowel function, and, when available, hemoglobin and urinalysis findings. Urge women to be honest about whether they are actually following a nutrition plan. If they are not, it probably means that more planning is needed, because the plan did not fit their lifestyle or degree of motivation. Examples of outcomes that would demonstrate improved nutrition are:

- Client plans weekly menus that include three main meals and two snacks per day.
- By next prenatal visit, client demonstrates knowledge of meat and nonmeat sources of protein by providing menus of meals eaten in the last week that include fish, eggs, beans, or peanut butter.
- Client verbalizes correct information about calcium needs during pregnancy.
- Client states she is able to make up later in each day meals missed because of nausea.
- Client's food lists for 1 week include three sources of calcium per day.
- Client describes pattern she is using to increase fluid intake to eight glasses fluid daily.

RELATIONSHIP OF MATERNAL NUTRITION TO INFANT HEALTH

During pregnancy, a woman must eat adequately to supply enough nutrients to the fetus, so it can grow, as well as to support her own nutrition (Crombleholme, 2009). Adequate protein intake is vital because so much is needed by a fetus to build a body framework. Adequate protein may also help prevent complications of pregnancy such as pregnancy-induced hypertension or preterm birth. Either deficiencies or overuse of vitamins may contribute to birth anomalies (Subramanian et al., 2008). Remember that people have some degree of "backsliding," especially at holidays and special events. To prevent this, help a woman make definite, concrete plans for an upcoming holiday or event. Always comment on the things a woman is doing correctly rather than what she is doing wrong. Positive reinforcement, a basic rule of teaching, enhances learning, self-esteem, and compliance more than criticism.

Be careful when nutrition counseling not to make general statements such as, "Eat high-protein foods." Food in the supermarket, after all, is not labeled "high-protein." Instead,

provide advice in more specific terms: "Eat three servings of some type of meat or fish every day."

The word "diet" has come to mean a form of unpleasant food denial. Rather than a "pregnancy diet," therefore, talk about "foods that are best for you during pregnancy" or "pregnancy nutrition." These statements sound more positive and refer more closely to what you are encouraging a woman to do. Giving a woman a clearly written list of suggested foods may help. Be sure the list is short, clear, and specific. Complicated lists of foods or a list of don'ts can be overwhelming and, therefore, ignored.

Recommended Weight Gain During Pregnancy

A weight gain of 11.2 to 15.9 kg (25 to 35 lb) is recommended as an average weight gain in pregnancy. If a woman is at high risk for nutritional deficits, a more precise estimation of adequate weight gain can be calculated (Rode et al., 2007). This is done by computing **body mass index** (BMI), the ratio of weight to height (Box 13.2; see also Appendix E). Women who are high or low in weight for their height (BMI below 18.5 or above 25 kg/m^2) need to have their expected outcomes for weight gain adjusted.

Weight gain in pregnancy occurs from both fetal growth and accumulation of maternal stores (Box 13.3) and occurs at approximately 0.4 kg (1 lb) per month during the first trimester and then 0.4 kg (1 lb) per week during the last two trimesters (a trimester pattern of 3-12-12). As a general rule, in the average woman, weight gain is considered excessive if it is more than 3 kg (6.6 lb) a month during the second and third trimesters; it is less than usual if it is less than 1 kg (2.2 lb) per month during the second and third trimesters. Women can be assured that most of the weight gained with pregnancy will be lost afterward (Bernstein & Weinstein, 2007).

Women who are underweight coming into pregnancy should gain slightly more weight than the average woman (0.5 kg per month or week rather than 0.4, or 30–40 lb). An obese woman might be advised to gain less than average (0.3 kg, or 15–25 lb). However, to ensure adequate fetal nutrition, advise women not to diet to lose weight during pregnancy. Weight gain will be higher for a multiple pregnancy than for a single pregnancy. You can encourage women pregnant with multiple fetuses to gain at least 1 lb per week for a

BOX 13.2 ✻ Calculating Body Mass Index

Body mass index calculators are available online at the National Heart, Lung, and Blood Institute, National Institutes of Health web site (http://www.nhlbisupport.com/bmi).

BMI also can be calculated using the formula:

1. Convert weight into kilograms (divide weight in pounds by 2.2).
2. Convert height into centimeters (multiply height in inches by 2.5).
3. Convert centimeters into meters (divide result by 100).
4. Square height in meters.
5. Divide weight in kilograms by height in meters squared.

For example: Mrs. Alarino is 5 ft 6 in tall and weighs 150 lb. To determine her BMI:

1. Convert weight into kilograms: 150 lb ÷ 2.2 = 68 kg.
2. Convert height into centimeters: 5′6″ = 66″ (5 × 12 = 60 + 6 = 66 inches) 66 × 2.5 = 165 cm.
3. Convert centimeters into meters: 165 ÷ 100 = 1.65 m.
4. Square height in meters (1.65 × 1.65 = 2.72).
5. Divide weight (kg) by m^2 (68 ÷ 2.72 = 25 BMI).

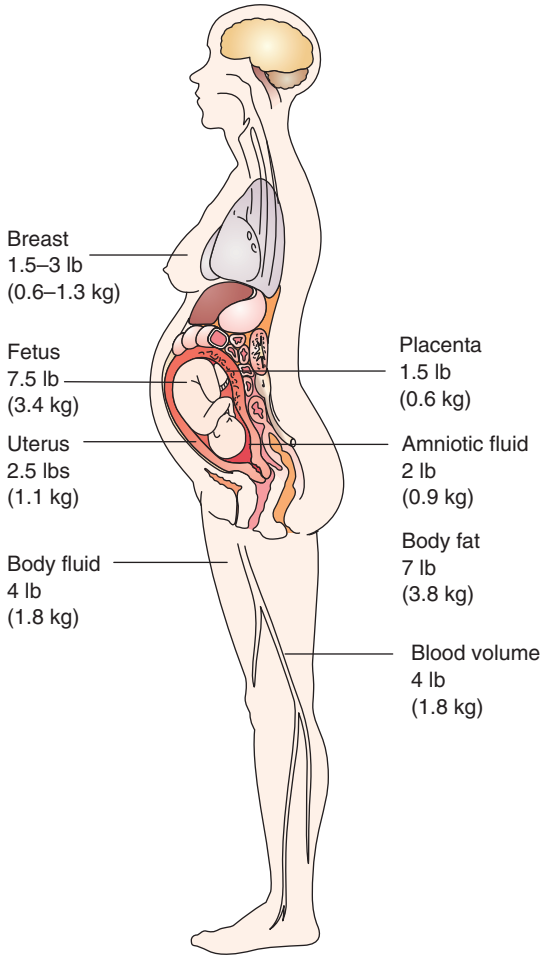
Normal Prepregnancy BMI

Underweight	Under 18.5
Normal weight	18.5–24.9
Overweight	25.0–29.9
Obese	Above 30.0
Morbidly obese	Above 40.0

With a BMI of 25, Mrs. Alarino enters pregnancy slightly overweight.

Source: Department of Health and Human Services. (2008). *BMI: body mass index.* Hyattsville, MD: Author.

Box 13.3 Assessment
Sources of Maternal Weight Gain



total of 40 to 45 lb (Rolfes, Pinna, & Whitney, 2009). Sudden increases in weight that suggest fluid retention or polyhydramnios (excessive amniotic fluid) or a loss of weight that suggests illness should be carefully evaluated at prenatal visits.

Components of Healthy Nutrition for the Pregnant Woman

The old saying that a pregnant woman must "eat for two" is not a myth; it is a truism. This does not mean, however, that a woman should eat enough for two adults, just enough to provide nutrients for herself and a growing fetus. To do this, many women will not have to increase by much the quantity of food they eat, but they will have to increase the quality of foods.

The Dietary Reference Intake (DRI) values for girls and women and the requirements during pregnancy are shown in Table 13.1. Women should be certain that foods they eat represent the food groups in a food pyramid (see Fig. 13.1). When discussing nutrition, refer to servings of food rather than milligrams or percentages, because this is how women measure amounts.

Energy (Calorie) Needs

The DRI of calories for women of childbearing age is 2200. An additional 300 calories, or a total caloric intake of 2500 calories, is recommended to meet the increased needs of pregnancy. In addition to supplying energy for a fetus, this increase provides calories to sustain an elevated metabolic rate in the woman from increased thyroid function and an increased workload from the extra weight she must carry. An inadequate intake of carbohydrates can lead to protein breakdown for energy, depriving a fetus of essential protein, and possibly resulting in ketoacidosis, a possible cause of fetal and neurologic disorders. Advise women to obtain calories from complex carbohydrates (cereals and grains) rather than simple carbohydrates (sugar and fruits) because these are more slowly digested so help regulate glucose and insulin levels. Do not recommend sugar substitutes for women during pregnancy, because a pregnant woman needs sugar to maintain glucose levels. Even obese women should never consume fewer than 1500 calories per day.

When helping a woman plan an increased caloric intake, consider her lifestyle. For example, many women commonly skip meals, have erratic eating patterns, or rely on fast and convenience foods. For pregnancy, a woman needs to add calories by eating foods rich in protein, iron, and other essential nutrients rather than eating more fast-food, empty-calorie foods such as pretzels and doughnuts. Suggest preparing snacks such as carrot sticks or cheese and crackers early in the day when fatigue is usually less, keeping them readily available in the refrigerator. Otherwise, later in the day when she is tired, a woman may snack on empty-calorie foods simply because they require no preparation.

The easiest method for determining if a woman's caloric intake is adequate is assessing the weight she is gaining. Keep in mind that the weight gain pattern is as important as the total weight gain. Even if a woman has surpassed her target weight before the end of the third trimester, encourage her not to restrict her caloric intake. She should continue to gain weight because a fetus grows rapidly during these final weeks.

Protein Needs

The DRI for protein in women is 46 g/d. During pregnancy, the need for protein increases to 71 g daily. If protein needs are met, overall nutritional needs are likely to be met as well

TABLE 13.1 ✻ Dietary Reference Intakes for Pregnant and Nonpregnant Women

	Nonpregnant Women				Pregnant Women
	Age 11–14	*Age 15–18*	*Age 19–30*	*Age 31–50*	
Calories (kcal)	2,200	2,200	2,200	2,200	2,500
Protein (g/d)	34	46	46	46	71
Fat-Soluble Vitamins					
Vitamin A (μg/d)	600	700	700	700	750
Vitamin D (μg/d)	5	5	5	5	5
Vitamin E (mg/d)	11	15	15	15	15
Water-Soluble Vitamins					
Ascorbic acid (mg/d) (vitamin C)	65	75	75	75	80
Folic acid (μg/d)	300	400	400	400	600
Niacin (mg/d)	12	14	14	14	18
Riboflavin (mg/d)	1.0	1.1	1.1	1.1	1.4
Thiamine (mg/d)(B_1)	1.0	1.1	1.1	1.1	1.4
Vitamin B_{12} (μg/d)	1.8	2.4	2.4	2.4	2.8
Vitamin B_6 (mg/d)	1.3	1.3	1.5	1.5	1.9
Minerals					
Calcium (mg/d)	1,300	1,300	1,000	1,000	1,300
Fluoride (mg/d)	2	3	3	3	3
Iodine (μg/d)	120	150	150	150	220
Iron (mg/d)	8	15	18	18	27
Magnesium (mg/d)	360	360	310	220	400
Phosphorus (mg/d)	1,250	1,250	700	700	700
Zinc (mg/d)	8	9	8	8	12

Institute of Medicine (2008). *Summary tables: dietary reference intakes.* Washington, DC: IOM.

(with the possible exceptions of vitamins C, A, and D) because of the high incorporation of other nutrients with protein foods. If protein intake is inadequate, iron, B vitamins, calcium, and phosphorus also will probably be inadequate. Vitamin B_{12} is found almost exclusively in animal protein, so if animal protein is excluded from the diet, vitamin B_{12} deficiency can occur unless this is supplemented.

Extra protein is best supplied by meat, poultry, fish, yogurt, eggs, and milk, because the protein in these forms contains all nine essential amino acids, or is **complete protein.** The protein in nonanimal sources does not contain all essential amino acids (and so is **incomplete protein).** It is possible to provide all amino acids by combining nonanimal proteins. Proteins that when cooked together provide all essential amino acids are termed *complementary proteins.* Examples are beans and rice, legumes and rice, or beans and wheat.

A woman with a family history of high cholesterol levels **(hypercholesterolemia)** probably should not eat more than two or three eggs per week because of the high cholesterol content of eggs. Encourage such women to eat lean meat, to cook with olive oil instead of lard or butter, and to remove the skin from poultry to reduce its fat content. She also should not eat lunch meats such as bologna or salami as food staples, because their protein content may not be high and their fat content is invariably exceptionally high.

Milk is a rich source of protein. Unfortunately, some women resist drinking it because it can be high in calories as well as fat. Others cannot drink it because of lactose intolerance. Some women find it difficult to drink a quart of milk a day because they simply do not like its taste. Nonfat milk supplies the same protein and half the calories as regular milk and is very low in fat. Buttermilk can be substituted, although it contains a large amount of sodium, or chocolate or another flavoring can be added to make milk palatable. Yogurt or cheese may also be substituted for milk, or milk may be incorporated into custards, eggnogs, or cream soups. Women who are lactose intolerant can add a lactase supplement, buy lactose-free milk, or take a calcium supplement (Bauchner, 2007).

✔ Checkpoint Question 13.1

Suppose Tori Alarino has a normal BMI. What would be the recommended weight gain for her during pregnancy?

a. 10 lb
b. 20 lb
c. 30 lb
d. 60 lb

Fat Needs

Only linoleic acid, an essential fatty acid necessary for new cell growth, cannot be manufactured in the body from other sources. Because linoleic acid must be obtained from food, women must be sure to consume a source of this nutrient during pregnancy. Vegetable oils are a good source. In addition, using vegetable oils (e.g., safflower, corn, olive, peanut, and cottonseed) that have a low cholesterol content rather than animal oils (butter) is recommended for all adults as a means of preventing hypercholesterolemia and coronary heart disease. Women should also try and ingest omega-3 oils, found primarily in fish, omega-3–fortified eggs, and the newer omega-3–fortified spreads (Bourre, 2007).

Vitamin Needs

The intake of vitamins as a daily dietary supplement has become so common that their importance may be underestimated by some women. Requirements for both fat-soluble and water-soluble vitamins increase during pregnancy to support the growth of new fetal cells (see Table 13.1).

Vitamin deficiency can result in several common problems. For example, vitamin D, essential for calcium absorption, when lacking, can begin to diminish both fetal and maternal mineral bone density. Lack of vitamin A results in tender gums and poor night vision. For as-yet-unknown reasons, there is an association between multivitamin supplementation during pregnancy and reduced cancers such as neuroblastoma, leukemia, and brain tumors in children (Goh et al., 2007).

Although vitamin needs do increase during pregnancy, most of the vitamin intake requirements (with the exception of folic acid) can be met by eating a healthy, varied diet with plenty of fruits and vegetables plus daily prenatal vitamins. Women who were taking oral contraceptives before they became pregnant should be certain to include good sources of vitamins A and B and folic acid in early pregnancy because oral contraceptives may deplete stores of these vitamins. Counsel women not to use mineral oil as a laxative because it can prevent absorption of fat-soluble vitamins from the gastrointestinal tract, limiting their availability to the body. If a woman is housebound, be certain that she is taking a prenatal vitamin containing vitamin D because she is probably not receiving as much sun exposure as normally (More, 2007).

Commonly, a prenatal vitamin is prescribed during pregnancy to be certain that pregnant women ingest sufficient vitamins (Box 13.4). Caution women to avoid taking megadoses

BOX 13.4 ✻ Focus on Pharmacology

Prenatal Vitamins (Natalins)

Action: Supplements nutrition to ensure adequate intake of vitamins and minerals during pregnancy. The folic acid content helps prevent megaloblastic anemia in the mother and neural tube defects in the fetus (Hale, 2007).

Ingredients: Vitamin A (4000 U), vitamin D (400 U), vitamin E (15 U), vitamin C (80 mg), vitamin B_1 (1.5 mg), vitamin B_2 (2.0 mg), vitamin B_6 (4 mg), vitamin B_{12} (2.5 μg), niacin (17 mg), folic acid (1.0 mg), pantothenic acid (7 mg), calcium (200 mg), iron (54 mg), copper (3 mg), zinc (25 mg), and magnesium (100 mg)

Dosage: One tablet daily

Possible Adverse Effects: None known. Folic acid may mask the signs of pernicious anemia.

Nursing Implications

- Encourage women to take the medication exactly as prescribed; caution women not to exceed the recommended dosage.
- Assist with ways to remind women to take the medication, such as a note on the refrigerator.
- Advise women to keep vitamins, like all medications, out of the reach of small children to prevent accidental poisoning.

of vitamins. The mechanism of placental transfer of water-soluble vitamins makes fetal blood levels regularly higher than maternal blood levels, so a maternal overdosage can cause fetal toxicity. Megadoses of vitamin C may cause withdrawal scurvy in the infant at birth. The fat-soluble vitamins are stored in the body rather than excreted and so can reach toxic levels even more easily. There may be an association between excessive vitamin A intake and fetal malformation. It is well documented that the intake of excessive vitamin A in the form of isotretinoin (Accutane), a medication prescribed for acne, causes congenital anomalies (Karch, 2009).

Although folic acid (folacin) belongs to the B-vitamin group, its importance during pregnancy warrants a separate discussion. Found predominantly in fresh fruits and vegetables, folic acid is necessary for red blood cell formation. As a woman's blood volume doubles during pregnancy, this makes her folic acid needs increase substantially. Without adequate folic acid, a megaloblastic anemia (large but ineffective red blood cells) may develop. If a woman has this blood pattern at the time of birth, the infant may be affected as well.

For this reason, as well as its importance in preventing neural tube defects, women should eat foods high in folic acid such as vegetables and fruit and should take a prenatal vitamin that contains a folic acid supplement of 0.4 to 1.0 mg (Subramanian et al., 2008). When cautioning women about vitamin use, advise them not to leave prenatal vitamins within the reach of small children. The excessive folic acid and iron in them can cause poisoning in small children.

Mineral Needs

Minerals are necessary for new cell building in a fetus. Because they are found in so many foods and because mineral absorption improves during pregnancy, mineral deficiency, with the exceptions of calcium, iodine, and iron, is rare.

Calcium and Phosphorus. The skeleton and teeth constitute a major portion of a fetus. Tooth formation begins as early as 8 weeks in utero. Bones begin to calcify at 12 weeks. To supply adequate calcium and phosphorus for bone formation, pregnant women need to eat foods high in calcium and vitamin D (necessary for calcium to be absorbed from the gastrointestinal tract and to enter bones). The recommended amount of calcium during pregnancy is 1300 mg. If a woman cannot drink milk or eat milk products such as cheese, she can be prescribed a daily calcium supplement. Most foods high in protein are also high in phosphorus, so by eating high-protein foods, women receive enough phosphorus, also important for bone growth.

Before nutrition counseling in pregnancy became common, women expected to lose "a tooth a child"—that is, they believed a fetus, as he or she grew, could drain calcium from their teeth. Although it is unlikely that a woman will lose a tooth with pregnancy today, the concern reflected in this myth about a fetus taking calcium from the mother is well founded. However, the calcium in teeth is not as readily absorbed as that of bone. It is more likely that inadequate calcium intake will result in diminished maternal bone density rather than weakened teeth. With an adequate calcium intake during pregnancy, a fetus will receive the needed calcium for growth and mineralization of the fetal skeleton without taking any away from the maternal bones or teeth.

Iodine. Iodine is essential for the formation of thyroxine and, therefore, for the proper functioning of the thyroid gland. As thyroid function increases during pregnancy, a woman needs to ingest enough iodine during pregnancy to supply this increased need. If iodine deficiency occurs, it can cause hypothyroidism and thyroid enlargement (goiter) in a woman. In extreme instances, it can cause the same symptoms in a fetus. Thyroid enlargement in a fetus at birth is serious because the increased pressure of the enlarged gland on the airway could lead to early respiratory distress. If not discovered at birth, hypothyroidism may lead to the infant's being cognitively challenged. The DRI for iodine is 220 μg daily during pregnancy. Seafood is the best source of iodine.

In areas where the water and soil are known to be deficient in iodine such as the Great Lakes area in the United States, it is suggested that women use iodized salt rather than plain salt to ensure a healthy iodine intake (Marchioni et al., 2008).

Iron. A fetus at term has a hemoglobin level of 17 to 21 g per 100 mL of blood, a level that is necessary to oxygenate the blood during intrauterine life. Iron is needed to build this high level of hemoglobin. In addition, after week 20 of pregnancy, a fetus begins to store iron in the liver to last through the first 3 months of life, when intake will consist mainly of milk, typically low in iron. In addition to supplying these high fetal needs, a woman needs iron to build an increased red cell volume for herself and to protect against iron lost in blood at birth.

The DRI for iron for pregnant women is 27 mg. An average diet supplies about 6 mg of iron per 1000 calories. If a woman eats a 2500-calorie diet daily, her daily intake, therefore, is about 15 mg iron. Because only 10% to 20% of dietary iron is absorbed, she is actually taking in less than this amount (closer to 1.5 to 3 mg). Therefore, dietary supplementation with 15 mg iron per day helps ensure that adequate iron is ingested and absorbed. Stress to women that iron supplementation is intended as a supplement to, not a replacement for, iron-rich foods.

Women with low incomes may find it difficult to eat adequate iron-rich foods, because the foods richest in iron (e.g., organ meats; eggs; green, leafy vegetables; whole grains; enriched breads; dried fruits) are also expensive. Iron absorption increases in an acid environment, so eating iron-rich foods or swallowing iron pills with ascorbic acid (found in orange juice) may increase absorption. Oral iron compounds turn stools black or blackish green. The compounds can be irritating to the stomach or cause constipation in some women. If this happens, urge women not to stop taking the iron compound but to always take the iron pills with food and increase fluid intake or fiber to relieve the constipation. Some women may need a prescribed stool softener such as docusate sodium (Colace); this stool softener is not associated with teratogenic action, so it can be taken safely during pregnancy.

Fluoride. Because fluoride aids in the formation of sound teeth, a pregnant woman should drink fluoridated water. In an area where the water is not fluoridated either naturally or artificially, supplemental fluoride may be recommended. Fluoride in large amounts causes brown-stained teeth, so a woman should not take the supplement more often than prescribed or if tap water in her area is already fluoridated. Many women, worried about added chemicals in their city water supply, switch to bottled water during pregnancy. If they do this, ad-

vise them to buy a fluoridated type or alert their health care providers that they may need a supplement.

Sodium. Sodium is the major electrolyte that acts to maintain fluid in the body: when sodium is retained rather than excreted by the kidneys, an equal or balancing amount of fluid is also retained. Retaining enough fluid during pregnancy in the maternal circulation is important to ensure a pressure gradient to allow optimal exchange of nutrients across the placenta.

Unless a woman is hypertensive or has heart disease with required sodium restriction when she enters pregnancy, she should continue to add salt to foods as usual during pregnancy. However, she should use moderation with foods that are extremely salty, such as lunch meats or potato chips, or with additive monosodium glutamate. Too much salt could result in retention of excessive amounts of fluid, putting a strain on her heart as blood volume doubles.

Zinc. Zinc is necessary for the synthesis of DNA and RNA. Although not proved, zinc deficiency may be associated with preterm birth. The DRI for zinc during pregnancy is 12 mg, or an increase of 3 mg over prepregnancy needs. Most people who take in adequate protein also take in adequate zinc because zinc is contained in foods such as meat, liver, eggs, and seafood. It is also a component of prenatal vitamins to help ensure an adequate intake (Rolfes, Pinna, & Whitney, 2009).

Fluid Needs

Extra amounts of water are needed during pregnancy to promote kidney function because a woman must excrete waste products for two. Two or three glasses of fluid daily over and above the three servings of milk recommended by the food pyramid is a common recommendation during pregnancy (a total of six to eight glasses daily).

Fiber Needs

Constipation can occur during pregnancy from slowed peristalsis because of the pressure of the uterus on the intestine. Eating fiber-rich foods, foods consisting of parts of the plant cell wall resistant to normal digestive enzymes such as broccoli and asparagus, are a natural way of preventing constipation, because the bulk of the fiber left in the intestine aids evacuation. Fiber also has the advantage of lowering cholesterol levels and may remove carcinogenic contaminants from the intestine. Therefore, encourage women to eat plenty of fresh fruits and vegetables, especially green, leafy vegetables, to provide fiber. Eating fiber-rich foods this way is a better choice for preventing constipation than taking a fiber laxative. Doing so allows a woman to receive nutrients from the food as well as preventing constipation (Derbyshire, 2007).

Foods to Avoid or Limit in Pregnancy

As discussed in Chapter 12, alcoholic beverages should not be ingested by a pregnant woman because of their potentially teratogenic effects on a fetus. Other foods to be avoided are those that contain food additives, because the effect of many of these is unknown.

Excess Seafood

Women should eat up to 12 ounces (2 to 3 meals) of seafood or shellfish a week for their omega-3 and iodine content. Fish such as shark, swordfish, king mackerel or tilefish are high in mercury contamination, however, so should be avoided (Genuis, 2008). Five types of fish that are low in mercury are shrimp, canned light tuna, salmon, pollock, and catfish. Women should check local advisories about the safety of fish caught by family and friends in local rivers and streams. If no advice is available, women can safely eat up to 6 ounces (one meal) per week of fish from local waters if they don't consume any other fish during that week.

Foods With Caffeine

Caffeine is thought of by many women as just an incidental ingredient in beverages. Actually, it is a central nervous system stimulant capable of increasing heart rate, urine production in the kidney, and secretion of acid in the stomach (Rolfes, Pinna, & Whitney, 2009).

A daily intake of caffeine of two or three cups of coffee has not been associated with low birth weight, but drinking over three cups is associated with an increased rate of early miscarriage (Applebee, 2008). To limit their caffeine intake, women may need to limit not only the amount of coffee they drink but also other sources of caffeine such as chocolate, soft drinks, and tea. If a woman has difficulty omitting these common foods from her diet, she can still reduce the amount of caffeine she ingests. Decaffeinated coffee, as the name implies, contains almost no caffeine.

The longer tea brews, the greater is the caffeine content. Green tea has less caffeine than black tea. Both herbal teas and decaffeinated tea are readily available.

The cocoa bean that is used to make chocolate and cocoa is yet another natural source of caffeine. Chocolate sources tend to be low in caffeine, however, compared with coffee. A cup of coffee contains approximately 120 mg of caffeine, whereas a cup of hot chocolate contains only 10 mg. Baking chocolate, used for cake frostings and glazes, is proportionately higher, containing about 35 mg of caffeine per ounce.

Soft drinks do not naturally contain caffeine; it is added to improve their flavor. To limit the amount of caffeine consumed, encourage pregnant women to choose caffeine-free types.

Artificial Sweeteners

Artificial sweeteners are used to improve the taste and to limit the caloric content of foods. It is probably safest for pregnant women to reduce their intake of these. For instance, although the sweetener aspartame has been approved by the U.S. Food and Drug Administration for consumption and is apparently safe during pregnancy, large amounts of the compound should be avoided by pregnant women until its safety is thoroughly confirmed. The use of saccharine is not recommended during pregnancy because it is eliminated slowly from the fetal bloodstream. In any event, pregnant women need carbohydrates furnished by sugar rather than artificial substances (Rolfes, Pinna, & Whitney, 2009).

What if... Tori Alarino states, "I love coffee. There's always a pot brewing where I work. And I love a cup of cappuccino for lunch." What suggestions could you make to help her reduce her caffeine intake?

Weight Loss Diets

As a rule, weight reduction is not healthy during pregnancy. Liquid reducing diets and/or diets that are combined with weight-reducing drugs are particularly contraindicated during pregnancy because they may lead to fetal ketoacidosis and poor growth. If women have been following such diets before becoming pregnant, they may have few nutritional stores, and additional vitamin supplementation may be necessary.

✔ Checkpoint Question 13.2

Which statement by Tori lets you know she understands how iron is best absorbed?

a. "I always take my iron pills with milk."
b. "I crush my iron pills to disguise the taste."
c. "I take the pills with a carbonated beverage."
d. "I swallow my iron pills with orange juice."

ASSESSMENT OF NUTRITIONAL HEALTH

Women who follow good nutrition practices before pregnancy come into pregnancy in better health and best prepared to avoid pregnancy complications (Box 13.5). The best method for assessing a woman's nutritional intake is to ask for a "typical day" history or a 24-hour nutrition recall to isolate usual patterns and possible nutritional risk factors (Table 13.2). First, ask if yesterday was a typical day. If it was, then ask a woman to list all the food she ate within the past 24 hours, starting with when she awakened until she went to sleep. Be certain she includes all the snack foods she ate, as well as sit-down meals. This method of history taking yields much more accurate information than if a woman is asked how often during the week she eats citrus fruit or how much milk she drinks every day because most people eat automatically with little thought to their food intake (Cohen & Farley, 2008). A woman who knows how much milk she ought to drink a day tends to say she drinks four glasses a day during pregnancy. However, if asked to list the foods she ate the day before, she may report that she drank only one glass of milk all day.

In addition to actual food intake, ask a woman if she thinks she has any problem with nutrition (such as cravings).

BOX 13.5 ✻ Focus on Evidence-Based Practice

Does high-fat nutrition during pregnancy influence the development of gestational diabetes?

What women eat during pregnancy certainly influences their serum glucose levels. Interested in learning if a diet high in total fatty acids, saturated fatty acids, and red meat increases women's risk of developing diabetes during pregnancy, researchers asked 1733 women to record everything they ate during the first trimester of their pregnancies. At 26 to 28 weeks, a glucose tolerance test was done to assess if gestational diabetes had occurred. Of the 1733 women studied, 91 (5%) developed gestational diabetes (a fasting serum glucose over 126 mg/dL) and 206 (11%) developed impaired glucose tolerance or a blood glucose 100 to 125 mg/dL. The types of food women ate, however, did not influence these results, and the type of nutrient or food intake in early pregnancy was not linked to a risk of gestational diabetes. Nutritional status entering pregnancy, as reflected by the women's prepregnancy BMI, appeared to be more predictive than was food eaten during pregnancy.

Would the results of this study be helpful in prepregnancy or adolescent counseling?

Source: Radesky, J. S., et al. (2008). Diet during early pregnancy and development of gestational diabetes. *Paediatric and Perinatal Epidemiology, 22*(1), 47–59.

Also, assess the circumstances of eating, such as cultural preferences, who prepares food in the family, and how many meals are eaten outside the home weekly, as these are important for a total nutrition picture (Table 13.3).

To strengthen history findings, assess a woman's prepregnancy weight and calculate her BMI. People with poor nutrition are typically overweight or underweight and show typical physical signs. Table 13.4 lists important physical examination assessments that suggest a good nutritional intake or evidence of poor nutrition.

TABLE 13.2 ✻ Nutritional Risk Factors During Pregnancy

Risk	Rationale
Adolescent (younger than 18 years)	Adolescent growth involves increased nutritional needs.
Short intervals between pregnancies	A woman's body has not had time to replace nutritional stores depleted during a previous pregnancy.
Low income	Family may not have resources to purchase adequate foods to meet pregnancy nutritional needs.
Food fads	Foods eaten may not be those adequate for pregnancy.
Drug use (including cigarettes and alcohol)	Drugs may be ingested in preference to healthy foods.
Existence of a chronic illness requiring a special diet	Intake may be low in an essential substance such as carbohydrate or protein.
Underweight or overweight	Underweight and overweight status may indicate chronic inadequate nutrition patterns.
Multiple pregnancy	A woman must supply enough nutrition for multiple fetal development.
Anemic at conception	A woman has no iron stores for fetal growth.
Lactose intolerance	A woman may not be ingesting adequate calcium for fetal skeletal growth.

TABLE 13.3 ✻ Areas to Be Assessed for a Total Nutrition History

Area of Assessment	Pertinent Questions
Food preparation	Who does the cooking at your house? Do you cook for people besides yourself? How do you usually prepare food (fried or baked)? What spices or condiments do you use commonly? What type of oil do you use for frying (saturated or unsaturated)?
Food pattern	How many meals do you eat on a typical day? Which is your biggest meal? How many snacks do you eat a day? What are they? How many meals do you eat outside your home? Where do you eat them? Cafeteria? Fast-food store? Restaurant? Bagged lunch? Are there any foods that you cannot or will not eat? Why?
Financial concerns	Does your family have enough money for food? Who does the food shopping? Would you eat differently if more money were available? Do you use any supplementary financial programs?
Activity level	Are you normally active or sedentary? (Could increase calorie need.)
Health	Do you have any allergies to food? Do you have any trouble with chewing or digestion? What is your bowel movement frequency? Were you taking oral contraceptives before pregnancy? Do you take supplemental vitamins? What type? How many? Do you drink alcohol? What type? How much? Do you smoke cigarettes? What is your stress level? Does stress affect your appetite?
Personal food preferences	Are there any foods you particularly enjoy or dislike? Are there any foods you feel are harmful or particularly beneficial during pregnancy? Do you have any special cultural or religious preferences?
Family dietary patterns	Is anyone in your family on a special diet? Is anyone obviously overweight or underweight? Does your family eat meals together? Is mealtime a social time?

TABLE 13.4 ✻ Physical Signs and Symptoms of Adequate Pregnancy Nutrition

Assessment Area	Signs of Good Nutrition	Signs of Poor Nutrition
Hair	Shiny; strong with good body	Hair dull and lifeless (possible protein deficit)
Eyes	Good eyesight, particularly at night; conjunctiva moist and pink	Pale and dry conjunctiva (iron and fluid deficit); difficulty with night vision (vitamin A deficit)
Mouth	No cavities in teeth; no swollen or inflamed gingiva; no cracks or fissures at corners of mouth; mucous membrane moist and pink; tongue smooth and nontender	Fissures at corners of mouth; tongue rough and tender (vitamin A deficit); mucous membrane pale (iron deficit)
Neck	Normal contour of thyroid gland	Thyroid gland enlarged (iodine deficit)
Skin	Smooth, with normal color and turgor; no ecchymotic or petechial areas present	Rough texture; poor turgor (fluid deficit) Vitamin K deficiency leads to petechia.
Extremities	Normal muscle mass and circumference; normal strength and mobility; edema limited to slight ankle involvement; normal reflexes	Poor muscle tone; diminished reflexes (protein deficit)
Fingernails and toenails	Smooth; pink; normal contour	Pale; break easily; little growth (protein deficit)
Weight	Within normal limits of ideal weight before pregnancy; following normal pattern of pregnancy weight gain	Overweight or underweight; unusually slow or rapid weight gain (inadequate or excessive carbohydrate).
Blood pressure	Within normal limits for length of pregnancy	Decreased from anemia (iron deficit); increased from hypertension

Hemoglobin or hematocrit determinations (see Appendix F) are also important assessments of good nutrition. These may reveal smoking habits, as cigarette smokers have higher hemoglobin levels than nonsmokers. These values are measured early in pregnancy and then usually repeated close to term and again at birth. A urinalysis can also be important because a finding such as elevated urine specific gravity could suggest a less-than-adequate fluid intake and elevated urine glucose levels suggest gestational diabetes (see Chapter 20).

After obtaining the full nutritional pattern, compare the types and amounts on the list with those shown in Figure 13.1 to see if all food groups and adequate amounts are included. Comparing foods from the person's 24-hour recall with a guide is a helpful way to show clients that what they thought was a "perfect" intake is imperfect or what they thought was a "little" problem actually involves the loss of an entire food group. Once a woman sees that a deficit exists, she may be more motivated to improve her nutrition. Such a picture also offers an instant reward for a woman who is ingesting adequate foods.

PROMOTING NUTRITIONAL HEALTH DURING PREGNANCY

Be certain that plans for improving nutritional patterns take into account a woman's lifestyle, family preferences, financial resources, customs, and cultural desires, because she and her family must follow them for 9 months (Fig. 13.2).

Family Considerations

Meal planning is best if it involves the entire family because even if a woman is receptive to changing her eating habits, she may have difficulty carrying out recommendations if her family resists the change. In families where a member has a special nutritional need, such as restricted sodium, change may be even more difficult. You may need to speak with the person who prepares meals for an adolescent as well as the adolescent to be certain that recommended changes will be carried out.

Financial Considerations

Food is costly, so to provide the extra servings required during pregnancy, a woman must spend more on food for herself per week than she is used to spending. Women generally view this increased expense as an investment in their child's health and do not regard it as a burden. However, a woman on a marginal income, although she may be willing to shoulder the additional cost, may have difficulty actually doing so. If this occurs, review what foods the woman is eating to be certain she is not buying only starchy foods because they are more filling and less expensive than protein foods. Help her secure available financial assistance such as food stamps, or inform her about nutritional aid programs such as WIC.

FIGURE 13.2 Encourage pregnant women and their partners to eat a varied diet with a high iron and protein content. This may be difficult for a woman early in pregnancy because of nausea and late in pregnancy because of fatigue. (© Barbara Proud.)

Under the food stamp program, a family with a low income can buy stamps that can be redeemed at grocery stores for any food items except alcohol or pet food. The cost of stamps varies, but the use of food stamps can increase a family's buying power as much as $150 a month.

The advantage of this type of program is that it helps to supplement the cost of food but places almost no restrictions on what foods can be selected and purchased. It can make the difference for a low-income family between being able to eat meat or living on a starchy diet.

WIC is a federal program that provides nutritional support for low-income women and children to reduce not only the risk of low birth weight but also medical costs by preventing costly newborn care. Established in 1972, WIC is funded by the Food and Nutrition Service of the U.S. Department of Agriculture. The program supplies supplemental foods and nutrition education for:

- Pregnant women
- Postpartum women up to 6 months
- Nursing mothers up to 1 year
- Children from birth to age 5

Each state defines the income eligibility level for its citizens, but the eligibility for all programs is based on income level, geographic area, and nutritional risk. To receive food, clients must live in an area that has been designated as a funding area. The nurse or nutritionist in the health care facility determines possible risk and nutritional need. Factors considered that put pregnant women at nutritional risk include age (an adolescent or a woman over 40); poor obstetric history such as previous spontaneous miscarriage, a short period between pregnancies, previous low-birth-weight infant, or gestational diabetes; anemia; poor weight gain; or inadequate consumption of food by nutrition history.

For the pregnant woman, foods typically offered by the program include those with high-quality protein, iron, calcium, and vitamins A and C, such as fruit juice, eggs, milk, and cheese. At predetermined intervals, WIC clients are reevaluated to see if the program supplements are still necessary. WIC has been successful in improving nutrition during pregnancy because not only does it supply additional food to recipients but also the periodic evaluations provide time for nutritional counseling (Watts et al., 2007).

School lunch programs are a way that some pregnant adolescents can receive help with nutrition. Millions of schoolchildren qualify for free or reduced-price school lunches. A school lunch (type A) is designed to provide one third of a child's DRI. For many adolescents, these school lunches may be the most nutritious meal they eat in a day. Although there may be a large selection of foods to choose, children who have a sense of self-efficacy are able to make the wisest choices at school lunches (Thompson et al., 2007).

TABLE 13.5 ✻ Characteristics of Certain Ethnic Diets

Group and Place of Origin	Staple Foods	Common Customs
Hispanic Americans from Puerto Rico	Steamed white rice; many varieties of beans; wheat breads; starchy vegetables such as cassavas, yams, breadfruit, plantains, and green bananas; green peppers; tomatoes; garlic; dried, salted fish; salt pork, bacon; lard; olive oil; sugar; jams and jellies, sweet pastries; sugared fruit juices; cafe con leche (coffee and hot milk)	Milk is rarely consumed as a beverage. Most food is cooked for long periods or fried. Malt beer is believed to be nutritious and may be given to children and breastfeeding mothers.
Hispanic Americans from Mexico, Central America	Many varieties of beans; steamed rice; corn products such as tortillas made from lime-soaked cornmeal; chili peppers, tomatoes; mangoes; prickly pear fruit; potatoes; meat and sausages; fish; poultry; eggs; milk cheeses; milk custards and bread puddings; lard; sweet chocolate and coffee drinks; cakes, pastries	Most vegetables are cooked so long that they lose nutritional value. Diet is high in fiber and starch. Animal fat is frequently added during food preparation. Because milk, green leafy vegetables, and fruit intakes are low, diet may be inadequate in calcium, iron, vitamin A, and vitamin C. Obesity is common.
Hispanic Americans from Cuba	Stews and casseroles flavored with sage, parsley, bay leaf, thyme, cinnamon, curry, capers, onion, cloves, garlic, saffron. Soup is served daily. Fried foods, especially fish, poultry, eggs; rice; many varieties of beans	Fruits and vegetables are not eaten on a regular basis. Main meal is usually served at lunch.
Southern African Americans from West Africa (many generations in United States)	Hominy grits; biscuits; cornmeal and corn bread; rice; legumes; potatoes; onions; tomatoes; hot peppers; green leafy vegetables cooked in fatback or salt pork; okra; sweet potatoes; squashes; corn; cabbage; melons; peaches; pecans; all parts of a pig; fresh meats and poultry; fish; thick stews; butter, shortening, and lard; sugar; bread puddings; pies and sweets	African American food patterns are similar to those of whites in same region. Northern African Americans may be unfamiliar with "soul food." Frying is common; diet tends to be high in fat and salt, low in calcium. High rate of obesity.
Chinese Americans (diets vary sometimes with region)	Rice and rice gruel; wheat noodles; corn; green vegetables, especially from the cabbage family; squashes; cucumbers; eggplant; leafy vegetables; various shoots, including bamboo, mung, and soy; sweet potatoes; radishes; onions; peas and pods; mushrooms; roots; many local, seasonal vegetables; pickled vegetables; sea vegetables; plums; peaches; tangerines; kumquats and other citrus fruits; litchis; longans; mangoes; papayas; pomegranates; soybean products such as tofu (soybean curd), soy sauces, bean noodles, and soy milk; tiny portions of meat, fish with bones, or poultry; seafood; soup or tea as beverage; sugar as seasoning	Yin (feminine)–yang (masculine) concept of balancing intake; moderation is valued. Obesity is rare. Regional differences in food choices exist. Rice symbolizes life and fertility. Raw vegetables are rarely served. Diet is high in fiber and many nutrients, is low in fat, and may be low in protein
Japanese Americans	Rice; vegetables; pickled vegetables; soy as miso (soup), tofu, bean paste, and soy sauce; fruits; salads; fish with bones; sugar as seasoning; sea vegetables; seafood; ginseng; green tea	Common preparation methods include broiling, steaming, boiling, and stir-frying. Meat portions are small. Milk is rarely used by adults. Diet is low in fat, rich in nutrients, high in sodium.
Vietnamese Americans	Rice, rice noodles; French bread and croissants with butter; hot peppers; curries of asparagus and potatoes; salads; tropical fruits and vegetables; lemons and limes; small portions of poultry; eggs; fish parts; *nuoc mam* (a strong, fermented fish sauce added to almost every cooked dish); sweets, candies, sweetened drinks; coffee; tea	Rice may be eaten at every meal. Fresh milk is not readily available; lactose intolerance is common. Little fat is used in preparation. Diet may be low in iron and calcium.

Group and Place of Origin	Staple Foods	Common Customs
Native Americans	Southeast: corn; cornmeal; coontie (flour from a palmlike plant); fried breads; swamp cabbage (now illegal to harvest); pumpkins; squashes; papayas; alligator, snake, wild hog, duck, fish, and shellfish. Northeast: blueberries; cranberries; beans; corn; pumpkins; fish; lobster; wild game; maple syrup. Midwest: bison; beans; corn; melons; squashes; tomatoes. Southwest: corn (many colors and varieties); beans; squash; pumpkins; chili peppers; melons; pinenuts; cactus. Northwest: salmon; caviar; other fish; otter; seal; whale; bear; elk; other game; wild fruits; acorns (and other wild nuts); wild greens	Food has great religious and social significance. Corn is a status food for most tribes. Milk is seldom used; calcium intake is usually low. Diets on some reservations are considered poor. High rate of obesity.

Source: Dudek, S. (2009). *Nutrition handbook for nursing practice* (5th ed.). Philadelphia: Lippincott Williams & Wilkins.

Cultural Considerations

When helping plan nutrition during pregnancy, try to suggest foods that are individually or culturally favored, as these are the foods women tend to enjoy and will eat most consistently. Common cultural differences to be aware of in nutritional counseling are shown in Table 13.5.

✔ Checkpoint Question 13.3

You need to obtain a nutrition history from Tori. What is the best way to do this?

a. Ask her to tell you how much protein she eats daily.
b. Assess if Tori feels satisfied with her nutrition.
c. Ask Tori to describe what she ate in the last 24 hours.
d. Tell Tori to describe her concept of ideal nutrition.

Managing Common Problems Affecting Nutritional Health

Specific nutrition problems may result during pregnancy from several factors or circumstances. Discomforts such as constipation and flatulence that can result from food choices, and possible solutions to these concerns, have been discussed (see Chapter 12).

Nausea and Vomiting

As many as 50% of pregnant women report nausea and vomiting (Rojas, Wood, & Blakemore, 2007). No definite cause has been established for this symptom of early pregnancy, but it may be related to:

- Sensitivity to the high level of chorionic gonadotropin hormone produced by the trophoblast cells
- High estrogen or progesterone levels
- Lowered maternal blood sugar caused by the needs of the developing embryo
- Lack of pyridoxine (vitamin B_6)
- Diminished gastric motility

Nausea is aggravated by fatigue and may be aggravated by emotional disturbance. Most women notice the sensation as early as the first missed menstrual period and experience it throughout the first 3 months of pregnancy. The sensation is usually most intense on arising but may occur while a woman is preparing meals or smelling food. Vomiting at least once a day is common. Women who work nights and sleep days often experience "evening sickness," because that is when they arise.

Methods such as acupressure, anti–motion sickness wrist bands, or avoiding fluid with meals are effective for some women. Mild-flavored ginger tea may be helpful (White, 2007). Increasing carbohydrate intake seems to relieve nausea better than any other nutrition remedy. The traditional solution is for women to keep dry crackers, such as Saltines, by their bedside and eat a few before rising; sourball candies may serve the same purpose. A woman can then eat a light breakfast or delay breakfast until 10 or 11 AM, past the time her nausea seems to persist. To be certain she maintains a good food intake during pregnancy even in the presence of nausea, she should compensate for any missed meals later in the day. If preparing food for others makes her feel queasy, she might try to give this responsibility to another family member, at least through the worst phase of this symptom. Preparing and freezing meals ahead of time, perhaps at night when the nausea is less bothersome, may also help.

It is a good rule for women not to go longer than 12 hours between meals during pregnancy to prevent hypoglycemia. A woman may need to eat a late-evening snack to compensate for a late breakfast. She may be able to tolerate fruit and raw vegetables during the morning before other food. Urge her to experiment with soups or vegetable drinks that she may not usually think of as breakfast foods but that will give her early-morning calories.

Common measures to take to relieve nausea are summarized in Box 13.6. Caution women against self-medicating for nausea by taking antacids. Excessive use of antacids containing sodium bicarbonate may cause fluid retention because of the sodium content.

Fortunately, nausea usually disappears spontaneously as a woman enters her fourth month of pregnancy. If it persists beyond this month or is so extreme in early pregnancy that it interferes with nutrition, it may indicate the development of hyperemesis gravidarum, a serious complication of pregnancy.

Cravings

Cravings for food or aversions to certain foods during pregnancy are so common that they are considered a normal part

BOX 13.6 ✻ Focus on Family Teaching

Measures to Reduce and Evaluate Nausea During Pregnancy

Q. Tori Alarino tells you, "I've been nauseated ever since I became pregnant. What can I take to make this better?"

A. If nausea and vomiting are causing a fluid imbalance, medications can be prescribed. Common nonpharmacologic measures you can take to reduce nausea are:

- Be aware that at least 50% of women experience nausea during pregnancy, so what you are experiencing is normal.
- Eat a few dry crackers, toast, or a sourball before you get out of bed in the morning to increase your carbohydrate intake.
- Eat small but frequent meals rather than large infrequent ones.
- Avoid greasy or highly seasoned food.
- Delay breakfast until nausea passes (dinner if it is evening nausea).
- Make up missed meals at some other time of the day to maintain nutrition.
- Avoid sudden movements and fatigue because these may increase or cause nausea.
- Eat a snack before bedtime so delaying breakfast will not cause you to go a long time between meals.
- Purchase a wrist acupressure band (purchased in travel stores for motion sickness).

If nausea is present:

- Try sipping a carbonated beverage, water, or an herbal noncaffeinated or ginger tea.
- Try a walk outside in the fresh air or take deep breaths through an open window.

Notify your health care provider if:

- You are losing weight rather than gaining it.
- You have not gained the projected amount of weight for your week of pregnancy.
- You are unable to make up for lost meals some other time of the day.
- You have signs of dehydration such as little urine output.
- Nausea has lasted past 12 weeks of pregnancy.
- You vomit more than once daily.

of adaptation to pregnancy. It was formerly considered that these strange desires for food reflected a woman's need to call attention to a pregnancy or were a reaction to her imposed dependent state. However, cravings are actually more likely the result of a physiologic need for more carbohydrates or particular vitamins and minerals such as iron.

Now that recommended pregnancy nutrition allows for more calories and a greater pregnancy weight gain is encouraged, cravings are seen less often than before. When taking a nutrition history, ask if a woman notices any particular cravings. As long as this is a healthy type of food, help her plan a nutrition intake that includes the food, at least in moderation. This is a positive approach to nutrition counseling: it allows her to enjoy her pregnancy without feeling guilty because she is eating foods she craves.

During pregnancy, some women report an abnormal craving for nonfood substances (termed **pica** from the Latin word for "magpie," a bird that is an indiscriminate eater). The most common form of pica in the past was a craving for laundry starch. Today, women are more apt to report cravings for clay, dirt, cornstarch, or ice cubes (Mills, 2007). Although some of these items can do no harm in themselves, the ingestion of large quantities of nonfood substances can leave a woman deficient in protein, iron, and calcium, nutrients essential for a healthy pregnancy outcome (Box 13.7).

Always ask women at prenatal visits if they crave any nonfood items, as most women do not supply this information unless asked directly. They worry that you will find their behavior odd, or they may not realize their habit is pregnancy related as much as being a nervous habit.

Encouraging a woman to stop eating the nonfood substance may not be effective because the habit may be deeply ingrained. Because pica is a symptom that often accompanies iron deficiency anemia, correcting this underlying problem with an iron supplement may correct the pica. At subsequent visits, be certain to assess if a woman's hemoglobin is increasing and ask if she notices any difference in her cravings.

Heartburn (Pyrosis)

Heartburn (pyrosis) is a burning sensation along the esophagus caused by regurgitation of gastric contents into the lower esophagus. In pregnancy, it may accompany early nausea, but it may persist beyond the resolution of nausea and even increase in severity as pregnancy advances.

Pyrosis is probably caused by decreased gastric motility, which slows gastric emptying, and pressure of the expanding uterus pushing up against the stomach. It is noticed by at least 50% of pregnant women (Orr, 2007). Common suggestions to help prevent reflux into the esophagus are:

- Eat small meals frequently rather than large meals.
- Sleep on the left side with two pillows to elevate the upper torso.
- Do not lie down immediately after eating; try and wait at least 2 hours.
- Avoid fatty and fried foods, coffee, carbonated beverages, tomato products, and citrus juices

Aluminum hydroxide (Amphojel, Alternagel) or a combination of aluminum and magnesium hydroxide (Maalox) may be prescribed for relief. If these do not relieve the discomfort, a histamine antagonist such as cimetidine (Tagamet) or ranitidine (Zantac) may be prescribed (Rojas, Wood, & Blakemore, 2007). Be certain a woman understands that this "chest" pain is from her gastrointestinal tract and that, although it is called heartburn, it has nothing to do with her heart.

Hypercholesterolemia

Women with a family history of hypercholesterolemia may enter pregnancy with an elevated cholesterol level. During pregnancy, increasing progesterone levels cause a further elevation of cholesterol. Combined with intrahepatic cholestasis, this can lead to an increased risk for gallstone formation (cholelithiasis) and cardiovascular disease. Preventing

BOX 13.7 ✻ Focus on Communication

Tori comes to your prenatal clinic for her first visit. You want to obtain a nutrition history from her.

Less Effective Communication

Nurse: Hi, Tori. Are you eating a nutritious diet?
Tori: I'm always hungry since I've been pregnant. No problem.
Nurse: Have you ever compared what you eat to a food pyramid to see if you're eating all the different types of food it shows?
Tori: Sure. Grain is on one side; meat is on the other. I eat both of those.
Nurse: It's important to drink at least a quart of milk a day during pregnancy. Are you doing that?
Tori: I'm drinking milkshakes so I not only get calcium but extra calories.
Nurse: That's great. Good nutrition is so important during pregnancy. I'm glad you're so aware of it.

More Effective Communication

Nurse: Hi, Tori. Are you eating a nutritious diet?
Tori: I'm always hungry since I've been pregnant. No problem.
Nurse: Tell me what you ate yesterday.
Tori: A muffin and coffee for breakfast, a milkshake for lunch, a hamburger and fries for supper. A soft drink before bed. And ice cubes. I suck on them all day like candy.
Nurse: Let's talk about ways you might get some fruit and vegetables into your day.

Most people believe they eat well, so if just asked general questions about nutrition, they respond that their nutrition is adequate. Only when they are asked to actually describe what they ate during one day is the truth revealed.

cholelithiasis during pregnancy is important because gallstones can cause extremely sharp pain. Fortunately, surgery to remove gallstones during pregnancy is possible with new ambulatory laparotomy techniques.

A woman who has had difficulty with hypercholesterolemia before pregnancy may need to continue to eat only moderate amounts of fat during pregnancy to prevent any increase in cholesterol. Helpful ways to reduce cholesterol include:

- Exercising daily
- Eating oat cereal
- Broiling meat rather than frying it
- Using a minimum of salad oils
- Substituting new omega-3 products in place of butter
- Eating fish high in omega-3 oil, such as salmon or trout

As discussed earlier, although high in omega-3 oil, current recommendations are that pregnant women limit their intake of tuna, swordfish, King mackerel, and tilefish because of their potentially high mercury content (Sunderland, 2007). Eating raw fish is also not advised because of the danger of parasitic contamination.

Urge women to check with their health care provider about the wisdom of continuing to take cholesterol-lowering drugs during pregnancy, because these drugs may be teratogenic (Karch, 2009). A low-cholesterol diet will automatically be lower in calories than the average diet, because oils and fats add many calories. Therefore, assess these women carefully for adequate weight gain during pregnancy. Make sure that a woman does include some oil daily (perhaps as olive oil on a salad) so she has included a source of linoleic acid in her daily intake.

✔ Checkpoint Question 13.4

Which statement by Tori would best suggest she has pica?

a. "I chew typewriter paper. It helps relieve my heartburn."
b. "I can't eat a thing before 11 o'clock every morning."
c. "I notice I've been eating more sweet stuff than usual."
d. "I crave oranges; can't get enough of them every day."

Promoting Nutritional Health in Women With Special Needs

The Adolescent

A pregnant adolescent needs a high caloric intake (2500 calories per day) to supply energy for her high level of activity and growth. The nutrients most often lacking from a typical adolescent diet tend to be calcium, iron, folic acid, and total calories. Look for sources of these when analyzing a teenager's pregnancy intake.

Good nutrition can be a problem with pregnant teenagers because of the dual demands of consuming enough food to provide for fetal growth and their own continuing growth. Often adolescents, in their search for identity, avoid foods that their parents see as important for them (e.g., milk, warm cereal, vegetables, or fruit) and indulge instead in foods such as soft drinks, potato chips, and French fries. To help an adolescent plan nutritional intake for pregnancy, respect her right to reject traditional foods as long as what she does eat includes sufficient nutrients. A cheese and sausage pizza, a glass of milk, and an apple compose a lunch that provides all basic food groups (meat: sausage; bread: pizza crust; vegetable: tomato sauce; dairy: cheese and milk; fruit: apple). A hamburger "with everything" plus a tangerine and milk provides the same.

Most adolescents snack frequently during the day. Toward the end of pregnancy, when fatigue may be a problem, they may begin to eat more and more "junk food" because preparing nutritious snacks takes more effort. Advise them to prepare nutritious snacks such as carrot sticks or cheese bites early each day when they have more energy so that later in the day, when they are tired, eating a nutritious snack will not involve much effort.

Counseling adolescents about pregnancy nutrition may not be effective, because they often are not responsible for cooking what food they eat. You may need to speak to their parents or support persons (with permission) about certain foods to prepare before you can alter their nutrition pattern. If possible, suggest several foods that would fill a deficit and let the adolescent choose from them to provide a sense of control.

A Woman 40 Years of Age

Today, many women are older than 40 by the time they have their first child, and many more are older than 40 when they have their second or third child (Crombleholme, 2009). The nutritional needs of women in this age group are poorly studied, but it is obvious women in this age group should maintain the same careful pregnancy nutrition as younger women. Because women in this age group may have slightly decreased kidney function, they should be sure to maintain a high fluid intake to remove waste products for themselves and for a fetus. They need adequate calcium to prevent bone density loss. Many women at this point in life are caring for elderly parents, and many have delayed childbearing to establish a career; this means they may eat whatever they are preparing for elderly parents or depend on packed or fast-food lunches for at least part of their nutrition each week. Focus your nutrition counseling on maintaining adequate nutrition during pregnancy, based on these lifestyles.

A Woman With Decreased Nutritional Stores

A woman with high parity or a short interval between pregnancies or one who has been dieting rigorously to lose weight before pregnancy may enter pregnancy with such depleted nutritional reserves that she has little to draw on during the first part of pregnancy. If her folic acid intake has been inadequate, her fetus may be susceptible to neural tube defects (Lumley et al., 2009). This shortage of nutrients may become critical during the time she is unable to eat well because of the normal nausea and vomiting of pregnancy. In addition, nutritional stores may be affected by other variables. Be alert that:

- Women from low-income families may enter pregnancy with anemia.
- Women who used diuretics for a dieting program may be deficient in potassium.
- Women who have been taking oral contraceptives may have decreased folate stores.
- Women who were using intrauterine devices or who have menorrhagia may be deficient in iron from excessive blood loss with menstrual flows.
- Women who drink alcohol excessively may be deficient in thiamine.

Women with these decreased nutritional stores need to be identified early in pregnancy through history taking so they can be referred to a nutritionist for specific nutritional counseling. They may need additional supplements during pregnancy to restore a particular nutrient.

A Woman Who Is Underweight

Today's emphasis on slim, model-like female figures makes it easy to overlook the health problem of a woman who is underweight. A woman who enters a pregnancy underweight, however, needs nutritional counseling just as much as an overweight woman.

Underweight is defined as a state in which a woman's weight is 10% to 15% less than the ideal weight for her height, or a BMI of less than 18.5 kg/m^2. Most women who are underweight tire easily because they have an accompanying iron deficiency anemia. Even when underweight women gain excessive weight during pregnancy, they still tend to have a higher-than-usual incidence of low-birth-weight infants, probably because of depleted nutrient stores at the pregnancy's beginning. This is one reason why preconceptual health care visits and assessments are so important (Bernstein & Weinstein, 2007).

Being underweight may occur for a variety of reasons:

- Dieting for weight loss
- Poverty and the inability to buy adequate food (however, many poor women are obese, not underweight, because starchy foods are less expensive than those that have a higher protein content, such as meat and eggs)
- Excessive worry or stress, emotions that can lead to a loss of appetite
- Depression, which causes a chronic loss of appetite
- An eating disorder, such as anorexia nervosa or bulimia, conditions in which a woman has developed revulsion to food (see Chapter 54)

However, the major reason for being underweight is insufficient intake of food because of chronic poor nutritional habits.

Convincing women who are underweight to eat more may be difficult because you are asking a woman to change lifelong eating habits (Abayomi et al., 2007). Counseling also can be challenging because during the first trimester of pregnancy, when fetal need is greatest and at a time when she has nausea and vomiting, possibly losing all desire to eat, you are asking her to take in additional food.

Begin counseling by asking a woman for a 24-hour nutrition recall. Total daily caloric intake for the underweight woman may need to be as high as 3500 calories (500 to 1000 calories more than the usual specified daily amount). Work with women to develop menus based on well-planned meals rather than on quick take-out foods. Suggest additional calories in the form of a concentrated formula such as an instant liquid breakfast drink. Be certain a woman understands this should not be a high-protein drink used for high-protein dieting regimens. Such diet drinks deliver a concentrated solute load (breakdown products of protein) to the kidney (already working to capacity because of the pregnancy) and provide so little carbohydrate in proportion to protein that they encourage the breakdown of protein for body energy, a process that results in acidosis. High-protein diets of this nature are not recommended for long-term use by anyone, but they should be totally avoided by women during pregnancy.

A 500-calorie increase over normal requirements should result in a weight gain of an additional pound per week. Be certain to plan for this additional gain when the total weight gain during pregnancy is calculated at each office visit. Otherwise, the total weight gain of a woman may seem excessive when it is actually healthy.

If a lack of nutritional stores makes a woman feel tired, urge her to schedule adequate rest periods daily so she can feel sufficiently energetic to prepare nutritious meals. Be certain she is taking her prescribed vitamin and iron supplements. Additional nutritional counseling in the postpartum period may be necessary so she can maintain better nutrition throughout her life and can enter a subsequent pregnancy (if she desires one) in a state of nutritional health.

A Woman Who Is Overweight

A woman is considered **overweight** if she is 20% above ideal weight or has a BMI over 25 kg/m^2. She is considered **obese** if she weighs more than 200 lb, she is 50% above ideal body

weight for height, or her BMI is above 30 kg/m^2. As many as 10% of pregnant women in the United States are overweight. Less-educated women and those living in poverty tend to be more overweight than others. Obesity in pregnancy is serious because it is associated with an increased incidence of gestational diabetes and pregnancy-induced hypertension (Rode et al., 2007).

Although obesity may occur from hypothyroidism, it most often occurs as a result of excessive caloric intake and decreased energy expenditure. Obesity becomes a problem during pregnancy for a variety of reasons:

- Pregnancy causes circulatory volume to increase 20% to 50% and metabolism to increase to meet the demands of the pregnancy, placing additional stress on a possibly already overworked body. Hypertension and thrombophlebitis are more likely to occur.
- It is often difficult to hear fetal heart tones in an obese woman; palpating for position and size of a fetus at birth is also difficult.
- Obese women are at an increased risk for giving birth to infants with *macrosomia* (excessive fetal growth); this increases the incidence of cesarean births in this population.
- Performing a cesarean birth, if necessary, may be difficult because of the excessive adipose tissue that must be incised to reach the uterus.
- Gestational diabetes is more apt to develop; the pregnancies of obese women are more apt to be prolonged, leading to postmature infants.
- Ambulating during pregnancy and immediately afterward is more difficult because of the increased energy expenditure necessary, increasing the risk for complications such as thrombophlebitis and pneumonia.

Most obesity is caused by overeating but the habit of overeating has many causes. For some women, this is a coping mechanism for stress; whenever they feel tense or worried, they help themselves to something "comforting" to eat. Because pregnancy is stressful, it may be a particularly difficult time for a woman to change her food intake pattern. Other women overeat because their parents did and they were raised to always "clean their plate." If a woman has been serving her family an excessive intake of calories as well as herself, then the entire family may have to change their eating pattern to bring about a change in a woman's intake.

Dieting to reduce weight is not recommended during pregnancy because if carbohydrates are reduced too much, the body will use protein and fat for energy. This could deprive a fetus of essential nutrients. It could lead to ketoacidosis. Although the long-term effects of mild ketoacidosis on a fetus are not well studied, it can be avoided if the daily caloric intake, even in the most obese woman, does not go below 1500 to 1800 per day.

Overweight women tend to exercise less than do women of normal weight. Exercising is more awkward and more tiring, and they may feel self-conscious wearing exercise clothing. Try to encourage them to engage in at least a minimum activity program, such as walking around the block once a day, in conjunction with lessened carbohydrate intake.

Helping a woman look at her nutrition in terms of empty-calorie versus nutritious foods may help her to eat more sensibly. Early in pregnancy, when she is eager to appear pregnant, she may resist limiting her intake. Stress that a fetus grows best on nutritious foods, not necessarily those with the most calories. Provide additional nutritional counseling in the postpartum period so she can prepare more nutritious meals in the future for herself and her growing family. If successful, she will not enter another pregnancy severely overweight.

A Woman Who Is Morbidly Obese

When a women weighs over 300 lb or has a BMI over 40 kg/m^2, she is classified as *morbidly obese*. During a pregnancy, she presents with a series of special care problems as she is even more prone to complications of pregnancy such as gestational or type 2 diabetes, hypertension, back pain, and thrombophlebitis than obese women. She is prone to sleep apnea so may feel tired over and above normal pregnancy fatigue. Hearing fetal heart sounds and palpating for fetal position can be difficult. Because exercise is difficult, a woman may be prescribed support hose to aid lower leg circulation and help avoid thromboembolitic complications. Pregnancies tend to be prolonged with a high rate of cesarean birth (Mahlmeister, 2007).

In addition, morbidly obese women may need special care equipment furnished for them such as a larger hospital bed, examining gown, wheelchair, and straps for fetal monitoring equipment than usual. Be discreet when arranging for this type of equipment for a woman as she may be sensitive to her appearance and weight.

Although women with morbid obesity generally eat large amounts of food, take a nutrition history to be assured that their large intake includes protein-rich, not empty-calorie, foods. Some women who are morbidly obese have had bariatric surgery for weight reduction (either a gastric bypass that causes weight loss by decreasing stomach space and promoting malabsorption or stomach banding that encourages weight loss by simple food restriction). Gastric bypass surgery results in a 60% to 80% loss in weight; banding is less effective, resulting in a 45% to 50% weight loss (Landsberger & Gurewitsch, 2007). Although still uncommon in adolescents, the proportion of older adolescents who are having this type of surgery is also increasing (Tsai, Inge, & Burd, 2007). Both women and adolescents are advised to not become pregnant for at least a year after bariatric surgery, during their period of greatest weight loss.

All women who have had bariatric surgery are unable to eat large meals or a meal rich in calories as this causes a "dumping syndrome" or sudden symptoms of nausea, bloating, and diarrhea. Mark their chart as someone who has had bariatric surgery so they are not scheduled for a routine 50 or 100 g glucose tolerance test because this will stimulate acute dumping symptoms. Because their overall intake will be small during pregnancy, their weight gain will be less than others and they are prone to develop iron, protein, folic acid, and vitamin B_{12} deficiencies. Women who have had a gastric bypass are also prone to fat-soluble vitamin deficiencies as fat is no longer well absorbed.

A Woman Who Is a Vegetarian

More women of childbearing age are turning to vegetarianism to maintain healthy nutrition and avoid excess fat and food contaminants. Vegetarian diets are consistent with Dietary Guidelines for Americans. Most women vegetarians are closer to their ideal weight and have lower serum cholesterol levels and lower blood pressure levels than women who eat a more typical American diet. Nurses may find that many

pregnant women, therefore, plan to exclude meat from their diets (Cox, 2008). There are many different types of vegetarians: lacto-ovo-vegetarians (no animal flesh or fish is eaten, but dairy products and eggs are), lactovegetarians (no meat, fish, or eggs are eaten, but dairy products are), and vegans (nothing derived from an animal is eaten). Most vegetarians are knowledgeable about their diets and can discuss what foods are high in various nutrients and how they incorporate such foods into their daily intake (Rifkin, 2007).

A vegetarian food pyramid is identical to a usual one, except it contains no meat (shows fish and eggs). Women should try to eat three or more servings a day of both fruits and vegetables, six or more servings per day of grains, and two or more servings per day of legumes such as kidney, black, or lima beans.

Special concerns for pregnant vegetarians include lack of vitamin B_{12} (meat is the chief source of this) and an inadequate intake of calcium (recommend dark-green vegetables as sources) and vitamin D (fortified milk and sunlight are the main sources of this). Urge women who are vegetarians to take a daily prenatal supplement, like all women, to ensure adequate iron and folic acid. Vegetarian nutrition for their new infant is discussed in Chapter 29.

A Woman With Phenylketonuria

Phenylketonuria (PKU), named for the breakdown product of phenylalanine, is an essential amino acid that is excreted in the urine in this form. It is an inherited disorder in which a person cannot convert phenylalanine into tyrosine, the form used for cell growth. Without conversion, phenylalanine accumulates in the person's blood serum, eventually leaving the bloodstream to invade body cells. When brain cells are invaded, severe cognitive challenge and accompanying neurologic damage, such as recurrent seizures, develop (see Chapter 48). A fetus of a woman with uncontrolled PKU can develop microcephaly, intrauterine growth restriction, and neurologic damage (Poustie, Wildgoose, & Rutherford, 2009).

Foods high in phenylalanine are those high in protein; examples of foods low in phenylalanine are fruits and vegetables such as orange juice, bananas, squash, spinach, and peas. Children with PKU follow a diet with restricted phenylalanine intake until at least past adolescence. A woman with PKU should consult her internist when she is planning to become pregnant and should plan to return to a low-phenylalanine diet for at least 3 months before she becomes pregnant. A woman typically follows this low-phenylalanine diet during the pregnancy and afterward as long as she is breastfeeding.

A woman with PKU needs support during pregnancy to adhere to these nutritional restrictions. It is particularly disappointing if she does not become pregnant immediately after starting the restricted diet, because each month she is "prepregnant" extends the period she must follow the restrictions. A woman with PKU is usually well informed about her particular nutritional needs. She is aware that phenylalanine is destructive to developing brain cells and that not following her restricted plan could leave her future child severely cognitively challenged.

A Woman With a Multiple Pregnancy

A woman with a multiple pregnancy gains more weight overall and at a greater pace than a woman carrying a single child because of the increased fetal weight (a total weight gain of 40–45 lb). To sustain her own nutrition stores, she must ingest high levels of protein and carbohydrate. In particular, there is an increased burden on maternal iron and folic acid stores. For this reason, multiple pregnancy needs to be recognized early so nutrition supplements can be added as needed (Bernstein & Weinstein, 2007).

What if... Tori Alarino was pregnant with a multiple pregnancy and told you she was "eating for three"? You notice she takes three desserts every day for lunch. Will this hurt her or just add a few extra pounds?

A Woman Who Smokes or Uses Drugs or Alcohol

The specific effects of alcohol, cigarette smoking, and recreational drug use on fetal growth are discussed in Chapter 12. In addition to specific teratogenic fetal effects, these substances can lead to general nutrition problems because a woman is ingesting these substances rather than eating nutritious foods.

A Woman With Concurrent Health Problems

Any health concern that requires rigid salt, protein, or carbohydrate restriction poses a potential threat to fetal nutrition during pregnancy. Women who have medical problems such as kidney disease, diabetes, tuberculosis, bulimia, inflammatory bowel disease, celiac disease, or anorexia nervosa should consult their primary care provider before pregnancy because of the specific metabolic disorders that occur with these illnesses. Nursing interventions and nutrition concerns for women with health problems such as these are discussed in Chapter 20.

A Woman Who Eats Many Fast-Food Meals

As many as 90% of women of childbearing age work at least part-time outside their homes. This means that nutritional counseling must involve helping women who rely on packed lunches or fast-food meals to maintain adequate pregnancy nutrition. The difficulty with fast-food restaurants is the limited choice of food available. This can cause a woman to grow tired of the same thing and so eat little. Unless there is a salad bar, there is likely to be a limited menu of fruits and vegetables. Fast-food restaurants have also been associated with outbreaks of infection because of undercooked hamburger or contaminated salad bars. Caution women to order hamburgers well done to help prevent *Escherichia coli* contamination and severe diarrhea, which could lead to a fluid and electrolyte imbalance (Todd, 2007).

A packed lunch poses few problems in pregnancy as long as a woman uses some creativity in preparation so she does not grow so tired of packed lunches that she reduces her noontime intake. Packing her lunch at bedtime rather than in the morning, when she may feel nauseated (and therefore packs little because nothing looks good), is a good recommendation early in pregnancy. Late in pregnancy, a woman may feel too tired at bedtime to do this and should change to preparing it in the morning, when she has more energy. Including a thermos with a cream soup is a good way to add milk and calcium to her diet. Packing carrot sticks or sliced cucumbers, tomatoes, or apples helps to make a lunch nutritious and also provides a mid-morning or mid-afternoon snack. Having these snacks available prevents her from having long stretches of time without eating or eating empty-calorie foods from vending machines (see Focus on Nursing Care Planning Box 13.8).

BOX 13.8 ✻ Focus on Nursing Care Planning

Multidisciplinary Care Map for a Pregnant Woman With an Inadequate Nutritional Pattern

Tori Alarino, 28, is 4 months pregnant and works at a fast-food restaurant during the day. She eats her breakfast and lunch at work. Her husband works four evenings a week, so she cooks for herself on those evenings. She dislikes milk, so she drinks milkshakes as a source of calcium. She is concerned because she has already gained 23 lb. She craves oranges, eating six to eight of them a day. She tells you, "I thought pregnant women always craved pickles and ice cream. What's wrong with me?"

Family Assessment ✻ Client lives with husband in four-bedroom home; husband works as an electrician. Client's father (aged 58) lives with them since recent divorce.

Client Assessment ✻ Primigravida; LMP 16 weeks ago. Height 5 ft 6 in. Prepregnancy weight: 150 lb (1–2 lbs over desirable weight for height); BMI 25.0.

Weight today: 133 lb. History of weight problem during adolescence; currently controls weight by eating only one main meal per day. 24-hour dietary recall: Breakfast—1 cup coffee with muffin; lunch—1 milkshake; dinner—1 hamburger with French fries, 1 milkshake; snacks—8-ounce soft drink. Reports feeling tired and "run-down".

Nursing Diagnosis ✻ Imbalanced nutrition, less than body requirements, related to desire to control weight

Outcome Criteria ✻ Client reports intake of foods adequate in calories, high in iron, calcium, and protein by next prenatal visit.
Demonstrates weight gain appropriate for stage of pregnancy and prepregnancy weight.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Assess if the fatigue client reports is interfering with adequate food preparation.	If fatigue is a problem, recommend preparing nutritious lunch early in day when less fatigued.	Fatigue can increase nausea/vomiting in early pregnancy; interfere with food preparation all through pregnancy.	Client states she is able to cook and realizes eating all fast foods may not be her best action.
		Consultations		
Nurse/physician/women's health practitioner	Assess nutrition requirements based on client's BMI and individual preferences.	Consult with nutritionist about recommended caloric and mineral requirements.	Caloric recommendations may need to be attached in light of client's BMI and prepregnancy and current weight.	An ideal nutrition plan is created and presented to client.
		Procedures/Medications		
Nurse	Assess if client has experience with keeping a journal.	Instruct client to keep a journal recording all food and fluid intake for 1 week, and review with client on next visit.	Keeping a journal provides concrete evidence of client's adherence to nutritional plan.	Client brings log to next prenatal visit and reviews it with prenatal staff.
		Nutrition		
Nutritionist	Assess the nutritional requirements based on client's BMI, present weight, and individual choices.	Provide client with food suggestions. Provide written information as needed.	Assistance from a dietitian ensures a nutritionally sound diet with culturally acceptable food choices. Printed information enhances learning.	Client lists an "ideal" nutrition plan for healthy pregnancy nutrition.

(continued)

BOX 13.8 ✻ Focus on Nursing Care Planning (continued)

		Patient/Family Education		
Nurse/ nutritionist	Assess if client is aware of the importance of healthy nutrition for pregnancy.	Review healthy pregnancy nutrition with client.	Knowledgeable clients can best follow a nutritious meal plan.	Client lists foods she will include for healthy pregnancy nutrition.
		Psychosocial/Spiritual/Emotional Needs		
Nurse	Question client about food likes and dislikes. Investigate any cultural influences on food choices.	Ask client to list foods in each food group that are her favorites and she enjoys cooking.	Ascertaining food preferences and cultural influences provides a baseline for future food selections and suggestions.	Client lists foods she prefers and knows she can eat consistently.
		Discharge Planning		
Nurse	Assess best times for client to return for prenatal appointments based on work/family obligations.	Schedule a follow-up appointment in 1 week.	Changing nutritional habits and behaviors can be difficult. Scheduling close follow-up provides an opportunity for evaluation and instruction.	Client states she will return for follow-up nutritional counseling.

A Woman With Lactose Intolerance

The sugar in milk is lactose. In the intestine, lactose is broken down into glucose and galactose by the enzyme **lactase.** Most of the world's population has sufficient lactase as an infant but the amount of lactase available fades by school age. After this point, people have difficulty digesting lactose or are lactose intolerant. African Americans, Native Americans, and Asians tend to have the highest percentage of lactose intolerance (approximately 70% of African American adults cannot drink milk). Those most able to tolerate milk are northern Europeans and their descendants.

When people who are lactose-intolerant drink milk, they experience nausea, diarrhea, cramps, gas, and a general feeling of bloating. The intestinal slowing that accompanies pregnancy does not change the intensity of symptoms (Bauchner, 2007).

Women who cannot drink milk because of lactose intolerance may be able to eat cheese because the processing of cheese changes the lactose content; yogurt may also be tolerated. Fortified soy milk is another possible substitute. Lactase tablets can be prescribed to supplement absent lactase. Typically, a woman chews these before ingesting milk products. Even with this, however, a calcium supplement (1200 mg daily) and a vitamin D supplement (400 IU) may be necessary. This is because the amount of cheese or yogurt needed to replace the calcium of milk is too great to be practical. Because milk is also a good source of protein, be sure to assess whether, without milk, a woman's intake of protein is adequate.

Many baby magazines, television advertisements, and government pamphlets on pregnancy mention repeatedly that it is important to drink milk during pregnancy. You may need to explain that as long as a woman ingests the same nutrients from other foods, the actual drinking of milk is not important.

A Woman With Hyperemesis Gravidarum

Hyperemesis gravidarum (sometimes called *pernicious* or *persistent vomiting*) is nausea and vomiting of pregnancy that is prolonged past week 12 of pregnancy or is so severe that dehydration, ketonuria, and significant weight loss occur within the first 12 weeks of pregnancy (Alalade, Khan, & Dawlatly, 2007). It occurs at an incidence of 1 in 200 to 300 women. The cause is unknown, but women with the disorder may have increased thyroid function because of the thyroid-stimulating properties of human chorionic gonadotropin. Some studies reveal that it is associated with *Helicobacter pylori,* the same bacteria that cause peptic ulcers (Golberg, Szilagyi, & Graves, 2007).

Assessment. With hyperemesis gravidarum, a woman's nausea and vomiting are so severe that she cannot maintain her usual nutrition. She may show an elevated hematocrit concentration at her monthly prenatal visit because her inability to retain fluid has resulted in hemoconcentration. Concentrations of sodium, potassium, and chloride may be reduced because of her low intake, and hypokalemic alkalosis may result if vomiting is severe. In some women, polyneuritis, because of a deficiency of B vitamins, develops. Weight loss can be severe. Urine may test positive for ketones, evidence that a woman's body is breaking down stored fat and protein for cell growth. If left untreated, the condition is associated with intrauterine growth restriction or preterm birth if a woman becomes dehydrated and can no longer provide a fetus with essential nutrients for growth.

Always try to determine exactly how much nausea and vomiting women are having during pregnancy. Ask a woman to describe the events of the day before if she says it was a typical day. How late into the day did the nausea last? How

many times did she vomit, and how much? What was the total amount of food she was able to eat?

Therapeutic Management. Women with hyperemesis gravidarum usually need to be hospitalized for about 24 hours to monitor intake, output, and blood chemistries and to restore hydration.

All oral food and fluids are usually withheld. Intravenous fluid (3000 mL of Ringer's lactate with added vitamin B, for example) may be administered to increase hydration. An antiemetic, such as metoclopramide (Reglan), may be prescribed to control vomiting. Throughout this period, carefully measure intake and output, including the amount of vomitus.

If there is no vomiting after the first 24 hours of oral restriction, small amounts of clear fluid may be begun and the woman may be discharged home, usually with a referral for home care. If she can continue to take clear fluid, small quantities of dry toast, crackers, or cereal may be added every 2 or 3 hours, then she can be gradually advanced to a soft diet, then to a normal diet. If vomiting returns at any point, enteral or total parenteral nutrition may be prescribed. Home care follow-up provides further information about the client's status after hospital discharge (see Chapter 4).

Nursing Diagnoses and Related Interventions

A woman with hyperemesis gravidarum needs the opportunity to express how she feels about this strange thing that is happening to her or how it feels to live with ever-present nausea. Some women are under such psychosocial stress that they appreciate counseling to help them decide whether to terminate a pregnancy or allow it to go to completion. An appropriate nursing diagnosis may be "ineffective coping related to stress of pregnancy or concurrent life events." Be certain that the outcomes established are realistic. It may not be possible to stop vomiting completely, but enough supplemental fluid to counteract the loss of fluid with vomiting can be supplied.

Nursing Diagnosis: Risk for deficient fluid volume related to vomiting secondary to hyperemesis gravidarum

Outcome Evaluation: Client remains free of signs and symptoms of dehydration (i.e., poor skin turgor or dry skin or mucous membranes); urine output is greater than 30 mL/h; urine specific gravity ranges between 1.003 and 1.030; no further episodes of vomiting occur.

Like the typical nausea and vomiting of pregnancy, the vomiting of hyperemesis gravidarum may be precipitated by fatigue and the smell of cooking. Encourage a woman to serve herself small portions so the amount on her plate does not appear overwhelming. It is best if foods are presented attractively. Hot foods should be hot, and cold foods should be cold. Remember not to talk about food while you give care (e.g., "What's the soup of the day in the cafeteria?") or to urge a woman to "Eat just a little more. You're starving your baby." Urging women with hyperemesis gravidarum to eat this way can cause them to feel guilty on top of feeling so nauseated that they cannot eat.

An emesis basin is an important piece of equipment for a woman who is vomiting. While she is hospitalized, put it out of sight and not on the bedside table, however, so she is not constantly reminded of vomiting. Try to limit her exposure to food odors. Be sure that food carts with smells of food such as fish, bacon, or coffee are not parked outside her door at mealtimes. Be sure to reinforce these instructions with other health care providers.

Nursing Diagnosis: Imbalanced nutrition, less than body requirements, related to prolonged vomiting

Outcome Evaluation: Client eats at least 2500 calories daily or receives supplemental nutrition intravenously or enterally.

Some women have such extreme symptoms that vomiting recurs with the introduction of food. To maintain adequate nutrition to support fetal growth, a woman may need to be maintained on total parenteral nutrition or enteral feedings. While she is receiving total parenteral nutrition at home, instruct her to check her urine for glucose and ketones twice daily. If there is glucose in the urine, this suggests that the infusion solution contains more glucose than her body's metabolism can use. Ketones in the urine mean that her body is not receiving enough nutrients and it is breaking down protein. If either of these findings is positive, she should call her health care provider because she needs a nutrition reassessment.

Fortunately, despite its extreme symptoms, excessive vomiting during pregnancy rarely leads to pregnancy loss or low-birth-weight newborns when it is properly treated.

✔ Checkpoint Question 13.5

Suppose Tori is a vegetarian. What is apt to be her greatest nutritional risk?

a. Lack of iron
b. Lack of vitamin C
c. Lack of folic acid
d. Lack of vitamin B_{12}

Key Points for Review

- Assessment of nutritional health should include a health history (24-hour recall) and physical examination.
- Nutrition during pregnancy should include about 300 additional calories daily to provide energy, spare protein, and provide for fetal growth requirements.
- Important minerals necessary for pregnancy include iron, iodine, calcium, fluoride, sodium, and zinc. Most women need to take an iron supplement to prevent iron deficiency anemia.
- Women should monitor their intake of caffeine, fish, and artificial sweeteners during pregnancy.
- Prenatal vitamins contain additional folic acid supplements and iron, so these should be used instead of over-

the-counter vitamins during pregnancy. Be certain that women regard pregnancy vitamins as medication and follow the medication rule: take nothing other than medications specifically recommended by their primary care providers, or else toxicity could result.

- Advise pregnant women not to go longer than 12 hours between meals, to avoid hypoglycemia.
- Women who are at high risk for inadequate nutrition include those who are adolescent or over age 40; those who have decreased nutrition stores; those with a multiple pregnancy; those who are lactose intolerant; those who are underweight or overweight; those on a special diet; those using recreational drugs, including alcohol or cigarettes; and those with hyperemesis gravidarum (extreme nausea and vomiting).
- Common nutrition concerns associated with pregnancy include nausea and vomiting, constipation, cravings (including pica), and pyrosis.
- Hyperemesis gravidarum is nausea and vomiting of pregnancy that extends past 12 weeks of pregnancy or is too extreme to allow for adequate nutrition. Women with this condition may need their nutrition supplemented by total parenteral nutrition or enteral feedings.

CRITICAL THINKING EXERCISES

1. Tori Alarino, whom you met at the beginning of the chapter, drinks milkshakes as a source of calcium. Is this a wise choice? Why do you think she craves oranges?
2. Tori works at a fast-food restaurant. She states she is too nauseated in the morning to eat before she leaves for work, and she is too tired of seeing food go by her to prepare a good meal after work. What suggestions could you give to help her increase her food intake?
3. Tori rarely eats vegetables; when she does, she fries them in butter. How would you use a food pyramid to explain better pregnancy nutrition to her?
4. Examine the National Health Goals related to nutrition and pregnancy. Most government-sponsored money for nursing research is allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to the Alarino family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to nutrition and pregnancy. Confirm your answers are correct by reading the rationales.

Chapter 14

Preparing a Family for Childbirth and Parenting

KEY TERMS

- alternative birthing centers (ABCs)
- birthing bed
- birthing chairs
- birthing room
- cleansing breath
- conditioned reflexes
- consciously controlled breathing
- conscious relaxation
- distraction
- doula
- effleurage
- gating control theory of pain perception
- labor-delivery-recovery-postpartum room (LDRP)
- Leboyer method
- psychoprophylactic
- vaginal birth after cesarean birth (VBAC)

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe common preparations for childbirth and parenting including common settings for birth.
2. Identify National Health Goals related to preparation for parenthood that nurses can help the nation achieve.
3. Use critical thinking to analyze ways that birth can be made more family centered through the use of prepared childbirth classes and alternative birth settings.
4. Assess a couple for readiness for childbirth in regard to choice of birth attendant, preparation for labor, and setting.
5. Formulate nursing diagnoses related to preparation for childbirth and parenting.
6. Identify expected outcomes for a couple preparing for childbirth and parenting.
7. Plan nursing care such as teaching exercises for strengthening abdominal and perineal muscles for childbirth.
8. Implement nursing care such as supporting a woman during labor by the Lamaze method of childbirth or helping a couple select and prepare for an alternative birth setting such as the home.
9. Evaluate outcome criteria for achievement and effectiveness of care.
10. Identify areas related to preparation for childbirth that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate the principles of prepared childbirth with nursing process to achieve quality maternal and child health nursing care.

Julia Marco is pregnant with her second child. During her first pregnancy, she did not attend any childbirth classes and received an epidural for the birth. During a prenatal visit for this pregnancy, Julia tells you that she would now like to have a natural birth in a birthing center. She asks you for information on childbirth education classes. Her husband, Joe, wants Julia to go to the hospital and have an epidural like the last time. He insists, "The doctors know what they're doing. We should just let them do their job." After speaking further with Joe, you discover he does not want Julia to go through the pain of natural childbirth because he fears he will not be able to help her during labor.

Previous chapters discussed normal anatomy, physiology, and nursing care necessary during pregnancy. This chapter adds information about ways that couples can make labor and birth a more satisfying experience. Such information helps protect the mental as well as physical health of both women and children throughout the continuum of pregnancy, birth, and childrearing.

How can you help alleviate some of Joe's concerns and best advise the Marcos on preparations for childbirth?

As active consumers of health care, expectant families can find themselves faced with a wide array of choices about a childbirth experience and preparation for parenting. Three of the most important decisions they need to make involve the choice of birth attendant and setting and how much or what type of analgesic they want to use in labor. For example, a woman may elect to have her family physician, obstetrician, or nurse-midwife attend the birth and to be supported by her husband, partner, family member, friend, or **doula** (a woman who is experienced in childbirth and provides continuous emotional and physical support). Most women choose to give birth in a birthing center or a hospital. Birthing centers and birthing rooms within hospitals both provide environments for families who desire a childbirth experience that is relaxed, "homey," and "family centered" yet close to medical sources should any complication arise during the birth or early postpartum period. Families who are rated as low risk have yet another option or may plan a home birth (Olsen & Jewell, 2009).

No matter what setting a woman or couple chooses, expectant parents are well advised to be as prepared as possible for the physical and emotional aspects of childbirth and nonpharmacologic methods of pain relief during labor such as aromatherapy (Burns et al., 2007). Preparation for childbirth courses that teach this material can be individualized to meet parents' needs by being structured for women with special needs such as adolescents, career women, women who are physically challenged, or those experiencing a high-risk pregnancy. Also available are classes to help prepare siblings or grandparents to learn more about their role. Women having a **vaginal birth after cesarean birth (VBAC)** or women who know they will have a cesarean birth also can attend specially designed classes for this.

Most childbirth preparation classes are sponsored by community health care agencies but some work sites also offer such classes. Classes benefit employers as much as employees, because prenatal care and guidance correlate with healthier pregnancy outcomes and fewer lost workdays. National Health Goals related to preparation for parenting or childbirth are shown in Box 14.1.

BOX 14.1 * Focus on National Health Goals

Preparation-for-childbirth classes supply information not only on how to prepare for childbirth but also on how to parent. Several National Health Goals speak directly to such classes:

- Increase the proportion of pregnant women who attend a series of prepared childbirth classes from a baseline of 66% to 77%.
- Increase the proportion of pregnant women who receive early and adequate prenatal care from a baseline of 74% to a target of 90%.
- Increase the proportion of pregnant women who receive early and adequate prenatal care beginning in the first trimester of pregnancy from a baseline of 83% to a target of 90%. (http://www.nih.gov).

Nurses participate as instructors in preparation for childbirth and parenting classes and help supervise prenatal care, so they have direct roles in helping the nation achieve these objectives. Issues such as what is the best timing during pregnancy for education about birth, what teaching techniques help parents retain information best, and what support parents want most from nurses during labor would be helpful research areas to better identify the needs for preparation for labor.

Nursing Process Overview

For Childbirth and Parenting Education

Assessment

Some couples have a clear idea of where and how they wish their child's birth to occur from the moment they realize they are pregnant. Others cannot even consider the actual birth until they have adjusted to the idea of pregnancy. Assessing each woman's or couple's readiness for decision making, as well as providing information early in the process, can help a woman or couple make this kind of decision. Whether women want or are able to take a childbirth and parenting preparation course depends a great deal on cultural and socioeconomic factors and individual choices (Greene, 2007). In some cultures, for example, the advice of a friend or family member carries more weight than the advice of a professional health care practitioner. Asking each woman separately whether she is interested in a course and being certain that women are fully informed about the options available to them are two ways to be certain all women receive as much advice and knowledge as they wish about childbirth.

Childbirth education is not just for primiparas because if a woman expecting her second or third child has waited several years between children, she usually appreciates refresher information as much as a primipara hungers for new information. Always, therefore, whether a woman is a primipara or multipara, ask whether either she or her support person wants to attend childbirth or parenting courses. Provide appropriate information on what classes are available and how and when they could enroll.

Nursing Diagnosis

Nursing diagnoses tend to cluster around whether a couple is sure of their decision about a birth setting or preparation. An example is:

- Health-seeking behaviors related to learning more about childbirth and newborn care

If there is a lack of a support person, diagnoses that might apply are:

- Ineffective coping related to lack of a support person
- Anxiety related to absence of significant other

For a couple unable to make a decision about a childbirth setting, an appropriate diagnosis might be:

- Decisional conflict related to lack of information about advantages and disadvantages of childbirth settings

If there are older children in the family, a nursing diagnosis might be:

- Anxiety related to role in pending birth event and ability to welcome a sibling

Outcome Identification and Planning

Be certain when planning with couples for labor and birth that the goals they set not only seem realistic but also flexible. Not all women want to go through labor without any analgesia, so setting a goal to do so would not be realistic for such a woman. Most women want to participate as fully as possible, however, so setting a goal for them to do that would be very realistic. Some women may be reluctant to attend a childbirth preparation course because they fear that would mean they are committing themselves to a medication-free birth. You can assure them that learning about methods to make childbirth easier does not preclude their learning about what medications are available for pain relief and using those medications if desired. At the same time a couple is planning goals for childbirth, encourage them to be flexible in their expectations. A woman who has decided ahead of time that she absolutely does not want any medication during labor and birth may find the intensity or duration of labor to be so severe that she will need an analgesic or epidural block to make the experience tolerable. If she and her support person have made the goal of medication-free labor too strict, they may believe they have failed when medication becomes necessary. A birth plan (discussed later) that includes information regarding a woman's or couple's preferences for labor, birth, immediate care of the newborn, and actions to be taken if complications should arise can help a woman and her support person set realistic expected outcomes.

Finally, talk to a woman or couple about the ultimate goal of childbirth: a healthy baby and healthy parents. This discussion can prevent them from concentrating on limited goals such as not having fetal monitoring or using a particular birthing position and concentrate instead on doing whatever is required to make the birth safest for both them and the baby.

Culture is a major determinant of the plans that women make for childbirth. A woman from a culture in which modesty is stressed, for example, may not want to have a mirror positioned over a birthing bed. A very old cross-cultural belief is that a knife placed under the mattress will "cut the pain" better than a Lamaze program. Whom women choose as a support person or coach in labor can also differ, depending on their cultural background. Some women would not think of choosing anyone but their male partner; others choose a female relative or friend. Assess each couple individually to be certain that cultural preferences such as these are respected.

Helpful Internet referral sources for couples are Childbirth Connection (http://www.childbirthconnection.org); Lamaze International (http://www.lamaze.org); International Childbirth Education Association (http://www.icea.org); La Leche League International (http://www.lalecheleague.org), and The Coalition for Improving Maternity Services (http://www.motherfriendly.org).

Implementation

It is important to provide a woman and her partner with information on the benefits and drawbacks of birthing options, without influencing them in a particular direction. To remain objective, examine your own attitudes, cultural influences, and values related to childbirth and explore how these beliefs might differ from those of your clients. Referring couples to a childbirth preparation course can answer many questions for them in a sympathetic group setting, where feelings and anxieties can be shared as well. Be familiar with the content of courses in your community so you can be certain that the courses you suggest present adequate and accurate information and are appropriate for individual couples.

Review the arrangements a woman needs to make for labor and birth at a midpoint in pregnancy. No matter how calm a woman seems when discussing these details, many women have some fear that at the last minute they will forget what they need to do when labor begins. Be certain that a woman has thought through arrangements for transportation to the hospital or birthing center and has arranged for child care if she has other children at home. Be certain that a woman who anticipates a home birth has organized her home and purchased supplies for birth well in advance of her expected due date.

Outcome Evaluation

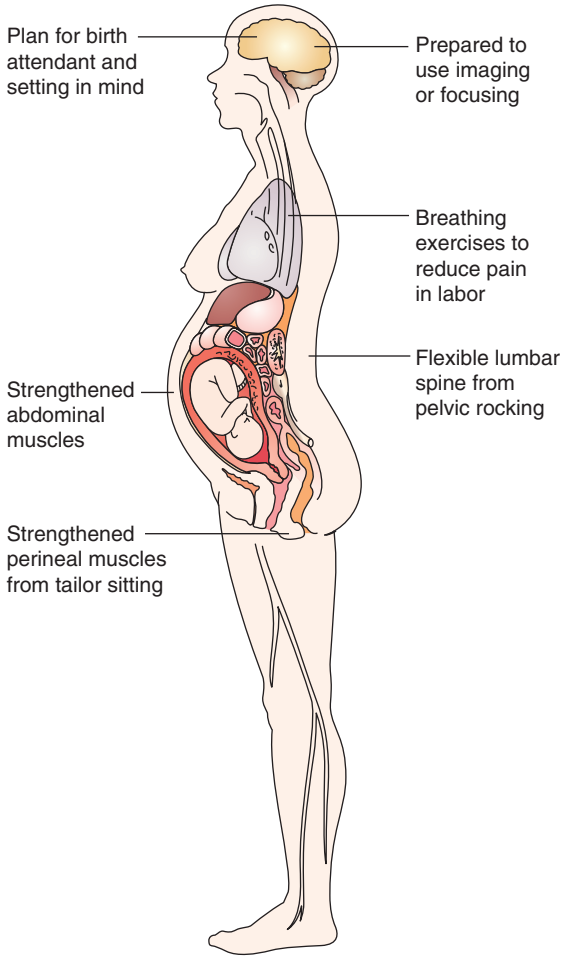
Evaluate whether expected outcomes for childbirth education have been achieved during the last few prenatal visits. By this time, a woman or couple should know where the baby will be born and should have worked out transportation and child care details. Encourage women who will be coached through childbirth by their husbands or another support person to continue practicing breathing and relaxation techniques together up to the time of birth so they do not lose these skills. Final evaluation regarding whether the couple was satisfied with their birth setting or preparation choices takes place after the birth. Examples of expected outcomes that would demonstrate the success of interventions are:

- Couple states they feel prepared for childbirth.
- Client states she feels confident she can use breathing exercises for contractions as long as 70 seconds.
- Client has made preparations for a doula to support her during labor.
- Sibling states she is ready to welcome a new brother or sister into the family.
- Couple states they were well enough prepared for birth that it was a satisfying and growth experience for them

CHILDBIRTH EDUCATION

Although parenting is unarguably an important occupation, it is one of the few that requires no formal education, no examination to test a person's ability to take on such a role, and no refresher course to ensure that a parent is following healthy standards of childrearing. Assessing whether couples need a preparation for childbirth or parenting class or encouraging them to take one, therefore, can be extremely important to make childbirth a satisfying experience, help a

Box 14.2 Assessment
Assessing a Woman's Preparation for Labor



family bond with its new member, and become effective parents (Box 14.2).

As many as 7% of women voice that they are afraid of what will happen in labor. Those who are young, have a low educational level, low self-rated health, and lack a social network express this most (Laursen, 2008).

Preparation for childbirth courses began initially in the early 1900s to encourage women to come for prenatal care. They continue because, with all the birth choices available today, they fulfill the important second need for education about labor and childbirth. The overall goals of childbirth education are to prepare expectant parents emotionally and physically for childbirth while promoting wellness behaviors that can be used by parents and families for life. Women enjoy such classes because they offer them a sense of empowerment and confirm that they can have direct input into their labor experience (Box 14.3).

Childbirth Educators and Methods of Teaching

Childbirth educators are health care providers who usually have a professional degree in the helping professions as well as a certificate from a course specifically about childbirth education. They teach expectant parents about the physical and emotional aspects of pregnancy, childbirth, and early parenthood and present coping skills and labor support techniques. Although childbirth education is an interdisciplinary field, it has historically been associated with nursing and nurses play a major role in designing and teaching such courses. Most classes are taught in a group format; most incorporate a variety of teaching techniques such as videotapes and slides, lecture, and demonstration (especially for content on relaxation and breathing techniques). One of the most important aspects of these courses, however, is group interaction. Women and their partners enjoy the opportunity to share their fears and hopes about their pregnancy and upcoming birth with others as they learn together (Box 14.4).

Efficacy of Childbirth Education Courses

Many studies have been done to determine just how effective childbirth courses are in reducing the pain of childbirth, shortening the length of labor, decreasing the amount of medication used, and increasing overall enjoyment of the experience. Because of the variability in courses offered, however, it is often difficult to compare results of attending childbirth classes versus not attending classes. This is partly because people who volunteer to attend classes already have a high degree

BOX 14.3 ✻ Focus on Communication

You care for Julia Marco at a prenatal clinic visit. She is in the 24th week of an uncomplicated pregnancy.

Less Effective Communication

Nurse: Have you signed up for a childbirth preparation class yet, Julia?
Julia: No.
Nurse: Don't wait too much longer. You're already in your sixth month.
Julia: I don't really need to go to one.
Nurse: Okay. You know best.

More Effective Communication

Nurse: Have you signed up for a childbirth preparation class yet, Julia?
Julia: No.
Nurse: Don't wait too much longer. You're already in your sixth month.
Julia: I don't really need to go to one.
Nurse: Why is that?
Julia: Classes are all at the wrong time. And cost too much.
Nurse: Let's work together to find a course that's right for you. We can use the Internet to find out what options are available.

It is important for couples to attend preparation for labor classes but, also, is easy to ignore the reasons clients present for not wanting to attend them. Careful listening often reveals that time or money concerns are reasons why couples choose not to attend a course. Helping to investigate the many options is the beginning of problem solving.

BOX 14.4 ✻ Focus on Family Teaching

Choosing a Birth Setting

Q. Julia and her husband Joe ask you, "There are so many options available for a birth setting. How do we decide which one to choose?"

A. Choosing a birth setting is a personal decision. Some questions to ask yourself to help with the decision are:

- What type of caregiver do I want to supervise my prenatal care and labor and birth? Nurse-midwife? Family doctor? Obstetrician?
- What settings does a particular childbirth provider let me choose from? A birthing room? An alternative birthing center? My home?
- Will the same person be present at prenatal visits as for birth? Does the setting offer preparation for childbirth or childrearing classes?
- Will I be allowed to choose a birth position? Will I have input into the amount of anesthesia used? Can administration of ophthalmic ointment for the baby be delayed? Can I begin breastfeeding immediately? Will nurses who are supportive and informed about breastfeeding be available? Can I use a doula?
- Will the setting allow my partner to participate? Will he or she be allowed to be with me throughout labor and birth? Could he or she cut the cord or help with the birth? Can older children participate? Can I record the birth on videotape or by photograph?
- Is early discharge available? Will a follow-up home visit be included in care?
- If I should have a complication during labor or birth, is there adequate equipment and personnel available for emergency care? If our baby should have a complication, is there provision for immediate emergency care or transport to a high-risk facility?

of positive motivation, which may skew the results. Despite these difficulties with measurement, it is generally accepted that preparation courses can increase satisfaction, reduce the amount of reported pain, and increase feelings of control (Lauzon & Hodnett, 2009). It is documented that by discussion of breastfeeding, classes can increase the proportion of new mothers who breastfeed (American College of Obstetrics and Gynecology [ACOG], 2007).

THE CHILDBIRTH PLAN

Most classes for expectant parents urge couples to make a written childbirth plan or spell out their choice of setting, birth attendant, special needs such as the extent of family participation they wish during labor, birthing positions, medication options, plans for the immediate postpartum period and baby care, and family visitation (Simkin, 2007). Urge couples to make decisions about these issues before the day of birth to avoid feeling stressed by last minute decisions.

BOX 14.5 ✻ Birth Plan: Julia Marco

Birth Attendant
Alexander Coppin, MD, or nurse-midwife Kaitlin Brandywine, whoever is on call for the big day.

Birth Setting
Room Number 1 at Huntington Alternative Birth Center

Support Person
Husband Joe (if out of town, my sister Adrienne). Adrienne can serve as my doula.

Activities During Labor
I want to walk around or rock in the rocking chair or play Monopoly.
I want to wear my own nightgown, and listen to a Garth Brooks CD.
I want to eat "anything chocolate" during labor.
I want an epidural for pain management.

Birth
Position for birth: on my side.
No episiotomy
Husband wants to cut cord and videotape the birth.
I want my son to watch if he wants to.

Postpartum
I want to breastfeed immediately.
I want to use skin-to-skin care to keep baby warm.
I want to room in.
Husband wants to sleep over on bedside cot.

A group setting of this kind can be the best way for a couple to sort out their questions and feelings about what they want to consider in a birth plan as they share information with others. If the expectant family has a strong desire in a certain area, planning ahead will allow them to communicate this so their wish can be accommodated if possible. Be certain all couples understand, however, that the birth plan should be flexible in case a complication or change of plans arises. For example, in the event of a complication of labor or birth that requires an emergency cesarean birth, a preference to have the baby without anesthesia will need to be modified. Box 14.5 is a sample birth plan.

PRECONCEPTION CLASSES

Preconception classes are held for couples who are planning to get pregnant within a short time and want to know more about what they can expect a pregnancy to be like and what are birth setting/procedure choices. These classes stress that pregnancy brings with it psychological as well as physical changes and include recommended preconception nutrition modifications such as a good intake of folic acid (green leafy vegetables) and protein (meat, tofu, beans) during the time waiting to get pregnant, to ensure a healthy fetus (Lu, 2007).

BOX 14.6 ✻ Focus on Evidence-Based Practice

Is periodontal disease a factor that can lead to preterm birth?

An important health care practice to remind women about during pregnancy is to continue care of their teeth through thorough toothbrushing and routine dental assessments. To study whether periodontal disease in pregnant women could be a factor that leads to preterm birth or restricted fetal growth, researchers assessed the oral health of 1635 pregnant women; 3.8% of these (62 women) had peridontal disease. Those women with periodontal disease had a significantly higher outcome of preterm or fetal growth restriction.

When writing out a curriculum for a preparation for childbirth class, would this information be important to include?

Source: Pitiphat, W., et al. (2008). Maternal periodontitis and adverse pregnancy outcomes. *Community Dentistry & Oral Epidemiology, 36*(1), 3–11.

EXPECTANT PARENTING CLASSES

Expectant parenting classes are designed for couples who are already pregnant. They focus on family health during a pregnancy, covering such topics as the psychological and physical changes of pregnancy, pregnancy nutrition, routine health care such as dental checkups, and newborn care (Box 14.6). A typical course plan for 8 weeks is shown in Box 14.7.

Most preparation-for-parenthood programs last 4 to 8 hours over a 4- to 8-week period. Both women and their support people are invited, and the curriculum is individualized for the group and its needs such as women in the military, sibling preparation, refresher classes for grandparents, classes for expectant adoptive parents, pregnant adolescents, or women with physical disabilities (Smeltzer, 2007). If all the women in the group already have children, for example, they may not need a tour of a maternity unit as part of the program; instead, they may want to learn what is new in baby food or child care. If all the women in the class work at least part-time, discussion of "brown bag nutrition" and how to include rest periods during work hours might be most useful. If all the women are teenagers, they may be most interested in what is going to happen to their bodies during pregnancy or what sports are safe to continue during pregnancy. They also need information on how to care for a newborn. They probably will want a tour of the maternity unit (Fig. 14.1).

Sibling Education Classes

Sibling classes are organized to acquaint older brothers and sisters with what happens during birth and what they can expect a newborn to look and act like. The classes review how babies grow and things children can do to help their mother during a pregnancy, such as eating healthy foods with her and not leaving toys on the floor she could trip over and fall.

BOX 14.7 ✻ Sample Content for Expectant Parents Class

- **Lesson 1** Review of Physiologic Changes of Pregnancy and Fetal Growth
- **Lesson 2** Personal Care During Pregnancy
  Nutrition
  Hygiene such as bathing, dental care
  Exercise
  Rest
- **Lesson 3** Emotional Changes During Pregnancy
- **Lesson 4** Labor and Birth
  The process of birth
  Exercises and breathing techniques
  Medication in labor
- **Lesson 5** Plans for Birth
  Birth settings available
  Supplies to take to birth settings
  Tour or film of a typical setting
- **Lesson 6** The Postpartum Period
- **Lesson 7** Infant Care
  Nutrition
  Hygiene
- **Lesson 8** Reproductive Life Planning

If the classes are held at a hospital, a tour of a newborn nursery is included so children can see how small their new sibling will be. A hospital room like the one their mother will occupy may also be visited.

To be certain that sibling classes will be successful, be sure that the information presented is age-appropriate. Chapters 29 to 33 discuss growth and development expectations by age group. Younger children may need reassurance that their parents will continue to love them after the new baby arrives. Older children may be interested in learning about newborn care and receiving assurance that their life will not be totally changed after this new family member's birth.

FIGURE 14.1 An enjoyable part of a preparation-for-parenthood class is touring a maternity service. Here, parents-to-be view a newborn nursery. (Photograph by Melissa Olson, with permission of Chestnut Hill Hospital, Philadelphia, PA.)

Breastfeeding Classes

Breastfeeding classes are designed to help women learn more about breastfeeding so they can appreciate the advantages of breastfeeding over formula feeding. Such classes cover the physiology of breastfeeding as well as psychological aspects. They stress that women should try to breastfeed exclusively for the first 6 months and ways to fit breastfeeding into busy schedules so they can continue it for the full first year (American Academy of Pediatrics [AAP], 2008). They are often taught by a certified La Leche League instructor who is an expert on what problems new mothers are apt to encounter (see Chapter 19 for breastfeeding techniques).

What if... Julia Marco tells you her husband won't be coming to class with her because he won't be able to be with her during labor. She asks you if it is really important to have someone with her. How would you advise her?

Preparation for Childbirth Classes

Preparation for childbirth classes focus mainly on explaining the birth process rather than pregnancy and ways to prevent or reduce the pain of childbirth. Common goals of preparation are to:

- Prepare an expectant woman and her support person for the childbirth experience
- Create clients who are knowledgeable consumers of obstetric care
- Help women reduce and manage pain with both pharmacologic and nonpharmacologic methods
- Help increase a couple's overall enjoyment of and satisfaction with the childbirth experience

In addition to teaching about normal labor, they include several exercises to ready the body for labor, as well as methods of pain prevention or pain relief in labor.

Prenatal Yoga

Prenatal yoga classes are aimed at helping a woman relax and manage stress better for all times in her life, not just pregnancy (Smith et al., 2007). Yoga exercises help a woman stay overall fit by their focus on gentle stretching and deep breathing. Yoga can also help a woman feel a high level of self-esteem as she masters difficult levels or positions. Yoga breathing techniques can be used in labor to help both relaxation and pain management.

Caution women, as pregnancy progresses, that it will become difficult to maintain difficult yoga positions. Women should use a chair or a wall for stabilization. They should avoid twisting exercises late in pregnancy because when joints soften in preparation for labor, muscle or joint strain could occur.

Perineal and Abdominal Exercises

In addition to encouraging an overall exercise program, childbirth preparation classes teach women specific exercises to strengthen pelvic and abdominal muscles and make these muscles stronger and more supple. Supple perineal muscles allow for stretching during birth, reduce discomfort, and help muscles revert more quickly to their normal condition and function more efficiently after childbirth (Hay-Smith & Dumoulin, 2009).

A woman may begin exercises as early in pregnancy as she likes. Many exercises to strengthen abdominal or perineal muscles can be incorporated into daily activities so they take little time from a woman's day. It is best, however, for a woman to set aside a specific time each day for practicing exercises; otherwise, her participation is apt to be sporadic. Initially, women should do each exercise only a few times, gradually increasing the number at each session.

In addition to specific exercises, encourage women to maintain an overall active exercise program during pregnancy, as being in good physical condition can help prevent the need for cesarean birth. Women should not enroll or participate in a formal exercise program without their physician's or nurse-midwife's approval. They should not attempt to exercise if any of the danger signs of pregnancy are present, and they should never exercise to a point of fatigue. Common safety precautions for preparation for childbirth exercises in pregnancy are summarized in Box 14.8.

BOX 14.8 ✻ Focus on Family Teaching

Exercise Guidelines for Labor Preparation

Q. Julia asks you, "How can I be sure the exercises I'm doing to be ready for birth won't hurt me or my baby?"

A. Good rules to follow are:

- Never exercise to a point of fatigue.
- Always rise from the floor slowly, to prevent feeling dizzy from orthostatic hypotension.
- To rise from the floor, roll over to the side first and then push up to avoid strain on the abdominal muscles or round ligaments as this can cause intense pain.
- To prevent leg cramps when doing leg exercises, never point the toes (extend the heel instead).
- To prevent back pain, do not attempt exercises that hyperextend the lower back.
- Do not hold your breath while exercising, because this increases intra-abdominal and intrauterine pressure.
- Do not continue with exercises if any danger signal of pregnancy occurs.
- Never practice second-stage pushing. Pushing increases intrauterine pressure and could rupture membranes.

Tailor Sitting

Although many women may be familiar with tailor sitting, they may have to be re-taught the position so it is done in a way that stretches perineal muscles without occluding blood supply to the lower legs. A woman should not put one ankle on top of the other but should place one leg in front of the other (Fig. 14.2). As she sits in this position, she should gently push on her knees toward the floor until she feels her perineum stretch. This is a good position to use to watch television, read, or talk to friends on the telephone or file papers in a lower cabinet at work. It is good to plan on sitting in this position for at least 15 minutes every day. If she does this, by the end of pregnancy,

FIGURE 14.2 Tailor sitting stretches perineal muscles to make them more supple. Notice that the legs are parallel so that one does not compress the other. A woman could use this position for television watching, telephone conversations, or playing with an older child.

FIGURE 14.3 Squatting helps to stretch the muscles of the pelvic floor. Notice that the feet are flat on the floor for optimal perineal stretching.

a woman's perineum should be so supple that when she tailor-sits, her knees will almost touch the floor if pushed.

Squatting

Squatting (Fig. 14.3) also stretches perineal muscles and can be a useful position for second-stage labor, so a woman should also practice this position for about 15 minutes a day. Most women need a demonstration of effective squatting; otherwise, they tend to squat on their tiptoes. For pelvic muscles to stretch, a woman should keep her feet flat on the floor. Incorporating squatting into daily activities such as picking up toys from the floor reduces the amount of time a woman must devote to daily exercises.

Pelvic Floor Contractions (Kegel Exercises)

Pelvic floor contractions can be done easily during daily activities. While sitting at her desk or working around the house, a woman can tighten the muscles of her perineum by doing Kegel exercises (see Chapter 12, Box 12.7). Such perineal muscle-strengthening exercises are helpful in the postpartum period to reduce pain and promote perineal healing. They have long-term effects of increasing sexual responsiveness and helping prevent stress incontinence (Hay-Smith & Dumoulin, 2009).

Abdominal Muscle Contractions

Abdominal muscle contractions help strengthen abdominal muscles during pregnancy and therefore may help prevent constipation as well as help restore abdominal tone after pregnancy. Strong abdominal muscles can also contribute to effective second-stage pushing during labor. Abdominal contractions can be done in a standing or lying position along with pelvic floor contractions. A woman merely tightens her abdominal muscles, then relaxes them. She can repeat the exercise as often as she wishes during the day.

Another way to do the same thing is to practice "blowing out a candle." A woman takes a fairly deep inspiration, then exhales normally. Holding her finger about 6 inches in front of herself, as if it were a candle, she then exhales forcibly, pushing out residual air from her lungs as if her finger were a lit candle. She can feel her abdominal muscles contract as she reaches the end of a forcible exhalation.

Pelvic Rocking

Pelvic rocking (Fig. 14.4) helps relieve backache during pregnancy and early labor by making the lumbar spine more

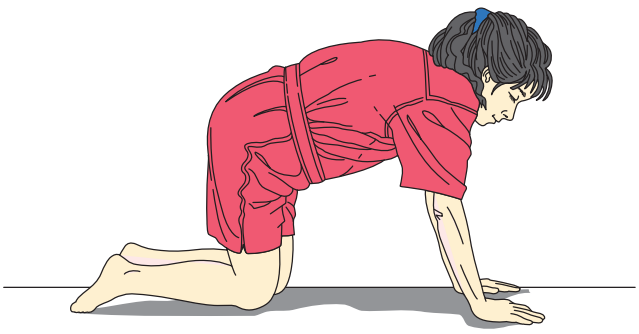


FIGURE 14.4 Pelvic rocking is helpful in relieving backache during pregnancy and labor. To do this, a woman first hollows her back and then arches it.

flexible. It can be done in a variety of positions: on hands and knees, lying down, sitting, or standing. A woman arches her back, trying to lengthen or stretch her spine. She holds the position for 1 minute, then hollows her back. If a woman does this at the end of the day about five times, it not only increases flexibility but also helps relieve back pain and make her more comfortable for the night.

✔ Checkpoint Question 14.1

Julia Marco asks you which type of exercise is best to strengthen perineal muscles. Your best answer would be:

a. Walk 20 minutes daily at a fairly rapid pace.
b. Tighten and relax perineal muscles as if stopping voiding.
c. Periodically push as if you're moving your bowels.
d. Lift both legs into the air while you lie supine.

Methods for Managing Pain in Childbirth

Beginning in the late 1950s, many specific methods for nonpharmacologic pain reduction during labor were developed. These included the Lamaze, Dick-Read, and Bradley methods, all named after the professionals who developed them. More recently, childbirth education has moved away from these strict method approaches to more eclectic ones. Ongoing research is being done to verify the effectiveness of each of these many techniques, and in practice many educators are teaching a variety of approaches including the use of complementary or herbal therapies (Smith, et al, 2009).

Most approaches are based on three premises:

1. Discomfort during labor can be minimized if a woman comes into labor informed about what is happening and prepared with breathing exercises to use during contractions. In classes, therefore, a woman learns about her body's response in labor, the mechanisms involved in childbirth, and breathing exercises she can use to aid relaxation.
2. Discomfort during labor can be minimized if a woman's abdomen is relaxed and the uterus is allowed to rise freely against the abdominal wall with contractions. Childbirth methods differ only in the manner by which they achieve this relaxation.
3. Pain perception can be altered by **distraction** techniques that effectively move a woman's concentration to other things than pain or by the **gating control theory of pain perception** (Box 14.9).

The Bradley (Partner-Coached) Method

The Bradley method of childbirth, originated by Robert Bradley, is based on the premises that pregnancy and childbirth are joyful natural processes and that a woman's partner should play an important role during pregnancy, labor, and the early newborn period. During pregnancy, a woman performs muscle-toning exercises and limits or omits foods that contain preservatives, animal fat, or a high salt content. She reduces pain in labor by abdominal breathing. In addition, she is encouraged to walk during labor and to use an internal focus point as a disassociation technique. The method is used

BOX 14.9 ✻ Gate Control Mechanisms to Reduce Pain

Pain Flows Through Pathways Because:

1. The endings of small peripheral nerve fibers detect a stimulus.
2. They transmit it to cells in the dorsal horn of the spinal cord.
3. Impulses pass through a dense, interfacing network of cells in the spinal cord (the substantia gelatinosa).
4. Immediately, a synapse occurs that returns the transmission to the peripheral site through a motor nerve. For example, a person touches a candle flame; the impulse travels to the spinal cord and back, and the person jerks his or her hand away from the flame.
5. After this short-circuit synapse, the impulse then continues in the spinal cord to reach the hypothalamus and cortex of the brain.
6. The impulse is interpreted (the candle is hot) and perceived as pain.

Gating Theory of Pain Control

The gating theory of pain refers to gate control mechanisms in the substantia gelatinosa that are capable of halting an impulse at the level of the spinal cord so the impulse is never perceived at the brain level as pain: a process similar to closing a gate.

Techniques to Assist Gating Mechanisms

- *Cutaneous Stimulation.* If large peripheral nerves next to an injury site are stimulated, the ability of the small nerve fibers at the injury site to transmit pain impulses appears to decrease. Therefore, rubbing an injured part or applying transcutaneous electrical nerve stimulation (TENS) or heat or cold to the site (cutaneous stimulation) are effective maneuvers to suppress pain. Effleurage, or light massage used in the Lamaze method, also accomplishes this.
- *Distraction.* If the cells of the brain stem that will register an impulse as pain are preoccupied with other stimuli, a pain impulse cannot register. Different childbirth classes use different breathing, vocalization, or focusing techniques such as imaging to accomplish this. Breathing techniques not only furnish distraction but can increase oxygenation to the mother and fetus.
- *Reduction of Anxiety.* Pain impulses are perceived more quickly if a woman is anxious. The third technique of gating, therefore, is to reduce patient anxiety as much as possible. Teaching a woman what to expect during labor is a means of achieving this.

widely in some areas of the United States and at specific centers (Bradley, 1996).

The Psychosexual Method

The psychosexual method of childbirth was developed by Sheila Kitzinger in England during the 1950s. The method stresses that pregnancy, labor and birth, and the early newborn period are some of the most important points in a woman's life. It includes a program of conscious relaxation and levels of progressive breathing that encourage a woman to "flow with" rather than struggle against contractions (Kitzinger, 1990).

The Dick-Read Method

The Dick-Read method is based on an approach proposed by Grantly Dick-Read, an English physician. The premise is that fear leads to tension, which leads to pain. If a woman can prevent fear from occurring, or break the chain between fear and tension or tension and pain, then she can reduce the pain of labor contractions. A woman achieves lack of fear through education about childbirth and relaxation and reduced pain by focusing on abdominal breathing during contractions (Dick-Read, 1987).

The Lamaze Philosophy

The Lamaze method of prepared childbirth, a philosophy based on the gating control theory of pain relief, is the one most often taught in the United States today (Amis & Green, 2007). The method is based on the theory that through stimulus-response conditioning, women can learn to use controlled breathing to reduce pain during labor. It was originally termed the **psychoprophylactic** method, as it focuses on preventing pain in labor (prophylaxis) by use of the mind (psyche).

The method was developed in Russia based on Pavlov's conditioning studies but was popularized by a French physician, Ferdinand Lamaze. Formal classes are organized by Lamaze International or the International Childbirth Education Association.

Lamaze preparation is not so much a method to help a woman cope with labor but rather a total philosophy of how to enjoy a safe and satisfying childbirth experience. Information to guide a woman and her coach through pregnancy such as prenatal nutrition, exercises, and common discomforts of pregnancy are discussed as well as information to prepare couples for unexpected circumstances of birth (e.g., malpresentation, cesarean birth, or the need for analgesia or anesthesia) is provided. Suggestions for supplies that a woman or couple might want to pack in advance and bring to the hospital for a Lamaze birth are shown in Table 14.1.

Throughout the program, six major concepts are stressed:

1. Labor should begin on its own, not be artificially induced.
2. Women should be able to move about freely during labor, not be confined to bed.
3. Women should receive continuous support during labor.
4. No routine interventions such as intravenous fluid are needed.
5. Women should be allowed to assume a nonsupine (e.g., upright or side-lying) position for birth.
6. Mother and baby should be housed together following birth, with unlimited opportunity for breastfeeding (Amis & Green, 2007).

TABLE 14.1 ✻ Supplies to Use During Labor

Item	Purpose
Lip balm	To prevent dry lips
Mouthwash	For rinsing dry mouth
Toothbrush and toothpaste	To prevent dry mouth
Warm socks	Comfort
Small rolling pin covered with soft cloth	Back massage
Focal point	To increase concentration
Busy work (e.g., book or laptop computer)	To pass time
Paper bag	To correct hyperventilation
Extra pillow	For semi-Fowler's position in labor
Wristwatch	For timing contractions
Baby powder	For reducing friction of effleurage
Lollipops	For energy and dry mouth
Snacks (e.g., apples or potato chips)	For coach's comfort
Tapes or compact discs and player	To increase relaxation

Three main premises are taught in the prenatal period related to the gating control method of pain relief:

1. Women learn in class about reproductive anatomy and physiology and the process of labor and birth in the belief that if women are familiar with what will happen in labor and the nature of contractions, the couple can enter labor with decreased tension.
2. A woman is taught to concentrate on breathing patterns and to use imagery or focusing (concentrating) on a specified object to block incoming pain sensations. The effectiveness of focusing can be observed in athletes who hurt themselves in basketball or football games but do not feel the pain until after the game because they are so focused on winning.
3. **Conditioned reflexes,** or reflexes that automatically occur in response to a stimulus, can also be used to displace pain during labor. For example, a woman is conditioned to relax automatically on hearing a command ("contraction beginning") or at the feel of a contraction beginning. The responses to contractions must be recently conditioned to be effective (because conditioned responses fade if not reinforced). This is the reason it is generally recommended that women attend Lamaze classes in the last trimester of pregnancy. A disadvantage of enrolling so late is that it limits the total amount of time directed to perineal exercises. If labor begins early, a woman may have had little or no practice with this type of exercise.

FIGURE 14.5 Every woman needs to be well prepared for birth. Here a couple practices positions for pushing in a childbirth preparation class. Caution women not to actually push.

Lamaze classes are kept small so that there is time for individual instruction and attention to each couple (Fig. 14.5). Advise a woman to bring a support person with her to class to practice breathing exercises. This person will then act as her coach in labor. Exercises taught in class vary from teacher to teacher, especially in terms of complexity, but have common features.

Conscious Relaxation. **Conscious relaxation** is learning to relax body parts so that, unknowingly, a woman does not remain tense and cause unnecessary muscle strain and fatigue during labor. She practices this during pregnancy by deliberately relaxing one set of muscles, then another and another until her body is completely relaxed. Her support person concentrates on noticing symptoms of tension such as a wrinkled brow, clenched fists, or a stiffly held arm. By either placing a comforting hand on the tense body area or telling a woman to relax that area, the support person helps her to achieve complete relaxation.

The Cleansing Breath. To begin all breathing exercises, a woman breathes in deeply and then exhales deeply (a **cleansing breath).** To end each exercise, she repeats this step. It is an important step to take because it limits the possibility of either hyperventilation (blowing off too much carbon dioxide) or hypoventilation (not exhaling enough carbon dioxide), both of which could happen with rapid breathing patterns, and so it helps ensure an adequate fetal oxygen supply. If women do become light-headed during labor from hyperventilation (develop respiratory alkalosis), breathing into a paper bag can help, as it causes rebreathing of exhaled carbon dioxide.

Consciously Controlled Breathing. Using **consciously controlled breathing,** or set breathing patterns at specific rates, provides distraction as well as prevents the diaphragm from descending fully and putting pressure on the expanding uterus. To practice, a woman inhales comfortably but fully, then exhales, with her exhalation a little stronger than her inhalation (to help prevent hypoventilation). She practices breathing in this manner at a controlled pace, depending on the intensity of contractions. Various levels of breathing are:

Level 1. Slow chest breathing of comfortable but full respirations at a rate of 6 to 12 breaths per minute. The level is used for early contractions.

Level 2. Lighter and more rapid breathing than level 1. The rib cage should expand but be so light the diaphragm barely moves. The rate of respirations is up to 40 per minute. This is a good level of breathing for contractions when cervical dilation is between 4 and 6 cm.

Level 3. Even more shallow and more rapid breathing. The rate is 50 to 70 breaths per minute. As the respirations become faster, the exhalation must be a little stronger than the inhalation to allow good air exchange and to prevent hypoventilation. If a woman practices saying "out" with each exhalation, she almost inevitably will make exhalation stronger than inhalation. A woman uses this level for transition contractions. Keeping the tip of her tongue against the roof of her mouth helps prevent her oral mucosa from drying out during such rapid breathing.

Level 4. A "pant-blow" pattern, or taking three or four quick breaths (in and out), then a forceful exhalation. Because this type of breathing sounds like a train (breath-breath-breath-huff), it is sometimes referred to as "choo-choo" or "hee-hee-hee-hoo" breathing.

Level 5. Quiet, continuous, very shallow panting at about 60 breaths per minute. This can be used during strong contractions or during the second stage of labor to prevent a woman from pushing before full dilatation.

Some courses stop teaching at the point a woman has mastered these levels of breathing; others have her learn to shift from one level to the other on command or at the point she feels a need for more pain relief.

Figure 14.6 illustrates the use of levels of breathing. An early labor contraction is mild. When the contraction begins, her coach says, "Contraction beginning." A woman takes a cleansing breath, then breathes at level 1; she feels no bite from the contraction and so does not need to change to a more involved breathing pattern. Later in labor, contractions are stronger and longer. Now, at the sound of "Contraction beginning," a woman takes a cleansing breath, then begins level 1 breathing (3 breaths); shifts to level 2 (4 to 6 breaths); then shifts to level 3 (10 breaths). The contraction is lessening. She shifts down to level 2 (4 to 6 breaths), then to level 1 (3 or 4 breaths). The contraction is gone. She takes a final cleansing breath. During actual labor, her coach can tell the strength of contractions by resting a hand on her abdomen or observing a uterine contraction monitor. A coach can tell a woman when to shift breathing levels depending on the coach's estimation of the strength of the contraction with words such as, "contraction beginning, getting stronger, now getting weaker, gone." In the time before transition to the second stage of labor, when contractions are longest and strongest, a woman may need to use her level 4 breathing or continuous light panting as well. A woman who can perform

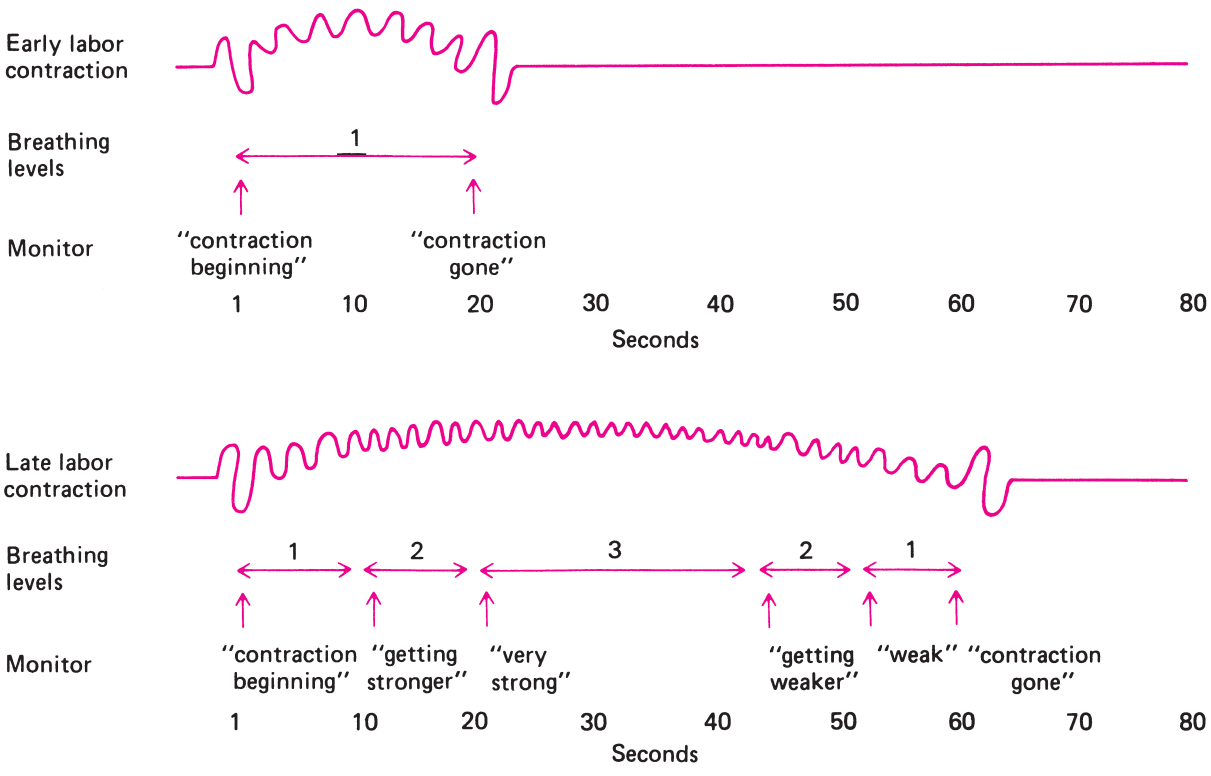

FIGURE 14.6 An example of differing breathing patterns during a single contraction; 1, 2, and 3 are levels of breathing. A cleansing breath is taken at the beginning and end of the contraction.

the various levels of breathing and maintain relaxation can be assured that she is prepared to handle all labor contractions up to the second stage of labor.

Effleurage. One additional technique to encourage relaxation and displace pain in the Lamaze method is **effleurage**, which is French for "light abdominal massage," done with just enough pressure to avoid tickling. To do this, a woman traces a pattern on her abdomen with her fingertips (Fig. 14.7). The rate of effleurage should remain constant even though breathing rates change. Effleurage serves as a distraction technique and decreases sensory stimuli transmission from the abdominal wall, helping limit local discomfort. If an external electronic monitor is in place on the abdomen, effleurage can be done superior or inferior to it or even on the thighs. Effleurage can also be done by the support person.

Focusing or Imagery. Focusing intently on an object (sometimes called "sensate focus") is another method of keeping sensory input from reaching the cortex of the brain. A woman brings into labor a photograph of her partner or children, a graphic design, or just something that appeals to her (Fig. 14.8). She concentrates on it during contractions. Be careful not to step into a woman's line of vision during a contraction and break this focused concentration. Other women use imagery by imagining they are in a calm place such as on a beach watching waves rolling in to them or relaxing on a porch swing (Stein, 2007). Try not to ask questions or talk to women using this technique or you will break their concentration.

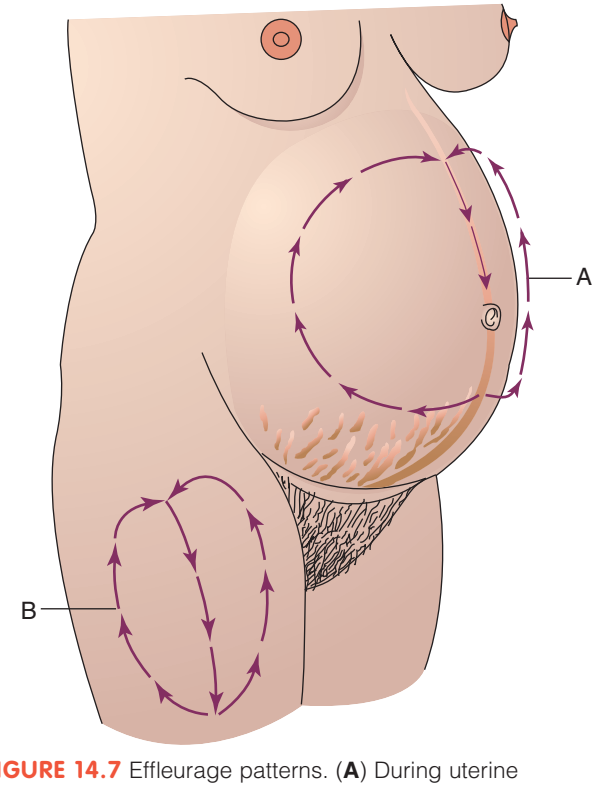

FIGURE 14.7 Effleurage patterns. (**A**) During uterine contractions, a woman traces a pattern on her bare abdomen with her fingers. (**B**) If electronic fetal monitoring is being used, effleurage may be performed on the thigh.

FIGURE 14.8 A woman chooses what object she wishes to focus on during labor. Here, a woman and nurse listen to the taped music the woman will focus on during contractions. (© Barbara Proud.)

Second-Stage Breathing. During the second stage of labor, when the baby will be actually pushed down the birth canal, the type of breathing that is best to use is controversial. In the past, women were told to hold their breath while they pushed. Now it is believed that holding the breath for a prolonged time impairs blood return from the vena cava (a Valsalva maneuver), so this is now discouraged. Based on this, most classes suggest that women breathe any way that is natural for them, except holding their breath during this stage of labor.

Women should not practice pushing. The possibility that they could rupture membranes by doing this is too great. They can practice assuming a good position for pushing (squatting, sitting upright, leaning on partner) but should always be cautioned not to actually push during pregnancy.

✔ Checkpoint Question 14.2

Julia Marco is considering using a Lamaze method for birth. What is the main principle of Lamaze childbirth?

a. Pain can be interrupted before it registers in the brain as pain.
b. Labor contractions are not pain; they are muscle inflammation.
c. "Brown pain" like labor contractions is easily relieved.
d. Labor contractions are intensified by abdominal massage.

Preparation for Cesarean Birth

The fact that cesarean birth may become necessary during labor to ensure a safe birth and what a couple can expect if this happens is covered in most childbirth classes, although as vaginal birth is encouraged, this may be done to varying degrees (Horey, Weaver, & Russell, 2009). Some women need this information because they know from the beginning of pregnancy that they will have a cesarean birth as these are offered in some communities as an alternative to vaginal birth to help prevent uterine prolapse or urinary incontinence in later years or to be more convenient for the family, although this policy is controversial (McCourt et al., 2007). Still other women had a cesarean birth for a first pregnancy and now need information on whether they should have a second birth vaginally or have a repeat cesarean one (Farnsworth & Pearson, 2007). Specific preparation needed for cesarean birth is discussed in Chapter 24.

THE BIRTH SETTING

Another important decision that a couple needs to make during pregnancy is choosing a birth setting. The decision they make depends on a woman's health and that of her fetus as well as the couple's preferences on how much and what kind of supervision they desire for the birth. Although hospitals are the usual site for birth today in the United States, that has not always been true. Up until the late 1800s, childbirth was conducted in the home. Analgesia or anesthesia for childbirth was unpopular until Queen Victoria delivered Prince Leopold under chloroform in 1853. Birth at that point became more complicated and less natural because extensive levels of anesthesia led to additional interventions. Women were not only asleep for one of the most memorable moments of their life, but under anesthesia, they were no longer able to push effectively during the second stage of labor. That made it necessary to use a lithotomy position and an episiotomy and forceps for birth.

Part of the reason for the use of so much anesthesia during birth can be attributed to physicians misinterpreting the type of pain of childbirth. It was assumed that the moment of birth was the major time of discomfort. As a result, women were allowed to labor without any pain medication and then were given anesthesia or analgesia right before the baby was born. Although the pain felt at birth is intense, it is also over quickly, unlike the hours of labor that precede it, so in reality, women may not be as uncomfortable during the actual birth as they are during labor. Birth is also such an exhilarating time that the excitement of the moment can mask pain.

Fortunately, birthing practices have changed to better meet women's needs based on their descriptions of the pain of childbirth. If women choose physicians or hospitals who subscribe to more progressive birth practices over the services of more traditional facilities, the overall standard of care in communities leans toward the more progressive settings. The addition of birthing rooms to hospitals in the past 20 years is an example of this. Nurses are in a strong position to advocate for making childbirth a "natural" process in the least restrictive setting possible. At the same time, nurses have a strong responsibility to encourage parents to maintain enough restrictions that birth remains safe.

Choosing the Appropriate Setting

Women having uncomplicated pregnancies may choose hospitals, birthing centers, or their homes as settings for birth. Women with high-risk pregnancies have less choice; women with potential complications are advised to give birth at hospitals where immediate emergency care will be available.

Choosing a Birth Attendant and Support Person

In the United States, most births are supervised by an obstetrician, a physician specializing in labor and birth. As the tendency for specialized physician practice declines, however, it is becoming more common for family practitioners to serve as birth attendants. It is also becoming more common for

certified nurse-midwives to attend births, especially at alternative birth centers.

In addition to selecting who will medically supervise her baby's birth, a woman needs to choose who will support her in labor. In years past, this support was offered by experienced women in the community. In the 1960s, the role was given to the father of the baby. Today, many different family members offer this type of support. In addition to having the father of their baby present, many women choose a doula, or a person specially prepared to assist with birth. Doulas can be helpful as fathers may find it hard to provide doula-type support during labor when they are so emotionally involved themselves in the birth. Having such a person present frees the father to enjoy the birth rather than feeling occupied with coaching instructions. Although research in the subject is not extensive, there are suggestions that rates of oxytocin augmentation, epidural anesthesia, and cesarean birth can all be reduced with doula support (McGrath & Kennell, 2008).

Hospital Birth

Maternity services of hospitals have changed a great deal in recent years, influenced by the First Consensus Initiative of the Coalition for Improving Maternity Services (CIMS). This organization rates hospitals regarding whether they are mother friendly based on, through its practices, if the hospital respects that birth is a normal, natural, and healthy process and a woman has the opportunity to:

- Experience a healthy and joyous birth experience, regardless of her age or circumstances
- Give birth as she wishes in an environment in which she feels nurtured and secure
- Have access to the full range of options for pregnancy, birth, and nurturing her baby
- Receive accurate and up-to-date information about the benefits and risks of all procedures, drugs, and tests suggested for use during pregnancy, birth, and the postpartum period, with the rights to informed consent and informed refusal
- Receive support for making informed choices about what is best for her and her baby based on her individual values and beliefs (CIMS, 1996)

Based on the above criteria, 10 steps to a mother-friendly hospital climate have been identified (Box 14.10). Urge women to ask hospitals in their community if they are rated as mother-friendly as this should influence their choice of a hospital or birth attendant.

BOX 14.10 ✻ Characteristics of a Mother-Friendly Hospital

A mother-friendly hospital:

1. Offers a birthing mother:
   - Unrestricted access to the birth companions of her choice, including fathers, partners, children, family members, and friends
   - Unrestricted access to continuous emotional and physical support from a skilled woman—for example, a doula or labor-support professional
   - Access to professional midwifery care.
2. Provides accurate descriptive and statistical information to the public about its practices and procedures for birth care, including measures of interventions and outcomes.
3. Provides culturally competent care—that is, care that is sensitive and responsive to the specific beliefs, values, and customs of the mother's ethnicity and religion.
4. Provides a birthing woman with the freedom to walk, move about, and assume the positions of her choice during labor and birth (unless restriction is specifically required to correct a complication), and discourages the use of the lithotomy position.
5. Has clearly defined policies and procedures for:
   - Collaborating and consulting throughout the perinatal period with other maternity services, including communicating with the original caregiver when transfer from one birth site to another is necessary
   - Linking the mother and baby to appropriate community resources, including prenatal and post-discharge follow-up and breastfeeding support
   - Does not routinely employ practices and procedures that are unsupported by scientific evidence such as routine perineal shaving
6. Educates staff in nondrug methods of pain relief and does not promote the use of analgesic or anesthetic drugs not specifically required to correct a complication.
7. Encourages all mothers and families, including those with sick or premature newborns or infants with congenital problems, to touch, hold, breastfeed, and care for their babies to the extent compatible with their conditions.
8. Discourages nonreligious circumcision of the newborn.
9. Promotes successful breastfeeding by:
   - Having a written breastfeeding policy that is routinely communicated to all health care staff
   - Educating all health care staff in skills necessary to implement this policy
   - Informing all pregnant women about the benefits and management of breastfeeding
   - Helping mothers initiate breastfeeding within a half-hour of birth
   - Showing mothers how to breastfeed and how to maintain lactation even if they should be separated from their infants
   - Giving newborn infants no food or drink other than breast milk unless medically indicated
   - Practicing rooming in to allow mothers and infants to remain together 24 hours a day
   - Encouraging breastfeeding on demand
   - Giving no pacifiers to breastfeeding infants
   - Fostering the establishment of breastfeeding support groups and referring others to them on discharge from hospitals or clinics (Hotelling, 2007).

Advantages and disadvantages of hospital birth are summarized in Box 14.11. The major advantage of a hospital is that equipment and expert personnel are readily available if the mother or fetus or newborn should have a complication.

In evaluating studies that compare the complications of birthing centers or home births with those of hospitals, women who gave birth in hospitals invariably have more complications than those who give birth in other settings but that happens because high-risk mothers give birth at hospitals so the number of complications in hospital settings is bound to be higher than in other settings.

A woman usually comes to the hospital when her contractions are approximately 5 minutes apart and regular in pattern. If she has preregistered at the hospital, she is admitted to a **birthing room** without any separation time from her support person. Birthing rooms are also called labor-delivery-recovery rooms (LDRs) or **labor-delivery-recovery-postpartum rooms (LDRPs)**. Such rooms are decorated in a homelike way; couples can bring favorite music or reading materials with them to use during labor; and the bed can be used as a labor bed until birth, when it converts into a **birthing bed** or a lithotomy position bed (Fig. 14.9). Women are expected to use a prepared method of childbirth with a minimum of analgesia and anesthesia (although an advantage of a hospital birth is that anesthesia such as an epidural is readily available if needed). An important aspect of birthing rooms is that the support person and often other family members can stay with a woman throughout labor and birth, allowing a couple and their families to feel that they have control over their birth experience. Women report greater satisfaction with birth when they use a more homelike setting than a bare, functional labor room for birth (Hodnett et al., 2009).

FIGURE 14.9 A birthing (labor-birth-recovery) room designed to maintain a homelike atmosphere in a hospital setting.

At the time of birth, additional cabinets in the room are opened and converted into a space for baby care. Women can choose a birthing position: lithotomy, squatting, supine recumbent, or side-lying. A support person remains with a woman during birth and in some settings can cut the umbilical cord if desired.

Most hospitals screen women in early labor with an external monitor for both fetal heart rate and uterine contractions. If the fetal heart rate is good, such a monitor can usually be removed and used again only for periodic screening as labor progresses. A woman may have intravenous access started as a prophylactic measure. If this is done, be sure to insert the needle into a dorsal vein of her nondominant hand so it causes little discomfort and she will be able to hold her newborn with little inconvenience.

Birthing chairs (Fig. 14.10) are comfortable reclining chairs with a slide-away seat that allows a woman to assume a comfortable position during labor and also furnishes perineal exposure so a birth attendant can assist with the birth. The semi-Fowler's position acts with gravity and so may speed the second stage of labor.

If a woman chooses to use a supine recumbent position (on her back with knees flexed) or a side-lying position rather than a lithotomy position (legs elevated into stirrups) for birth, she uses a birthing bed. Such positions reduce tension on the perineum and may result in fewer perineal tears than a lithotomy position.

Postpartum Care

Women giving birth in LDRPs remain in the room with their families for the rest of their hospital stay. Women giving birth in birthing rooms may be transferred to a postpartum unit after birth; they remain there for the length of their hospital stay. Both LDRPs and postpartum units serve as "rooming-in" units in which the infant remains in the

BOX 14.11 ❇ Advantages and Disadvantages of Hospital Birth

Advantages

- A woman is encouraged to be prepared to control the discomfort of labor through nonmedication measures such as controlled breathing although anesthesia such as an epidural is readily available.
- A woman is encouraged to be knowledgeable about the labor process and make decisions about procedures performed.
- A woman is encouraged to consider breastfeeding to aid uterine contraction and infant bonding after birth.
- Labor, birth, and immediate postpartal care can all be scheduled in a single room.
- A woman is attended by skilled professionals during labor and birth and the postpartal period.
- Emergency care and extended high-risk care are immediately available.

Disadvantages

- Separation of the family for at least one night
- Mother may not feel as much in control of the childbirth experience as she may wish.
- Care may be fragmented, particularly if a woman's physician is not present during the entire labor and birth, or if labor nurses change shifts in the middle of labor. (Many nurse-midwives and physicians make it a point, however, to remain with their client throughout the entire childbirth experience.)

FIGURE 14.10 (**A**) A birthing chair allows a woman to maintain a semi-Fowler's position. (**B**) A birthing chair used during labor. (© Caroline Brown, RNC, MS, DEd.)

mother's room for most of the day. After birth, encourage mothers to breastfeed immediately. Urge a couple to keep their newborn with them in their hospital room so they have ample time to become acquainted. Breastfeeding on demand for infants should be the rule. There should be no restrictions on visiting for the primary support person; in many institutions, a rollaway bed is provided so he or she can remain constantly. Siblings of the newborn should be allowed to visit at least once and touch and become acquainted with the newborn.

Alternative Birthing Centers

Alternative birthing centers (ABCs) are wellness-oriented childbirth facilities designed to remove childbirth from the acute care hospital setting while still providing enough medical resources for emergency care should a complication of labor or birth arise. Such a setting is established within, or at least within an easy distance of a hospital. Because it is located outside an acute care setting, where infections abound, the risk of hospital-acquired infection to a woman is thought to be reduced. The birth attendants tend to be nurse-midwives. Women who deliver in ABCs are screened for complications before being admitted. Because women are carefully screened, the mortality rate of mothers and infants is no higher and may be lower in these out-of-hospital settings than in hospital settings.

Like hospitals, ABCs have LDRP rooms where a woman and her support person can invite friends and siblings to participate in the birth. In some centers, a central play area for siblings and cooking facilities are also available. ABCs encourage a woman to express her own needs and wishes during the labor process. A minimum of analgesia and anesthesia is provided, and she can choose a birth position. She can bring her own music or distraction objects, and the partner can perform such tasks as cutting the umbilical cord if he or she chooses. Advantages and disadvantages of ABCs are summarized in Box 14.12.

Women remain in an ABC from 4 to 24 hours after birth. Because a minimum of analgesia or anesthesia is used, a woman recovers quickly after birth and is ready to be discharged this early. The Nursing Care Plan (Box 14.13) summaries preparation for birth in such an alternative setting.

Home Birth

Home birth is the usual mode of birth in developing countries. It is also a popular choice for birth in Europe, but only about 1% of women in the United States choose this method. Home birth may be supervised by a physician, but nurse-midwives are the more likely choice as birth attendants in this setting (Vedam, Goff, & Marnin, 2007). The Frontier Nursing Service of Kentucky is an example of an organization in the United States that maintains an active and well-accepted program of home birth.

BOX 14.12 ✻ Advantages and Disadvantages of ABCs

Advantages

- A woman is encouraged to be prepared to control the discomfort of labor through nonmedication measures such as controlled breathing.
- A woman is encouraged to be knowledgeable about the labor process and to help care providers with decision making.
- A woman is encouraged to breastfeed to aid uterine contraction and infant bonding after birth.
- Family integrity can be maintained because family members may accompany a woman to the birthing center.
- A woman is attended by skilled professionals during labor and birth.
- Emergency care is immediately available. Extended high-risk care is easily arranged.

Disadvantages

- Extended high-risk care is not immediately available.
- A woman may be fatigued after birth because of brief health care setting stay.
- She must independently monitor her postpartal status because of brief health care setting stay.

BOX 14.13 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Family Who Desires Birth at an Alternative Birth Center

Julia Marco is pregnant with her second child. During her first pregnancy, she did not attend childbirth classes and she received an epidural for the birth. During a prenatal visit, Julia tells you that she would now like to have a natural birth in a birthing center. She asks you for information on childbirth education courses. Her husband, Joe, wants Julia to go to the hospital and have an epidural like the last time. He insists, "The doctors know what they're doing. We should just let them do their job."

Family Assessment ✻ Family lives with 4-year-old Josh in apartment in central downtown. Julia is a stay-at-home mom; Joe works as a parking garage attendant. Family has limited financial resources, with no medical insurance.

Client Assessment ✻ Pregnancy progressing without evidence of problems or complications. Gravida 2, para 1, 24 weeks' gestation. Client states that she wants to use alternative birth center (ABC); reports concern over previous hospital birth of son. Wants son Josh, now 4 years old, to be a part of new baby's birth. Wants a doula but doesn't know how to contact one. Wants to walk during labor and have a ready supply of "anything chocolate" to eat. No childbirth education classes attended with previous pregnancy; not enrolled in any with this pregnancy at present.

Nursing Diagnosis ✻ Decisional conflict related to choice of birth setting and birth process

Outcome Criteria ✻ Client and partner state advantages and disadvantages of birth setting options; plans for birth and birth setting chosen by 3 weeks time.

Client and partner verbalize goal of healthy mother and baby as motivation for choice of birth setting.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Assess the family to see what plans they want to make for child care during labor.	Suggest the couple ask a family member to be caretaker for son during the birth.	A caretaker can enhance the experience for the older child promoting a positive, family-centered event.	Couple states they have located a suitable caretaker for son.
		Consultations		
Nurse/nurse-midwife	Assess what family expects of a doula for labor.	Give couple list of available doulas in community and help arrange for meeting.	Doulas can offer strong support in labor; prearrangements help meet mutual goals.	Couple confirms they have arranged for a doula to help offer support in labor.
		Consultations		
Nurse/social worker	Investigate the type of birth facilities available in local area in regard to wishes for labor.	Review the requirements, advantages, and disadvantages for birth setting choices available.	Review of options allows the couple to make an informed decision appropriate for their needs.	Client and partner state they have reviewed and understand options available to them.
		Procedures/Medications		
Physician/nurse	Determine if there are any contraindications to walking during labor.	Educate client about the few situations, such as placenta previa, that would contradict walking in labor.	Walking during labor has the potential to decrease the time of labor unless contraindicated.	Client states that she will be flexible in regard to wishes in labor based on her own and fetal safety.

		Nutrition		
Nurse	Assess whether client knows if her chosen food options during labor are approved by local facilities.	Help client modify her goals for nutrition during labor as appropriate based on facility requirements.	As many choices for food exist, coordinating plans with facility should result in least stress during labor.	Client confirms that she has agreed on food type agreeable with chosen agency.
		Patient/Family Education		
Nurse	Obtain information about local childbirth education classes available.	Assist couple as necessary with selecting class that fits their resources.	Education can enhance the chances of a positive childbirth experience. Choosing a program that fits the couple's resources helps to promote adherence.	Client attends the chosen preparation for childbirth class before the 38th week of pregnancy.
Nurse	Assess if any classes for sibling preparation for birth are available in community.	Help couple plan for mother and son to attend class on sibling preparation for birth or meet with nurse for instruction.	Adequate preparation for all involved improves the chances of a positive experience.	Couple states that they will either attend a class for sibling preparation or meet with nurse for information.
		Psychosocial/Spiritual/Emotional Needs		
Nurse/nurse-midwife	Explore with client and partner past experiences with childbirth and current expectations and beliefs.	Encourage couple to verbalize feelings, concerns, and needs.	Verbalization of feelings permits a safe outlet for emotions and assists in increasing the other person's awareness.	Couple states their overall goal for childbirth is a safe one for mother and new child.
		Discharge Planning		
Nurse	Assess if couple has any further questions about birth centers.	Ascertain couple has phone number and directions to chosen birthing center.	Advance planning can help avoid increased stress at time of birth.	Couple states they are happy with birth setting decision and prepared to follow through on plans.
Social worker	Assess the finances the couple will need to complete birth at their chosen setting.	Review financing options with couple.	Advance planning can help avoid increased stress at time of birth.	Couple states they have a plan for financial arrangements.

Most women who choose home birth in the United States are well educated and from middle-income families. They choose home birth so they can have their baby close by after birth, can have more control over the childbirth experience, and can give birth in familiar, low-cost surroundings.

The main advantage of a home birth is that it encourages family integrity: a woman and her family are not separated so the baby can be immediately integrated into the family. On the other hand, it puts responsibility on a woman to prepare her home for the birth (which is difficult if she is exhausted toward the end of pregnancy) and to take care of the infant after birth. Some people, however willing, may be unable to take on these roles in a crisis situation such as childbirth. Many women passing through their first postpartum or "taking-in" phase may be happier maintaining a dependent passive role than immediately taking responsibility for the infant's care.

To be a candidate for a home birth, a woman must be in good health, must be able to adjust to changing circumstances, and must have adequate support people who will sustain her during labor and assist her for the first few days after birth. Women with any complication of pregnancy are not candidates for home birth. Advantages and disadvantages of home birth are summarized in Box 14.14.

Freebirthing

Freebirthing refers to women giving birth without any health care provider supervision (Cooper & Clarke, 2008). Women may also refer to it as unassisted birth or couples birth. It differs from home birth because using this technique, a woman learns pregnancy care from reading articles on the Internet and then arranges to have her child at home,

perhaps accompanied by her family or friends and support person, but without health care supervision.

Freebirthing is potentially dangerous because if a complication of birth should occur, the woman may not recognize that the complication is occurring until damage to her child or herself results. Even after she recognizes that a problem is occurring, there is a space of time before emergency help can arrive to assist her. Freebirthing is particularly dangerous if a woman avoids prenatal care or depends solely on Internet information. Educating women that not all Internet information is reliable and that supervised birth does not mean that they have no choice in their care such as whether they want pain relief or to use a special position for birth are effective ways to help women make safer choices about birth.

What if... Julia and her husband have a serious disagreement about whether to plan for a home birth or hospital birth? What issues would you suggest they explore? If they cannot agree, how could they compromise?

Children Attending the Birth

Most birthing centers and some hospitals allow children to view the birth of a sibling. Attendance at sibling classes designed to prepare children to witness the birth is often required. If children will be present, a person separate from the main support person needs to be designated to provide entertainment, explanations, food, and a place for them to sleep. A child who is without supervision during this time could remember the experience as a time of rejection rather than an exciting, happy experience. The mother should not be expected to provide such supervision during labor as she will want to concentrate on distraction or breathing techniques.

BOX 14.14 ✻ Advantages and Disadvantages of Home Birth

Advantages

- A woman is encouraged to become knowledgeable about the birth process and be an active participant in independently reducing the discomfort of labor.
- A woman has the greatest freedom for expressing her individuality.
- There is no separation of the family at birth.
- A skilled professional can attend the birth.

Disadvantages

- Adequate equipment other than first-line emergency equipment is unavailable.
- An abrupt change of goals is necessary if hospitalization is required.
- A woman and support person may become exhausted because of the responsibility placed on them.
- Interference with the "taking-in phase" may occur postpartally because a woman must "take hold."
- A woman must independently monitor her postpartal status.

Help couples consider whether the birth experience will be a positive and enjoyable one for the child based on the child's developmental level. Allowing a child to witness the birth of kittens or puppies might be a more appropriate way to expose a child to birth.

ALTERNATIVE METHODS OF BIRTH

In addition to varied settings, several different methods of childbirth have become popular in the past 15 to 20 years. These include alternative birth methods such as the Leboyer method and birth under water.

Leboyer Method

Frederick Leboyer was a French obstetrician who postulated that moving from a warm, fluid-filled intrauterine environment to a noisy, air-filled, brightly lit birth room creates a major shock for a newborn (Leboyer, 1975). With the **Leboyer method,** the birthing room is darkened so there is no sudden contrast in light; it is kept pleasantly warm, not chilled. Soft music is played, or at least harsh noises are kept to a minimum. The infant is handled gently; the cord is cut late; and the infant is placed immediately after birth into a warm-water bath.

Some neonatologists question the wisdom of a warm bath because it could reduce spontaneous respirations and allow a high level of acidosis to occur. Late cutting of a cord can lead to excess blood viscosity in a newborn. Certainly, soft music, gentle handling, and a welcoming atmosphere are important ingredients for all birth attendants to try to incorporate into birth. Providing dim lights (or at least not bright, glaring ones) and providing a warm temperature could be given more consideration in most institutions.

Hydrotherapy and Water Birth

Reclining or sitting in warm water during labor can be soothing; the feeling of weightlessness that occurs under water as well as the relaxation from the warm water both can contribute to reducing discomfort in labor. Using this principle, many birthing centers allow women to labor in warm showers or give birth in spa tubs of warm water (Maude & Foureur, 2007). The baby is born underwater and then immediately brought to the surface for a first breath. Most women who choose underwater birth are very pleased that they chose this method. A potential difficulty is contamination of the bath water with feces expelled with pushing efforts during the second stage of labor. This could lead to uterine infection in the mother or aspiration of contaminated bath water by a newborn, which could lead to pneumonia. Maternal chilling when a woman leaves the water is another factor to consider and prevent.

✔ Checkpoint Question 14.3

Suppose Julia Marco decides on a hospital birth. What is an advantage of hospital birth over other settings?

a. Women can use breathing exercises.
b. Labor and childbirth can be pain free.
c. Extended high-risk care is available.
d. The cost of a hospital stay is low.

Key Points for Review

- Couples should be encouraged to make a childbirth plan early in pregnancy that includes birth attendant, setting, desired method of pain management, and any special wishes.
- Common exercises taught in pregnancy to strengthen perineal muscles are tailor sitting, squatting, and Kegel exercises. Abdominal muscle-contraction and pelvic rocking exercises strengthen the abdominal muscles and help relieve backache.
- Types of childbirth preparation include the Bradley (partner-coached), psychosexual (Kitzinger), Dick-Read, yoga, and Lamaze methods. Lamaze is the most common method used in the United States.
- Commonly used nonpharmacologic techniques for pain relief in labor are conscious relaxation, consciously controlled breathing, effleurage, focusing, imagery, and hydrotherapy.
- Classes for expectant parents provide information on pregnancy, birth, and childcare.
- Common sites for childbirth include hospitals, alternative birthing centers, and homes.
- Couples should ask birth settings if they are rated as mother-friendly before choosing them as a birth site.

CRITICAL THINKING EXERCISES

1. Joe Marco, the husband you met at the beginning of the chapter, wants his wife to have their baby at a hospital and have epidural anesthesia for pain relief. He insists, "The doctors know what they're doing. We should just let them do their job." After further speaking with Joe, you discover he does not want Julia to go through the pain of natural childbirth because he fears he will not be able to help her during labor. How would you convey to Joe that natural childbirth can be a positive experience for him and his wife? How would you assure him that he and Julia can have a safe and active part in the birth of their child?
2. Suppose Julia told you she does not intend to take a preparation for labor class because she wants to have epidural anesthesia as soon as she is admitted to the hospital in labor. Would you advise her to attend a class?
3. Suppose Julia wants to have a Leboyer birth. How would you prepare her birthing room?
4. Examine the National Health Goals related to childbirth education. Most government-sponsored money for nursing research is allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to Julia and her husband and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to preparation for childbirth and parenting. Confirm your answers are correct by reading the rationales.

Chapter

15 Nursing Care of a Family During Labor and Birth

KEY TERMS

- attitude
- breech presentation
- cardinal movements of labor
- cephalic presentation
- crowning
- dilatation
- effacement
- engagement
- episiotomy
- fetal descent
- Leopold's maneuvers
- lie
- molding
- pathologic retraction ring
- physiologic retraction ring
- position
- ripening of the cervix
- station
- transition

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe common theories explaining the onset of labor and the role of passenger, passage, and powers in labor.
2. Identify National Health Goals related to safe labor and birth that nurses can help the nation achieve.
3. Use critical thinking to analyze ways that nurses can make labor and birth more family centered.
4. Assess a family in labor, identifying the woman's readiness, stage, and progression.
5. Formulate nursing diagnoses related to the physiologic and psychological aspects of labor and birth.
6. Establish expected outcomes to meet the needs of a family throughout the labor process.
7. Plan nursing interventions to meet the needs and promote optimal outcomes for a woman and her family during labor and birth.
8. Implement nursing care for a family during labor such as teaching about the stages of labor.
9. Evaluate expected outcomes for achievement and effectiveness of care.
10. Identify areas related to labor and birth that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of nursing care in labor with nursing process to achieve quality maternal and child health nursing care.

Celeste Bailey is a 26-year-old woman you admit to a birthing room. She has been having labor contractions 45 seconds long and 3 minutes apart for the last 6 hours. She tells you she wants to have her baby "naturally" without any analgesia or anesthesia. Her husband is in the Army and assigned overseas, so he is not with her. Although her sister lives only two blocks from the hospital, Celeste does not want her called. She asks if she can talk to her mother on the telephone instead. As you finish assessing contractions, she screams with pain and shouts, "I'm doing everything I'm supposed to do! How much longer does this go on?"

Previous chapters described the anatomic and physiologic changes that occur in pregnancy as well as effective steps women can take to prepare for labor. This chapter adds information about the actual labor process and how to offer effective support and education to a woman in labor. Without adequate support, labor can be a frightening rather than an enjoyable event.

What additional teaching does Celeste need about labor and birth?

Labor is the series of events by which uterine contractions and abdominal pressure expel a fetus and placenta from a woman's body. Regular contractions cause progressive dilatation (enlargement or widening of the cervical canal) and create sufficient muscular force to allow a baby to be pushed from the birth canal (or vagina). It is a time of change, both an ending and a beginning, for a woman, a fetus, and her family.

Labor and birth require a woman to use all the psychological and physical coping methods she has available. Regardless of the amount of childbirth preparation or the number of times she has been through the experience before, family-focused nursing care is needed to support the family as they mark the beginning of a new family structure. This need is further emphasized by National Health Goals (Box 15.1).

Nursing Process Overview

For a Woman in Labor

Assessment

Assessment of a woman in labor must be done quickly yet thoroughly and gently. A woman is keenly aware of words spoken around her and the manner with which procedures are carried out. Because of this sensitivity, she may have difficulty relaxing for a vaginal examination if she fears that pressure on the fetal head will cause her pain.

BOX 15.1 ✻ Focus on National Health Goals

Because labor and birth are high-risk times for both a fetus and a mother, several National Health Goals speak directly to them:

- Reduce the rate of maternal deaths to no more than 3.3 per 100,000 live births, from a baseline of 7.1 per 100,000.
- Reduce the rate of fetal deaths at 20 or more weeks' gestation to no more than 4.1 per 1000 live births, from a baseline of 6.8 per 1000.
- Reduce the rate of fetal and infant deaths during the perinatal period (28 weeks' gestation to 7 days after birth) to no more than 4.5 per 1000 live births, from a baseline of 7.5 per 1000 live births (http://www.nih.gov).

Nurses can help the nation achieve these goals by closely monitoring women during labor and birth and by teaching women as much as possible about labor, so that they are able to use as little analgesia and anesthesia as possible. The less anesthesia and analgesia used, the fewer are the complications that can result in fetal or maternal death.

Topics that could benefit from additional nursing research in this area are what women feel are advantages and disadvantages of various birthing settings, the best way to teach unprepared women a breathing pattern in labor, how support people can best be prepared for their role, and advantages and disadvantages of various birthing or labor positions.

Remember that pain is a subjective symptom. Only the woman can evaluate how much she is experiencing or how much she wants to endure.

Assess how much discomfort a woman in labor is having, not only by what she scores on a pain scale but also by subtle signs of pain such as facial tenseness, flushing or paleness of the face, hands clenched in a fist, rapid breathing, or rapid pulse rate. Knowing the extent of a woman's discomfort helps guide the choice of comfort interventions she may need.

Nursing Diagnosis

Common nursing diagnoses pertinent to labor include:

- Pain related to labor contractions
- Anxiety related to process of labor and birth
- Health-seeking behaviors related to management of discomfort of labor
- Situational low self-esteem related to inability to use prepared childbirth method

Although the discomfort of labor is commonly referred to as "contractions" rather than "pain," do not omit the word "pain" from a nursing diagnosis, because the term strengthens an understanding of the problem.

Outcome Identification and Planning

When establishing expected outcomes for a woman in labor and her partner, be certain they are realistic. Because labor usually takes place over a relatively short timeframe (average, 12 hours), outcomes must be met within this period. On the other hand, it is important not to project a definite time limit for labor to be completed, because the length of labor can vary from woman to woman and still be within normal limits. It is necessary also to appreciate the magnitude of labor. It is unlikely that all the fear or anxiety experienced during a woman's labor can be alleviated. Often, because it is such an unusual and significant experience, an average couple may need assistance with using additional coping measures.

Be certain to incorporate both the woman and her support person in planning, so that the experience is a shared one. Planning may include review and education about the normal labor process. Although a couple may have learned this information during pregnancy, the reality of labor may seem much different from what they imagined. Planning also must be flexible, changing with the progress of labor, and individualized, allowing a woman to experience the significance of the event for herself. Good web sites to use for referral are The National Women's Health Information Center (http://www.womenshealth.gov) and The American Pregnancy Association (http://www.americanpregnancy.org).

Comfort promotion is a vital part of care. A plan that addresses the discomforts of labor includes planning for education, validation, and response to a woman's pain to help her maintain realistic perceptions about it. Be certain to include nonpharmacologic comfort measures such as changing a wet sheet or offering a moisturizing cream for dry lips.

Implementation

Interventions in labor must always be carried out between contractions if possible, so that a woman is free to use a

prepared childbirth technique to limit the discomfort of contractions. This calls for good coordination of care among health care providers and planning with the woman and her support person. The person a woman chooses to stay with her during childbirth can be a husband, the father of the child, a sister or parent, or a close friend. Which of these persons a woman chooses is somewhat culturally determined.

It is important for women to be able to understand what is happening to them during labor. If the woman is not proficient in English, make arrangements to locate an interpreter. If she is hearing challenged, it is the hospital's responsibility to provide an interpreter for her so that she can receive adequate explanations of her progress. Remember that whether a woman enjoys being touched or not during labor is in part culturally determined. Assess early in a woman's labor whether she might benefit from such caring measures as having her hand held or her back rubbed.

Outcome Evaluation

During labor, evaluation must be ongoing to preserve the safety of a woman and her new child. After birth, evaluation helps to determine a woman's opinion of her experience with labor and birth. Ideally, the experience should be not only one that she was able to endure but one that allowed her self-esteem to grow and the family to grow through a shared experience. It is advantageous to talk to women in the early postpartum period about their labor experience. Doing so serves as a means of evaluating nursing care during labor. It also provides a woman the chance to "work through" this experience and incorporate it into her self-image. Examples of possible outcome criteria include:

- Client states that pain during labor was tolerable because of her advance preparation.
- Client verbalizes that her need for additional comfort measures was met.
- Client and family members state that the labor and birth experience was a positive growth experience for them, both individually and as a family.

THEORIES OF LABOR ONSET

Labor normally begins when a fetus is sufficiently mature to cope with extrauterine life yet not too large to cause mechanical difficulty with birth. Although in animals it has been shown that progesterone withdrawal is the trigger that simulates labor, the association that converts the random, painless Braxton Hicks contractions of pregnancy into strong, coordinated, productive labor contractions in women is still largely undocumented (Crombleholme, 2009). In some instances, labor begins before a fetus is mature (preterm birth). In others, labor is delayed until the fetus and the placenta have both passed beyond the optimal point for birth (postterm birth).

Several theories including a combination of factors originating from both the woman and fetus have been proposed to explain why progesterone withdrawal begins:

- Uterine muscle stretching, which results in release of prostaglandins
- Pressure on the cervix, which stimulates the release of oxytocin from the posterior pituitary
- Oxytocin stimulation, which works together with prostaglandins to initiate contractions
- Change in the ratio of estrogen to progesterone (increasing estrogen in relation to progesterone, which is interpreted as progesterone withdrawal)
- Placental age, which triggers contractions at a set point
- Rising fetal cortisol levels, which reduces progesterone formation and increases prostaglandin formation
- Fetal membrane production of prostaglandin, which stimulates contractions

SIGNS OF LABOR

A common concern of women as they near the end of pregnancy is how they will know if they are beginning labor.

Preliminary Signs of Labor

Before labor, a woman often experiences subtle signs that signal labor is imminent. It is important to review these with women during the last trimester of pregnancy so they can more easily recognize beginning signs.

Lightening

In primiparas, *lightening*, or descent of the fetal presenting part into the pelvis, occurs approximately 10 to 14 days before labor begins. This **fetal descent** changes a woman's abdominal contour, because it positions the uterus lower and more anterior in the abdomen. Lightening gives a woman relief from the diaphragmatic pressure and shortness of breath that she has been experiencing and in this way "lightens" her load. Lightening probably occurs early in primiparas because of tight abdominal muscles. In multiparas, it is not as dramatic and usually occurs on the day of labor or even after labor has begun. As the fetus sinks lower into the pelvis, a woman may experience shooting leg pains from the increased pressure on her sciatic nerve, increased amounts of vaginal discharge, and urinary frequency from pressure on her bladder.

Increase in Level of Activity

A woman may awaken on the morning of labor full of energy, in contrast to the feeling of chronic fatigue she felt during the previous month. This increase in activity is related to an increase in epinephrine release initiated by a decrease in progesterone produced by the placenta. This additional epinephrine prepares a woman's body for the work of labor ahead.

Slight Loss of Weight

As progesterone level falls, body fluid is more easily excreted from the body. This increase in urine production can lead to a weight loss between 1 and 3 pounds.

Braxton Hicks Contractions

In the last week or days before labor begins, a woman usually notices extremely strong Braxton Hicks contractions. Women having their first child may have great difficulty distinguishing between these and true contractions. A woman may come

TABLE 15.1 ✻ Differentiation Between True and False Labor Contractions

False Contractions	True Contractions
Begin and remain irregular.	Begin irregularly but become regular and predictable.
Felt first abdominally and remain confined to the abdomen and groin.	Felt first in lower back and sweep around to the abdomen in a wave.
Often disappear with ambulation or sleep.	Continue no matter what the woman's level of activity.
Do not increase in duration, frequency, or intensity.	Increase in duration, frequency, and intensity.
Do not achieve cervical dilatation.	Achieve cervical dilatation.

to the labor unit of a hospital or birthing center because false contractions so closely simulate true labor. It is discouraging for a woman who is having what seem like contractions (and strong Braxton Hicks contractions cause true discomfort) to be told she is not in true labor and should return home. When this happens, you can assure a woman that misinterpreting labor signals is common. Remind her that if false contractions have become strong enough to be mistaken for true labor, true labor is not far away. Table 15.1 summarizes the ways in which false contractions can be differentiated from true labor.

Ripening of the Cervix

Ripening of the cervix is an internal sign seen only on pelvic examination. Throughout pregnancy, the cervix feels softer than normal to palpation, similar to the consistency of an earlobe (Goodell's sign). At term, the cervix becomes still softer (described as "butter-soft"), and it tips forward. Cervical ripening this way is an internal announcement that labor is very close at hand.

Signs of True Labor

Signs of true labor involve uterine and cervical changes. The more a woman knows about these labor signs, the better she will be able to recognize them. This is helpful both to prevent preterm birth and for the woman to feel secure knowing what will happen during labor.

Uterine Contractions

The surest sign that labor has begun is productive uterine contractions. Because contractions are involuntary and come without warning, their intensity can be frightening in early labor. Helping a woman appreciate that she can predict when her next one will occur and therefore can control the degree of discomfort she feels by using breathing exercises offers her a sense of well-being.

Show

As the cervix softens and ripens, the mucus plug that filled the cervical canal during pregnancy (operculum) is expelled. The exposed cervical capillaries seep blood as a result of pressure exerted by the fetus. This blood, mixed with mucus, takes on a pink tinge and is referred to as "show" or "bloody show." Women need to be aware of this event so that they do not think they are bleeding abnormally.

Rupture of the Membranes

Labor may begin with rupture of the membranes, experienced either as a sudden gush or as scanty, slow seeping of clear fluid from the vagina. Some women may worry if their labor begins with rupture of the membranes, because they have heard that labor will then be "dry" and that this will cause it to be difficult and long. Actually, amniotic fluid continues to be produced until delivery of the membranes after the birth of a fetus, so no labor is ever "dry." Early rupture of the membranes can be advantageous as it can cause the fetal head to settle snugly into the pelvis, actually shortening labor.

Two risks associated with ruptured membranes are intrauterine infection and prolapse of the umbilical cord, which could cut off the oxygen supply to the fetus (Lewis et al., 2007). In most instances, if labor has not spontaneously occurred by 24 hours after membrane rupture and the pregnancy is at term, labor will be induced to help reduce these risks.

✔ Checkpoint Question 15.1

Celeste Bailey did not recognize for over an hour that she was in labor. A sign of true labor is:

a. Sudden increased energy from epinephrine release.
b. "Nagging" but constant pain in the lower back.
c. Urinary urgency from increased bladder pressure.
d. "Show" or release of the cervical mucus plug.

COMPONENTS OF LABOR

A successful labor depends on four integrated concepts:

1. A woman's pelvis (the *passage*) is of adequate size and contour.
2. The *passenger* (the fetus) is of appropriate size and in an advantageous position and presentation.
3. The *powers* of labor (uterine factors) are adequate. (The powers of labor are strongly influenced by the woman's position during labor.)
4. A woman's *psychological outlook* is preserved, so that afterward labor can be viewed as a positive experience.

Passage

The passage refers to the route a fetus must travel from the uterus through the cervix and vagina to the external perineum. Because the cervix and vagina are contained inside the pelvis, a fetus must also pass through the bony pelvic ring. (Pelvic anatomy is discussed in Chapter 11; see Figs. 11.4 and 11.5.) Two pelvic measurements are important to determine

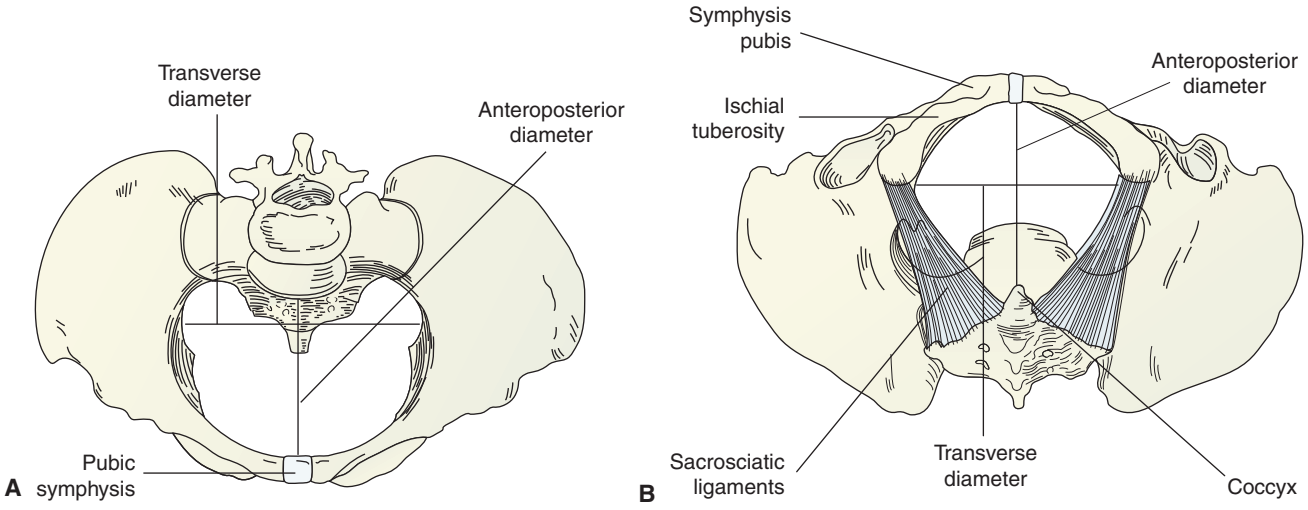

FIGURE 15.1 Views of the pelvic inlet and outlet. (**A**) Pelvic inlet. (**B**) Pelvic outlet.

the adequacy of the pelvic size: the diagonal conjugate (the anteroposterior diameter of the inlet) and the transverse diameter of the outlet. At the pelvic inlet, the anteroposterior diameter is the narrowest diameter; at the outlet, the transverse diameter is the narrowest (Fig. 15.1).

In most instances, if a disproportion between fetus and pelvis occurs, the pelvis is the structure at fault. If the fetus is the cause of the disproportion, it is often because the fetal head is presented to the birth canal at less than its narrowest diameter, not because the fetal head is actually too large. Keep this in mind when discussing with parents why an infant cannot be born vaginally. In this situation, emphasize that it is the pelvis that is too small, not that the head is too big. When parents learn that a child cannot be born vaginally because the mother's pelvis is too small, it can be upsetting. It can be much more upsetting, however, to think that their infant's head is too large, because it implies that something may be seriously wrong with their baby (which usually is not true). Avoiding this type of negative thought helps promote good parent–child bonding.

Passenger

The passenger is the fetus. The body part of the fetus that has the widest diameter is the head, so this is the part least likely to be able to pass through the pelvic ring. Whether a fetal skull can pass depends on both its structure (bones, fontanelles, and suture lines) and its alignment with the pelvis.

Structure of the Fetal Skull

The cranium, the uppermost portion of the skull, is composed of eight bones. The four superior bones—the frontal (actually two fused bones), the two parietal, and the occipital—are the bones that are important in childbirth. The other four bones of the skull (sphenoid, ethmoid, and two temporal bones) lie at the base of the cranium so are of little significance in childbirth because they are never presenting parts. The chin, referred to by its Latin name *mentum,* can be a presenting part.

The bones of the skull meet at suture lines. The sagittal suture joins the two parietal bones of the skull. The coronal suture is the line of juncture of the frontal bones and the two parietal bones. The lambdoid suture is the line of juncture of the occipital bone and the two parietal bones. The suture lines are important in birth because, as membranous interspaces, they allow the cranial bones to move and overlap, molding or diminishing the size of the skull so that it can pass through the birth canal more readily.

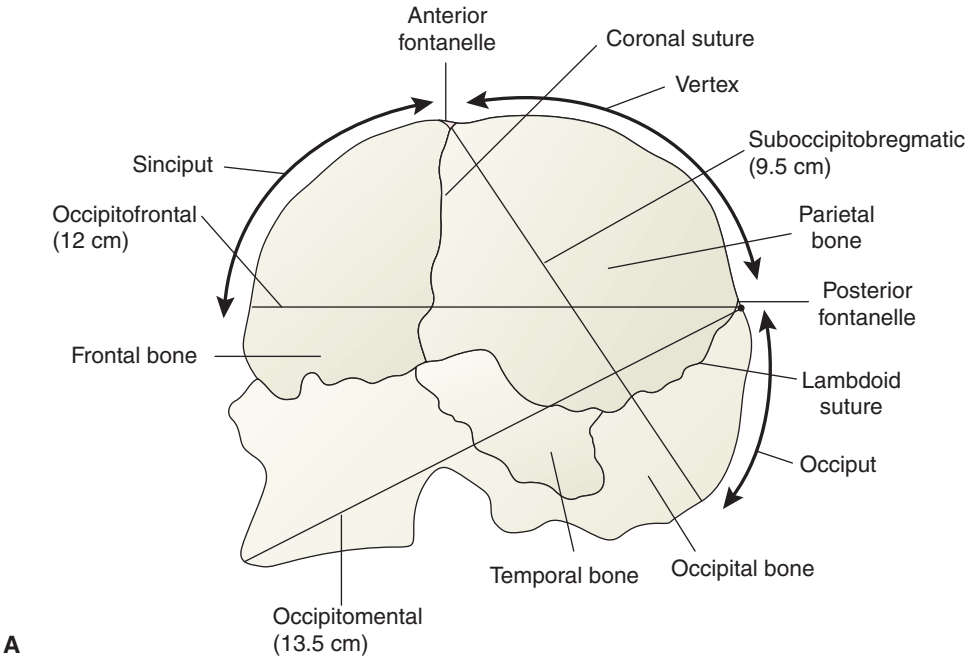
Significant membrane-covered spaces called the fontanelles are found at the junction of the main suture lines. The anterior fontanelle (sometimes referred to as the bregma) lies at the junction of the coronal and sagittal sutures. Because the frontal bone consists of two fused bones, four bones (counting the two parietal bones) are actually involved at this junction so the anterior fontanelle is diamond shaped. Its anteroposterior diameter measures approximately 3 to 4 cm; its transverse diameter, 2 to 3 cm. It closes when the infant is 12 to 18 months of age.

The posterior fontanelle lies at the junction of the lambdoidal and sagittal sutures. Because three bones—the two parietal bones and the occipital bone—are involved at this junction, the posterior fontanelle is triangular shaped. It is smaller than the anterior fontanelle, measuring approximately 2 cm across its widest part. Because of its small size, it closes when an infant is about 2 months of age.

Fontanelle spaces compress during birth to aid in molding of the fetal head. Their presence can be assessed manually through the cervix after the cervix has dilated during labor. Palpating for them during a pelvic examination helps to establish the position of the fetal head and whether it is in a favorable position for birth. The space between the two fontanelles is referred to as the vertex. The area over the frontal bone is referred to as the sinciput. The area over the occipital bone is referred to as the occiput (Fig. 15.2).

Diameters of the Fetal Skull

The shape of a fetal skull causes it to be wider in its anteroposterior diameter than in its transverse diameter. To best fit through the birth canal, a fetus must present the smaller



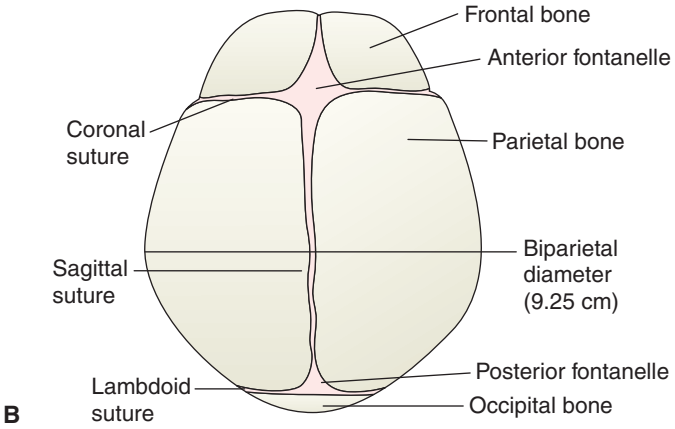


FIGURE 15.2 The fetal skull. (**A**) Lateral view. (**B**) Vertex view.

diameter (the transverse diameter) to the smaller diameter of the maternal pelvis; otherwise, progress can be halted and birth may not be accomplished.

The diameter of the anteroposterior fetal skull depends on where the measurement is taken. The narrowest diameter (approximately 9.5 cm) is from the inferior aspect of the occiput to the center of the anterior fontanelle (the suboccipitobregmatic diameter). The occipitofrontal diameter, measured from the occipital prominence to the bridge of the nose, is approximately 12 cm. The occipitomental diameter, which is the widest anteroposterior diameter (approximately 13.5 cm), is measured from the posterior fontanelle to the chin.

The anteroposterior diameter of the pelvis, a space approximately 11 cm wide, is the narrowest diameter at the pelvic inlet so to be born most easily, a fetus must present a biparietal diameter, the narrowest fetal head diameter (approximately 9.25 cm) to this (see Fig. 15.2A). At the outlet, the fetus must rotate to present the narrowest fetal head diameter to the maternal transverse diameter, a space approximately 11 cm wide. If a fetus presents the anteroposterior diameter of the skull (a measurement wider than the biparietal diameter) to the anteroposterior diameter of the inlet, **engagement,** or the settling of the fetal head into the pelvis, may not occur. If the fetus does not rotate so the anteroposterior diameter of the skull is presented to the transverse diameter of the outlet, arrest of progress may occur.

Which anteroposterior diameter that presents to the birth canal is determined not only by rotation but by the degree of flexion of the fetal head (Fig. 15.3). In full flexion, a fetal head flexes so sharply the chin rests on the chest, and the smallest anteroposterior diameter, the suboccipitobregmatic, is presented to the birth canal. If the head is held in moderate flexion, the occipitofrontal diameter will be presented. In poor flexion (the head hyperextended), the largest diameter (the occipitomental) will present. It follows

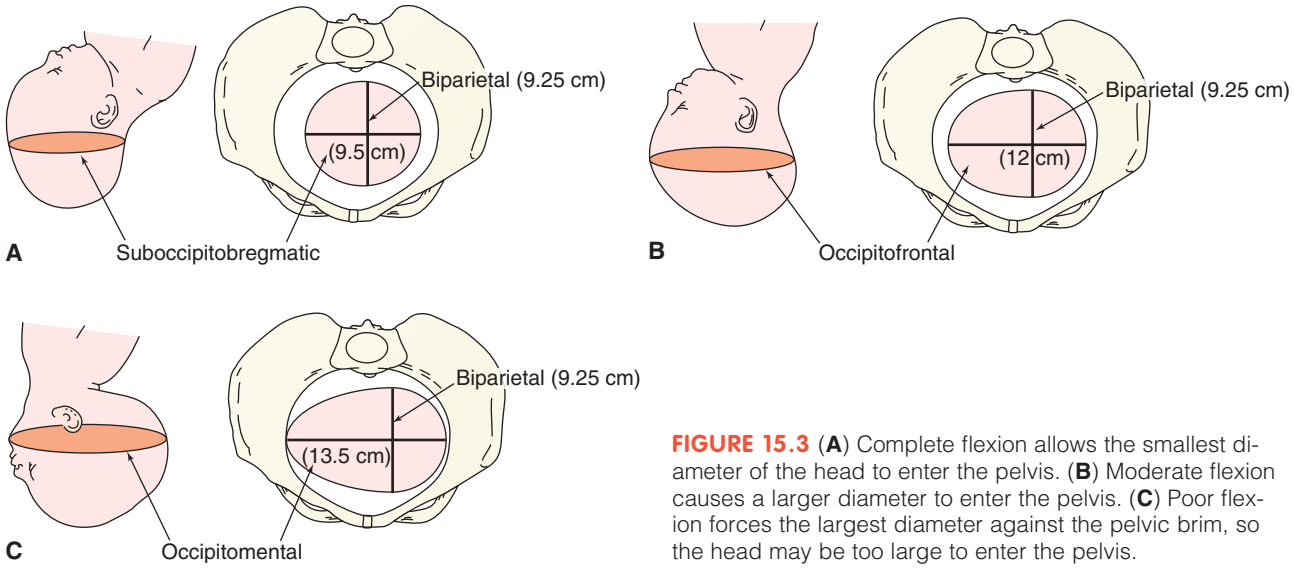

FIGURE 15.3 (**A**) Complete flexion allows the smallest diameter of the head to enter the pelvis. (**B**) Moderate flexion causes a larger diameter to enter the pelvis. (**C**) Poor flexion forces the largest diameter against the pelvic brim, so the head may be too large to enter the pelvis.

that a fetal head presenting a diameter of 9.5 cm will fit through a pelvis much more readily than if the diameter is 12.0 or 13.5 cm.

Molding

Molding is a change in the shape of the fetal skull produced by the force of uterine contractions pressing the vertex of the head against the not-yet-dilated cervix. Because the bones of the fetal skull are not yet completely ossified and therefore do not form a rigid structure, pressure causes them to overlap and molds the head into a narrower and longer shape, a shape that facilitates passage through the rigid pelvis. Molding is commonly seen in infants just after birth. The overlapping of the sagittal suture line and, generally, the coronal suture line can be easily palpated in the newborn skull. Parents can be reassured that molding only lasts a day or two and is not a permanent condition. There is little molding when the brow is the presenting part (described later), because frontal bones are fused. No skull molding occurs when a fetus is breech, because the buttocks, not the head, are presented first.

Fetal Presentation and Position

Two other factors play a part in whether a fetus is lined up in the best position to be born: fetal presentation and position.

Attitude. **Attitude** describes the degree of flexion a fetus assumes during labor or the relation of the fetal parts to each other (Fig. 15.4). A fetus in *good* attitude is in complete flexion: the spinal column is bowed forward, the head is flexed forward so much that the chin touches the sternum, the arms are flexed and folded on the chest, the thighs are flexed onto the abdomen, and the calves are pressed against the posterior aspect of the thighs (see Fig. 15.4A). This normal "fetal position" is advantageous for birth because it helps a fetus present the smallest anteroposterior diameter of the skull to the pelvis and also because it puts the whole body into an ovoid shape, occupying the smallest space possible.

A fetus is in moderate flexion if the chin is not touching the chest but is in an alert or "military position" (see Fig. 15.4B). This position causes the next-widest anteroposterior diameter, the occipital frontal diameter, to present to the birth canal. A fair number of fetuses assume a military position during the early part of labor. This does not usually interfere with labor, because later mechanisms of labor (descent and flexion) force the fetal head to fully flex.

A fetus in partial extension presents the "brow" of the head to the birth canal (see Fig. 15.4C). If a fetus is in complete extension, the back is arched, and the neck is extended, presenting the occipitomental diameter of the head to the birth canal (a face presentation; see Fig. 15.4D). This unusual position presents too wide a skull diameter to the birth canal for normal birth. Such a position may occur if there is less than the normal amount of amniotic fluid present (*oligohydramnios*), which does not allow a fetus adequate movement. It also may reflect a neurologic abnormality in the fetus causing spasticity.

Engagement. Engagement refers to the settling of the presenting part of a fetus far enough into the pelvis to be at the level of the ischial spines, a midpoint of the pelvis. Descent to this point means that the widest part of the fetus (the biparietal diameter in a cephalic presentation; the intertrochanteric diameter in a breech presentation) has passed through the pelvis inlet or the pelvic inlet has been proved adequate for birth. In a primipara, nonengagement of the head at the beginning of labor indicates a possible complication, such as an abnormal presentation or position, abnormality of the fetal head, or cephalopelvic disproportion. In multiparas, engagement may or may not be present at the beginning of labor. The degree of engagement is assessed by vaginal and cervical examination. A presenting part that is not engaged is said to be "floating." One that is descending but has not yet reached the ischial spines is said to be "dipping."

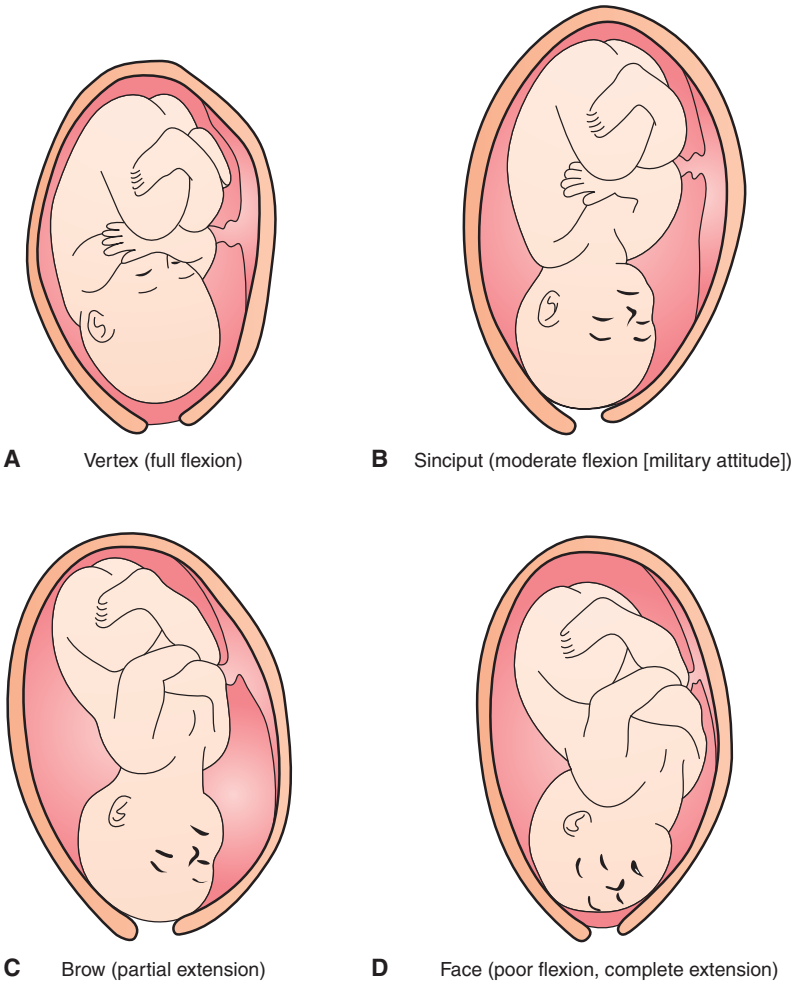

FIGURE 15.4 Fetal attitude. (**A**) Fetus in full flexion presents smallest (suboccipitobregmatic) anteroposterior diameter of skull to inlet in this good attitude (vertex presentation). (**B**) Fetus is not as well flexed (military attitude) as in **A** and presents occipitofrontal diameter to inlet (sinciput presentation). (**C**) Fetus in partial extension (brow presentation). (**D**) Fetus in complete extension presents wide (occipitomental) diameter (face presentation).

Station. **Station** refers to the relationship of the presenting part of a fetus to the level of the ischial spines (Fig. 15.5). When the presenting fetal part is at the level of the ischial spines, it is at a 0 station (synonymous with engagement). If the presenting part is above the spines, the distance is measured and described as minus stations, which range from −1 to −4 cm. If the presenting part is below the ischial spines, the distance is stated as plus stations (+1 to +4 cm). At a +3 or +4 station, the presenting part is at the perineum and can be seen if the vulva is separated (i.e., it is crowning).

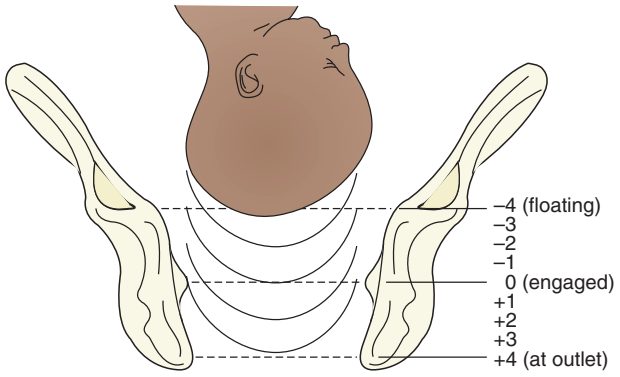

FIGURE 15.5 Station (anteroposterior view). Station, or degree of engagement, of the fetal head is designated by centimeters above or below the ischial spines. At −4 station, head is "floating." At 0 station, head is "engaged." At +4 station, head is "at outlet."

Fetal Lie. **Lie** is the relationship between the long (cephalocaudal) axis of the fetal body and the long (cephalocaudal) axis of a woman's body; in other words, whether the fetus is lying in a horizontal (transverse) or a vertical (longitudinal) position. Approximately 99% of fetuses assume a longitudinal lie (with their long axis parallel to the long axis of the woman). Longitudinal lies are further classified as cephalic, which means the head will be the first part to contact the cervix, or breech, with the breech, or buttocks, as the first portion to contact the cervix.

Types of Fetal Presentation

Fetal presentation denotes the body part that will first contact the cervix or be born first. This is determined by a combination of fetal lie and the degree of fetal flexion (attitude).

Cephalic Presentation. A **cephalic presentation** is the most frequent type of presentation, occurring as often as

TABLE 15.2 ✻ Types of Cephalic Presentation

Type	Lie	Attitude	Description
Vertex	Longitudinal	Good (full flexion)	The head is sharply flexed, making the parietal bones or the space between the fontanelles (the vertex) the presenting part. This is the most common presentation and allows the suboccipitobregmatic diameter to present to the cervix.
Brow	Longitudinal	Moderate (military)	Because the head is only moderately flexed, the brow or sinciput becomes the presenting part.
Face	Longitudinal	Poor	The fetus has extended the head to make the face the presenting part. From this position, extreme edema and distortion of the face may occur. The presenting diameter is so wide that birth may be impossible.
Mentum	Longitudinal	Very poor	The fetus has completely hyperextended the head to present the chin. The widest diameter (occipitomental) is presenting. As a rule, a fetus cannot enter the pelvis in this presentation.

95% of the time. With this type of presentation, the fetal head is the body part that will first contact the cervix. The four types of cephalic presentation (vertex, brow, face, and mentum) are described in Table 15.2. The vertex is the ideal presenting part, because the skull bones are capable of effectively molding to accommodate the cervix. This may actually aid in cervical dilatation and prevents complications such as a prolapsed cord (i.e., a portion of the cord passing between the presenting part and the cervix and entering the vagina before the fetus) (Kish & Collea, 2007). During labor, the area of the fetal skull that contacts the cervix often becomes edematous from the continued pressure against it. This edema is called a *caput succedaneum*. In the newborn, the point of presentation can be analyzed from the location of the caput.

Breech Presentation. A **breech presentation** means that either the buttocks or the feet are the first body parts that will contact the cervix. Breech presentations occur in approximately 3% of births and are affected by fetal attitude. A good attitude brings the fetal knees up against the fetal abdomen; a poor attitude means that the knees are extended. Breech presentations can be difficult births, with the presenting point influencing the degree of difficulty. Three types of breech presentation (complete, frank, and footling) are possible (Table 15.3).

Shoulder Presentation. In a transverse lie, a fetus lies horizontally in the pelvis so that the longest fetal axis is perpendicular to that of the mother. The presenting part is usually one of the shoulders (acromion process), an iliac crest, a hand, or an elbow (Fig. 15.6).

Fewer than 1% of fetuses lie transversely. This presentation may be caused by relaxed abdominal walls from grand multiparity, which allow the unsupported uterus to fall forward. Another cause is pelvic contraction, in which the horizontal space is greater than the vertical space. Placenta previa (in which the placenta is located low in the uterus, obscuring some of the vertical space) may also limit a fetus's ability to turn, resulting in a transverse lie. With a transverse lie, the usual contour of the abdomen at term is distorted or is fuller side to side rather than top to bottom.

If an infant is preterm and smaller than usual, an attempt to turn the fetus to a horizontal lie may be made. Most infants in a transverse lie must be born by cesarean birth, however, because they cannot be turned and cannot be born vaginally from this "wedged" position. Discovering a shoulder presentation is an important assessment, because it almost always identifies a birth position that puts both mother and child in jeopardy unless skilled health care personnel are available to complete a cesarean birth.

Types of Fetal Position

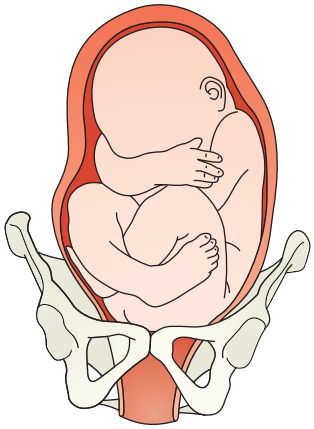
Position is the relationship of the presenting part to a specific quadrant of a woman's pelvis. For convenience, the maternal pelvis is divided into four quadrants according to the mother's right and left: (a) right anterior, (b) left anterior, (c) right posterior, and (d) left posterior.

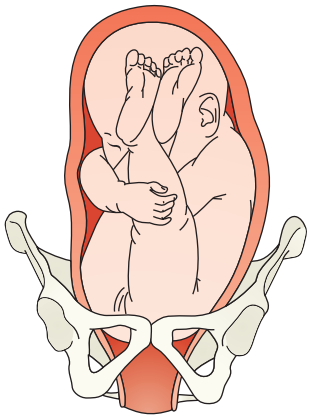
Four parts of a fetus have been chosen as landmarks to describe the relationship of the presenting part to one of the pelvic quadrants. In a vertex presentation, the occiput is the chosen point; in a face presentation, it is the chin (mentum); in a breech presentation, it is the sacrum; and in a shoulder presentation, it is the scapula or the acromion process.

Position is indicated by an abbreviation of three letters. The middle letter denotes the fetal landmark (O for occiput, M for mentum or chin, Sa for sacrum, and A for acromion process). The first letter defines whether the landmark is pointing to the mother's right (R) or left (L). The last letter defines whether the landmark points anteriorly (A), posteriorly (P), or transversely (T).

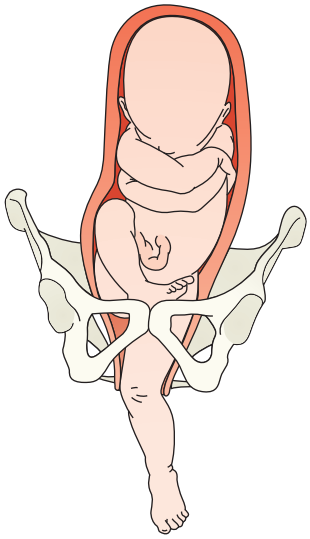
If the occiput of a fetus points to the left anterior quadrant in a vertex position, for example, this is a left occipitoanterior (LOA) position. If the occiput points to the right posterior quadrant, the position is right occipitoposterior (ROP). LOA is the most common fetal position, and right occipitoanterior (ROA) the second most frequent. Box 15.2

TABLE 15.3 ✻ Types of Breech Presentation

Type	Lie	Attitude	Description
Complete	Longitudinal	Good (full flexion)	The fetus has thighs tightly flexed on the abdomen; both the buttocks and the tightly flexed feet present to the cervix.
			


Frank	Longitudinal	Moderate	Attitude is moderate because the hips are flexed but the knees are extended to rest on the chest. The buttocks alone present to the cervix.
			


Footling	Longitudinal	Poor	Neither the thighs nor lower legs are flexed. If one foot presents, it is a single-footling breech; if both present, it is a double-footling breech.
			



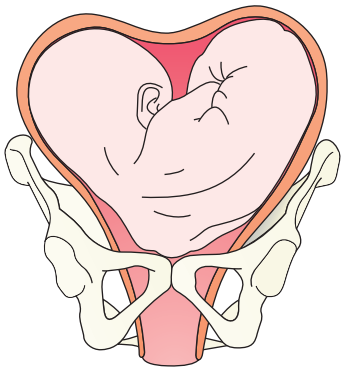


FIGURE 15.6 Transverse or shoulder presentation.

summarizes the possible positions. Six common positions in cephalic presentations are illustrated in Figure 15.7.

Position is important, because it can influence the process and efficiency of labor. Typically, a fetus is born fastest from an ROA or LOA position. Labor is considerably extended if the position is posterior (ROP or LOP). Posterior positions may also be more painful for a woman, because the rotation of the fetal head puts pressure on sacral nerves, causing sharp back pain. Encouraging a woman to rest in a Sims' position on the same side as the fetal spine may encourage rotation from an occipitoposterior to an occipitoanterior position before and during labor (Ridley, 2007).

BOX 15.2 ✻ Possible Fetal Positions

Vertex Presentation (occiput)
LOA, left occipitoanterior
LOP, left occipitoposterior
LOT, left occipitotransverse
ROA, right occipitoanterior
ROP, right occipitoposterior
ROT, right occipitotransverse

Breech Presentation (sacrum)
LSaA, left sacroanterior
LSaP, left sacroposterior
LSaT, left sacrotransverse
RSaA, right sacroanterior
RSaP, right sacroposterior
RSaT, right sacrotransverse

Face Presentation (mentum)
LMA, left mentoanterior
LMP, left mentoposterior
LMT, left mentotransverse
RMA, right mentoanterior
RMP, right mentoposterior
RMT, right mentotransverse

Shoulder Presentation (acromion process)
LAA, left scapuloanterior
LAP, left scapuloposterior
RAA, right scapuloanterior
RAP, right scapuloposterior

✔ Checkpoint Question 15.2

Celeste's obstetrician asks you which fetal position and presentation are ideal. Your best answer would be:

a. Right occipitoanterior with full flexion.
b. Left transverse anterior in moderate flexion.
c. Right occipitoposterior with no flexion.
d. Left sacroanterior with full flexion.

Mechanisms (Cardinal Movements) of Labor

Passage of a fetus through the birth canal involves several different position changes to keep the smallest diameter of the fetal head (in cephalic presentations) always presenting to the smallest diameter of the pelvis. These position changes are termed the **cardinal movements of labor:** descent, flexion, internal rotation, extension, external rotation, and expulsion (Fig. 15.8).

Descent. Descent is the downward movement of the biparietal diameter of the fetal head to within the pelvic inlet. Full descent occurs when the fetal head extrudes beyond the dilated cervix and touches the posterior vaginal floor. Descent occurs because of pressure on the fetus by the uterine fundus. The pressure of the fetal head on the sacral nerves at the pelvic floor causes the mother to experience a pushing sensation. Full descent may be aided by abdominal muscle contraction as the woman pushes.

Flexion. As descent occurs and the fetal head reaches the pelvic floor, the head bends forward onto the chest, making the smallest anteroposterior diameter (the suboccipitobregmatic diameter) present to the birth canal. Flexion is also aided by abdominal muscle contraction during pushing.

Internal Rotation. During descent, the head enters the pelvis with the fetal anteroposterior head diameter (suboccipitobregmatic, occipitomental, or occipitofrontal, depending on the amount of flexion) in a diagonal or transverse position. The head flexes as it touches the pelvic floor, and the occiput rotates to bring the head into the best relationship to the outlet of the pelvis (the anteroposterior diameter is now in the anteroposterior plane of the pelvis). This movement brings the shoulders, coming next, into the optimal position to enter the inlet, putting the widest diameter of the shoulders (a transverse one) in line with the wide transverse diameter of the inlet.

Extension. As the occiput is born, the back of the neck stops beneath the pubic arch and acts as a pivot for the rest of the head. The head extends, and the foremost parts of the head, the face and chin, are born.

External Rotation. In external rotation, almost immediately after the head of the infant is born, the head rotates (from the anteroposterior position it assumed to enter the outlet) back to the diagonal or transverse position of the early part of labor. This brings the aftercoming shoulders into an anteroposterior position, which is best for entering the outlet. The

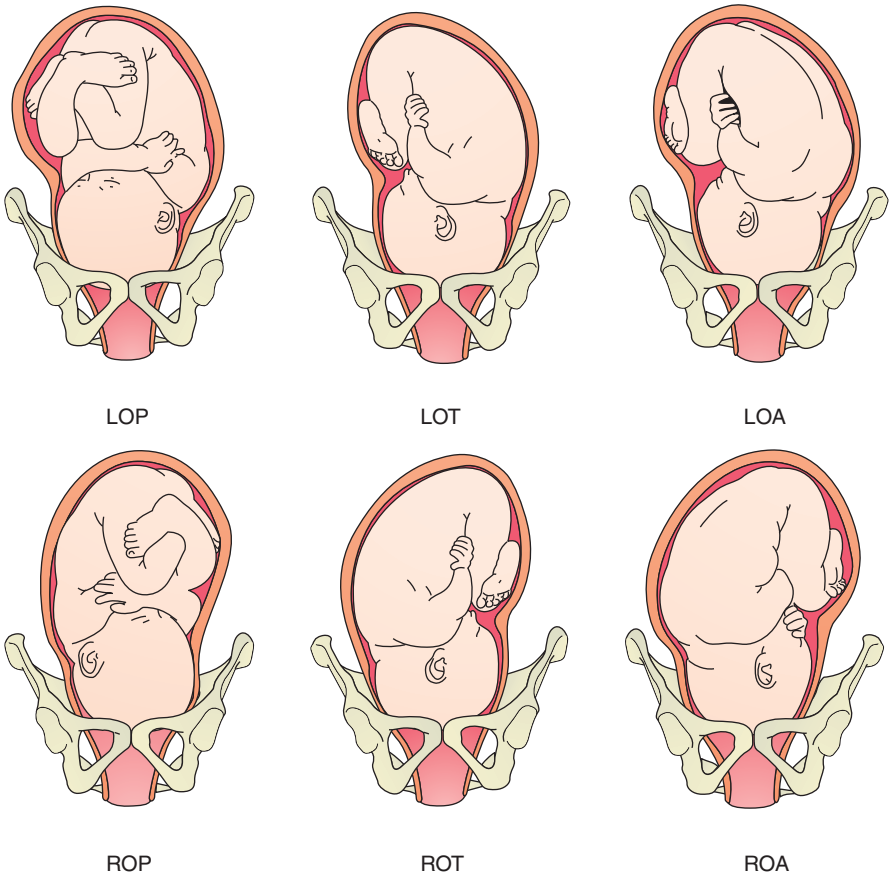

FIGURE 15.7 Fetal position. All are vertex presentations. A = anterior; L = left; O = occiput; P = posterior; R = right; T = transverse.

anterior shoulder is born first, assisted perhaps by downward flexion of the infant's head.

Expulsion. Once the shoulders are born, the rest of the baby is born easily and smoothly because of its smaller size. This movement, called expulsion, is the end of the pelvic division of labor. For a view of the complete birth sequence, see Figure 15.9.

Importance of Determining Fetal Presentation and Position

It is important to document fetal presentation and position, because these help predict if the presentation of a body part other than the vertex could be putting a fetus at risk. If a body part other than the vertex presents to the cervix, labor is invariably longer because of ineffective descent of the fetus, ineffective dilatation of the cervix, or irregular and weak uterine contractions.

It may also lead to early rupture of membranes, increasing the possibility of infection, fetal anoxia, and meconium staining, complications that lead to respiratory distress at birth and may require cesarean birth.

When labor is ineffective for any reason, the longer it extends, the more it tires both a woman and her fetus, as well as reducing the excitement of the experience. If a cesarean birth is necessary and postoperative complications occur, a woman may require a longer hospital stay and have more pain and disability after the birth. If a fetus is born vaginally after a complicated labor, there is an increased risk for perineal tears or cervical lacerations, which may also increase a woman's disability and possibly interfere with her future childbearing (Fitzgerald et al., 2007). If labor is threatening and unsatisfactory, it can also interfere with maternal–child bonding.

Four methods are used to determine fetal position, presentation, and lie: (a) combined abdominal inspection and palpation, called Leopold's maneuvers; (b) vaginal examination; (c) auscultation of fetal heart tones; and (d) ultrasound.

Powers of Labor

The second important requirements for a successful labor are effective powers of labor. This is the force supplied by the fundus of the uterus, implemented by uterine contractions, a natural process that causes cervical dilatation and then expulsion of the fetus from the uterus. After full dilatation of the cervix, the primary power is supplemented by use of the abdominal muscles. It is important for women to understand they should not bear down with their abdominal muscles until the cervix is fully dilated. Doing so impedes the primary force and could cause fetal and cervical damage.

Uterine Contractions

The mark of effective uterine contractions is rhythmicity and progressive lengthening and intensity.

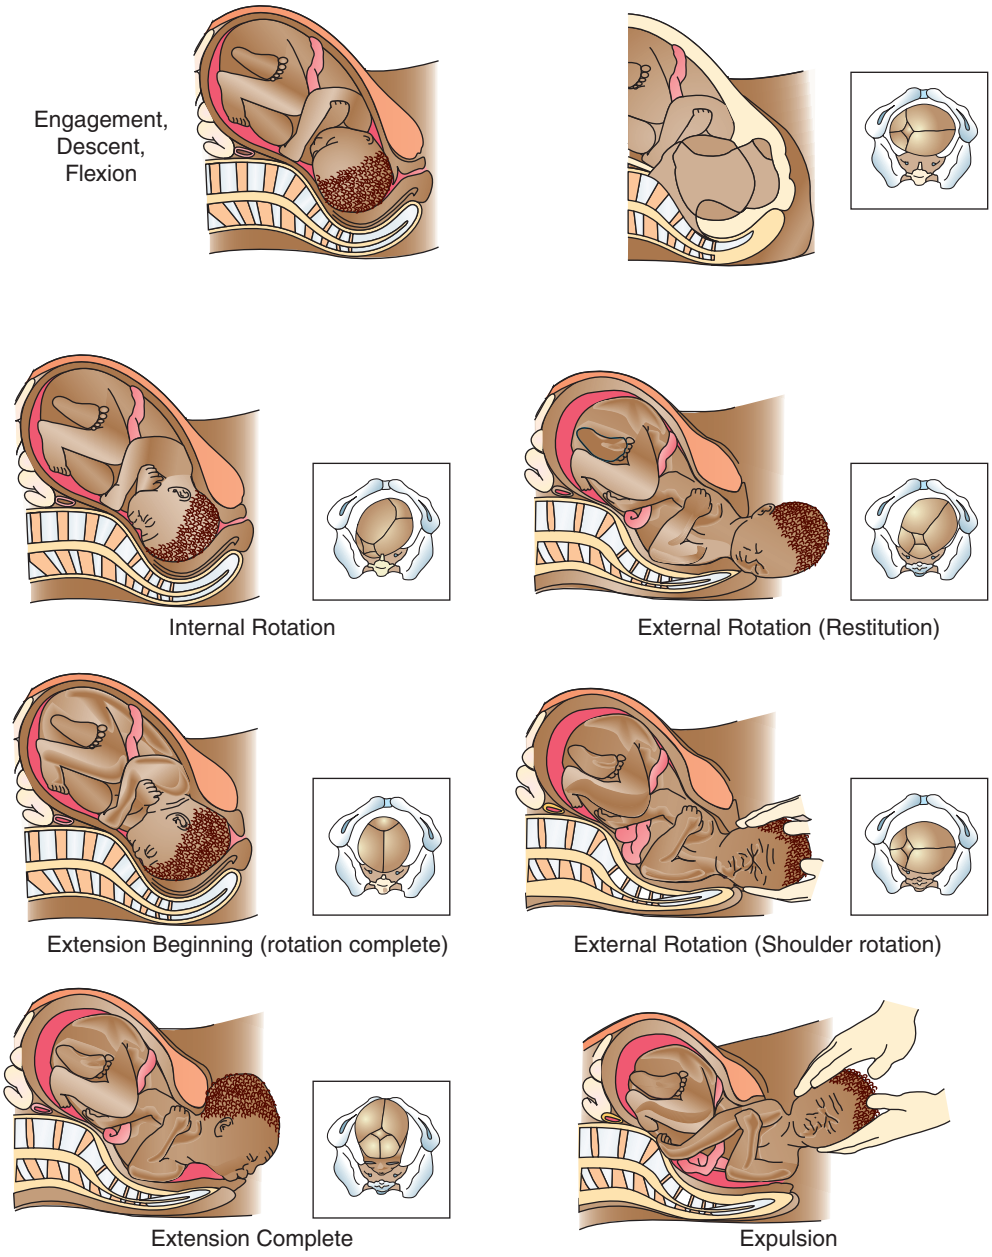

FIGURE 15.8 Mechanism of normal labor and cardinal positions of the fetus from a left occipitoanterior position.

Origins. Like cardiac contractions, labor contractions begin at a "pacemaker" point located in the uterine myometrium near one of the uterotubal junctions. Each contraction begins at that point and then sweeps down over the uterus as a wave. After a short rest period, another contraction is initiated and the downward sweep begins again.

In early labor, the uterotubal pacemaker may not be working in a synchronous manner. This makes contractions sometimes strong, sometimes weak, and perhaps irregular. This mild incoordination of early labor improves after a few hours as the pacemaker becomes more attuned to calcium concentrations in the myometrium and begins to function smoothly.

In some women, contractions appear to originate in the lower uterine segment rather than in the fundus. These are reverse, ineffective contractions, and they may actually cause tightening rather than dilatation of the cervix. That contractions are being initiated in a reverse pattern is difficult to tell from palpation. It can be suspected if the woman tells you she feels pain in her lower abdomen before the contraction is readily palpated at the fundus. It is truly revealed only when cervical dilatation does not occur.

Some women seem to have additional pacemaker sites in other portions of the uterus. If so, contractions can be unco-

(text continues on page 358)

6:00 AM: Early in labor, a mother-to-be is supported by her husband and her sister.

9:00 AM: The nurse checks the fetal monitor and documents fetal and maternal status.

10:00 AM: The doctor makes a final check of cervical dilatation and says it's time to push.

11:15 AM: She pushes from an alternative position, using a support bar.

10:30 AM: The mother pushes in the lithotomy position, with her coach.

FIGURE 15.9 A day in the life of a new family.

12:15 PM: Mom holds her son for the first time. Her mother and sister (now a grandmother and aunt!) look on.

12:30 PM: The nurse suctions to clear the airway and takes the baby's footprints.

1:15 PM: Cleaned and swaddled, the newborn gets a kiss from Mom.

3:00 PM: The new mom gives Stephen his first feeding, with support from the nurse.

5:00 PM: New parents bond with the new member of their family.

FIGURE 15.9 *(continued)*

ordinated. Uncoordinated contractions may slow labor and can lead to failure to progress and fetal distress as they may not allow for adequate placental filling. All of these possibilities make evaluating the rate, intensity, and pattern of uterine contractions an important nursing responsibility.

Phases. A contraction consists of three phases: the increment, when the intensity of the contraction increases; the acme, when the contraction is at its strongest; and the decrement, when the intensity decreases (Fig. 15.10). Between contractions, the uterus relaxes. As labor progresses, the relaxation intervals decrease from 10 minutes early in labor to only 2 to 3 minutes. The duration of contractions also changes, increasing from 20 to 30 seconds to a range of 60 to 90 seconds.

Contour Changes. As labor contractions progress and become regular and strong, the uterus gradually differentiates itself into two distinct functioning areas. The upper portion becomes thicker and active, preparing it to be able to exert the strength necessary to expel the fetus when the expulsion phase of labor is reached. The lower segment becomes thin walled, supple, and passive, so that the fetus can be easily pushed out of the uterus. As these events occur, the boundary between the two portions becomes marked by a ridge on the inner uterine surface, the **physiologic retraction ring.**

The contour of the overall uterus also changes from a round, ovoid structure to an elongated one whose vertical diameter is markedly greater than its horizontal diameter. This lengthening serves to straighten the body of the fetus, placing it in better alignment with the cervix and pelvis. As the uterus contracts, the round ligaments tighten, keeping the fundus forward, again to assist in placing the fetus in good alignment with the cervix. The elongation of the uterus exerts pressure against the diaphragm and causes the often-expressed sensation that a uterus is "taking control" of a woman's body.

Although rarely seen today because abnormal contractions or fetal response to contractions is detected, in a difficult labor, particularly if the fetus is larger than the birth canal, the round ligaments of the uterus can become so tense they may be palpable on the abdomen. The normal physiologic retraction ring may become prominent and observable as an abdominal indentation. Termed a **pathologic retraction ring** or Bandl's ring, it is a danger sign that signifies impending rupture of the lower uterine segment if the obstruction to labor is not relieved.

Cervical Changes

Even more marked than the changes in the body of the uterus are two changes that occur in the cervix: effacement and dilatation.

Effacement. **Effacement** is shortening and thinning of the cervical canal. Normally, the canal is approximately 1 to 2 cm long. With effacement, the canal virtually disappears (Fig. 15.11). This occurs because of longitudinal traction from the contracting uterine fundus.

In primiparas, effacement is accomplished before dilatation begins. Be sure to inform women of this fact. Otherwise, they can become discouraged if, for example, at noon after a cervical examination a woman is told she is 2 cm dilated and then at 4 PM is told she is still 2 cm dilated. This type of report makes it seem as if absolutely nothing has happened in 4 hours. However, effacement will have been occurring, and when it is complete, dilatation will then progress rapidly.

In multiparas, dilatation may proceed before effacement is complete. Effacement must occur at the end of dilatation, however, before the fetus can be safely pushed through the cervical canal; otherwise, cervical tearing could result.

Dilatation. **Dilatation** refers to the enlargement or widening of the cervical canal from an opening a few millimeters wide to one large enough (approximately 10 cm) to permit passage of a fetus (see Fig. 15.11).

Dilatation occurs for two reasons. First, uterine contractions gradually increase the diameter of the cervical canal lumen by pulling the cervix up over the presenting part of the fetus. Second, the fluid-filled membranes press against the cervix. If the membranes are intact, they push ahead of the fetus and serve as an opening wedge. If they are ruptured, the presenting part serves this same function.

As dilatation begins, there is an increase in the amount of vaginal secretions (show), because the last of the operculum

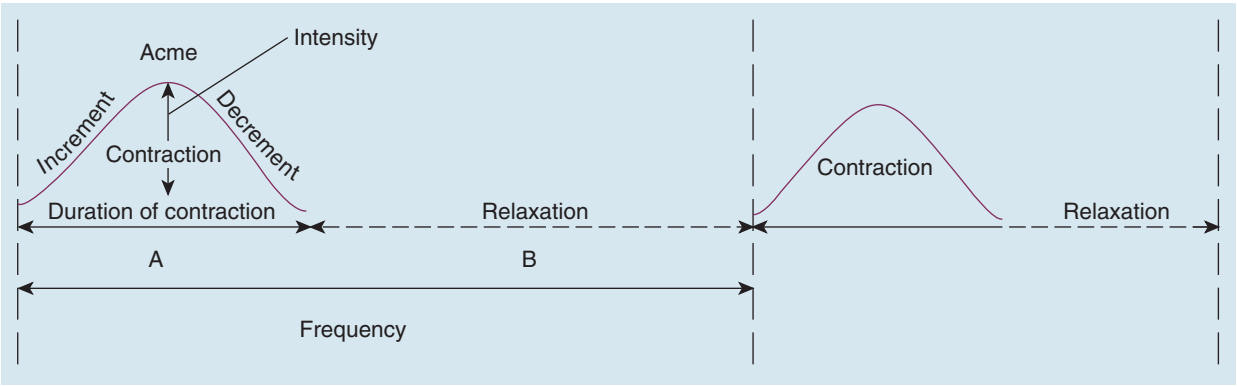

FIGURE 15.10 The interval and duration of uterine contractions. The frequency of contractions is the time from the beginning of one contraction to the beginning of the next contraction. It consists of two parts: (**A**) the duration of the contraction and (**B**) the period of relaxation. The broken line indicates an indeterminate period because the relaxation time (**B**) is usually of longer duration than the actual contraction (**A**).

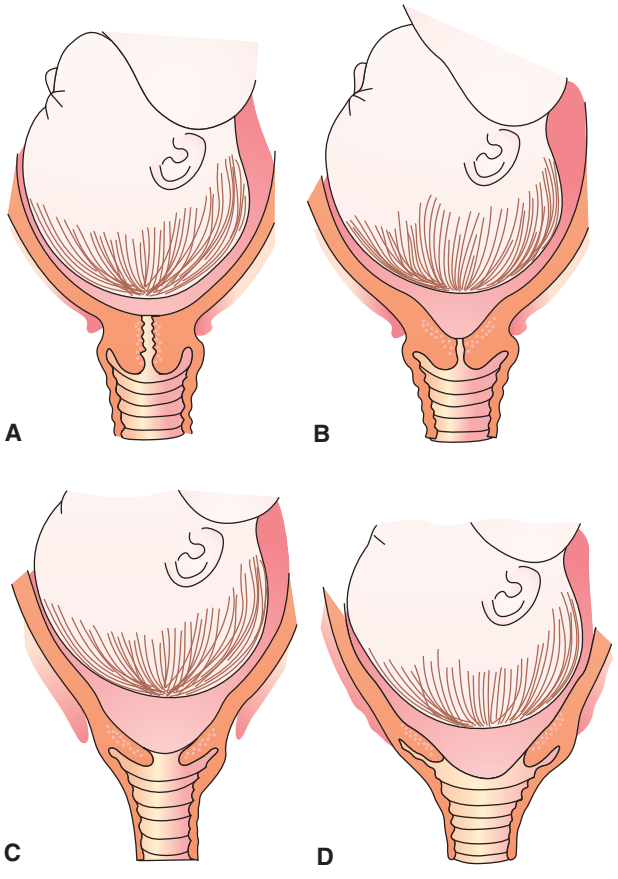

FIGURE 15.11 Effacement and dilatation of cervix. (**A**) Beginning labor. (**B**) Effacement is beginning; dilatation is not apparent yet. (**C**) Effacement is almost complete. (**D**) After complete effacement, dilatation proceeds rapidly.

or mucus plug in the cervix is dislodged and minute capillaries in the cervix rupture.

Psyche

The fourth "P," or a woman's psychological outlook, refers to the psychological state or feelings that a woman brings into labor. For many women, this is a feeling of apprehension or fright. For almost everyone, it includes a sense of excitement or awe.

Women who manage best in labor typically are those who have a strong sense of self-esteem and a meaningful support person with them. These factors allow women to feel in control of sensations and circumstances that they have not experienced previously and that may not be at all what they pictured as happening. Women without adequate support can have an experience so frightening and stressful they can develop a posttraumatic stress syndrome (Tam & Chung, 2007).

Encouraging women to ask questions at prenatal visits and to attend preparation for childbirth classes helps prepare them for labor. Encouraging them to share their experience after labor serves as "debriefing time" and helps them integrate the experience into their total life.

STAGES OF LABOR

Labor is traditionally divided into three stages: a first stage of dilatation, which begins with the initiation of true labor contractions and ends when the cervix is fully dilated; a second stage, extending from the time of full dilatation until the infant is born; and a third or placental stage, lasting from the time the infant is born until after the delivery of the placenta. The first 1 to 4 hours after birth of the placenta is sometimes termed the "fourth stage" to emphasize the importance of the close maternal observation needed at this time. These designations are helpful in planning nursing interventions to ensure the safety of both a woman and her fetus.

Friedman (1978), a physician who studied the process of labor extensively, used data to divide the first two stages of labor into phases: latent and active labor. Table 15.4 lists clinical features of these divisions of labor. When plotted in graph form, these divisions are useful in monitoring an individual woman's labor progress (Fig. 15.12). How much and what type of analgesia a woman receives in labor can influence the length of labor. Because "norms" refer to averages, an individual woman's labor can vary greatly from the ideal projected course of labor and still be normal for that woman.

Typically, a labor progress graph is labeled as:

- Left side numbered from 1 to 10 (representing the centimeters of cervical dilatation)

TABLE 15.4 ✻ Principal Clinical Features of the Divisions of Labor

	First Stage		Second Stage
Feature	***Preparatory Division***	***Dilatational Division***	***Pelvic Division***
Functions	Contractions coordinated, cervix prepared	Cervix actively dilating	Pelvis negotiated; mechanisms of labor; fetal descent; birth
Interval	Latent phase	Acceleration and phase of maximum slope	Deceleration phase and maximum descent
Measurement	Elapsed duration	Linear rate of dilatation	Linear rate of descent
Diagnosable disorders	Prolonged latent phase	Protracted dilatation; protracted descent	Prolonged deceleration; secondary arrest of dilatation; arrest of descent; failure of descent

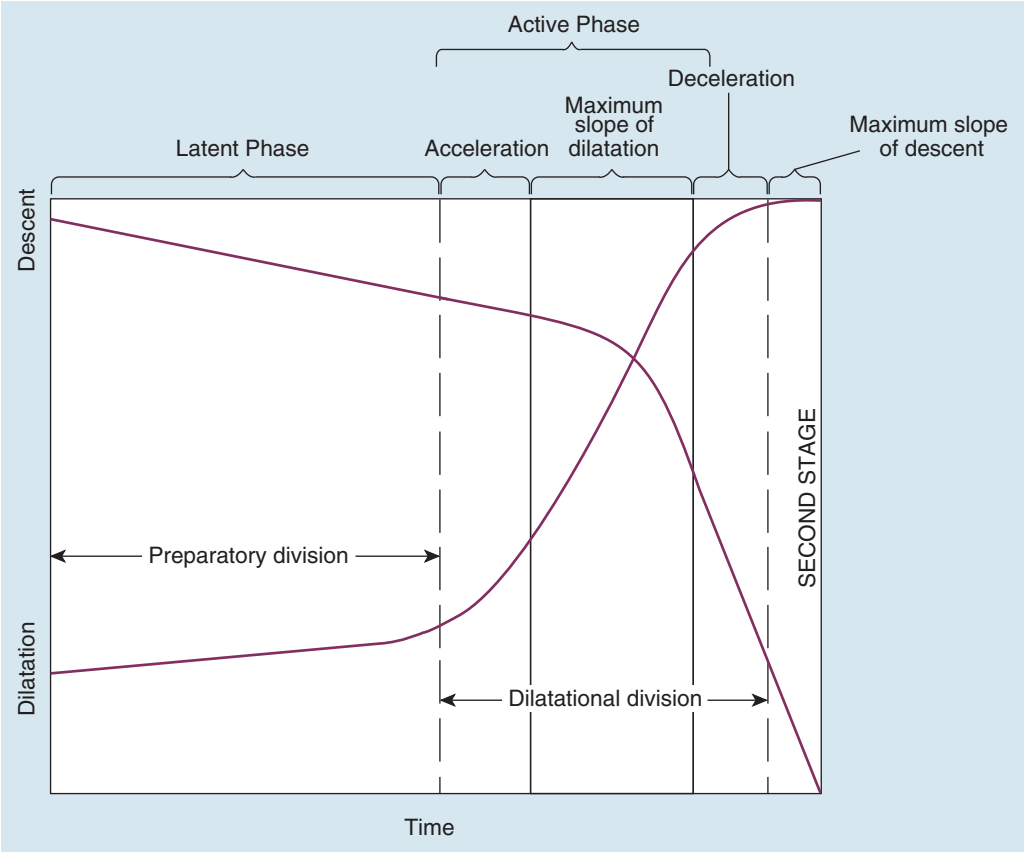

FIGURE 15.12 Divisions of labor.

- Bottom line numbered to represent the number of hours of labor
- Right side numbered from −4 to +4 (representing the station of the presenting part)

After each cervical examination, cervical dilatation and fetal descent are plotted on the graph. The pattern of cervical dilatation usually plots as an S-shaped curve. The fetal descent pattern forms a downward curve. Both lines cross at the point of maximum cervical dilatation. A typical labor graph is shown in Figure 15.13. You may need to remind women that assessments of cervical dilation are subjective so one examiner may report a different finding from another (Buchmann & Libhaber, 2007).

First Stage

Three separate divisions mark the first stage of labor: the latent, the active, and the transition phase.

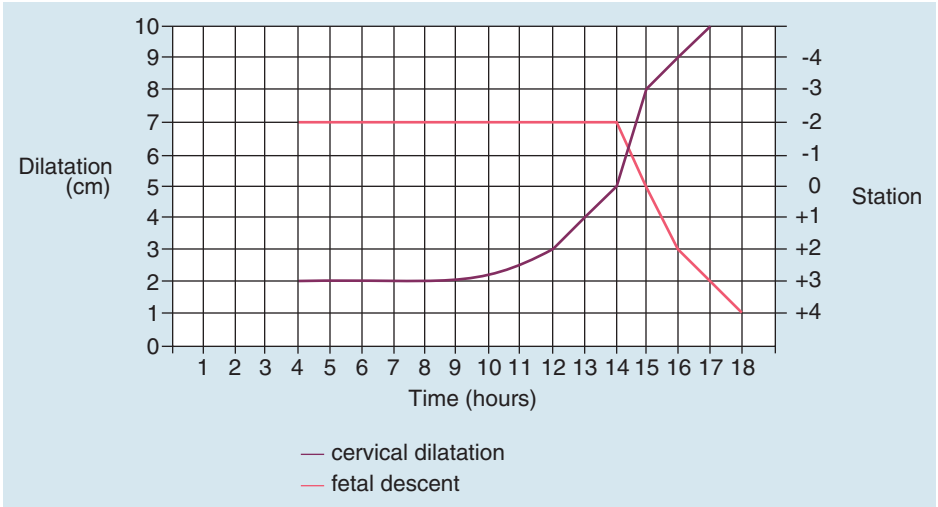

FIGURE 15.13 Normal labor graph. Fetal descent and cervical dilatation are occurring at the same time.

Latent Phase

The latent or preparatory phase begins at the onset of regularly perceived uterine contractions and ends when rapid cervical dilatation begins. Contractions during this phase are mild and short, lasting 20 to 40 seconds. Cervical effacement occurs, and the cervix dilates from 0 to 3 cm. The phase lasts approximately 6 hours in a nullipara and 4.5 hours in a multipara. A woman who enters labor with a "nonripe" cervix will have a longer than usual latent phase. Although women should not be denied analgesia at this point, analgesia given too early may prolong this phase. Measuring the length of the latent phase is important because a reason for a prolonged latent phase is cephalopelvic disproportion (a disproportion between the fetal head and pelvis) that could require a cesarean birth.

In a woman who is psychologically prepared for labor and who does not tense at each tightening sensation in her abdomen, latent phase contractions cause only minimal discomfort. A woman can (and should) continue to walk about and make preparations for birth, such as doing last-minute packing for her stay at the hospital or birthing center, preparing older children for her departure and the upcoming birth, or giving instructions to the person who will take care of them while she is away. In a birth setting, allow her to continue to be active (Greulich & Tarrant, 2007). Encourage her to continue or begin alternative methods of pain relief such as aromatherapy or distraction (Smith et al., 2007).

Active Phase

During the active phase of labor, cervical dilatation occurs more rapidly, increasing from 4 to 7 cm. Contractions grow stronger, lasting 40 to 60 seconds, and occur approximately every 3 to 5 minutes. This phase lasts approximately 3 hours in a nullipara and 2 hours in a multipara. Show (increased vaginal secretions) and perhaps spontaneous rupture of the membranes may occur during this time. This phase can be a difficult time for a woman because contractions grow strong, last longer, and begin to cause true discomfort. It is also an exciting time, because something dramatic is suddenly happening. It can be a frightening time as a woman realizes labor is truly progressing and her life is about to change forever.

The active stage of labor in a Friedman graph can be subdivided into the following periods: acceleration (4 to 5 cm) and maximum slope (5 to 9 cm). During the period of maximum slope, cervical dilatation proceeds at its most rapid pace, averaging 3.5 cm per hour in nulliparas and 5 to 9 cm per hour in multiparas. Encourage women to remain active participants in labor by assuming what position is most comfortable for them during this time (Albers, 2007).

Transition Phase

During the **transition** phase, contractions reach their peak of intensity, occurring every 2 to 3 minutes with a duration of 60 to 90 seconds and causing maximum cervical dilatation of 8 to 10 cm. If the membranes have not previously ruptured or been ruptured by amniotomy, they will rupture as a rule at full dilatation (10 cm). If it has not previously occurred, show occurs as the last of the mucus plug from the cervix is released. By the end of this phase, both full dilatation (10 cm) and complete cervical effacement (obliteration of the cervix) have occurred.

During this phase, a woman may experience intense discomfort, so strong that it is accompanied by nausea and vomiting. Because of the intensity and duration of the contractions, a woman may also experience a feeling of loss of control, anxiety, panic, or irritability. Sensations may be so intense it may seem as though labor has taken charge of her. A few minutes before, she enjoyed having her forehead wiped with a cool cloth. Now she may knock a husband's hand away. A moment before, she enjoyed having her partner rub her back. Now she may resist being touched and push that person away. Her focus is entirely inward on the task of birthing her baby.

The peak of the transition phase can be identified by a slight slowing in the rate of cervical dilatation when 9 cm is reached (termed deceleration on a labor graph). As a woman reaches the end of this stage at 10 cm of dilatation, a new sensation (i.e., an irresistible urge to push) occurs.

Second Stage

The second stage of labor is the period from full dilatation and cervical effacement to birth of the infant; with uncomplicated birth, this stage takes about 1 hour (Archie, 2007). A woman feels contractions change from the characteristic crescendo–decrescendo pattern to an overwhelming, uncontrollable urge to push or bear down with each contraction as if to move her bowels. She may experience momentary nausea or vomiting because pressure is no longer exerted on her stomach as the fetus descends into the pelvis. She pushes with such force that she perspires and the blood vessels in her neck may become distended.

As the fetal head touches the internal side of the perineum, the perineum begins to bulge and appears tense. The anus may become everted, and stool may be expelled. As the fetal head pushes against the perineum, the vaginal introitus opens and the fetal scalp appears at the opening to the vagina. At first, the opening is slitlike, then becomes oval, and then circular. The circle enlarges from the size of a dime, then a quarter, then a half-dollar. This is called **crowning**.

It takes a few contractions of this new type for a woman to realize everything is still all right, just different, and to appreciate that it feels good, not frightening, to push with contractions. In fact, the need to push becomes so intense that she cannot stop herself. She barely hears the conversation in the room around her. All of her energy, her thoughts, her being are directed toward giving birth. As she pushes, using her abdominal muscles to aid the involuntary uterine contractions, the fetus is pushed out of the birth canal.

Third Stage

The third stage of labor, the placental stage, begins with the birth of the infant and ends with the delivery of the placenta. Two separate phases are involved: placental separation and placental expulsion.

After the birth of an infant, a uterus can be palpated as a firm, round mass just inferior to the level of the umbilicus. After a few minutes of rest, uterine contractions begin again, and the organ assumes a discoid shape. It retains this new shape until the placenta has separated, approximately 5 minutes after the birth of the infant.

Placental Separation

As the uterus contracts down on an almost empty interior, there is such a disproportion between the placenta and the contracting wall of the uterus that folding and separation of the placenta occur. Active bleeding on the maternal surface of the placenta begins with separation; this bleeding helps to separate the placenta still farther by pushing it away from its attachment site. As separation is completed, the placenta sinks to the lower uterine segment or the upper vagina.

The following signs indicate that the placenta has loosened and is ready to deliver:

- Lengthening of the umbilical cord
- Sudden gush of vaginal blood
- Change in the shape of the uterus
- Firm contraction of the uterus
- Appearance of the placenta at the vaginal opening

If the placenta separates first at its center and last at its edges, it tends to fold onto itself like an umbrella and presents at the vaginal opening with the fetal surface evident. Appearing shiny and glistening from the fetal membranes, this is called a *Schultze* presentation. Approximately 80% of placentas separate and present in this way. If, however, the placenta separates first at its edges, it slides along the uterine surface and presents at the vagina with the maternal surface evident. It looks raw, red, and irregular, with the ridges or cotyledons that separate blood collection spaces showing; this is called a *Duncan* presentation. A simple trick of remembering the presentations is associating "shiny" with Schultze (the fetal membrane surface) and "dirty" with Duncan (the irregular maternal surface) (Fig. 15.14).

Bleeding occurs as part of the normal consequence of placental separation, before the uterus contracts sufficiently to seal maternal sinuses. The normal blood loss is 300 to 500 mL.

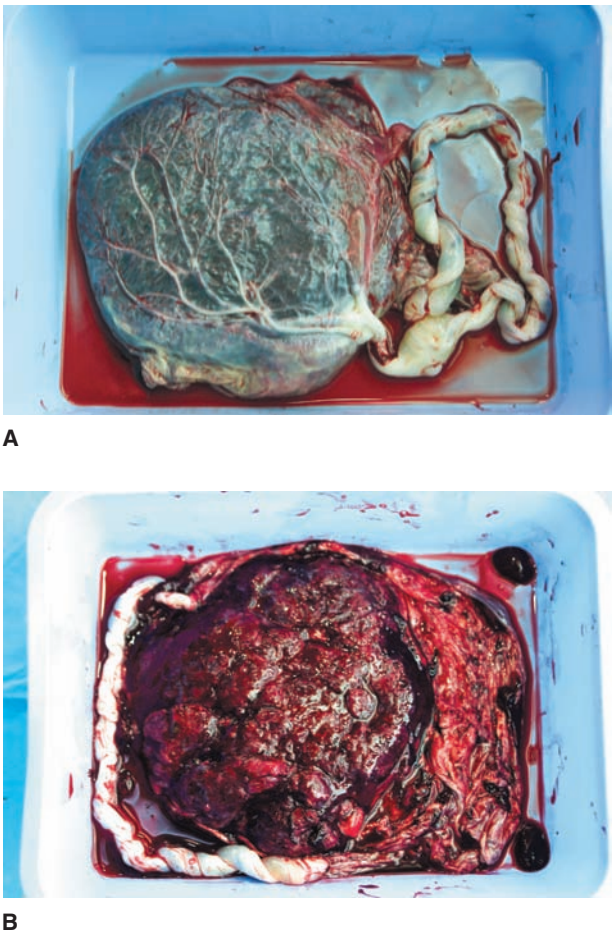

FIGURE 15.14 Fetal (**A**) and maternal (**B**) surface of the placenta. (Photographs by Joe Mitchell.)

Placental Expulsion

After separation, the placenta is delivered either by the natural bearing-down effort of the mother or by gentle pressure on the contracted uterine fundus by a physician or nurse-midwife (Credé's maneuver). Pressure must never be applied to a uterus in a noncontracted state, because doing so may cause the uterus to evert and hemorrhage. This is a grave complication of birth, because the maternal blood sinuses are open and gross hemorrhage could occur (Poggi, 2007). If the placenta does not deliver spontaneously, it can be removed manually. With delivery of the placenta, the third stage of labor is complete.

For most health care providers in the United States, a placenta has little importance or meaning after its work of oxygenation is done and it is delivered. For many women, however, the placenta has continuing importance. For this reason, women may ask if they can take it home with them. In several Asian and Native American cultures, women bury the placenta to ensure that the child will continue to be healthy. In some parts of China, the placenta is cooked and eaten to ensure the continued health of the mother. Ask parents whether saving the placenta is important to them before it is destroyed. Be certain when supplying placentas to women to take home with them that you respect standard infection precautions and hospital policy.

In major health centers, women may be asked to donate their newborn's placenta so blood can be removed and banked to be available for bone marrow or stem cell transplantation (Scott, 2007). Placental membranes can be salvaged to be used as temporary coverings for burns.

MATERNAL AND FETAL RESPONSES TO LABOR

Because labor is such an intense process, it has systemic physiologic effects on both a woman and her fetus.

Physiologic Effects of Labor on a Woman

Labor is a local process that involves the abdomen and reproductive organs, but its intensity is so great that almost all body systems are affected by it.

Cardiovascular System

Labor involves strenuous work and effort and requires a response from the cardiovascular system.

Cardiac Output. Each contraction greatly decreases blood flow to the uterus because the contracting uterine wall puts

pressure on the uterine arteries. This increases the amount of blood that remains in a woman's general circulation, leading to an increase in peripheral resistance, which in turn results in an increase in systolic and diastolic blood pressure. In addition, the work of pushing during labor may increase cardiac output by as much as 40% to 50% above the prelabor level.

The average blood loss with birth (300 to 500 mL) is not detrimental to most women because of the blood volume increase that occurred during pregnancy and may actually play an advantageous role by reducing blood volume to prepregnancy levels. Immediately after birth, with the weight and pressure removed from the pelvis, blood from the peripheral circulation floods into the pelvic vasculature, momentarily dropping blood pressure in the vena cava. The body quickly compensates for this by sending a heavy bolus of blood to the heart, raising cardiac output to about 80% above prelabor levels. Cardiac output then gradually decreases from this high level, within the first hour after birth, by about 50%. An average woman's heart adjusts well to these sudden changes. If she has a cardiac problem, however, these sudden hemodynamic changes can have implications for her health (see Chapter 25).

Blood Pressure. With the increased cardiac output caused by contractions during labor, systolic blood pressure rises an average of 15 mm Hg with each contraction. Higher increases could be a sign of pathology. When a woman lies in a supine position and pushes during the second stage of labor, pressure of the uterus on the vena cava causes her blood pressure to drop precipitously, leading to hypotension. An upright or side-lying position during the second stage of labor not only makes pushing more effective but also can help avoid such a problem (Gupta, Hofmeyr, & Smyth, 2009).

Hemopoietic System

The major change in the blood-forming system that occurs during labor is the development of leukocytosis, or a sharp increase in the number of circulating white blood cells, possibly as a result of stress and heavy exertion. At the end of labor, the average woman has a white blood cell count of 25,000 to 30,000 cells/mm^3, compared with a normal count of 5000 to 10,000 cells/mm^3.

Respiratory System

Whenever there is an increase in cardiovascular parameters, the body responds by increasing the respiratory rate to supply additional oxygen. Total oxygen consumption increases by about 100% during the second stage of labor. Women adjust well to this change, which is comparable to that of a person performing a strenuous exercise such as running. It can result in hyperventilation. Using appropriate breathing patterns during labor can help avoid severe hyperventilation.

Temperature Regulation

The increased muscular activity associated with labor can result in a slight elevation (1° F) in temperature. Diaphoresis occurs with accompanying evaporation to cool and limit excessive warming.

Fluid Balance

Because of the increase in rate and depth of respirations (which causes moisture to be lost with each breath) and diaphoresis, insensible water loss increases during labor. Fluid balance is further affected if a woman eats nothing but sips of fluid or ice cubes or hard candy. Although not a concern in usual labor, the combination of increased fluid losses and decreased oral intake may make intravenous fluid replacement necessary if labor becomes prolonged.

Urinary System

With a decrease in fluid intake during labor and the increased insensible water loss, the kidneys begin to concentrate urine to preserve both fluid and electrolytes. Specific gravity may rise to a high normal level of 1.020 to 1.030. It is not unusual for protein (trace to 1+) to be evident in urine because of the breakdown of protein caused by the increased muscle activity. Pressure of the fetal head as it descends in the birth canal against the anterior bladder reduces bladder tone or the ability of the bladder to sense filling. Therefore, unless the woman is asked to void approximately every 2 hours during labor, overfilling may occur, possibly decreasing bladder tone in the postpartal period.

Musculoskeletal System

All during pregnancy, relaxin, an ovarian-released hormone, has acted to soften the cartilage between bones. In the week before labor, considerable additional softening causes the symphysis pubis and the sacral/coccyx joints to become even more relaxed and movable, allowing them to stretch apart to increase the size of the pelvic ring by as much as 2 cm. A woman may report this increased pubic flexibility as increased back pain or irritating, nagging pain at the pubis as she walks or turns in labor.

Gastrointestinal System

The gastrointestinal system becomes fairly inactive during labor, probably because of the shunting of blood to more life-sustaining organs and also because of pressure on the stomach and intestines from the contracting uterus. Digestive and emptying time of the stomach become prolonged. Some women experience a loose bowel movement as contractions grow strong, similar to what they may experience with menstrual cramps.

Neurologic and Sensory Responses

The neurologic responses that occur during labor are responses related to pain (increased pulse and respiratory rate). Early in labor, the contraction of the uterus and dilatation of the cervix cause the discomfort. This pain is registered at uterine and cervical nerve plexuses (at the level of the 11th and 12th thoracic nerves). At the moment of birth, the pain is centered on the perineum as it stretches to allow the fetus to move past it. Perineal pain is registered at S2 to S4 nerves.

Psychological Responses of a Woman to Labor

Labor can lead to emotional distress because it represents the beginning of a major life change for a woman and her partner.

BOX 15.3 ✻ Focus on Family Teaching

Admission Procedures for a Woman in Labor

Q. Celeste Bailey asks you, "What will happen when I arrive at a birthing center?"

A. Every setting differs, but actions you can expect include:

- Orientation to a birthing room
- Baseline assessment of your temperature, pulse, respirations, and blood pressure
- Interview to obtain your pregnancy history
- Brief physical examination
- Assessment of fetal heart rate
- Vaginal examination
- Urine and necessary blood samples obtained
- Explanation of fetal or uterine monitoring equipment if this will be used and connection of this equipment

Even for the most patient woman, pain reduces the ability to cope and may make her short-tempered or quick to criticize things around her. Admitting her quickly to a birthing room, an environment free from outside interference, can help her begin to control her breathing patterns and reduce the pain of early contractions, as well as begin to organize coping strategies (Box 15.3).

Fatigue

By the time a date of birth approaches, a woman is generally tired from the burden of carrying so much extra weight. In addition, most women do not sleep well during the last month of pregnancy (Beebe & Lee, 2007). They have a backache in a side-lying position; they turn on their back and a fetus kicks and wakens them; they turn to their side and their back aches again; and so on. Sleep hunger from this discomfort can make it difficult for them to perceive situations clearly or to adjust rapidly to new situations. It can make a little deficiency such as a wrinkled sheet appear as a threatening discrepancy in their care. It can make the process of labor loom as an overwhelming, unendurable experience unless they have competent support people with them.

Fear

Women appreciate a review of the labor process early in labor as a reminder that childbirth is not a strange, bewildering event but a predictable and well-documented one.

Being taken by surprise—labor moving faster or slower than the woman thought it would or contractions harder and longer than she remembers from last time—can lead a woman to feel out of control and increase the pain she experiences (Box 15.4). It may make her begin to worry that her infant may die or be born with an abnormality; it may make her afraid that she will not meet her own behavioral expectations. Explain that labor is predictable, but also variable, to limit this kind of fear. Be sure to explain that contractions last a certain length and reach a certain firmness but always have a pain-free rest period in between.

BOX 15.4 ✻ Focus on Evidence-Based Practice

Is the average woman worried or fearful of labor and birth?

Even though a woman attends a preparation for childbirth class, a first labor and birth are still unknown experiences for her. To discover how many women fear beginning labor, researchers asked women attending a prenatal clinic if they were fearful of labor and birth early in pregnancy (about 16 weeks) and again late in pregnancy (about 32 weeks). In this study, 7.6% of women said they feared childbirth early in pregnancy; 7.4% feared this late in pregnancy. Those most apt to feel fearful were those without solid support people around them (Laursen et al., 2008).

In a second but similar study, women attending a prenatal clinic were asked to fill out a questionnaire at 37 to 38 weeks of pregnancy and then again 6 weeks after birth that asked them to report their reaction to anticipating birth or their impressions of their labor and birth.

Women who were well prepared anticipated *"quick," "easy," "smooth,"* or *"short" labors*. When labor and birth went as planned or anticipated, women reported the experience as *"wonderful," "like a dream," "perfect," "enjoyable and fulfilling," "incredibly empowering,"* and *"amazing."* In contrast, women who were not that well prepared anticipated labor and birth as being scary, potentially dangerous, and stressful. When labor did not go as planned, respondents wrote of feeling *"worried about being harmed," "nervous at the thought of having no control,"* and *"fearful for my safety."* An important factor in making labor and birth a positive experience was laboring in a relaxed setting and being supported by a knowledgeable health care professional (Baves, Fenwick, & Hauck, 2008).

Could you use these studies to guide actions when caring for women during labor and birth?

Sources: Laursen, M., et al. (2008). Fear of childbirth: predictors and temporal changes among nulliparous women in the Danish National Birth Cohort. *BJOG: An International Journal of Obstetrics and Gynaecology, 115*(3), 354–360; and Baves, S., Fenwick, J., & Hauck, Y. A. (2008). Qualitative analysis of women's short accounts of labour and birth in a Western Australian public tertiary hospital. *Journal of Midwifery and Women's Health, 53*(1), 53–61.

Cultural Influences

Cultural factors can strongly influence a woman's experience of labor. In the past, American women were accustomed to following hospital procedures and the medical model of care; therefore, they followed instructions during labor with few questions. Today, women are educated to help plan their care. In addition, every woman responds to cultural cues in some way. This makes her response to pain, her choice of nourishment, her preferred birthing position, the proximity and involvement of a support person, and customs related to the immediate postpartal period individualized (Price, Noseworthy, & Thornton, 2007).

To make labor a positive experience, be prepared to adapt your care to the woman's specific circumstances. A woman may have traditions that run counter to American hospital protocols. Address these differences, and make arrangements to accommodate her beliefs or customs if possible (e.g., providing warm food or fluids during labor, saving the placenta for the mother to take home). If the woman is not proficient in English, arranging for an interpreter or working closely with a family member who can interpret is important.

Physiologic Effects of Labor to a Fetus

Although a fetus is basically a passive participant in labor, the pressure and circulatory changes that occur with contractions cause detectable physiologic changes.

Neurologic System

Uterine contractions exert pressure on the fetal head, so the same response that is involved with any instance of increased intracranial pressure occurs. The fetal heart rate (FHR) decreases by as much as 5 beats per minute (bpm) during a contraction, as soon as contraction strength reaches 40 mm Hg. This decrease appears on a fetal heart monitor as a normal or early deceleration pattern.

Cardiovascular System

The ability to respond to cardiovascular changes is usually mature enough that the fetus is unaffected by the continual variations of heart rate that occur with labor—a slight slowing and then a return to normal (baseline) levels. During a contraction, the arteries of the uterus are sharply constricted and the filling of cotyledons almost completely halts. The amount of nutrients, including oxygen, exchanged during this time is reduced, causing a slight but inconsequential fetal hypoxia. Increased intracranial pressure caused by uterine pressure on the fetal head serves to keep circulation from falling below normal during the duration of a contraction.

Integumentary System

The pressure involved in the birth process is often reflected in minimal petechiae or ecchymotic areas on a fetus (particularly the presenting part). There may also be edema of the presenting part (caput succedaneum).

Musculoskeletal System

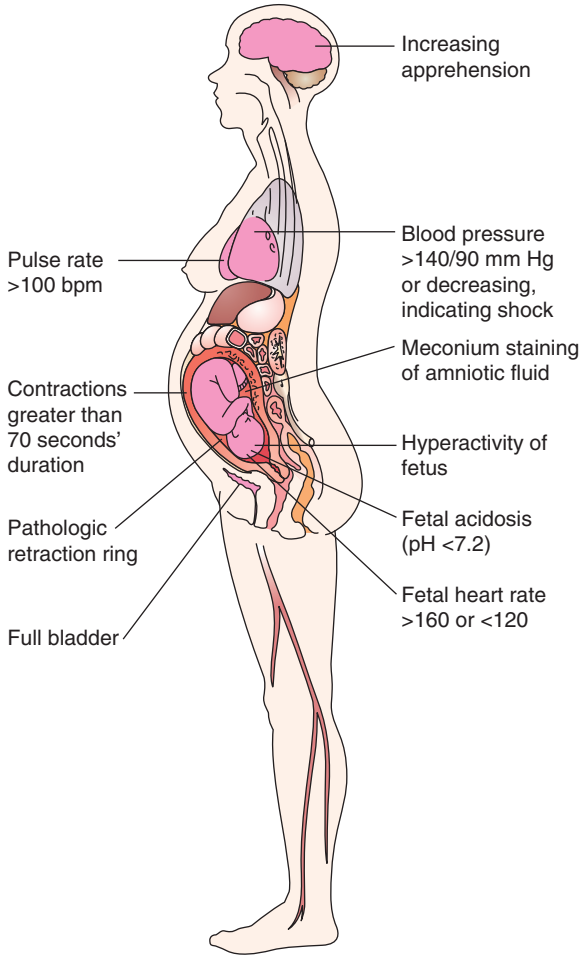
The force of uterine contractions tends to push a fetus into a position of full flexion, the most advantageous position for birth.

Respiratory System

The process of labor appears to aid in the maturation of surfactant production by alveoli in the fetal lung. The pressure applied to the chest from contractions and passage through the birth canal helps to clear it of lung fluid. For this reason, an infant born vaginally is usually able to establish respirations more easily than a fetus born by cesarean birth.

Box 15.5 Assessment

Assessing for Danger Signs of Labor



Danger Signs of Labor

Wide variation exists among individuals in their patterns of labor contractions and in maternal responses to labor and birth. Certain signs, however, indicate that the course of events is deviating from normal. These signs, both fetal and maternal, are described in Box 15.5. Nursing care of a woman who is experiencing these signs or has developed a complication during labor or birth is addressed in Chapter 23.

Maternal Danger Signs

High or Low Blood Pressure. Normally, a woman's blood pressure rises slightly in the second (pelvic) stage of labor because of her pushing effort. A systolic pressure greater than 140 mm Hg and a diastolic pressure greater than 90 mm Hg, or an increase in the systolic pressure of more than 30 mm Hg or in diastolic pressure of more than 15 mm Hg (the basic criteria for pregnancy-induced hypertension), should be reported. Just as important to report is a falling blood pressure, because it may be the first sign of intrauterine hemorrhage. A

falling blood pressure is often associated with other clinical signs of shock, such as apprehension, increased pulse rate, and pallor.

Abnormal Pulse. Most pregnant women have a pulse rate of 70 to 80 bpm. This rate normally increases slightly during the second stage of labor because of the exertion involved. A maternal pulse rate greater than 100 bpm during the normal course of labor is unusual and should be reported. It may be another indication of hemorrhage.

Inadequate or Prolonged Contractions. Uterine contractions normally become more frequent, intense, and longer as labor progresses. If they become less frequent, less intense, or shorter in duration, this may indicate uterine exhaustion (inertia). If this problem cannot be corrected, a cesarean birth may be necessary.

A period of relaxation must be present between contractions so that the intervillous spaces of the uterus can fill and maintain an adequate supply of oxygen and nutrients for the fetus. As a rule, uterine contractions lasting longer than 70 seconds should be reported, because contractions of this length may begin to compromise fetal well-being by interfering with adequate uterine artery filling.

Pathologic Retraction Ring. An indentation across a woman's abdomen, where the upper and lower segments of the uterus join, may be a sign of extreme uterine stress and possible impending uterine rupture. For this reason, it is important to observe the contours of a woman's abdomen periodically during labor. Fetal heartbeat auscultation automatically provides a regular opportunity to assess a woman's abdomen. If an electronic monitor is in place, it is necessary to make this observation deliberately.

Abnormal Lower Abdominal Contour. If a woman has a full bladder during labor, a round bulge on her lower anterior abdomen may appear. This is a danger signal for two reasons: first, the bladder may be injured by the pressure of a fetal head; second, the pressure of the full bladder may not allow the fetal head to descend. To avoid a full bladder, women need to try to void about every 2 hours during labor.

Increasing Apprehension. Warnings of psychological danger during labor are as important to consider in assessing maternal well-being as are physical signs. A woman who is becoming increasingly apprehensive despite clear explanations of unfolding events may only be approaching the second stage of labor. She may, however, not be "hearing" because she has a concern that has not been met. Using an approach such as, "You seem more and more concerned. Could you tell me what is worrying you?" may be helpful. Increasing apprehension also needs to be investigated for physical reasons, because it can be a sign of oxygen deprivation or internal hemorrhage.

Fetal Danger Signs

High or Low Fetal Heart Rate. As a rule, an FHR of more than 160 bpm (fetal tachycardia) or less than 110 bpm (fetal bradycardia) is a sign of possible fetal distress. An equally important sign is a late or variable deceleration pattern (described later) on a fetal monitor. The FHR may return to a normal range in between these irregular patterns, giving a false sense of security if FHR is assessed only between contractions.

Meconium Staining. Meconium staining, a green color in the amniotic fluid, is not always a sign of fetal distress but is highly correlated with its occurrence. It reveals that the fetus has had loss of rectal sphincter control, allowing meconium to pass into the amniotic fluid. It may indicate that a fetus has or is experiencing hypoxia, which stimulates the vagal reflex and leads to increased bowel motility. Although meconium staining may be normal in a breech presentation, because pressure on the buttocks causes meconium loss, it should always be reported immediately so that its cause can be investigated.

Hyperactivity. Ordinarily, a fetus is quiet and barely moves during labor. Fetal hyperactivity may be a sign that hypoxia is occurring, because frantic motion is a common reaction to the need for oxygen.

Oxygen Saturation. If a fetus is assessed for oxygen saturation level by a catheter inserted next to the cheek, a low oxygen saturation level (under 40%) or if fetal blood was obtained by scalp puncture, the finding of acidosis (blood pH <7.2) suggests that fetal well-being is becoming compromised. Oxygen saturation in a fetus is normally 40% to 70%.

✔ Checkpoint Question 15.3

Suppose Celeste is having long and hard uterine contractions. What length of contraction would you report as abnormal?

a. Any length over 30 seconds.
b. A contraction over 70 seconds in length.
c. A contraction that peaks at 20 seconds.
d. A contraction shorter than 60 seconds.

MATERNAL AND FETAL ASSESSMENT DURING LABOR

Nursing assessment is instrumental to keep women safe during labor.

Immediate Assessment of a Woman in Stage 1

Several immediate assessment measures are necessary to safeguard maternal and fetal health when a woman first arrives at a birthing facility. Encourage every woman to bring a support person with her into labor (Hodnett et al., 2009). After she and her support person are oriented to the area, focus on obtaining vital assessment data.

Initial Interview and Physical Examination

Important data that need to be obtained include a description of labor thus far, the woman's general physical condition, and her preparedness for labor and birth.

Ask about the following areas:

- Expected date of birth
- Frequency, duration, and intensity of contractions
- Amount and character of show

- Whether rupture of membranes has occurred
- Time the woman last ate
- Any known drug allergies
- Past pregnancy and previous pregnancy history
- Her birth plan or what individualized measures she has planned, such as no analgesia or who will cut the umbilical cord

Assess:

- Vital signs—temperature, pulse, respirations, and blood pressure (assessed between contractions)
- Contractions (frequency, duration and intensity)
- Her preparedness and readiness for labor

This amount of information is scant but helps to establish whether the woman is in active labor and needs immediate preparation for birth or whether she has arrived at the birthing setting at an early stage of labor and therefore can benefit most from paced interventions.

Detailed Assessment During the First Stage of Labor

If the woman is in active labor, the history taken on arrival may be the only history obtained until after her baby is born. If birth is not imminent, obtain a more extensive history and physical examination.

History

The full history should include a review of a woman's pregnancy, including both physical and psychological events, and a review of past pregnancies, her general health, and family medical information—all data necessary to plan nursing care.

Performing a detailed interview of a woman in labor can be difficult because of the constant interruptions caused by labor contractions. Be patient. Remember that the longest contraction is rarely more than 60 seconds. If a woman concentrates so intently on a breathing exercise she completely forgets a question asked just before a contraction, repeat the question as the contraction subsides, as if it had not been asked before, or as if it is no trouble to ask it again.

Current Pregnancy History. Important information needed for a complete history includes documentation of gravida and para status; a description of this pregnancy (planned or not, pattern and place of prenatal care, adequacy of nutrition, whether any complication such as spotting, falls, hypertension of pregnancy, infection, or alcohol or drug ingestion has occurred); plans for labor (does she want medication for pain, will she use breathing exercises, will she have a support person with her); and future child care (will she breastfeed or formula feed, has she chosen a pediatrician).

Past Pregnancy History. Document prior pregnancies, including number, dates, types of birth, any complications, and outcomes, including sex and birth weights of children. What is the current health status of the children?

Past Health History. Document any previous surgeries (surgical adhesions might interfere with free fetal passage); heart disease or diabetes (special precautions are required during labor and birth); anemia (blood loss at birth may be more important than it is usual); tuberculosis (lung lesions may be reactivated at birth by changes in lung contour); kidney disease or hypertension (blood pressure must be monitored even more carefully than usual); or if she has ever had a sexually transmitted infection such as herpes (the infant may be exposed to the disease by vaginal contact if the disease is still active). Determine also whether a woman's lifestyle places her at high risk for prescription or nonprescription drug use or human immunodeficiency virus (HIV) exposure.

Family Medical History. Ask if any family member is cognitively challenged or has a condition such as heart disease, a blood dyscrasia, diabetes, kidney disease, cancer, allergies, seizures, or a congenital disorder. Adequate preparation can then be made for a child who might have special needs.

Physical Examination

After history taking, a woman receives a thorough physical examination, including a pelvic examination, to confirm the presentation and position of the fetus and the stage of cervical dilatation.

Physical assessment during labor begins, as does all physical assessment, with the woman's overall appearance: Does she appear tired? Pale? Ill? Frightened? Is there obvious edema or dehydration? Does she have open lesions anywhere? Be prepared to adapt further examination techniques to a woman's stage of labor, frequency of contraction, and labor progression.

Palpate for enlargement of lymph nodes to detect the possibility of infection. Inspect the mucous membrane of the mouth and the conjunctiva of the eyes for color. Does the color (paleness) suggest anemia? What is the condition of the woman's teeth? Are there any caries? Do any teeth appear abscessed (such a condition needs to be documented because it might account for a postpartal fever)? Examine the outer and inner surfaces of her lips carefully. Does she have herpes lesions (pinpoint vesicles on an erythematous base)? Mothers with active lesions, regardless of the lesion site, should use care when handling their infants, such as ensuring that they wash their hands before touching the infant. Either the woman or family members with oral herpetic lesions should avoid kissing the newborn. Breastfeeding is encouraged even if the woman is taking an antiviral drug as long as there are no lesions on the breasts (Aziz & Cohen, 2007).

Assess lungs to be certain they are clear to auscultation. Listen for normal heart sounds and rhythms. Many pregnant women at term have a grade II to III systolic ejection murmur because of the extra volume of blood that must cross the heart valves. Inspect and palpate her breasts. Are they free of cysts and lumps? Mark the chart of a woman who has a palpable mass in her breasts for re-examination after labor and birth. This is probably an enlarged milk gland but needs further evaluation.

Abdominal Assessment. Assessing a woman's abdomen is important to estimate fetal size by fundal height (should be at the level of the xiphoid process at term). Palpate and percuss the bladder area (over the symphysis pubis) to detect a full bladder. Assess for abdominal scars to reveal previous abdominal or pelvic surgery that could have left adhesions.

Finally, inspect lower extremities for skin turgor to assess hydration, and also for edema and varicose veins. Women

with large varicosities are more prone to thrombophlebitis after birth than other women. Severe edema suggests hypertension of pregnancy. A blood pressure of 140/90 mm Hg or higher confirms this.

Leopold's Maneuvers

Leopold's maneuvers are a systematic method of observation and palpation to determine fetal presentation and position. Steps for this are described in Box 15.6.

Assessing Rupture of Membranes

One of every four labors begins with spontaneous rupture of the fetal membranes. When this occurs, a woman feels a sudden gush of amniotic fluid from her vagina. This is a startling sensation because it feels as if she has lost bladder control. She may feel embarrassed before she realizes the warm fluid on her perineum and legs is not urine but a sudden announcement that labor is beginning. In other women, rupture of membranes is subtle, occurring as a slow loss of fluid. When this happens, there may be a question of whether the membranes have ruptured.

A vaginal examination using a sterile speculum usually reveals whether amniotic fluid is present in the vagina. After vaginal secretions are obtained (usually with the use of a sterile, cotton-tipped applicator), test them with a strip of Nitrazine paper. Vaginal secretions are usually acid; amniotic fluid, in contrast, is alkaline. If amniotic fluid has passed through the vagina recently, the pH of the vaginal fluid will probably be alkaline (>6.5) when tested by Nitrazine paper (appears blue-green or gray to deep blue). A false reading may occur in a woman with intact membranes who has a heavy, bloody show, because blood is also alkaline. An additional test is a fern test (examination of vaginal secretions under a microscope). Because of its high estrogen content, amniotic fluid will show a fern pattern (see Chapter 5, Fig. 5.14) when dried and examined in this way; urine will not.

If the woman's membranes ruptured at home, ask her to describe the color of the amniotic fluid. It should be as clear as water. Yellow-stained fluid may indicate a blood incompatibility between mother and fetus (the amniotic fluid is bilirubin stained from the breakdown of red blood cells). Green fluid suggests meconium staining. Although meconium staining is normal in breech births because of buttocks compression, in a vertex presentation it may indicate fetal anoxia. Either way, a fetus with meconium staining needs immediate assessment to safeguard well-being. The infant will need continuing close assessment after birth to rule out possible meconium aspiration.

Vaginal Examination

A vaginal examination is necessary to determine the extent of cervical effacement and dilatation and to confirm the fetal presentation, position, and degree of descent. The technique for a vaginal examination during labor is shown in Box 15.7.

Vaginal examinations may be done either between contractions or during contractions. More of the fetal skull may be palpated during a contraction, because the cervix retracts more at that time. However, examination during a contraction is more painful and rarely is justified by the additional amount of information gained. Palpation of membranes during a contraction, when they are under pressure, may cause them to rupture.

Women are anxious to have frequent progress reports during labor, to reassure them everything is progressing well. Tell a woman immediately after an examination, therefore, about her progress. Most women are aware of dilatation but not the word "effacement." Just saying, "no further dilatation" is a depressing report. "You're not dilated a lot more, but a lot of thinning is happening and that's just as important" is the same report given in a positive manner. After finishing a vaginal examination, plot the new degree of dilatation and descent of the presenting part on a labor progress graph, as described earlier.

Do not conduct vaginal examinations in the presence of fresh bleeding, because this may indicate a placenta previa (implantation of the placenta so low in the uterus that it encroaches on the cervical os) is present. Performing a vaginal examination in this instance might tear the placenta and cause hemorrhage, resulting in danger to both mother and fetus. If in doubt, err on the side of postponing a vaginal examination.

Assessment of Pelvic Adequacy

Evaluating pelvic adequacy using internal conjugate and ischial tuberosity diameters is generally done during pregnancy, so that, by weeks 32 to 36 of pregnancy, the nurse-midwife or physician is alerted that a cephalopelvic disproportion could occur. Women with this potential problem are cautioned not to attempt a home birth or use a birthing center without nearby hospital facilities available.

Whether the pelvis is wide enough to allow the fetus to pass through the internal diameters can be reassessed during early labor. Because these procedures involve vaginal manipulation and discomfort (and the diameters obtained during pregnancy have not changed), they are not retaken if already obtained. However, if the woman did not receive prenatal care, they need to be estimated at this time. (These procedures are described in Chapter 11.)

The suprapubic angle may be estimated early in labor to determine how readily the fetal head will be born (if the angle is too steep, the fetal head can lock behind it and perineal tissue may tear during birth as the fetal head is pushed posteriorly). To estimate this angle, place the fingers vaginally and press up against the pubic arch. If the fingers cannot be separated in this position, the angle is unusually steep (less than 90 degrees).

Ultrasound

Although not routine, an ultrasound may be used at term to determine the diameters of the fetal skull and to determine presentation, presenting part, position, flexion, and degree of descent of a fetus. If a woman is going to be transported to another department to have this done, be sure someone accompanies her, so that, if labor should become more active, she can be returned quickly to the labor and birth service.

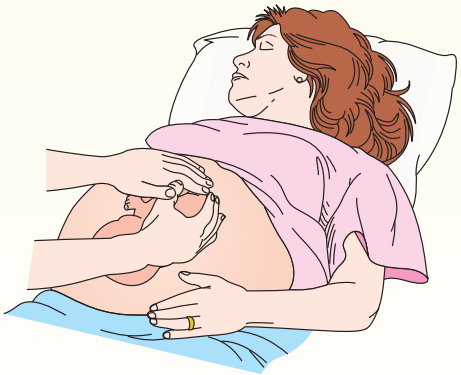
Vital Signs

Vital signs are taken at the beginning and then periodically during labor, as summarized in Table 15.5.

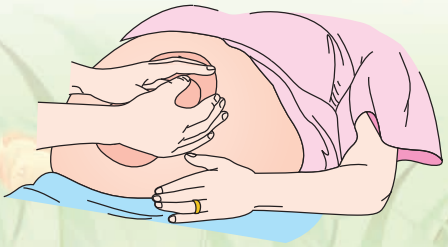
(text continues on page 372)

Box 15.6 Nursing Procedure ✻ Leopold's Maneuvers

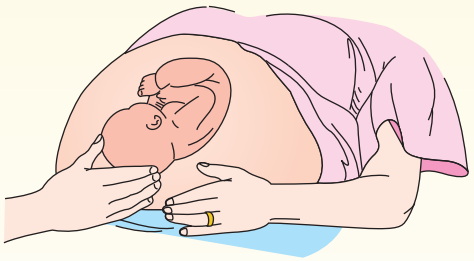
Purpose: Systematically observing and palpating the abdomen to determine fetal presentation and position

Procedure	Principle
1. Prepare the client.	
a. Explain the procedure.	**a.** Explanation reduces anxiety and enhances cooperation.
b. Instruct the client to empty her bladder.	**b.** Doing so promotes comfort and allows for more productive palpation because fetal contour will not be obscured by a distended bladder.
c. Position the woman supine with knees slightly flexed. Place a small pillow or rolled towel under one side.	**c.** Flexing the knees relaxes the abdominal muscles. Using a pillow or towel tilts the uterus off the vena cava, thus preventing supine hypotension syndrome.
d. Wash your hands using warm water.	**d.** Handwashing prevents the spread of possible infection. Using warm water aids in client comfort and prevents tightening of abdominal muscles.
e. Observe the woman's abdomen for longest diameter and where fetal movement is apparent.	**e.** The longest diameter (axis) is the length of the fetus. The location of activity most likely reflects the position of the feet.
2. Perform the first maneuver.	**2.** This maneuver determines whether fetal head or breech is in the fundus.
a. Stand at the foot of the client, facing her, and place both hands flat on her abdomen.	**a.** Proper positioning of hands ensures accurate findings.
b. Palpate the superior surface of the fundus. Determine consistency, shape, and mobility.	**b.** When palpating, a head feels more firm than a breech. A head is round and hard; the breech is less well defined. A head moves independently of the body; the breech moves only in conjunction with the body.
	


3. Perform the second maneuver.	**3.** This maneuver locates the back of the fetus.
a. Face the client and place the palms of each hand on either side of the abdomen.	**a.** Proper positioning of hands ensures accurate findings.
b. Palpate the sides of the uterus. Hold the left hand stationary on the left side of the uterus while the right hand palpates the opposite side of the uterus from top to bottom. Then hold the right hand steady, and repeat palpation using the left hand on the left side.	**b.** This method is most successful to determine the direction the fetal back is facing. One hand will feel a smooth, hard, resistant surface (the back), while on the opposite side, a number of angular nodulations (the knees and elbows of the fetus) will be felt.
	



Box 15.6 Nursing Procedure ✻ Leopold's Maneuvers (continued)

Procedure	Principle
4. Perform the third maneuver.	**4.** This maneuver determines the part of the fetus at the inlet and its mobility.
a. Gently grasp the lower portion of the abdomen just above the symphysis pubis between the thumb and index finger and try to press the thumb and finger together. Determine any movement and whether the part is firm or soft.	**a.** If the presenting part moves upward so an examiner's hands can be pressed together, the presenting part is not engaged (not firmly settled into the pelvis). If the part is firm, it is the head; if soft, then it is the breech.
	


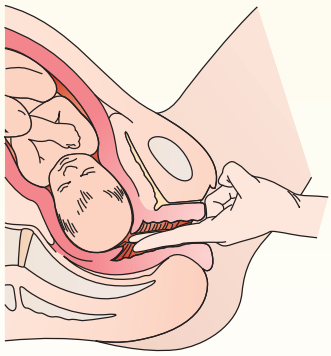
5. Perform the fourth maneuver.	**5.** This maneuver determines fetal attitude and degree of fetal extension into the pelvis; it should be done only if the fetus is in a cephalic presentation. Information about the infant's anteroposterior position may also be gained from this final maneuver.
a. Place fingers on both sides of the uterus approximately 2 inches above the inguinal ligaments, pressing downward and inward in the direction of the birth canal. Allow fingers to be carried downward.	**a.** The fingers of one hand will slide along the uterine contour and meet no obstruction, indicating the back of the fetal neck. The other hand will meet an obstruction an inch or so above the ligament—this is the fetal brow. The position of the fetal brow should correspond to the side of the uterus that contained the elbows and knees of the fetus. If the fetus is in a poor attitude, the examining fingers will meet an obstruction on the same side as the fetal back. That is, the fingers will touch the hyperextended head. If the brow is very easily palpated (as if it lies just under the skin), the fetus is probably in a posterior position (the occiput is pointing toward the woman's back).
	

Box 15.7 Nursing Procedure ✻ Vaginal Examination

Purpose: Determine cervical readiness and fetal position and presentation.

Procedure	Principle
1. Wash your hands; explain procedure to client. Provide privacy.	**1.** Handwashing helps prevent spread of microorganisms; explanations ensure client cooperation and compliance. Privacy enhances self-esteem.
2. Assess client status and adjust plan to individual client need.	**2.** Care is always individualized according to a client's needs.
3. Assemble equipment: sterile examining gloves, sterile lubricant, antiseptic solution. Ask the woman to turn onto her back with knees flexed (a dorsal recumbent position). Put on sterile examining gloves.	**3.** Organization and planning improve efficiency. Positioning in this manner allows for good visualization of perineum. Use of a sterile glove prevents contamination of birth canal.

Box 15.7 Nursing Procedure ✻ Vaginal Examination

Procedure	Principle
4. Discard one drop of clean lubricating solution and drop an ample supply on tips of gloved fingers.	**4.** Discarding the first drop ensures that quantity used will not be contaminated.
5. Pour antiseptic solution over vulva using nondominant hand.	**5.** This prevents the spread of organisms from perineum to birth canal.
6. Place nondominant hand on the outer edges of the woman's vulva and spread her labia while inspecting the external genitalia for lesions. Look for red, irritated mucous membranes; open, ulcerated sores; clustered, pinpoint vesicles.	**6.** Positioning hands in this way allows for good perineal visualization. Presence of any lesions may indicate an infection and possibly preclude vaginal birth.
7. Look for escaping amniotic fluid or the presence of umbilical cord or bleeding.	**7.** Amniotic fluid implies membranes have ruptured and umbilical cord may have prolapsed. Bleeding may be a sign of placenta previa. *Do not do a vaginal examination if a possible placenta previa is present.*
8. If there is no bleeding or cord visible, introduce your index and middle fingers of dominant hand gently into the vagina, directing them toward the posterior vaginal wall.	**8.** The posterior vaginal wall is less sensitive than the anterior wall. Stabilize the uterus by placing your nondominant hand on the woman's abdomen.
9. Touch the cervix with your gloved examining fingers.	**9.** The cervix feels like a circular rim of tissue around a center depression.
a. Palpate for cervical consistency and rate if *firm* or *soft*.	**a.** Firm is similar to the tip of a nose; soft is as pliable as an earlobe. The anterior rim is usually the last portion to thin.
b. Measure the extent of dilatation; palpate for an anterior rim or lip of cervix.	**b.** The width of the fingertip helps to estimate the degree of dilatation. An index finger averages about 1 cm; a middle finger about 1½ cm. If they can both enter the cervix, the cervix is dilated 2½ to 3 cm. If there would be room for double the width of your examining fingers in the cervix, the dilatation is about 5 to 6 cm. When the space is four times the width of your fingertips, dilatation is complete—10 cm. Measure the width of your fingertips on a centimeter scale if you are going to do a vaginal examination, so you know how wide your index and middle fingers are at the tip.
	


10. Estimate the degree of effacement.	**10.** Effacement is estimated in percentage depending on thickness. A cervix before labor is 2 to 2½ cm thick. If it is only 1 cm thick now, it is 50% effaced. If it is tissue paper thin, it is 100% effaced. With a 100% effaced cervix, dilatation is difficult to feel because the edges of the cervix are so thin.
11. Estimate whether membranes are intact.	**11.** The membranes (with a slight amount of amniotic fluid in front of the presenting part) are the shape of a watch crystal. With a contraction, they bulge forward and become prominent and can be felt much more readily.
12. Locate the ischial spines. Rate the station of the presenting part. Identify the presenting part.	**12.** Ischial spines are palpated as notches at the 4 and 8 o'clock positions at the pelvic outlet. Station is the number of centimeters above or below the spines where the presenting part is. Identifying the presenting part confirms findings obtained with Leopold's maneuvers. Differentiating a vertex from a breech may be more difficult than would first appear. A vertex has a hard, smooth surface. Fetal hair may be palpable but massed together and wet; it may be difficult to appreciate through gloves. Palpating the two fontanelles, one

Box 15.7 Nursing Procedure ✻ Vaginal Examination (continued)

Procedure	Principle
	diamond-shaped and one triangular, helps the identification. Buttocks feel softer and give under fingertip pressure. Identifying the anus may be possible because the sphincter action will "trap" the index finger.
13. Establish the fetal position.	**13.** The fontanelle palpated is invariably the posterior one because the fetus maintains a flexed position, presenting the posterior not the anterior fontanelle. In an ROA position, the triangular fontanelle will point toward the right anterior pelvic quadrant. In an LOA position, the posterior fontanelle will point toward the left anterior pelvis. In a breech presentation, the anus can serve as a marker for position. When the anus is pointing toward the left anterior quadrant of the woman's pelvis, the position is LSA.
14. Withdraw your hand. Wipe the perineum front to back to remove secretions or examining solution. Leave client comfortable and turned to side.	**14.** Use as gentle a technique with withdrawal as with insertion. Wiping front to back prevents moving rectal contamination forward to the vagina. Side-lying is the best position to prevent supine hypotension syndrome in labor.
15. Document procedure and assessment findings and how client tolerated procedure.	**15.** Documentation provides a means for communication and evaluation of care and client outcomes.

Temperature. Temperature is usually obtained every 4 hours during labor. Report a temperature greater than 37.2° C (99° F) to the attending physician or nurse-midwife, because it may indicate the development of infection. Unless there are accompanying symptoms, however, temperature elevation in a woman who is taking no fluids by mouth usually reflects dehydration. After rupture of the membranes, temperature should be taken every 2 hours, because the possibility for infection increases markedly after this time.

TABLE 15.5 ✻ Time Intervals for Nursing Interventions During First Stage of Labor

Intervention	Assessment on Admission	Latent Phase (0–3 cm)	Active Phase (4–7 cm)	Transition Phase (8–10 cm)
Assess and Record				
Temperature	X	q4hr (unless membranes are ruptured, then q2hr)	q4hr (unless membranes are ruptured, then q2hr)	q4hr (unless membranes are ruptured, then q2hr)
Pulse	X	q30–60 min	q30–60 min	q15–30 min
Respirations	X	q30–60 min	q30–60 min	q15–30 min
Blood pressure	X	q30–60 min	q30–60 min	q15–30 min
Voiding	X	q2hr	q2hr	q2hr
Fetal heart rate	X	Continuously by monitor or q30–60 min	Continuously by monitor or q15–30 min	Continuously by monitor or q15–30 min
Contractions	X	Continuously by monitor or q30–60 min	Continuously by monitor or q15–30 min	Continuously by monitor or q10–15 min
Perineum	X	q30–60 min	q30 min	q15 min
Provide				
Ambulation	X	Until membranes rupture	Until membranes rupture	
Support	X	Continuously	Continuously	Continuously

Pulse and Respiration. Pulse and respiration rate should be measured and recorded every 4 hours during labor. A woman's pulse may be rapid on admission because she is nervous and anxious. After she has become better acquainted with her surroundings and has been assured that everything is going well, her pulse usually ranges between 70 and 80 bpm. A persistent pulse rate of more than 100 bpm suggests tachycardia from dehydration or hemorrhage. Respiratory rate during labor is usually 18 to 20 breaths per minute. Do not count respirations during contractions, because women tend to breathe rapidly from pain. Conversely, if a woman is using controlled breathing to decrease pain in labor, her respirations could be abnormally slow.

Observe for hyperventilation (rapid, deep respirations). Prolonged hyperventilation leads to the "blowing off" of carbon dioxide and accompanying symptoms of dizziness and tingling of hands and feet. Rebreathing into a paper bag and reassurance help to reverse this process.

Blood Pressure. Blood pressure is usually measured and recorded every 4 hours during labor. Always measure this between contractions, both for a woman's comfort and for accuracy, because blood pressure tends to rise 5 to 15 mm Hg during a contraction. An increase in blood pressure may indicate the development of pregnancy-induced hypertension. A decrease in blood pressure or a decrease in the pulse pressure (the difference between the systolic and diastolic pressures) may indicate hemorrhage. If a woman receives an analgesic agent (such as meperidine) that tends to be hypotensive, check her blood pressure approximately 15 minutes after administration to be certain that extreme hypotension is not occurring.

Laboratory Analysis

Most women have some preliminary laboratory studies done in early labor.

Blood. Blood is drawn for hemoglobin and hematocrit, a serologic test for syphilis (VDRL), hepatitis B antibodies, and blood typing to determine a woman's baseline level of health. These findings can be used to alert the laboratory that a woman with a certain blood type is in labor and to help predict whether a blood incompatibility is likely to exist in the newborn. If a woman gives permission for human immunodeficiency (HIV) testing, blood for this will be drawn as well.

Urine. Obtain a clean-catch urine specimen and test it at the point of care for protein and glucose; then send it to the laboratory for a complete urinalysis. If a woman reports any symptoms that suggest a urinary tract infection (e.g., burning on urination, blood in urine, extreme frequency, flank pain), obtain a clean-catch specimen for culture. A woman in labor is able to void most easily if she is allowed to use a bathroom. However, if a woman has ruptured membranes, check whether she should ambulate to a bathroom until it is confirmed that the fetal head is engaged, so that gravity will not cause a prolapsed cord. A bedpan or receptacle placed on a commode allows for collection of any material passed from the vagina.

Assessment of Uterine Contractions

Uterine contractions may be monitored intermittently by a hand or continuously by an internal or external system. Most women are monitored for a short period in early labor to screen for fetal well-being. Continuing to monitor the duration, strength, and interval between contractions can aid in tracking the progress of labor, although use of extensive monitoring with low-risk women may lead to an increase in cesarean birth (Gourounti & Sandall, 2007).

Length of Contractions. To determine the length of a contraction with a monitor in place, simply observe the rhythm strip and count the time interval of the contraction. To determine the beginning of a contraction without a monitor, rest a hand on a woman's abdomen at the fundus of the uterus very gently to sense the gradual tensing and upward rising of the fundus that accompanies a contraction (Fig. 15.15). It is possible to palpate this tensing approximately 5 seconds before the woman is able to feel the contraction. (Contractions are palpable when the intrauterine pressure reaches approximately 20 mm Hg. The pain of a contraction is not usually felt until pressure reaches approximately 25 mm Hg.). Time the duration of a contraction from the moment the uterus first tenses until it has relaxed again.

Intensity of Contractions. In addition to observing the duration of contractions, estimate the intensity or strength. On a monitor, this is the height of the waveform. If you are assessing manually, rate a contraction as mild if the uterus does not feel more than minimally tense, as moderate if the uterus feels firm, and as strong if the uterus feels as hard as a wooden board at the peak of the contraction. With a strong contraction, you will also not be able to indent the uterus with your fingertips.

FIGURE 15.15 Contractions can be assessed by very gently placing the hand over the fundus of the uterus.

After estimating the intensity and duration of a contraction, recheck the fundus at the conclusion of the contraction, to be certain that it is relaxing and becoming soft to the touch again. This demonstrates that the uterus is not in continuous contraction but is providing a relaxation time during which blood vessels can fill to supply the fetus with adequate oxygen.

Frequency of Contractions. Next, time the frequency of contractions. The frequency is timed from the beginning of one contraction to the beginning of the next (see Fig. 15.10).

Use as light a touch as possible on a woman's abdomen while timing contractions or estimating their strength manually. The fundus of the uterus becomes tender if it has to push against the extra weight of a hand with each contraction. This is an unnecessary discomfort for a woman in labor.

Initial Fetal Assessment

Although passive in labor, a fetus is subjected to extreme pressure by uterine contractions and passage through the birth canal, so it is important to ascertain that the FHR remains within normal limits despite these pressures.

Auscultation of Fetal Heart Sounds

Fetal heart sounds are transmitted best through the convex portion of a fetus, because that is the part that lies in closest contact with the uterine wall. This means that in a vertex or breech presentation, fetal heart sounds are usually best heard through the fetal back; in a face presentation, the back becomes concave so the sounds are best heard through the more convex thorax. In breech presentations, fetal heart

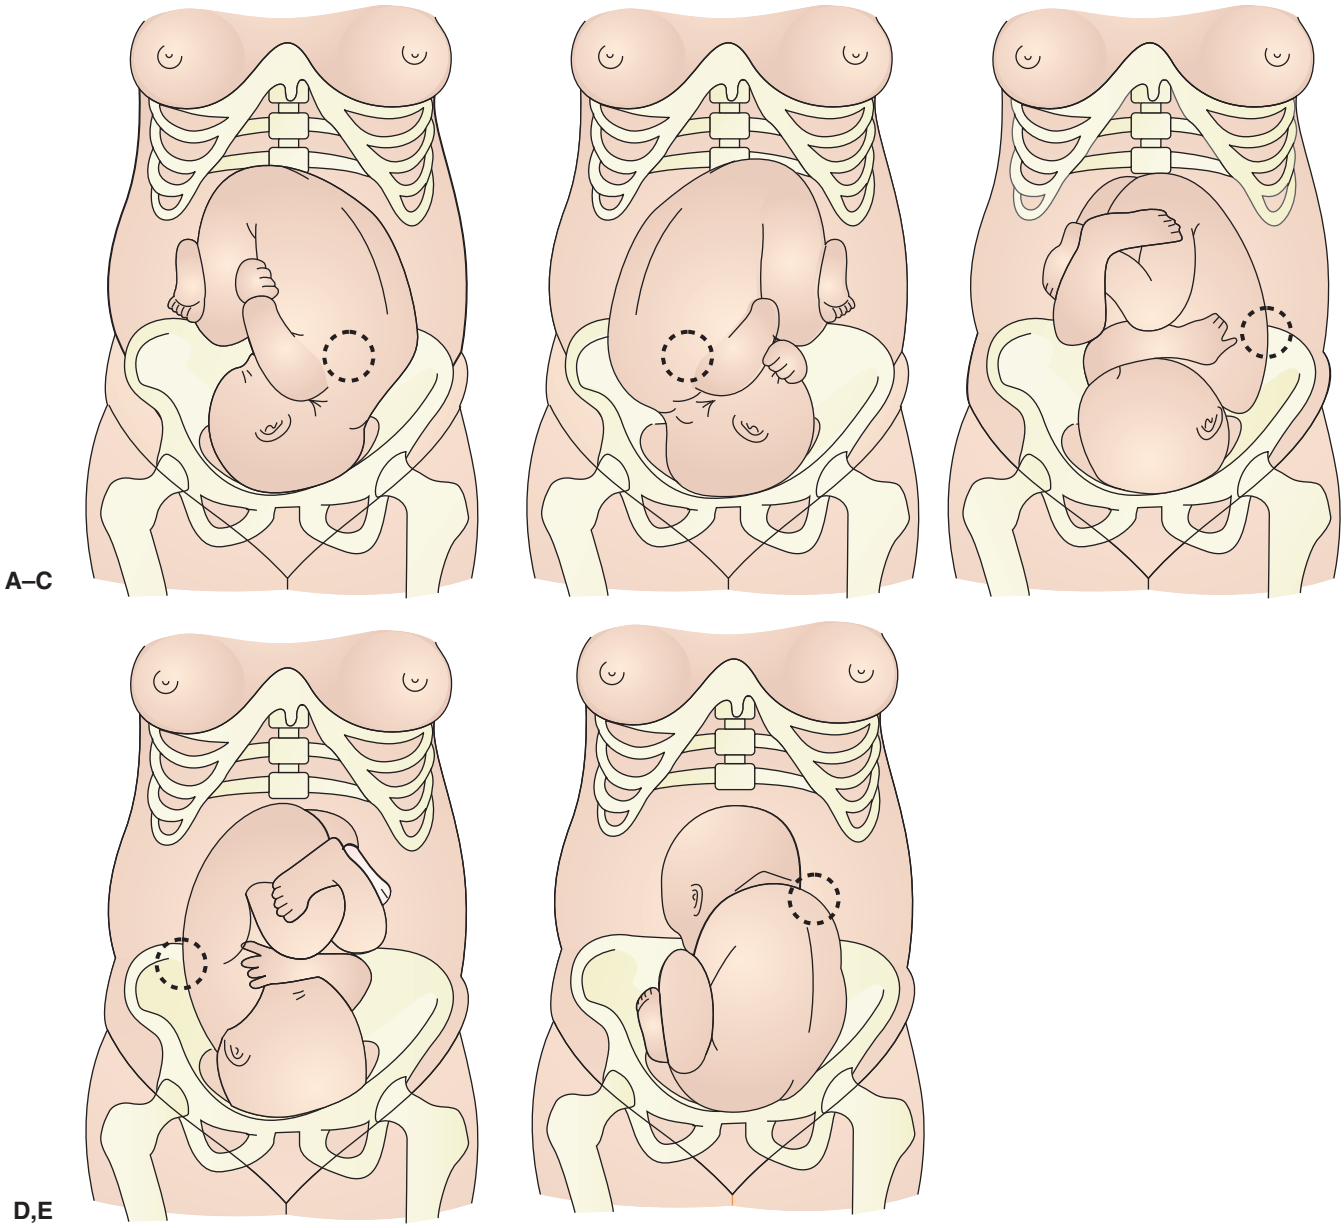


FIGURE 15.16 Locating fetal heart sounds by fetal position. (**A**) LOA. (**B**) ROA. (**C**) LOP. (**D**) ROP. (**E**) LSA.

sounds are heard most clearly high in the uterus, at a woman's umbilicus or above. In cephalic presentations, they are heard loudest low in the abdomen. In an ROA position, the sounds are heard best in the right lower quadrant; in an LOA position, in the left lower quadrant. In posterior positions (LOP or ROP), heart sounds are loudest at a woman's side. Figure 15.16 shows how to locate heart sounds for various fetal positions.

Hearing fetal heart sounds in these positions provides confirmatory information about fetal position. Conversely, recognizing fetal position aids in locating fetal heart sounds.

Determine the FHR every 30 minutes during beginning labor, every 15 minutes during active labor, and every 5 minutes during the second stage of labor. This can be done by viewing the FHR monitoring strip or by periodic auscultation.

To auscultate fetal heart sounds, use either a stethoscope or a fetoscope (a modified stethoscope attached to a headpiece), or obtain them with a Doppler unit, which uses ultrasound waves that bounce off the fetal heart to produce echoes or clicking noises (Fig. 15.17). Each click reflects the fetal heartbeat.

Electronic Monitoring

In most settings, FHR is screened at least for a short time in early labor by an external electronic monitoring system. The monitor is left in place for continuous monitoring on women who are categorized as high risk for any reason or who have oxytocin stimulation.

The use of fetal monitors has provoked one of the biggest controversies in modern obstetric health care. Monitors were widely adopted in the mid-1970s as a means of immediately detecting variations in FHR. However, prepared childbirth advocates have long criticized the overuse of monitoring devices, arguing that they intrude on the childbirth experience, causing needless discomfort and distraction to the mother. The medical profession readily admits that monitors contribute to the growing number of cesarean births (National Center for Health Statistics, 2009). Advocates of monitoring would say that the prevention of complications in even one baby is worth this increase. However, others believe that monitors often point to a problem where none exists, resulting in unnecessary cesarean births (which carries its own set of risks) and unnecessary frightening of parents (which could adversely affect early parent–infant bonding).

Monitoring does offer many advantages from a health care provider's standpoint. Observing the FHR on a monitor is easier than listening with a stethoscope, fetoscope, or Doppler. In addition, most health care providers have grown accustomed to monitors and may feel insecure without them. Few people advocate a return to the use of stethoscopes for total assessment; use of monitors for periodic assessment rather than continuous monitoring is a compromise solution.

Be certain to tell parents that the FHR can vary greatly during labor and that the monitor is only an aid and should not be the focus of their attention. Parents can become so focused on what is happening on the monitor that they can lose the ability to concentrate on previously learned relaxation and breathing techniques.

External Electronic Monitoring

External electronic monitoring is useful for monitoring both uterine contractions and FHR continuously or intermittently. The information is obtained from sensors strapped to the woman's abdomen (Fig. 15.18).

Contractions are monitored by means of a pressure transducer or tocodynamometer (*toko* is the Greek word for "contraction"). Place the transducer over the uterine fundus or the area of greatest contractility. Verify that it is securely held in

A B

FIGURE 15.17 (**A**) Auscultation of the fetal heartbeat using a fetoscope. (**B**) A Doppler ultrasound device can be used to monitor fetal heart rate intermittently in low-risk labor. (Photographs by Keith Cotton.)

FIGURE 15.18 External electronic monitoring in place. Two devices (a transducer for the uterus and an ultrasound sensor for the fetus) are strapped to the woman's abdomen. (© Caroline Brown, RNC, MS, DEd.)

place by an adjustable strap or stockinette girdle (Fig. 15.19A). The transducer converts the pressure registered by the contraction into an electronic signal that is recorded on graph paper. These may be difficult to apply to morbidly obese women and the readings may not be as accurate (Euliano et al., 2007).

The FHR is monitored with the use of an ultrasonic sensor or monitor (see Fig. 15.19A), also strapped against a woman's abdomen at the level of the fetal chest. The small Doppler unit converts fetal heart movements into audible beeping sounds and also records them on graph paper.

A woman who is worried that something will happen to her child during labor can find it reassuring to listen to the regular beeping sound of the undistressed fetal heart from a fetal heart transducer. Many women ask for and can have a short graph tracing to save for their child's baby book.

External monitoring is not as reliable as internal monitoring, because a change in maternal or fetal position can interfere with the quality of the tracing. However, it is noninvasive and easily applied and does not require cervical dilatation or fetal descent before it can be used. This means it can be introduced at any time during labor.

A woman may feel discomfort from the strap holding an external monitor in place. The snugness of the sensor head also may limit her ability to breathe deeply. Spreading talcum powder on her abdomen may make the strap more comfortable. Removing the sensor periodically and allowing for a position change is also helpful. If a woman changes her position herself (and she should change position often during labor), the sensor often needs to be repositioned. Remind a woman that the fetal heart signal may stop when she changes position, so she does not think by the silence she hears that her baby's heart has stopped.

Women do not need to lie on their backs for monitoring (they might lie on their side, sit in a chair, or bend forward over the foot of the bed), so the likelihood of supine hypotension syndrome is not increased. When giving care, be sure not to focus solely on the equipment; continue to communicate and offer support to the woman and her partner as needed. Although not well studied, if a fetus shows an unresponsive heartbeat during labor, vibroacoustic stimulation can be used the same as is done for nonstress tests during pregnancy to be certain that a fetus is responding well (East et al., 2009).

What if... You enter Celeste Bailey's room while she has an electronic monitor in place and discover that she is lying on her back, seemingly frozen in one position? Would you urge her to turn or let her lie in that position because the monitor strip is recording so well?

Internal Electronic Monitoring

Internal electronic monitoring is the most precise method for assessing FHR and uterine contractions. A pressure-sensing catheter is passed through the vagina, into the uterine cavity, and alongside the fetus, after the membranes have ruptured and the cervix has dilated to at least 3 cm (see Fig. 15.19B). The end of the catheter extending from the vagina is attached to a pressure recorder. As each contraction puts pressure on the uterine contents, the pressure exerted on the catheter is recorded. When uterine contractions are monitored by an internal pressure gauge in this way, the frequency, duration, baseline strength, and peak strength of contractions can all be evaluated. Strength of contractions is evaluated by the height of the peak of the contraction on the tracing. Equally important to evaluate is the return of the uterine tone to baseline strength between contractions. This ensures placental filling between contractions.

With contractions during the latent phase, the baseline level is usually less than 5 mm Hg; with active contractions, it is about 12 mm Hg. During the second stage of labor, the baseline may be as high as 20 mm Hg. Baseline readings that do not return to 20 mm Hg or less suggest uterine hypertonia and a possible compromise of fetal well-being.

The FHR recording is obtained from a fetal scalp electrode. Once the fetal head is engaged, the electrode is inserted vaginally and attached to the fetal scalp. A fetal electrocardiograph signal is obtained, amplified, and then fed into a cardiotachometer. The output from the cardiotachometer is recorded on permanent graph paper.

The level of information obtained by internal monitoring cannot be matched by external monitoring, which records only the frequency and duration of contractions. The detail on fetal heartbeats is also clearer with internal monitoring. On the other hand, internal monitoring is invasive, carries the risk of uterine infection, and limits a woman's movement. Because of these drawbacks, it is not used routinely but reserved for women who are high risk during labor.

Telemetry

Telemetry allows monitoring of both FHR and uterine contractions to be carried out free of connecting wires that could hamper the woman's movements in labor. An internal pressure uterine lead is inserted, as in internal monitoring, and a fetal scalp electrode is also attached. A miniature radio transmitter is then placed in the vagina to transmit the FHR and uterine contraction signals to a distant monitor.

Nurses and physicians view the distant monitor located at a nursing station to track fetal status instead of visiting

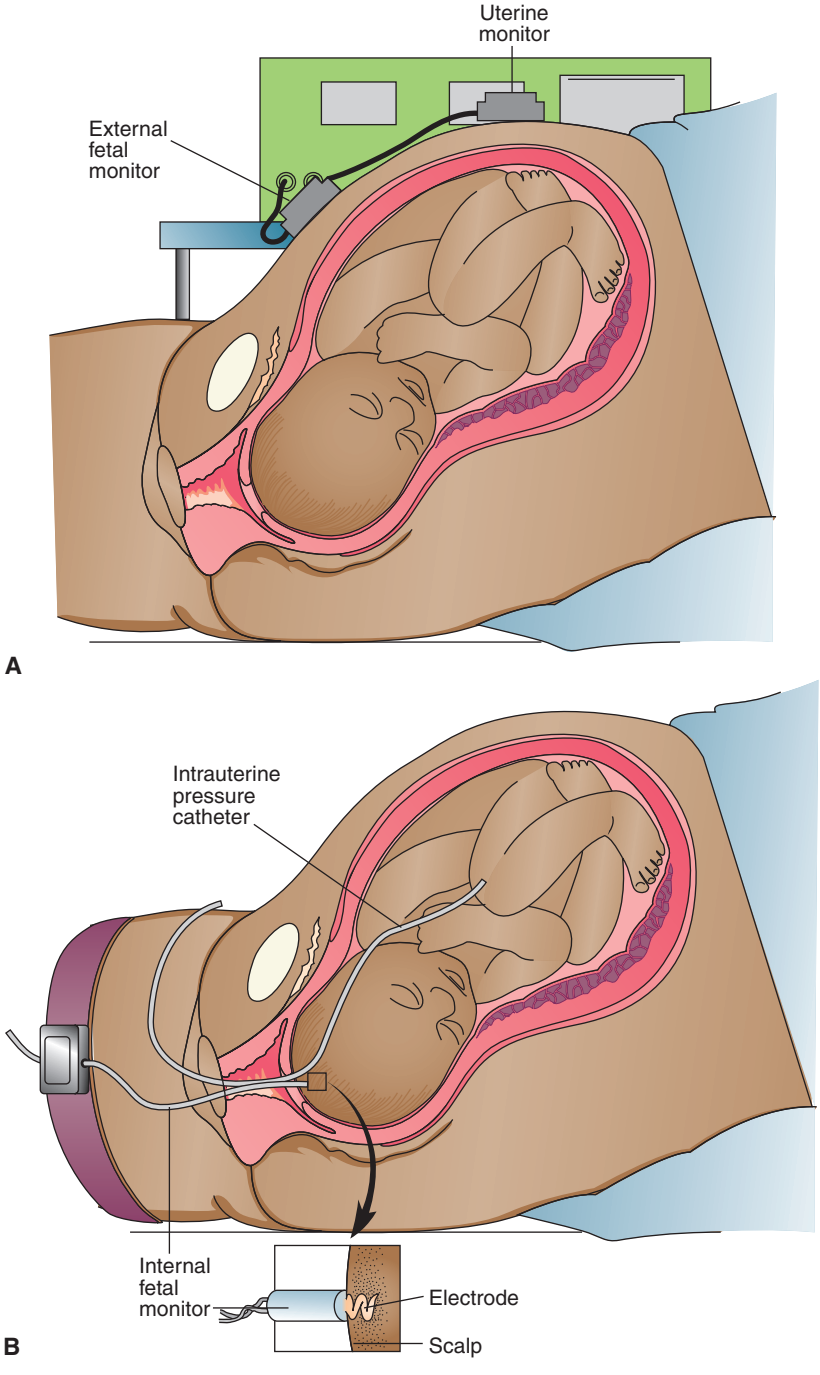

FIGURE 15.19 Placement of electronic monitoring leads. (**A**) External leads to monitor for FHR and uterine contractions. (**B**) An internal fetal heart rate lead in place on the fetal scalp. Uterine contractions are monitored by the intrauterine catheter.

individual birthing rooms. The major advantage of telemetry is that it allows a woman to ambulate while being internally monitored. Although central monitoring of this type has been used effectively in intensive care units for years and has the advantage of saving footsteps, because it reduces bedside contact, a worry is that its use can isolate laboring women, fragment their care, and reduce supportive care during labor. It also does not appear to make a difference in the cesarean birth rate or newborn outcomes (Devoe, 2008). Because it is more expensive than other equipment, not all birth settings have telemetry capability.

FETAL HEART RATE AND UTERINE CONTRACTION RECORDS

Labor monitors trace both the FHR and the duration and interval of uterine contractions onto an oscilloscope screen and produce a permanent record on paper rolls (Fig. 15.20). Uterine contraction information is recorded on the bottom half of the paper, FHR on the top half. Time can be calculated by counting the number of bold vertical lines on the paper (the space between two bold lines represents 60 seconds).

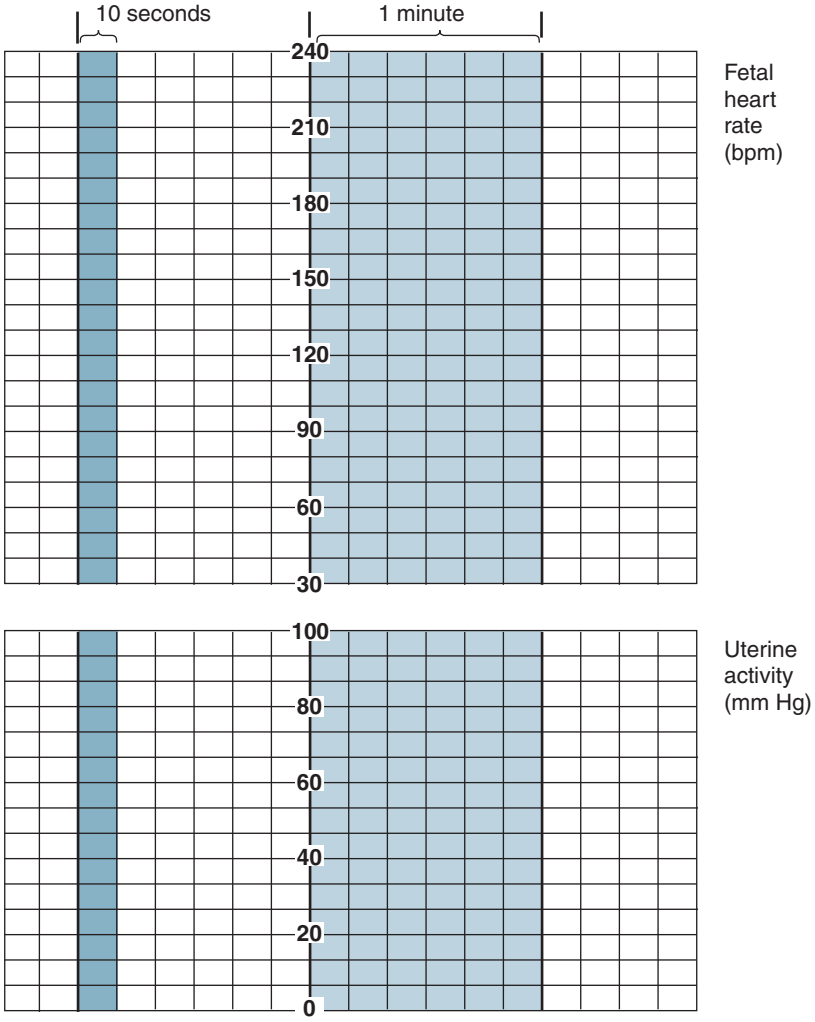

FIGURE 15.20 Paper strip for recording electronic fetal monitoring data.

Fetal Heart Rate Patterns

Assessing and interpreting FHR patterns involve evaluating three parameters: the baseline rate, variabilities in the baseline rate (long term and short term), and periodic changes in the rate (acceleration and deceleration) (Lawson & Bienstock, 2007).

Baseline Fetal Heart Rate

A baseline FHR is determined by analyzing the range of fetal heartbeats recorded on a 10-minute tracing that was obtained between contractions. A normal rate is 120 to 160 bpm. The rate fluctuates slightly (5 to 15 bpm) when a fetus moves or sleeps. If an increase or decrease occurs and is sustained for a 10-minute period, then a new baseline or a baseline change is established. Abnormal patterns in the baseline rate include fetal bradycardia and fetal tachycardia.

Fetal bradycardia occurs when the FHR is lower than 120 bpm for 10 minutes. A moderate bradycardia of 100 to 119 bpm is not considered serious and is probably because of a vagal response elicited by compression of the fetal head during labor. Marked bradycardia (less than 100 bpm) is a sign of possible hypoxia and is potentially dangerous.

Fetal tachycardia occurs when the rate is 160 bpm or faster (for a 10-minute period). Moderate tachycardia is 161 to 180 bpm. Marked tachycardia is a rate greater than 180 bpm. Marked fetal tachycardia may be caused by fetal hypoxia, maternal fever, drugs, fetal arrhythmia, or maternal anemia or hyperthyroidism. In all instances, the cause needs to be investigated.

Variability

FHR variability is one of the most reliable indicators of fetal well-being. Baseline variability is the variation or differing rhythmicity in the heart rate over time and is reflected on the FHR tracing as a slight irregularity or "jitter" to the wave. The degree of baseline variability increases when the fetus is stimulated and slows when the fetus sleeps. If no variability is present, it indicates that the natural pacemaker activity of the fetal heart (effects of the sympathetic and parasympathetic nervous systems) has been affected. This may occur as a response to narcotics or barbiturates administered to a woman in labor, but the possibility of fetal hypoxia and acidosis must be investigated. Very immature fetuses show diminished baseline variability because of reduced nervous system response to stimulation and immature cardiac node function.

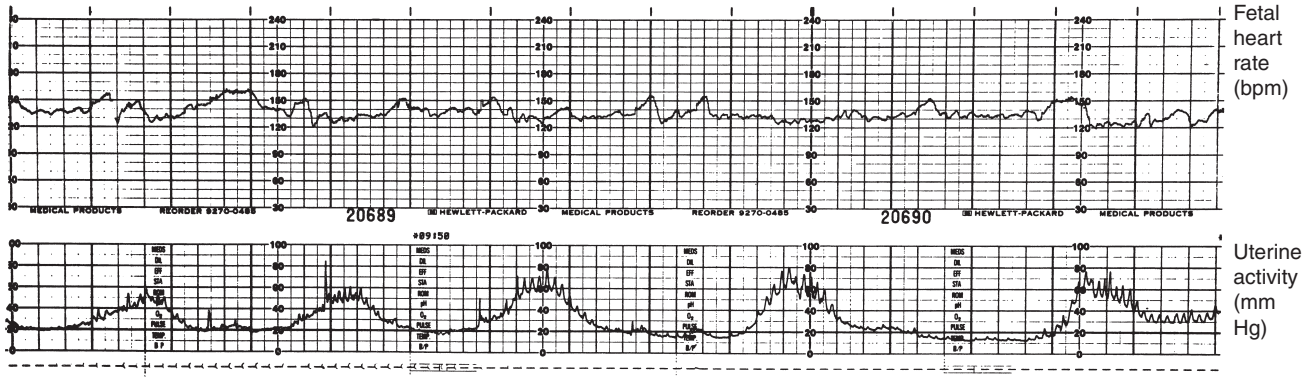

FIGURE 15.21 Fetal monitoring strip showing both long-term and short-term (beat-to-beat) variability.

Baseline variability is defined as being either long term or short term (beat-to-beat) (Fig. 15.21). Long-term variability is seen on a broad view of the recording and results from fluctuations in the FHR, of 6 to 10 bpm, that occur 3 to 10 times per minute. Short-term or beat-to-beat variability refers to the difference between successive heartbeats, usually about 3 to 5 bpm. These changes are very subtle and can be picked up only with internal electronic monitoring. Beat-to-beat variability can be rated as "present," "decreased," or "absent." Decreasing variability indicates the development of fetal distress. Absent variability is considered a severe sign, indicating that serious fetal compromise must be present.

Periodic Changes

Periodic changes or fluctuations in FHR occur in response to contractions and fetal movement and are described in terms of accelerations or decelerations. Periodic changes are short-term changes in rate rather than baseline; they last from a few seconds to 1 or 2 minutes. Four such responses are acceleration, early deceleration, late deceleration, and variable deceleration.

Accelerations. Nonperiodic accelerations are temporary normal increases in FHR caused by fetal movement, a change in maternal position, or administration of an analgesic. They are innocent findings.

Early Decelerations. Early decelerations are normal periodic decreases in FHR resulting from pressure on the fetal head during contractions. Parasympathetic stimulation in response to vagal nerve compression brings about a slowing of FHR. Early deceleration follows the pattern of the contraction, beginning when the contraction begins and ending when the contraction ends. However, the waveform of the FHR change is the inverse of the contraction waveform, with the lowest point of the deceleration occurring with the peak of the contraction. In this way, it serves as a mirror image of the contraction. The rate rarely falls below 100 bpm, and it returns quickly to between 120 and 160 beats at the end of the contraction (Fig. 15.22).

Early decelerations normally occur late in labor, when the head has descended fairly low. As such, they are viewed as a normal pattern. However, if they occur early in labor, before the head has fully descended, the head compression causing the waveform change could be the result of cephalopelvic disproportion and is a cause to investigate.

Late Decelerations. Late decelerations are those that are delayed until 30 to 40 seconds after the onset of a contraction

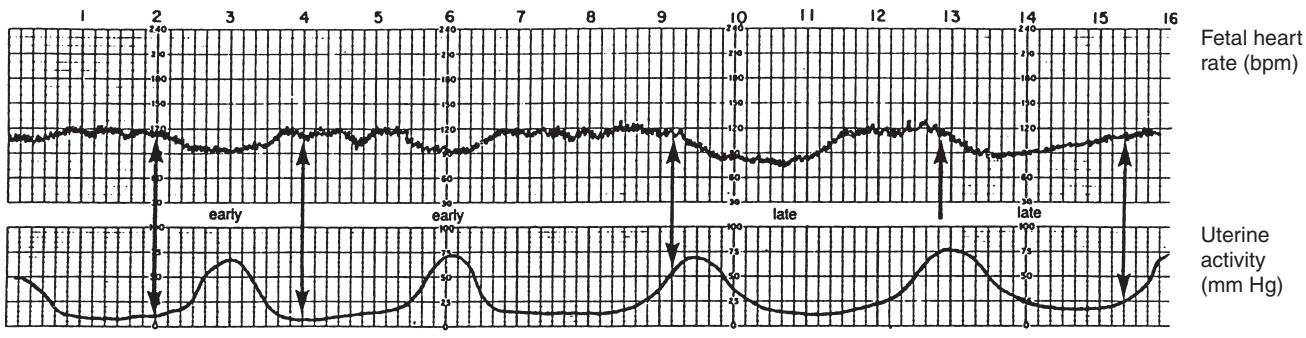

FIGURE 15.22 Schematic drawing of periodic FHR changes. Although the shape and depth of early and late decelerations are similar, note the differences in the onset of the decelerations and the recovery time to the baseline rate.

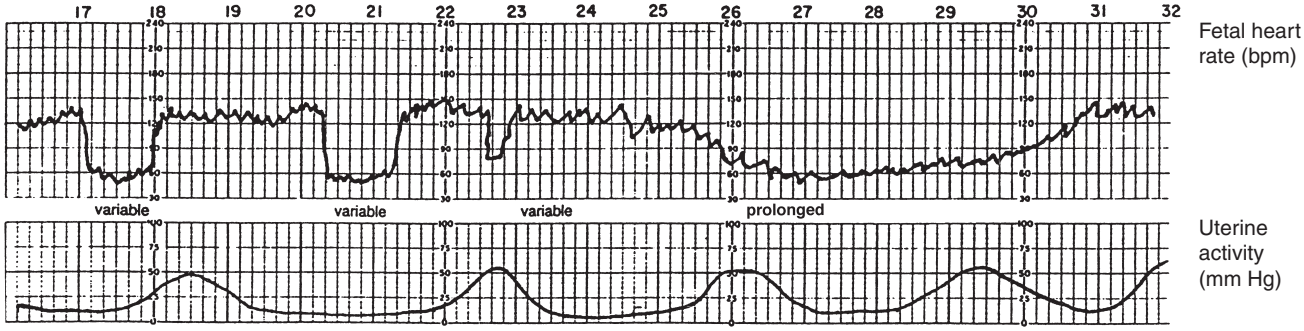

FIGURE 15.23 Schematic drawing of variable and prolonged decelerations. Note the abrupt drop in FHR in both types of decelerations. The variable decelerations return to baseline more quickly than the prolonged deceleration at 26–31 minutes, however.

and continue beyond the end of a contraction (see Fig. 15.22). This is an ominous pattern in labor, because it suggests uteroplacental insufficiency or decreased blood flow through the intervillous spaces of the uterus during uterine contractions. The lowest point of the deceleration (nadir) occurs near the end of the contraction instead of at its peak. This pattern may occur with marked hypertonia or increased uterine tone caused by the administration of oxytocin. Immediate steps to correct the situation must be initiated. If oxytocin is being used, stop or slow the rate of administration. Change the woman's position from supine to lateral (to relieve pressure on the vena cava and supply more blood to the uterus and fetus). Administer intravenous fluids or oxygen as prescribed. Prepare for possible prompt birth of the infant if the late decelerations persist or if FHR variability becomes abnormal (absent or decreased).

Prolonged Decelerations. Prolonged decelerations are decelerations that last longer than 2 to 3 minutes but less than 10 minutes. They generally reflect an isolated occurrence, but they may signify a significant event, such as cord compression or maternal hypotension. For this reason, they must be reported and documented.

Variable Decelerations. The pattern of variable decelerations refers to decelerations that occur at unpredictable times in relation to contractions. They indicate compression of the cord, which can be an ominous development in terms of fetal well-being (Fig. 15.23). Cord compression may occur because of a prolapsed cord, but it also may occur because the fetus is lying on the cord. It tends to occur more frequently after rupture of the membranes than when membranes are intact, or with oligohydramnios (the presence of less than a normal amount of amniotic fluid), such as occurs in postterm pregnancy or with intrauterine growth restriction. Because the pattern this produces is variable, often exhibited as U-, V-, or W-shaped waves, it can be completely missed if monitoring is not continuous. If this pattern is recognized on the monitor, change the woman's position from supine to lateral or to a Trendelenburg position to relieve pressure on the cord. Administer fluids and oxygen as prescribed. If variable decelerations are not relieved by these measures, amnioinfusion (addition of a sterile fluid into the uterus to supplement the amniotic fluid) may be prescribed to lift the uterine wall away from the cord (see Chapter 23).

Sinusoidal Fetal Heart Rate Pattern

In a fetus who is severely anemic or hypoxic, central nervous system control of heart pacing may be so impaired that the FHR pattern resembles a frequently undulating wave. Long-term variability consists of 5 to 15 bpm every 3 to 5 minutes; beat-to-beat variability is minimal or absent; and there is a lack of specific responses to contractions. Although the cause of this pattern is poorly understood, it is recognized to be as ominous as a late deceleration or variable deceleration pattern.

Other Assessment Techniques

Scalp Stimulation

If FHR variability is depressed, the welfare of a fetus can be further assessed by scalp stimulation. This is done by applying pressure with the fingers to the fetal scalp through the dilated cervix (Fig. 15.24). This causes a tactile response in

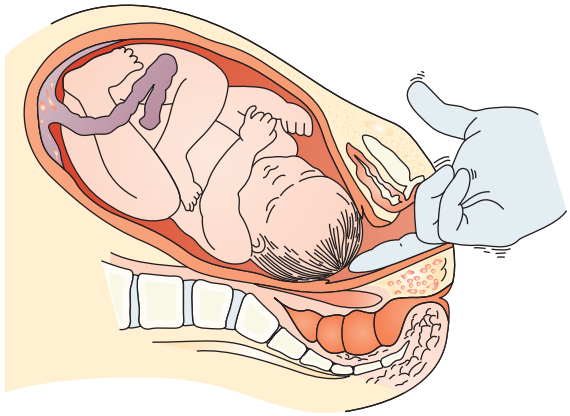

FIGURE 15.24 Technique for scalp stimulation. (Redrawn from *Journal of Perinatal and Neonatal Nursing, (1)*16; with permission from Aspen Publishers, Inc.)

the fetus that momentarily increases the FHR. If the fetus is in distress and becoming acidotic, FHR acceleration will not occur. Scalp stimulation, therefore, is an assessment of acid–base balance in a fetus.

Fetal Oxygen Saturation Level

Fetal oxygen saturation may be measured by an oxygen saturation sensor that is introduced into the uterus and placed beside the fetus's cheek after membranes have ruptured. Although oxygen saturation may be important to measure in some women, it is generally reserved for women who have an internal contraction or fetal monitor already in place (Potera, 2007).

Fetal Blood Sampling

Monitoring of the fetal blood composition may reveal hypoxia in a fetus before it becomes apparent on an electrocardiogram or external monitoring system. As this is invasive, it is reserved only for a fetus at high risk (see Chapter 23).

✔ Checkpoint Question 15.4

You assess Celeste Bailey's uterine contractions. In relation to a contraction, when does a late deceleration begin?

a. Forty-five seconds after the contraction is over.
b. Thirty seconds after the start of a contraction.
c. After every 10th or more contraction.
d. Totally unrelated to a contraction.

CARE OF A WOMAN DURING THE FIRST STAGE OF LABOR

Labor is a natural process and nurses can be instrumental in keeping labor as free of unnecessary interventions as possible (Sleutel, Schultz, & Wyble, 2007). Six major concepts to make labor and birth as natural as possible are:

1. Labor should begin on its own, not be artificially induced.
2. Women should be able to move about freely throughout labor, not be confined to bed.
3. Women should receive continuous support during labor.
4. No interventions such as intravenous fluid should be used routinely.
5. Women should be allowed to assume a nonsupine (e.g., upright, side-lying) position for birth.
6. Mother and baby should be together after the birth, with unlimited opportunity for breastfeeding (Amis & Green, 2007).

The first stage of labor begins with the beginning of uterine contractions and ends when the cervix has reached full dilatation. Most women have had labor contractions for hours before they arrive at a birthing center, because they deliberately stay at home until they are well into the first stage. This means that most likely, they have been experiencing pain and relying on their own judgment that everything is going well for a long time. One of their chief needs when they arrive at a birthing center, therefore, is to be reassured that everything is going well. For a woman who has been unable to manage pain by breathing exercises, pain relief may be her priority need.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Powerlessness related to duration of labor

Outcome Evaluation: Client expresses preferences for position and techniques to control pain; asks questions about her progress and states feelings about what is happening.

Care during the first stage of labor centers on helping a woman feel confident in her ability to control the pain and progress of labor and maintain physiologic stability. At first, it is exciting for a woman to feel labor contractions. They are little more than menstrual cramps and project a "this-is-really-happening" sensation. Soon, however, if a woman is not concentrating on controlled breathing exercises, the contractions become biting in their intensity. Despite the fact that she is becoming more and more uncomfortable, however, nothing seems to be happening. A couple can begin to worry that something is going wrong; they may think that because the 9 months are over, victory is near, yet it is eluding them. Give couples frequent progress reports during labor so they do not become discouraged or fearful at this seeming lack of progress (Box 15.8).

BOX 15.8 ✻ Focus on Communication

Celeste Bailey's baby is in an occipitoposterior position, so she has had extensive back pain since labor began.

Less Effective Communication

Nurse: You don't look very comfortable, Celeste. Would you feel better if you sat in the rocking chair rather than stay in bed?
Celeste: Can I do that?
Nurse: I told you on admission. You can do whatever is most comfortable for you.
Celeste: Can I walk over to the window?
Nurse: I told you on admission. Do whatever is most comfortable for you.
Celeste: I guess I'm not being a very good patient.

More Effective Communication

Nurse: You don't look very comfortable, Celeste. Would you feel better if you sat in the rocking chair rather than stay in bed?
Celeste: Can I do that?
Nurse: You can use any position that is comfortable for you.
Celeste: Can I walk over to the window?
Nurse: Whatever is most comfortable for you.
Celeste: Thank you. You're very understanding.

Women in labor may be enduring so much pain and are under so much stress they do not "hear" or process instructions well. Reminding them that they have not processed information well is not therapeutic, because it can lower their self-esteem and sense of self-control.

A woman needs to feel that she has some control over her situation during labor to face this big event in her life. Most women accomplish this by stating their preferences, breathing with contractions, and changing their position to the one that makes them most comfortable. In contrast, some women handle the stress of labor by becoming extremely quiet and passive. Others feel most comfortable when they can show their emotions by shouting or crying. Help a woman express her feelings in her own way, one that works the best for her.

Respect Contraction Time. Do not interrupt a woman who is in the middle of breathing exercises during labor because, once her concentration is disrupted, she will feel the extent of the contraction. If she has been successfully using breathing exercises to reduce pain, suddenly feeling the full force of a contraction can be frightening. She tenses, the pain becomes worse, and she may doubt her ability to breathe constructively in the face of such sharp pain with the next contraction. Instead of interrupting, allow her to finish breathing with her contraction, then ask questions or announce what procedure needs to be done next, or ask the question but wait patiently for the answer. (See Chapter 16 for a discussion of pain management techniques during labor.)

Promote Change of Positions. Because the bed is the main piece of furniture in a birthing room, many women assume that they are expected to lie quietly in bed during labor. In early labor, however, a woman may be out of bed walking or sitting up in bed or in a chair, kneeling, squatting, or in whatever position she prefers (Fig. 15.25). Reassure a woman that she may move about as she wants.

A woman whose membranes have ruptured should lie on her side until a fetal monitor shows good baseline variability and no variable decelerations or until she has been checked by a physician or nurse-midwife, because, unless the head of the fetus is well engaged (firmly fitting into the pelvic inlet), the umbilical cord may prolapse into the vagina if she walks.

If medication such as a narcotic is given, educate a woman to remain in bed for approximately 15 minutes afterward to avoid a fall if she should become dizzy from the medication. While a woman is in bed, encourage her to lie on her side, preferably the left side. This position causes the heavy uterus to tip forward, away from the vena cava, allowing free blood return from the lower extremities and adequate placental filling and circulation. Most women are comfortable in this position and adjust to it readily. Position the chair for the support person facing the laboring woman. Otherwise, she will keep turning to her back to talk.

Some women have learned to do breathing exercises in a supine position and may need additional coaching to do them in a side-lying position. If a woman must turn to her back during a contraction to make her breathing exercises effective, help her to remember to return to her side between contractions. A squatting position is very effective for birth because it helps to align the fetal presenting part with the cervix and also uses the fetal weight to help bring about cervical dilatation.

FIGURE 15.25 Finding a comfortable position during early labor is important. Here, a nurse assists a woman with walking during labor.

Promote Voiding and Provide Bladder Care. A full bladder or bowel can impede fetal descent, so encourage a woman to void, if possible, at least every 2 to 4 hours. The way a full bladder can impede descent of a fetus is illustrated in Figure 15.26. You need to remind a woman to void during labor, because she may mistakenly interpret the discomfort of a full bladder as part of the sensations of labor. Assess for a full bladder by percussion (an empty bladder sounds dull; a full one sounds resonant). If she cannot void and the bladder becomes distended, she may need to be catheterized. Catheterizing a woman in labor is uncomfortable for her and difficult for you: the vulva is edematous from the pressure of the fetal presenting part, stretching the urethral canal downward and making the urethra difficult to locate. For best results, use a small catheter (no. 12F–14F), and insert it between contractions. Use extremely careful aseptic technique

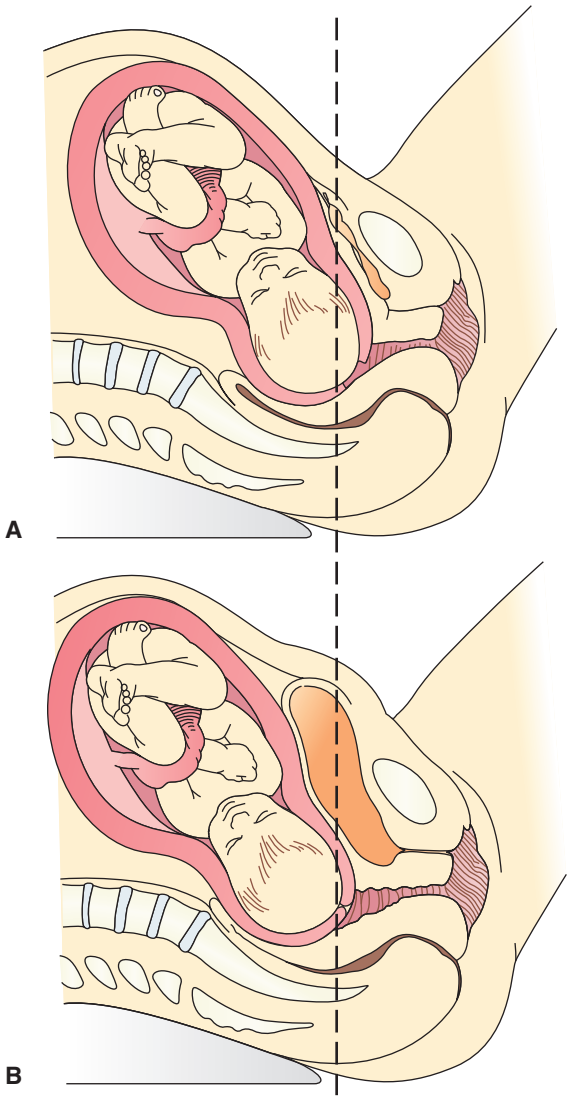

FIGURE 15.26 Effect of a full bladder on fetal descent. (**A**) Bladder is empty. (**B**) A full bladder impedes fetal progress.

to avoid introducing any microorganisms that might then result in a urinary tract infection.

Nursing Diagnosis: Risk for ineffective breathing pattern related to breathing exercises

Outcome Evaluation: Client's respiratory rate is within normal limits; skin is normal color, cool, and dry. No reports of lightheadedness or tingling/numbness in extremities.

Hyperventilation (an accelerated rate of respiration) occurs when a woman exhales more deeply than she inhales. As a result, extra carbon dioxide is blown off and respiratory alkalosis results. This can occur when a woman is practicing breathing exercises in preparation for labor, but it is most apt to occur during actual labor. The woman feels lightheaded and may have tingling or numbness in her toes and fingertips. If allowed to progress, hyperventilation can lead to coma.

To halt hyperventilation, urge a woman to keep a paper bag nearby when doing breathing exercises. Breathing in and out into the paper bag causes her to rebreathe the carbon dioxide she has exhaled, replacing the carbon dioxide lost. If a paper bag is unavailable, she can use her cupped hands instead.

The best way to handle hyperventilation is to prevent it. Be certain when a woman is breathing rapidly that she is not hyperventilating and that she ends all breathing sessions with a long cleansing breath to help restore carbon dioxide balance.

Nursing Diagnosis: Anxiety related to stress of labor

Outcome Evaluation: Client states she feels in control of her situation; she and her support person express confidence in themselves and in health care personnel.

Labor is such an intense process that it creates a high level of emotional stress for both a woman and her support person. Ability to tolerate stress (to cope adequately) depends on a person's perception of the event, the support people available, and past experience in using coping mechanisms. Ways to reduce stress in labor, therefore, center on helping a woman to perceive labor clearly and providing the opportunity for her partner to provide support.

Offer Support. There is no substitute for personal touch and contact as a way to provide support during labor. Patting a woman's arm while telling her that she is progressing in labor, brushing a wisp of hair off her forehead, wiping her forehead with a cool cloth—these are indispensable methods of conveying concern. This caring attitude has several benefits. First, it may make the difference in helping a woman feel safe and able to continue in control. In addition, a woman who is touched, who experiences the warmth and friendliness of human contact during labor—a time when she is physically dependent—may handle her newborn (who is also physically dependent and undergoing an adjustment not unlike the one she has just gone through) more warmly and affectionately. On the other hand, not all women care for physical contact during labor, as enjoyment of touch is culturally determined.

Respect and Promote the Support Person. Admit a woman's support person to the birthing area and allow him or her to remain with a woman throughout the birth. Having someone with her during labor is important, because everything is new and unexpected. Acquaint the woman and her support person with the physical facilities, and point out where supplies such as towels, washcloths, and ice chips are stored, so the support person can get them when necessary. Review procedures and reassure the support person early in labor that he or she is welcome there. Also, be sure that all health care personnel are aware of who the support person is and make him or her feel welcome.

Often the support person will be acting as a labor coach. Ask both the woman and the support person whether they have been to prepared childbirth classes and whether the support person plans to help the woman with her breathing. If so, support this person's

FIGURE 15.27 Encouraging a support person, so he can continue to give support, is an important nursing role. (© Barbara Proud.)

role. If he or she is hesitant, it is better to review techniques than to take over. Offer praise not only for the woman but for the support person as well because watching a birth is apt to be as totally a new experience for this person as for the mother (Rosich-Medina & Shetty, 2007). Relieve the support person as necessary, so that he or she can take a break and get something to eat or visit with older children (Fig. 15.27). If older children will view the birth, be certain that they are oriented and have a child care provider.

In addition to having the father of their baby present, many women choose a doula or another woman to be with them in labor. This is because fathers may find it hard to provide doula-type support during labor because of their own emotional involvement in the birth. Having such a person present frees the father to enjoy the birth rather than feel occupied with coaching instructions. Although research in the subject is not extensive, there are suggestions that rates of oxytocin augmentation, epidural anesthesia, and cesarean birth can be reduced by doula support (McGrath & Kennell, 2008).

What if... A doula and Celeste Bailey's mother disagree on whether Celeste needs additional medication for pain while in labor? Whose suggestion would you pay most attention to? How could you resolve the issue?

Support a Woman's Pain Management Needs. Many women plan on using nonpharmacologic pain relief measures such as aromatherapy during labor; ask what the woman has planned and what your role should be (Burns et al., 2007). Some women believe that using a prepared childbirth method will create a pain-free, effortless labor. When this does not happen, they may panic and lose the ability to use prepared breathing. Some support people are more nervous than they anticipated and have difficulty being supportive, leaving the woman to manage her anxiety on her own. In these instances, accepting an analgesic might be a way to reduce anxiety or take the edge off contractions. Following this degree of relaxation, a woman may then be able to return to effective breathing techniques. Sometimes, simply the support of a person, such as a nurse, who is confident that breathing can be effective in reducing the discomfort of labor is all a woman needs to resume her breathing exercises with success.

Nursing Diagnosis: Risk for fluid volume deficit related to prolonged lack of oral intake and diaphoresis from the effort of labor

Outcome Evaluation: Client states she does not feel thirsty; voids at least 30 mL per hour every 2 to 4 hours.

How much fluid or food a woman should ingest during labor is controversial. Most women enjoy ice chips, popsicles, or lollipops to provide a source of fluid. Because of this limited intake, a woman's mouth and lips may become uncomfortably dry from mouth breathing. Applying a cream to her lips or suggesting that she suck on hard candy or ice chips to relieve this discomfort can be helpful. Women in prolonged labor may need isotonic sports drinks to prevent secondary uterine inertia (a cessation of labor contractions) as well as generalized dehydration and exhaustion. If all oral fluids are contraindicated by the birth plan, intravenous glucose solutions may be administered to maintain caloric reserve.

Amniotomy

Amniotomy is the artificial rupturing of membranes. Rupturing membranes if they do not rupture spontaneously allows a fetal head to contact the cervix more directly and, although not well proved to do so, may increase the efficiency of contractions and speed the pace of labor. For this, a woman's cervix must be dilated at least 3 cm. She is placed in a dorsal recumbent position; an amniohook (a long, thin instrument) or a hemostat is passed vaginally. The membranes are torn, and amniotic fluid is allowed to escape. This puts a fetus momentarily at risk for cord prolapse, because there is a possibility that a loop of cord will escape with the fluid. Always measure the FHR immediately after the rupture of membranes to determine that this did not happen (Szymanski & Bienstock, 2007).

CARE OF A WOMAN DURING THE SECOND STAGE OF LABOR

The second stage of labor is the time from full cervical dilatation to birth of the newborn. Even women who have taken childbirth education classes are surprised at the intensity of the contractions in this phase of labor. Because the feeling to push is so strong, some women react to this change in contractions by growing increasingly argumentative and angry or by crying and screaming. Other women react by tensing their abdominal muscles and trying to resist, making the sensation even more painful and frightening. In the past, women were told to hold their breath while they pushed. Now it is believed that holding the breath for a prolonged time impairs blood return from the vena cava (a Valsalva maneuver), so this is now discouraged. Encourage women to as-

sume any position, which is comfortable for them and breathe any way that is natural for them, except holding their breath (Roberts & Hanson, 2007).

A support person plays a vital role during this time, because all of the preparations done up to this point may still not be enough to sustain a woman during these final contractions unless she feels well supported. This participation also creates an important sharing time, after the birth, that gives a couple a sense of family for the first time.

Women need to have an experienced health care person with them as well as they enter this stage of labor, to reassure them that the change in contractions is normal and to give knowledgeable support that everything is all right (see Focus on Nursing Care Planning Box 15.9).

Assess fetal heart sounds at the beginning of the second stage of labor to be certain that the start of the baby's passage into the birth canal is not occluding the cord and interfering with fetal circulation. A general timetable for second-stage interventions is shown in Table 15.6. Prolonged second stages of labor are associated with chorioamionitis (uterine infection) and an increased rate of cesarean birth (Cheng et al., 2007).

Preparing the Place of Birth

For a multipara, convert a birthing room into a birth room by opening the sterile packs of supplies on waiting tables when the cervix has dilated to 9 to 10 cm. For a primipara, this can be delayed until the head has crowned to the size of a quarter or half-dollar (full dilatation and descent). A table set with equipment such as sponges, drapes, scissors, basins, clamps, bulb syringe, vaginal packing, and sterile gowns, gloves, and towels can be left, covered, for up to 8 hours. Be certain that drapes and materials used for birth are sterile, so that no microorganisms can be accidentally introduced into the uterus.

To provide for baby care, open the partition at the end of the room to reveal the "baby island," or newborn care area. Such areas include a radiant heat warmer, equipment for suction and resuscitation, and supplies for eye care and identification of the newborn. Turn on the radiant heat warmer in advance, so that the bottom mattress is pleasantly warm to the touch at the time of birth. Place sterile towels and a blanket on the warmer, so that they will also be warm to use to dry and cover the infant.

Positioning for Birth

Women can choose a variety of positions for birth. At one time, the lithotomy position was the major position for birth, but it is no longer the position of choice in birthing rooms or alternative birth centers—although the labor beds in these locales have attached stirrups to allow birth in a lithotomy position. Alternative birth positions include the lateral or Sims' position, the dorsal recumbent position (on the back with knees flexed), semi-sitting, and squatting.

Nurse-midwives tend to favor these alternative birth positions for their clients because they place less tension on the perineum, resulting in fewer perineal tears (Hastings-Tolsma, 2007).

If a physician prefers a lithotomy position for birth, position the woman into the bed stirrups while the physician is scrubbing and donning a sterile mask, gown, and gloves. Raise both of the woman's legs at the same time to prevent strain on her back and lower abdominal muscles. The strap holding the leg in the stirrups should be secured snugly but not so tightly that it causes constriction. Many women perceive stirrups as an unnatural position for birth, but they provide the best position for performing an episiotomy or a forceps-assisted birth or for viewing the perineum to detect lacerations or other problems at birth, and they are generally not uncomfortable. Pad the stirrups with abdominal pads if a woman has ankle edema; to prevent thrombophlebitis, be certain that there is no pressure on her calves.

Because pushing becomes less effective in a lithotomy position, the top portion of the table should be raised to a 30- to 60-degree angle, so that the woman can continue to push effectively. Lying for longer than 1 hour in a lithotomy position leads to intense pelvic congestion, because blood flow to the lower extremities is impeded. Pelvic congestion may lead to an increase in thrombophlebitis in the postpartal period. It may also contribute to excessive blood loss with birth and placental loosening. For these reasons, place the woman's legs in a lithotomy position only at the last moment.

Once a woman is in a lithotomy position, the bed's lower half is folded downward ("broken") so the physician can be in close proximity to the birth outlet. Make sure there is always someone at the foot of a broken birthing bed so that, if birth should occur precipitously, the infant will not fall and be injured.

Promoting Effective Second-Stage Pushing

For the most effective pushing during the second stage of labor, a woman should wait to feel the urge to push even though a pelvic examination has revealed that she is fully dilated. She should push with contractions and rest between them. Pushing is usually best done from a semi-Fowler's, squatting, or "all-fours" position rather than lying flat, to allow gravity to aid the effort (Fig. 15.28). A woman can use short pushes or long, sustained ones, whichever are more comfortable. Holding the breath during a contraction could cause a Valsalva maneuver or temporarily impede blood return to the heart because of increased intrathoracic pressure. This could also interfere with blood supply to the uterus. To prevent her from holding her breath during pushing, urge her to breathe out during a pushing effort.

In a multipara, to keep the second stage of labor from moving too fast, it may be necessary to prevent the woman from pushing. To accomplish this, ask her to pant with contractions. Because it is difficult to push effectively when she is using her diaphragm for panting, this limits pushing. Remember that pushing is involuntary. Regardless of how much a woman wants to cooperate, stopping this overwhelming urge to push is almost beyond her power. Demonstrating "panting like a puppy" and panting with her may be most effective. Be sure she is inhaling adequately. Otherwise, she might hyperventilate and become lightheaded while panting. Have her take deep cleansing breaths between contractions to prevent this.

Perineal Cleaning

To remove vaginal or rectal secretions and prepare the cleanest environment for the birth of the baby, clean the perineum

(text continues on page 388)

BOX 15.9 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Woman During Labor and Birth

Celeste Bailey is a 26-year-old you admit to a birthing room. She tells you she wants to have her baby "naturally" without any analgesia or anesthesia. Her husband is in the Marines and is assigned overseas, so he is not with her. Although her sister lives only two blocks from the hospital, Celeste does not want her called. She asks if she can talk to her mother on the telephone instead. As you finish assessing contractions, she screams with pain and shouts, "I'm doing everything I'm supposed to! How much longer does this go on?"

Family Assessment ✻ Client lives with husband in Marine base apartment. Husband currently assigned overseas. Finances rated as "horrible. If you want to be rich, don't marry a Marine." Both her mother and her married sister live nearby.

Client Assessment ✻ Gravida 1, para 0. Contractions of moderate intensity, 45 seconds' duration, 3 minutes apart. Cervix dilated 3 cm, 60% effaced. Membranes intact. FHR 148; fetus in ROA position. Attended childbirth education classes, but is using breathing exercises ineffectively without coach. Brought a red rose to use as a focusing object.

Nursing Diagnosis ✻ Pain related to uterine contractions and pressure on pelvic structures during labor

Outcome Criteria ✻ Client manages her discomfort in labor with nonpharmacologic methods; identifies need for additional pain relief measures if needed; responds to questions and instructions; states labor and birth were a positive experience for her.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Inspect the client's suprapubic area and palpate for bladder distention.	Encourage client to void every 2 hours.	A full bladder contributes to the client's discomfort and impedes fetal descent, possibly prolonging labor.	Client has no signs of bladder distention; voids every 2 hours during labor.
Nurse	Assess level of pain from uterine contractions and pelvic pressure by both verbal and nonverbal indicators; use 1 to 10 pain score.	Review and observe Lamaze breathing patterns with client to be certain she is obtaining maximum relief. Inform client about possible pharmacologic relief methods available to her if she should need them.	Pain is a subjective symptom, so only the client can determine her degree of pain or need for analgesia.	Client rates her level of pain from labor contractions as good to tolerable.
		Consultations		
Physician/ Nurse	Determine what personnel are available to prescribe or administer pharmacologic pain relief during labor, such as an epidural block if she voices a need for this.	Consult with nurse anesthetist about client's wish to not receive any pharmacologic pain relief.	Respecting client's wishes is a prime mode of encouraging self-efficacy.	Pain management team supports client's wish for no pharmacologic interventions, but will be prepared to administer pain relief if client's wishes change or an emergency should change the client's goal.

		Procedures/Medications		
Nurse	Assess what particular care measures, if any, client desires during labor (e.g., walking or not, birth position).	Establish a birth plan with client so all staff members can be aware of her individual preferences.	Respecting a client's choice helps to maintain self-esteem and a feeling of control.	Client expresses her preferences during labor.
		Nutrition		
Nurse	Assess when client last ate. Ask about preferences for fluid during labor.	Provide client with ice chips, hard candy, or other fluid as desired.	Ice chips or hard candy can relieve mouth dryness from breathing exercises.	Client states she has no mouth discomfort and does not feel hungry.
		Patient/Family Education		
Nurse	Assess what client knows about the usual process and time intervals of labor.	Provide information to supplement client's knowledge of labor; update client frequently on labor progress.	Teaching is most efficient if it is based on prior knowledge. Frequent updates about client's progress help to alleviate anxiety.	Client states that she understands the process of usual labor; indicates progress reports are helpful.
		Psychosocial/Spiritual/Emotional Needs		
Nurse	Assess if physical environment seems conducive to labor without pharmacologic support.	Provide a comfortable environment (e.g., change sheets frequently, adjust room temperature, offer cool washcloths to forehead).	A comfortable environment aids in relaxation and minimizes distractions, promoting effective coping to manage discomfort.	Client reports that environment is comfortable and she feels secure.
		Encourage client to assume different positions and to change them regularly. Allow client to walk or sit in chair, if desired.	Position changes promote comfort, reduce muscle tension, relieve pressure, and promote fetal descent.	Client assumes a variety of positions during labor as desired.
		Respect the need for focusing during contractions. Refrain from intervening with client during a contraction.	Interrupting client's focusing can be distracting, making the technique ineffective as a pain relief measure.	Client expresses that she is able to focus during contractions unimpaired by health care providers.
Nurse	Assess if client would like to have a support person with her.	Help client locate a suitable support person (mother?). If none is available, serve as primary support person.	A support person can play a major role in making labor a tolerable experience.	Client names a person she wants as her support person. Person or nurse serves as a support person during labor.
		Discharge Planning		
Nurse	Assess how client evaluates her labor experience.	Help client voice her satisfaction or dissatisfaction with her labor experience.	Reviewing a possibly traumatic experience helps debrief (put it into perspective among life events).	Client states that labor and birth was at worst a tolerable experience; at best, a highlight of her life.

TABLE 15.6 ✻ Time Intervals for Nursing Interventions During Second Stage of Labor

Intervention	Beginning of Second Stage	Continued Frequency	After Birth of Infant	After Delivery of Placenta
Assess and Record				
Temperature	X	q2hr		q1hr
Pulse	X	q1hr	X	q15 min
Respirations	X	q5–30 min	X	q15 min
Blood pressure	X	q5–30 min	X	X
Fetal heart rate	X	Continuously by monitor or q5 min		
Contractions	X	Continuously by monitor or q5 min		
Perineum	X	q15 min		q15 min
Provide				
Support	X	Continuously	Continuously	Continuously

with a warmed antiseptic such as Iodophor (cold solution causes cramping) and then rinse it with a designated solution before birth, according to the policy of the physician, nurse-midwife, or agency. Always clean from the vagina outward (so that microorganisms are moved away from the vagina, not toward it), using a clean compress for each stroke. Be sure and include a wide area (vulva, upper inner thighs, pubis, and anus). Figure 15.29 shows a typical pattern for cleaning. If a physician or nurse-midwife plans to use sterile drapes, help place them around the perineum.

As the woman pushes, the pressure of the fetal head on the bowel may cause fecal material to be expelled from the rectum. The physician or nurse-midwife will sponge this away as it occurs, to prevent contamination of the birth canal.

FIGURE 15.28 Positions for pushing during second stage labor. (**A**) Squatting with support person. (**B**) All-fours. (**C**) All-fours with chest support. (© Barbara Proud.)

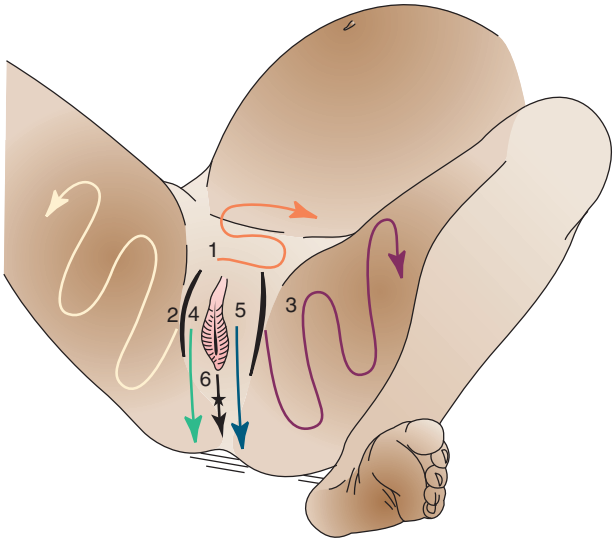

FIGURE 15.29 Pattern for cleaning perineum before birth. Cleaning from the birth canal outward moves bacteria away from, not into, the vagina. Numbers refer to steps of the procedure.

Episiotomy

An **episiotomy** is a surgical incision of the perineum that is made both to prevent tearing of the perineum and to release pressure on the fetal head with birth (Lawson & Bienstock, 2007).

Rarely used today, an episiotomy incision is made with blunt-tipped scissors in the midline of the perineum (a midline episiotomy) or is begun in the midline but directed laterally away from the rectum (a mediolateral episiotomy) (Fig. 15.30). Mediolateral episiotomies have the advantage over midline cuts in that, if tearing occurs beyond the incision, it will be away from the rectum, creating less danger of complication from rectal mucosal tears (de Leeuw et al., 2008). Anal sphincter tears can lead to fecal incontinence later in life (Mous, Muller, & de Leeuw, 2008). Midline episiotomies, however, heal more easily, cause less blood loss, and result in less postpartal discomfort.

Obstetric practice varies regarding which type of episiotomy is done and how it is done. At one time this procedure was done only if tearing seemed imminent; later, it was considered routine with a normal birth; and now it is rarely used again. The advantage of an episiotomy is that it substitutes a clean cut for a ragged tear, minimizes pressure on the fetal head, and may shorten the last portion of the second stage of labor (Incerpi, 2007).

The pressure of the fetal presenting part against the perineum is so intense that the nerve endings in the perineum are momentarily deadened. This lack of sensation allows an episiotomy to be done without anesthesia. For some women, a pudendal block may be done beforehand to ensure that there is no pain; for this, lidocaine is injected via a long needle through the vaginal wall near the ischial spine, numbing the lower vaginal area and the perineum.

At the time of an episiotomy incision, there is a slight loss of blood, but the pressure of the presenting part immediately seals the cut edges and minimizes bleeding. The fetal head usually moves forward considerably once the tension on the perineum is relieved.

Birth

As soon as the head of a fetus is prominent (approximately 8 cm across) at the vaginal opening, the physician or nurse-midwife may place a sterile towel over the rectum and press forward on the fetal chin while the other hand is pressed downward on the occiput (a Ritgen maneuver) (Fig. 15.31). This helps a fetus achieve extension, so that the head is born with the smallest diameter presenting. This also controls the rate at which the head is born. Pressure should never be applied to the fundus of the uterus to effect birth, because uterine rupture could occur.

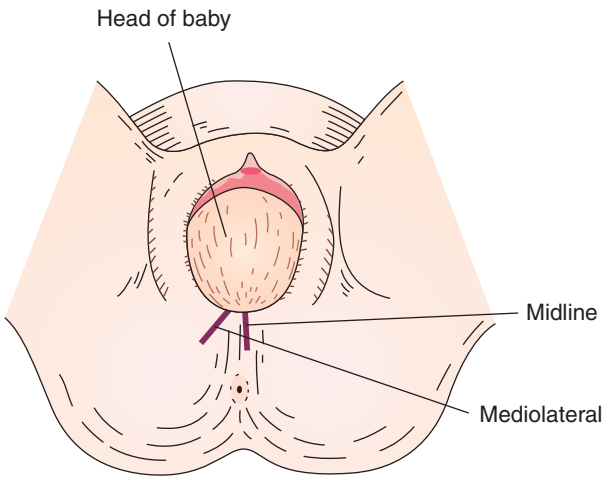

FIGURE 15.30 Position of episiotomy incision in a woman during second stage of labor. Baby's head is presenting to vagina outlet (crowning).

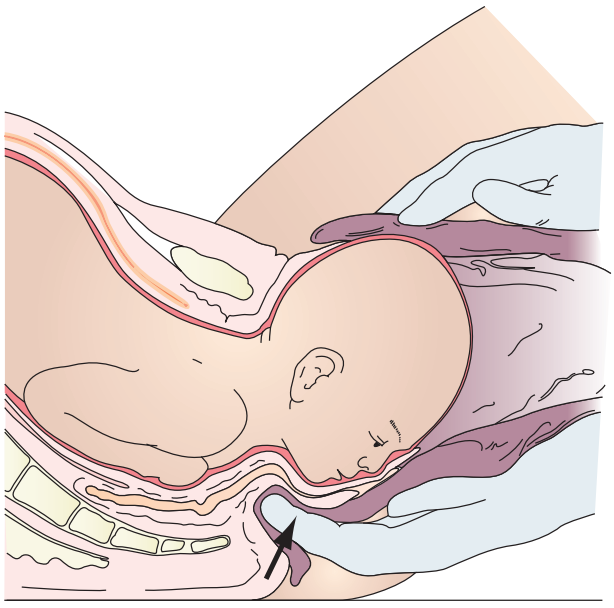

FIGURE 15.31 Ritgen's maneuver. The *arrow* shows direction of pressure.

A woman is asked to continue pushing until the occiput of the fetal head is firmly at the pubic arch. Then the head is born between contractions. This helps to prevent the head from being expelled too rapidly. It also helps to avoid perineal tears and a rapid change in pressure in the infant's head (which could rupture cerebral blood vessels). The woman may be asked to pant deliberately, so that she does not push during a contraction. She may be asked to push again without a contraction present to deliver the shoulders. Instructions should be repeated as necessary, because often a woman is so involved with the coming birth that she does not hear. Offer guidance and support to the partner as well, because he or she may be almost as overwhelmed by the birth process as the woman.

A woman who has not had anesthesia experiences the birth of the head as a flash of pain or a burning sensation, as if someone had momentarily poured hot water on her perineum. It is a fleeting sensation and is not particularly uncomfortable.

Immediately after birth of the baby's head, the physician or nurse-midwife suctions the infant's mouth with a bulb syringe and then passes his or her fingers along the occiput to the newborn's neck, to determine whether a loop of umbilical cord is encircling the neck. It is not uncommon for a single loop of cord to be positioned this way (termed a nuchal cord). If such a loop is felt, it is gently loosened and drawn down over the fetal head. If it is too tightly coiled to allow this, it is clamped and cut before the shoulders are born. Otherwise, it could tear and interfere with the fetal oxygen supply.

After expulsion of the fetal head, external rotation occurs. Gentle pressure is exerted downward on the side of the infant's head, and the anterior shoulder is born. Slight upward pressure on the side of the head allows the anterior shoulder to nestle against the symphysis as the posterior shoulder is born. The remainder of the body then slides free without any further difficulty.

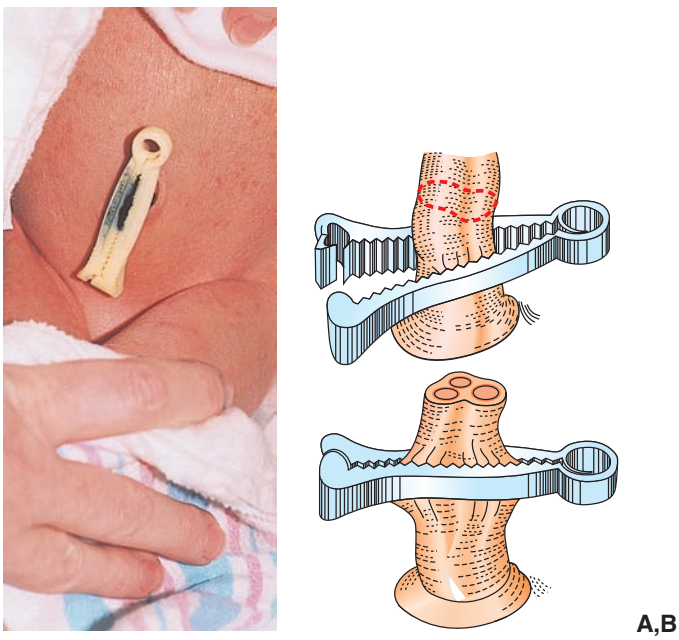
A child is considered born when the whole body is born. This is the time that should be noted and recorded as the time of birth—a nursing responsibility. (Most physicians and nurse-midwives regard it as their responsibility or pleasure to announce the sex of the infant.) With the birth of the infant, the second stage of labor is complete (Fig. 15.32).

FIGURE 15.32 A child is considered born when the whole body is delivered. (© Barbara Proud.)

Cutting and Clamping the Cord

The newborn is held with his or her head in a slightly dependent position, to allow secretions to drain from the nose and mouth. The mouth may be gently aspirated by a bulb syringe to remove additional secretions. The infant is then laid on the abdominal drape of the mother while the cord is cut. The cord continues to pulsate for a few minutes after birth, and then the pulsation ceases. There are several theories about the best time for cutting the cord. Delaying the cutting until pulsation ceases and maintaining the infant at a uterine level allows as much as 100 mL of blood to pass from the placenta into the fetus; this helps ensure an adequate red blood cell count in the newborn. On the other hand, late clamping of the cord could cause overinfusion with placental blood and the possibility of polycythemia and hyperbilirubinemia, a particular concern in preterm infants. The timing of cord clamping, therefore, varies depending on the physician's or nurse-midwife's preference and the maturity of the infant. Placing the infant on the mother's abdomen may modify the amount of blood infused as well as allowing the parents a free, unobstructed view of their new child.

The cord is clamped with two Kelly hemostats placed 8 to 10 inches from the infant's umbilicus and then is cut between them. A cord blood sample is obtained to provide a ready source of infant blood if blood typing or other emergency measures such as establishing whether fetal acidosis was present need to be done. Blood may also be taken for cord blood banking so the family has stem cells available if needed in the future. An umbilical clamp is then applied (Fig. 15.33). Some umbilical clamps have an alarm attached that will ring if the infant is taken farther than set hospital boundaries, a precaution against newborn kidnapping. The vessels in the cord are then counted to be certain that three are present. In most births, the woman's partner may have the privilege of cutting the cord.



A,B

FIGURE 15.33 (**A**) Umbilical clamp applied to cord. (© Caroline Brown, RNC, MC, DEd.) (**B**) Placing clamp; locking clamp.

Cutting the cord is part of the stimulus that initiates a first breath. With this, the infant's most important transition to the outside world, the establishment of independent respirations, has begun.

Introducing the Infant

After the cord is cut, it is time for the new parents to spend some time with their newborn. Take the infant from the physician or nurse-midwife and wrap the infant in a sterile blanket. Be sure to hold newborns firmly, because they are covered with slippery amniotic fluid and vernix. Lay the infant on a radiant heat warmer and dry him or her well with a warmed towel. Rewrap the infant snugly and cover the head with a wrapped towel or cap. Assuming that the newborn's respirations are good, take the infant to the head of the table to visit with the new parents.

Both the mother and her partner usually want to see and touch their newborn immediately; this assures them the baby is well and is an important step in establishing a parent–child relationship. Do not administer prophylactic eye ointment to the infant until after the parents have had this chance to see their infant (and the infant has had a chance to see them). (See Chapter 18 for infant care after birth.) If the woman wishes to breastfeed, this is an optimal time for her to begin. An infant sucking at the breast stimulates the release of endogenous oxytocin, encouraging uterine contraction and involution, or the return of the uterus to its prepregnant state.

CARE OF A WOMAN DURING THE THIRD AND FOURTH STAGES OF LABOR

The third stage of labor is the time from the birth of the baby until the placenta is delivered. For most women, this is a time of excitement, because the infant has safely been born, but also a time of feeling anticlimactic, because the infant has finally arrived after being expected for so long. The fourth stage includes the first few hours after birth. It signals the beginning of dramatic changes because it marks the beginning of a new family.

Placenta Delivery

If the placenta does not deliver spontaneously, the physician or nurse-midwife will ask the new mother to bear down gently or else apply gentle pressure on the contracted uterine fundus or gentle traction on the umbilical cord. If these measures are not successful, the placenta can be removed manually to limit the amount of postpartum bleeding (Bair & Williams, 2007). After delivery, the placenta is inspected to be certain that it is intact and normal in appearance and weight. Normally, a placenta is one-sixth the weight of the infant. If it is unusually large or small, you may be asked to weigh it.

Oxytocin

Once the placenta is delivered, oxytocin is usually ordered to be administered intramuscularly or intravenously to the mother. Such medication increases uterine contractions and thereby minimizes uterine bleeding (Bair & Williams, 2007).

BOX 15.10 ❊ Focus on Pharmacology

Oxytocin (Pitocin)

Action: A synthetic form of the hormone produced by the hypothalamus and stored in the posterior pituitary. An oxytocic, it stimulates the uterus to contract to control postpartum hemorrhage (Karch, 2009).

Pregnancy Category: X

Dosage: Add 10–40 units to 1000 mL of a nonhydrating intravenous solution, or administer 10 units intramuscularly after delivery of the placenta.

Possible Adverse Effects: Hypertension, excessive uterine contractility.

Nursing Implications

- Do not administer after delivery of the placenta until the physician or nurse-midwife approves the drug's use.
- Monitor the woman for blood pressure, because hypertension can occur.

Oxytocin (Pitocin) may be added to an existing intravenous line (10 to 40 U/L in intravenous fluid) or given as 10 U intramuscularly (Karch, 2009) (Box 15.10). Carboprost tromethamine (Hemabate) may be administered if the woman has excess bleeding with poor uterine contraction.

The administration of oxytocin is a nursing responsibility in most health care facilities. Do not administer it until the physician or nurse-midwife indicates it is appropriate. Although the agent may be given as early as the birth of the fetal anterior shoulder, the physician or nurse-midwife may want to inspect the placenta first to ensure that it is intact and without gross abnormalities and that none of its cotyledons remain in the uterus. Because oxytocin causes hypertension by vasoconstriction, be sure to obtain a baseline blood pressure measurement before administration. Question the use of such a drug with women who have elevated blood pressure.

If a uterus is resistant to contraction, intravenous administration of oxytocin may be continued for up to 8 hours after birth to ensure uterine contraction. Continue to monitor blood pressure during this time.

Perineal Repair

After delivery of the placenta, if an episiotomy was performed, the woman needs perineal stitches put into place. This process can be a tedious one from the mother's perspective. She must lie on her back and wait for the procedure to be completed, while the attention of others is riveted on the newborn lying in the warmer off to one side. It is important to be sensitive to the mother's needs at this time. Be certain to include her in explanations and appreciate how anticlimactic she may feel at this time.

Theoretically, if suturing of an episiotomy is done immediately after the birth of the placenta, a woman who gave birth without anesthesia will still have so much natural-pressure anesthesia of the perineum that she will not require an anesthetic. In actuality, by the time the placenta is delivered (approximately 5 minutes), enough sensation has returned to the perineum that the woman will probably need

some type of medication for comfort. Women who received a regional anesthetic during labor (e.g., pudendal block) and those who have had epidural anesthesia will probably not need additional medication during episiotomy repair.

Immediate Postpartum Assessment and Nursing Care

Following placenta delivery, lower both of a woman's legs from stirrups, if they were used, at the same time to prevent back injury.

Obtain vital signs (i.e., pulse, respirations, and blood pressure) every 15 minutes for the first hour and then according to agency policy. Pulse and respirations may be fairly rapid immediately after birth (80 to 90 bpm and 20 to 24 respirations per minute) and blood pressure slightly elevated because of the excitement of the moment and recent oxytocin administration. Palpate a woman's fundus for size, consistency, and position and observe the amount and characteristics of lochia. Perform perineal care, and apply a perineal pad.

If the birth was in a birthing room, return the birthing bed to its original position. Offer a clean gown and a warmed blanket, because a woman often experiences a chill and shaking sensation 10 to 15 minutes after birth. This may be because of the low temperature of the birthing room but may also be a result of the sudden release of pressure on pelvic nerves or of excess epinephrine production during labor. In any event, it is a normal phenomenon but it can be frightening to the mother. She may associate the shaking chill with fever or infection and worry she will be ill at a time when she most wants to be well to care for her new child. You can reassure her that this is a normal, transitory sensation.

Aftercare

This is the beginning of the postpartal period or the fourth stage of labor. Because the uterus may be so exhausted from labor that it cannot maintain contraction, there is a high risk for hemorrhage during this time. In addition, a woman often is so exhausted that she may be unable to assess her own condition or report any changes. Specific assessments done during this time are continued throughout the postpartal period. These assessments are discussed in Chapter 17.

UNIQUE CONCERNS OF A WOMAN IN LABOR

A Woman Without a Support Person

Some women have chosen to reject or want to labor without the infant's father, who is the usual support person during labor. Such women may appreciate having a family member or close friend act as their support person. A woman who has no support person needs a supportive nurse to be with her.

A woman whose acceptance of her pregnancy was slow to develop because of lack of adequate support people may not have completed the psychological tasks of pregnancy by the time she is in labor. This could make her more apprehensive about a new life role and calls for increased assessment of parent–child bonding in the immediate postpartal period.

A Woman Who Will Be Placing Her Baby for Adoption

If a woman has decided to place her baby for adoption, she needs to be an active participant in her labor and birth experience and be allowed to hold her child as desired. Each state has a set number of days in which a mother must decide whether to keep her baby. Although this decision may have seemed easy to make during pregnancy, once she holds the baby in her arms, the prospect of giving up the child may be more painful than she realized. She needs support no matter what decision she eventually makes. Be certain you do not offer influencing advice, because the woman is the only person who knows whether keeping this child is right for her.

Vaginal Birth After Cesarean Birth

Women who have had a previous cesarean birth that involved a low transverse uterine incision are usually candidates for vaginal birth with their next pregnancy (Landon, 2008). The length of labor for vaginal birth after cesarean birth (VBAC) is usually comparable to that of primiparas, not multiparas, because it is the first vaginal birth. Most women are anxious for vaginal birth to be successful so that they do not have to undergo surgery again. At the same time, they may be surprised and dismayed at the length and discomfort of labor and wish that they could have another cesarean. Keep the woman well informed, and urge her to breathe with contractions and to push effectively to make the experience a positive one for her. Afterward, many women are relieved to realize that, although they did have more discomfort before birth, they have appreciably less pain afterward.

If during the previous labor a complication occurred that necessitated the cesarean birth, a woman cannot help but worry that this will happen again. She needs a support person with her and health care providers who are aware of her possible level of apprehension. Women having a VBAC usually have external electronic monitoring because of the risk for uterine rupture. The outcome of VBAC is usually without complication. If necessary, oxytocin augmentation (see Chapter 23) can be used to strengthen uterine contractions; vacuum extraction and forceps birth can be used as necessary.

✔ Checkpoint Question 15.5

Celeste has an amniotomy (artificial rupture of the membranes). After this procedure, which of the following would be an important nursing assessment?

a. Ask her if her pain level is tolerable postprocedure.
b. Assess maternal heart rate to detect possible bleeding.
c. Assess FHR to detect possible cord prolapse.
d. Document the amount of amniotic fluid that has been lost.

Key Points for Review

- Labor is the series of events by which uterine contractions expel a fetus and placenta from a woman's body.
- The exact reason why labor begins is unknown. It most likely occurs because of an interplay between fetal and uterine factors that registers as progesterone withdrawal.

- Effective labor depends on interactions between the passage, the passenger, the power of contractions, and a woman's psychological readiness.
- Labor is an almost overwhelming experience because it involves such intense sensations and emotions. Women enjoy having a support person with them to help them cope with the experience.
- Fetal presentation (the fetal body part that will initially contact the cervix) and position (the relationship of the fetal presenting part to a specific quadrant of the woman's pelvis) are both important in determining the success of labor.
- The first stage of labor lasts from the onset of cervical dilatation until dilatation is complete (10 cm). The second stage extends from the time of full dilatation until the infant is born. A third or placental stage lasts from the time the infant is born until after delivery of the placenta. A fourth stage comprises the first few hours after birth.
- Danger signs of labor include an abnormal FHR, meconium staining of amniotic fluid, abnormal maternal pulse or blood pressure, inadequate or prolonged contractions, formation of a pathologic retraction ring (development of an abnormal lower abdomen contour), and increasing apprehension.
- Monitoring of uterine contractions and FHR is an important nursing responsibility. Fetal bradycardia, tachycardia, and late and variable decelerations are important observations to make. Interventions such as keeping the woman on her left side and promoting voiding help to prevent fetal distress. Offering psychological support is crucial to maternal well-being.
- Pushing during the second stage of labor should be guided by the woman's need to push. Urge her to breathe out while pushing, if possible.
- The placental stage follows birth and consists of placental separation and expulsion. Observe for excessive bleeding during this time. Do not pull on the cord to hasten separation, because this can lead to uterine inversion.
- A fetus is in potential danger when the membranes rupture, because of the possibility of cord prolapse. Always assess FHR at this point to safeguard the fetus.
- A woman is at potential risk for hemorrhage throughout labor because of the possibility that the placenta could be dislodged. Assess for vaginal bleeding and vital signs to be certain this is not occurring.

CRITICAL THINKING EXERCISES

1. Celeste Bailey, the woman you met at the beginning of the chapter, was certain her labor was not normal because it had lasted for 6 hours. Is this an unusually long time for a first stage of labor? Do you think she would have been more comfortable knowing the usual length?
2. Suppose that, when Celeste is admitted to a birthing room, she states she has read nothing during her pregnancy about labor and so has no idea what to expect. What would you want to teach her early in labor? Midway in labor? Why might a woman enter labor without having learned anything about it?
3. Most women today accept fetal monitoring equipment as an expected part of labor care. What would you do if Celeste Bailey absolutely refuses to have this type of fetal monitoring?
4. Examine the National Health Goals related to labor. Most government-sponsored funds for nursing research are allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to the Bailey family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to care of families in labor. Confirm your answers are correct by reading the rationales.

Chapter 16

Providing Comfort During Labor and Birth

KEY TERMS

- analgesia
- anesthesia
- doula
- endorphins
- epidural anesthesia
- pain
- pressure anesthesia
- pudendal nerve block
- transcutaneous electrical nerve stimulation (TENS)

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe the physiologic basis of contractions during labor and how analgesia, anesthesia, and alternative therapies can be used to promote a woman's comfort during labor and birth.
2. Identify National Health Goals related to analgesia, anesthesia, and childbirth that nurses can help the nation achieve.
3. Use critical thinking to analyze ways to maintain family-centered care when analgesia and anesthesia are used in childbirth.
4. Assess the degree and type of discomfort a woman is experiencing during labor and birth, including her ability to cope with it effectively.
5. Formulate nursing diagnoses related to the effect of pain or pain management during labor and birth.
6. Establish expected outcomes to meet the needs of a woman experiencing discomfort during labor and birth.
7. Plan nursing interventions to promote comfort during labor and birth such as teaching about relaxation or breathing exercises.
8. Implement common complementary and pharmacologic measures for pain management during labor and birth.
9. Evaluate expected outcomes for effectiveness and achievement of care.
10. Identify areas related to promoting comfort during labor that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of pain management during labor and birth with the nursing process to achieve quality maternal and child health nursing care.

Susan Baranca is a primipara in early labor whom you admit to a birthing unit. Her cervix is dilated 3 cm. She tells you her sister had epidural anesthesia that completely obliterated her pain in labor for the birth of her baby 3 months ago. Based on her sister's experience, Susan expected to be given epidural anesthesia as soon as she arrived at the hospital. As she is barely in labor, however, her physician asked her to wait until she is 4 cm dilated. When you enter her room, you find her lying on her back in a birthing bed, crying from pain. Her husband shouts that his wife deserves better care than this. The previous chapter discussed the process of labor and care for a woman in labor. This chapter adds information to your knowledge base about how to promote comfort during labor. Pain management in labor can help change labor from an experience so negative that it can result in posttraumatic stress syndrome to a positive, forward-moving experience.

Was the advice Susan received from her sister realistic?

What are some immediate interventions you could do to help Susan better manage her pain?

Concerns about the discomfort and pain that accompany labor and birth can dominate a pregnant woman's or couple's thoughts about childbirth during pregnancy and particularly as the baby's due date approaches. Providing information during prenatal visits about the numerous methods of comfort promotion and pain control available to women can help allay some of these fears. As discussed in Chapter 14, prepared childbirth classes can provide couples with an opportunity to learn and practice a variety of techniques, such as breathing patterns, to help reduce the pain of labor. Often, however, the labor experience is so overwhelming, or so much greater than the couple expected, that administration of an analgesic or a regional anesthetic is necessary to reduce discomfort sufficiently to allow a woman to regain control over her labor process and use breathing patterns. If the use of regional anesthesia makes labor a satisfying, positive experience, the intervention can ultimately promote the entire family's health. Using or not using medication only reflects different routes to becoming new parents (Carlton et al., 2009).

Much has been written in nursing literature about using the neutral term *contractions* instead of *labor pains,* to keep from reminding a woman how painful contractions can be. The theory is a sound one, not only because a woman is experiencing a *contracting* sensation but also because calling it *pain* could magnify her fear and tension. Tension, in turn, magnifies pain. Remember, however, that renaming it will not change its basic nature. By any name, discomfort accompanies labor. Fortunately, many nursing interventions can help reduce pain, so that labor is as fulfilling and rewarding an experience as a woman hoped it would be.

Making labor and birth a memorable experience for families is so important that National Health Goals have been established to address this topic. These are shown in Box 16.1.

BOX 16.1 ✻ Focus on National Health Goals

Because administration of either analgesia and anesthesia during labor can increase both maternal and fetal mortality, several National Health Goals are related to the types of pain relief used in labor. Examples include:

- Reduce the maternal mortality rate to no more than 3.3 per 100,000 live births, from a baseline of 7.1 per 100,000.
- Reduce the fetal death rate during the perinatal period (28 weeks of gestation to 7 days after birth) to no more than 4.5 per 1000 live births, from a baseline of 7.5 per 1000 (http://www.nih.gov).

Nurses can help the nation achieve these goals by educating women about the advantages of preparing for childbirth, helping them to use breathing patterns or other complementary and alternative therapies and techniques during labor so that they need a minimum of analgesia and anesthesia, and conscientiously monitoring women who receive analgesics and anesthesia during labor and birth.

Areas that could benefit from additional nursing research include women's satisfaction with complementary or alternative therapy comfort measures, women's satisfaction with regional anesthesia in labor, and reasons that childbirth methods women prepare are not adequate for pain relief.

Nursing Process Overview

For Pain Relief During Childbirth

Assessment

Pain, the sensation of discomfort, is a subjective, personal symptom; it is what the person says it is and present when the person says it is (Cho & Penning, 2007). It is unique to each individual, so a woman is the only person who can describe or know the extent of her pain. To assess the amount of discomfort a woman is having in labor, listen carefully to what she is saying as well as how she rates her discomfort level on a pain assessment scale. Also look for subtle signs such as facial tenseness, flushing or paleness, hands clenched in fists, rapid breathing, or rapid pulse rate.

Nursing Diagnosis

Although pain related to labor contractions is the most obvious nursing diagnosis applicable to labor, it is not the only relevant one during this time. Pain can create other problems for the laboring woman that can negatively affect the childbirth experience. If not resolved, these problems can intensify pain. Some women may become more concerned with their reaction to the pain than to the pain itself. Because of this, applicable nursing diagnoses might include:

- Pain related to labor contractions
- Powerlessness related to the unexpected duration and intensity of labor
- Anxiety related to lack of knowledge about "normal" labor process
- Risk for situational low self-esteem related to ineffectiveness of prepared childbirth breathing exercises
- Decisional conflict related to use of analgesia or anesthesia during labor

Outcome Identification and Planning

When developing outcomes and planning interventions to manage discomfort during labor, consider the woman's perceptions about childbirth, her past childbirth experiences (if any), and the amount and type of childbirth preparation she and her partner made so the expected outcomes are realistic. For example, an expectation that no medication will be used might be inappropriate.

Be aware that pharmacologic agents used during labor and birth may pose risks for both the woman (e.g., hypotension) and the fetus (e.g., bradycardia). Therefore, their use must always be weighed against the alternative risk of having labor become an unbearable experience. The decision may also affect family functioning if the method chosen limits the partner's participation in the birth. A good Internet site for referral is the American Pain Society web page (http://www.ampainsoc.org).

Implementation

Keeping a woman and her support person informed about their options and how they differ as labor progresses is important. Simply knowing that birth is getting even a little closer can make the next few contractions easier to withstand. Supporting and encouraging a woman to use methods of complementary and alternative therapies for pain management (e.g., relaxation) also are helpful. Offering analgesia or assisting with anesthesia administration during labor or birth requires nursing judgment and a caring presence to help one woman accept analgesia when she needs it and to encourage another to experience childbirth without heavy sedation.

Outcome Evaluation

Evaluation is ongoing and typically must occur within a short timeframe. Examples of expected outcomes that would indicate successful achievement of outcomes are:

- Client states that pain during labor was within a tolerable level for her.
- Couple report that they felt in control throughout the labor process.
- Client states that she does not feel intimidated by degree of pain during labor.

Long-term evaluation should reveal that the woman found labor and birth to be an experience that was not only endurable but allowed her to grow in self-esteem and the family to grow through a shared experience. Asking a woman to describe her labor experience afterward in relation to pain not only aids evaluation of whether pain management was adequate but helps her work through this emotional period of life and integrate it into her previous experiences.

EXPERIENCE OF PAIN DURING CHILDBIRTH

Pain accompanies labor contractions for several different reasons and is manifested in different ways in individual women (Box 16.2).

Etiology of Pain During Labor and Birth

Normally, contractions of involuntary muscles, such as the heart, stomach, and intestine, do not cause pain. This concept makes uterine contractions unique because they do cause pain. Several explanations exist for why this happens. During contractions, blood vessels constrict, reducing the blood supply to uterine and cervical cells, resulting in anoxia to muscle fibers. This anoxia can cause pain in the same way that blockage of the cardiac arteries causes the pain of a heart attack. As labor progresses and contractions become longer and harder, the ischemia to cells increases, the anoxia increases, and the pain intensifies.

Pain also probably results from stretching of the cervix and perineum. This phenomenon is the same as that causing intestinal pain when accumulating gas stretches the intestines. At the end of the transitional phase in labor, when stretching of the cervix is complete and the woman feels she has to push, pain from the contractions often disappears as long as the woman is pushing, until the fetal presenting part causes the final stretching of the perineum.

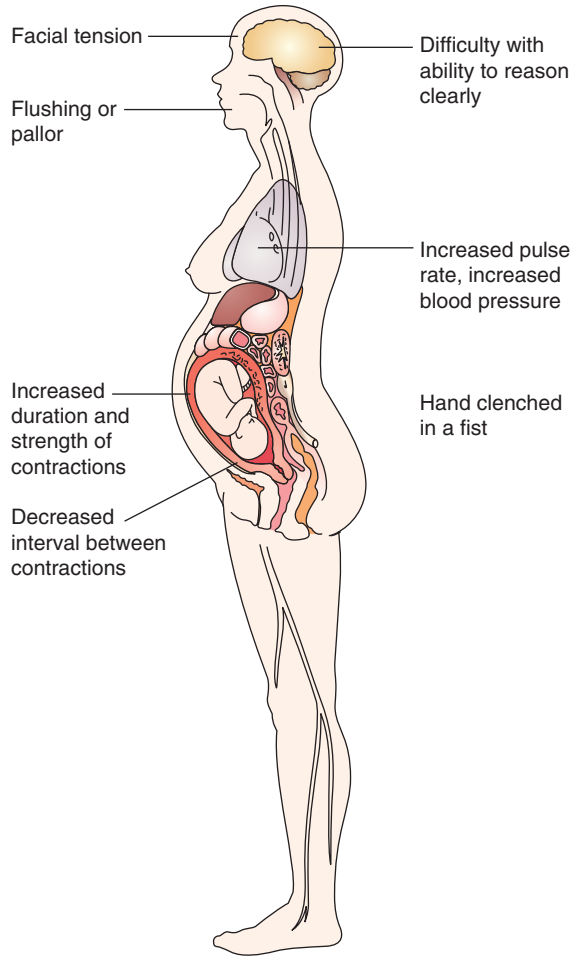
Additional discomfort in labor may stem from the pressure of the fetal presenting part on tissues, including pressure on surrounding organs, such as the bladder, the urethra, and the lower colon. Pain at birth largely results from stretching of the perineal tissue.

In addition, the perception of pain is, in part, culturally determined. Some women believe that being stoic and nonverbal is what is expected of them. Others believe that expressing their discomfort by screaming or verbalizing their feelings will best reduce pain. If a woman is not proficient in English, it may be particularly difficult for her to describe her level of discomfort. Assess each woman individually to determine not only what level of comfort she feels is right for her during labor but also the manner in which she feels most able to express discomfort (Herr et al., 2007).

The amount of analgesia that women desire or will accept is both situationally and culturally determined. In a culture in which birth is seen as a "natural" process, less analgesia is generally desired. Women who have an effective support person with them may need less pharmacologic pain relief than

Box 16.2 Assessment

Assessing Pain Level for a Woman in Labor



those who do not. Nursing support can have a positive influence on pain relief in labor.

Physiology of Pain During Labor and Birth

Pain is a basic protective mechanism that alerts a person that something threatening is happening somewhere in the body. The sensation of pain begins in nociceptors, the end points of afferent nerves, when they are activated by mechanical, chemical, or thermal stimuli. Nociceptors are located predominantly in the skin, bone periosteum, joint surfaces, and arterial walls. When these end terminals are stimulated, chemical mediators such as prostaglandins, histamine, bradykinin, and serotonin are synthesized and help transmit the pain impulse along small, unmyelinated C fibers and large, myelinated A-delta fibers to the spinal cord. The more numerous C fibers conduct slowly and apparently carry dull, low-level pain; the fewer A-delta fibers apparently carry sharp, well-localized pain such as labor contractions.

In the dorsal horn of the spinal cord, somatostatin, cholecystokinin, and substance P serve as neurotransmitters or assist the pain impulse across the synapse between the peripheral nerve and the spinal nerve. The pain impulse then ascends the spinal cord to the brain cortex, where it is interpreted as pain.

The Melzack-Wall gate control theory of pain control (Melzack & Wall, 1965), the most widely accepted theory of pain response, proposes that pain can be halted at three points: the peripheral end terminals, the synapse points in the dorsal horn, or the point at which the impulse is interpreted as pain in the brain cortex.

Pain in peripheral terminals is automatically reduced by the production of endorphins and enkephalins, naturally occurring opiates that limit transmission of pain from the end terminals. Pain can be reduced further by mechanically irritating nerve fibers by an action such as rubbing the skin. This technique blocks nerve transmission.

A major action of pain medications is to block spinal cord neurotransmitters, never allowing the pain impulse to cross to a spinal nerve. The brain cortex can be distracted from sensing impulses as pain by the use of such techniques as imagery, thought stopping, aromatherapy, or yoga.

Sensory impulses from the uterus and cervix synapse at the spinal column at the level of T10 through L1. Pain relief measures for the first stage of labor, therefore, must block these upper synapse sites. For the elimination of pain during cesarean birth, higher receptors at the level of T6 through T8 must also be blocked, so that both the upper and lower uterus receptors are blocked.

Sensory impulses from the perineum are carried by the pudendal nerve to join the spinal column at S2, S3, and S4. When the perineum is initiating the pain, pain relief must block these lower receptor sites. This is an important point to remember when talking to a woman in labor about pain relief. Some interventions relieve pain for both the first and second stages of labor, whereas others work for one stage but not both.

Perception of Pain

The amount of discomfort a woman experiences during contractions differs according to her expectations of and preparation for labor; the length of her labor; the position of her fetus; the presence of fear, anxiety, or worry; body image; self-efficacy; and the availability of support people around her (Fig. 16.1). Women who believe that they can control their situation (have self-efficacy) are more apt to report a satisfactory birth experience than are those who do not feel in control.

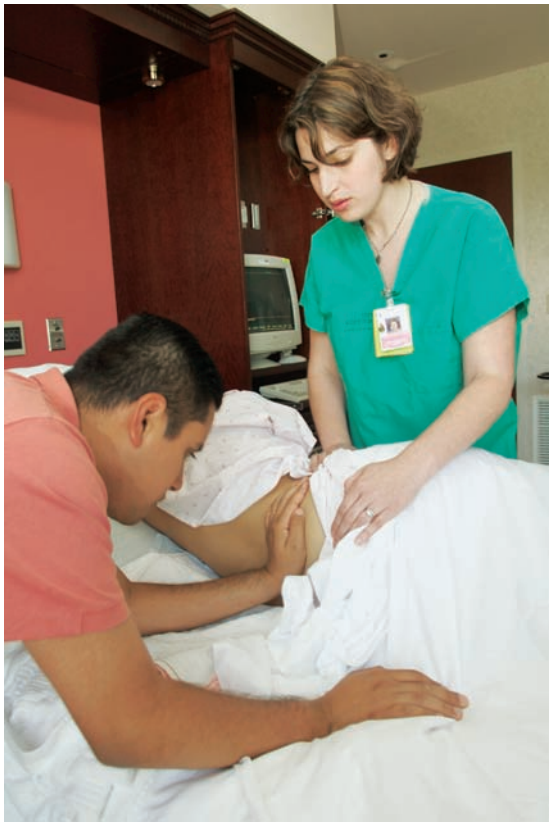


FIGURE 16.1 The discomfort a woman experiences during childbirth may be related to the amount of support she receives from her family or health care providers. Here, the woman's support person uses the palm of his hand to apply counterpressure to her lower back, helping to ease back pain, while the nurse assists.

Fetal position is a physical variable that can influence the degree of pain a woman experiences. If the fetus is in an occiput posterior position, for example, the woman often reports intense or nagging back pain, even between contractions.

Pain is perceived differently by different individuals because of psychosocial, physiologic, and cultural responses. The body's ability to produce and maintain **endorphins** (naturally occurring opiate-like substances) may influence a person's overall pain threshold and the amount of pain a person perceives at any given time. Women who come into labor believing the pain will be horrible are usually surprised afterward to realize that the agony they expected never materialized. On the other hand, women who thought that pain would be minimal can be overwhelmed by its intensity. Unreal expectations of pain this way can make a woman so tense during labor that her pain is worse than it would have been if she had been relaxed. A woman cannot relax simply because she is instructed to do so by another person, however. Some additional interventions must be used.

COMFORT AND PAIN RELIEF MEASURES

The pattern of interventions to promote comfort and manage pain in labor has swung from a philosophy of no intervention (none given because pain in labor was a "woman's lot"), to a philosophy that drug intervention was required (too much given), to a modern approach of empowering women and their partners with information so that they can choose how to best relieve pain during labor, within the limits of medical safety. For centuries, in Western civilization, offering pain relief in labor was thought to be amoral because, according to the Biblical account, God commanded Eve, "I will greatly multiply thy sorrow and thy conception; in sorrow thou shalt bring forth children..." (Genesis 3:16).

With the discovery of ether and chloroform in the 1800s, it became apparent that childbirth could be managed relatively pain free. Unfortunately, this goal was achieved by means of complete anesthesia or unconsciousness during labor and birth. Women, afterward, had difficulty realizing that the birth was over and they were a new parent.

This led to an era in which women refused pharmacologic pain relief in labor, depending entirely on prepared childbirth measures. Since the advent of epidural anesthesia (anesthetic agent placed just inside the ligamentum flavum in the epidural space), women have become more agreeable to accepting interventions for pain management (Green & Baston, 2007). Nurses play a key role in educating women and their support persons about the numerous comfort and pain relief strategies available and making sure couples understand the choices available to them along with the benefits and risks. Throughout their decision-making process, couples need support for their choices so that they can feel confidence in the method chosen.

Support From a Doula or Coach

A woman's husband or the father of her child has traditionally served as the chief support person in labor. However, some husbands or fathers find it difficult to provide effective coaching or support in labor because of their emotional involvement in the birth. Women who are aware that they may not have effective one-to-one support in labor from their baby's father should be encouraged to identify an additional person who could come with them and provide this support. A **doula** is a woman who is experienced in childbirth, but without professional credentials, who guides and assists women in labor (McGrath & Kennell, 2008). Having a doula can increase a woman's self-esteem as well as decrease rates of oxytocin augmentation, epidural anesthesia, and cesarean birth.

✔ Checkpoint Question 16.1

Susan asks you what is the purpose of a doula in labor. Your best answer would be:

a. "She can time contractions to keep them from becoming too long."
b. "She can cook you something to keep you from becoming dehydrated."
c. "She can serve as a support person and coach during your labor."
d. "She replaces your husband as your support person during labor."

Complementary and Alternative Therapies for Pain Relief

Complementary and alternative therapies for pain relief involve nonpharmacologic measures that may be used either as a woman's total pain management program or to complement pharmacologic interventions. Most of these interventions are based on the gate control theory concept that distraction can be effective in preventing the brain from processing pain sensations coming into the cortex.

Relaxation

The technique of relaxation, as discussed in Chapter 14, is taught in most preparation for childbirth classes. Relaxation keeps the abdominal wall from becoming tense, allowing the uterus to rise with contractions without pressing against the hard abdominal wall. It also serves as a distraction technique because, while concentrating on relaxing, a woman cannot concentrate on pain. In addition to conscious relaxation, having a woman shift position or find the position in labor that is most comfortable for her can be helpful. Asking a woman to bring favorite music tapes or aromatherapy with her to enjoy in the birthing room is a good way to aid relaxation (Burns et al., 2007).

Focusing and Imagery

Concentrating intently on an object is another method of distraction, or another method of keeping sensory input from reaching the cortex of the brain. For this technique, a woman uses a photograph of someone important to her or some image she finds appealing. She concentrates on it during contractions (focusing). Other women concentrate on a mental image, such as waves rolling onto a beach (imagery). Do not ask questions or talk to a woman while she is using imagery or focusing, because it breaks her concentration.

Prayer

For many women, any time they are facing a stressful situation, prayer is the first measure that they use to relieve stress. Women may bring helpful worship objects such as a Bible or cross into a hospital with them to use during prayer. These are sacred objects so be careful when changing sheets during labor that you do not accidentally throw away such important objects.

Breathing Techniques

Breathing patterns are also taught in most preparation for childbirth classes (see Chapter 14). They are advantageous because they help to relax a woman's abdomen. They are largely distraction techniques, because a woman concentrating on slow-paced breathing cannot concentrate on pain. Breathing strategies can be taught to a woman in labor if she is not familiar with their advantages before labor.

Herbal Preparations

Several herbal preparations have traditionally been used to reduce pain with dysmenorrhea or labor, although there is little factual support for their effectiveness. Examples include raspberry leaves, fennel, and life root. Blue cohosh (squaw root), an herb that induces uterine contractions, is not recommended

because of the risk of acute toxic effects (e.g., cerebrovascular accident) to the mother or fetus (DerMarderosian & Beutler, 2007).

Aromatherapy and Essential Oils

Aromatherapy is the use of aromatic oils to complement emotional and physical well-being. Their use is based on the principle that the sense of smell plays a significant role in overall health. When an essential oil is inhaled, its molecules are transported via the olfactory system to the limbic system in the brain. The brain responds to particular aromas with emotional responses. When applied externally, they are absorbed by the skin and then carried throughout the body. The oils used may be able to penetrate cell walls and transport nutrients or oxygen to the inside of cells. Jasmine and lavender are oils thought to be responsible for an easier labor. When a drop of oil, such as lavender, is placed on the skin, a woman is able to taste it within 15 seconds.

Heat or Cold Application

Heat and cold have always been used for pain relief after injuries such as minor burns or strained muscles. It is only lately that they have been investigated as effective ways to help relieve the pain of labor contractions. Women who are having back pain may find application of heat to the lower back by a heating pad or a moist compress comforting.

Women who become warm from the exertion of labor find a cool washcloth to the forehead comforting. Ice chips to suck on to relieve mouth dryness are also refreshing.

Bathing or Hydrotherapy

Standing under a warm shower or soaking in a tub of warm water, jet hydrotherapy tub, or whirlpool is another way to apply heat to help reduce the pain of labor (Maude & Foureur, 2007). The temperature of water used should be between 95° and 100° F (35.0° and 37.8° C) to prevent hyperthermia. Soaking in a tub is not usually recommended for women at the beginning of labor because the heat and relaxations may slow contractions and not in women whose membranes have ruptured because of the risk of infection.

Therapeutic Touch and Massage

Therapeutic touch is the use of touch to comfort and relieve pain (Engebretson & Wardell, 2007). It is based on the concept that the body contains energy fields that, when plentiful, lead to health and, when in lesser supply, result in ill health. Krieger (1990), in a classic work, defined therapeutic touch as the laying on of hands to redirect the energy fields that lead to pain. Although the action is not well documented, touch and massage probably work to relieve pain by increasing the release of endorphins. Massage, especially, can be helpful in the first and second stages of labor (Kimber, 2007). Both these techniques also serve as forms of distraction. Effleurage, the technique of gentle abdominal massage often taught with Lamaze preparation for childbirth classes, is a form of therapeutic touch (see Fig. 14.7).

Yoga and Meditation

Yoga, a term derived from the Sanskrit word for "union," describes a series of exercises that were originally designed to bring people closer to their God. It offers a significant variety of proven health benefits, including increasing the efficiency of the heart, slowing the respiratory rate, improving fitness, lowering blood pressure, promoting relaxation, reducing stress, and allaying anxiety. Exercises consist of deep breathing exercises, body postures to stretch and strengthen muscles, and meditation to focus the mind and relax the body. It may be helpful in reducing the pain of labor through its ability to relax the body and possibly through the release of endorphins that may occur (Smith, 2009).

Meditation is a self-directed practice for relaxing the body and calming the mind (Gaudet, 2007). Mindfulness-based stress reduction (MBSR), based on Vipassana meditation from India, is based on the cultivation of intentional awareness of experiences in the present moment. Transcendental meditation (TM) is a simple, natural, effortless effort while resting comfortably with the eyes closed. Using this technique, an individual experiences a state of deep rest that can change physical and emotional responses to stress.

Reflexology

Reflexology is the practice of stimulating the hands, feet, and ears as a form of therapy (O'Mathuna, 2007). Professional reflexologists apply pressure to specific areas of the hands, feet, and ears to alleviate common ailments such as headaches, back pain, sinus colds, and stress. The theory behind reflexology is that each of the body's organs and glands are linked to corresponding areas of the hands and feet. The body is divided into 10 zones that run in longitudinal lines from the top of the head to the tips of the toes. Application of pressure to the specific area aims to restore energy to the body and improve the overall condition.

Crystal or Gemstone Therapy

Some gemstones or crystals are thought to have healing powers, and women may bring these into a birthing room to have with them during labor. A woman who uses crystals or gemstones may believe that their healing power is magnified when they are positioned around her body. Be especially careful when changing bedding or rearranging equipment in a birthing room to respect the position of these crystals. A woman may feel that they do not work their healing powers in an altered position.

Hypnosis

Hypnosis is yet another method of pain relief for labor. A woman who wants to use this modality needs to meet with her hypnotherapist during pregnancy. At these visits, she is evaluated for and further conditioned for susceptibility to hypnotic suggestion. At the last prenatal visit, she is given the posthypnotic suggestion that she will experience reduced pain or absence of pain during labor. For a woman who is susceptible to hypnotic suggestion, the method can provide a very satisfactory drug-free method of pain relief (Stephenson, 2007).

Biofeedback

Biofeedback is based on the belief that people have control and can regulate internal events such as heart rate and pain responses (Smith, 2009). Women who are interested in using biofeedback for pain relief in labor must attend several sessions

during pregnancy to condition themselves to regulate their pain response. During these sessions, a biofeedback apparatus is used to measure muscle tone or the woman's ability to relax.

Transcutaneous Electrical Nerve Stimulation

Transcutaneous electrical nerve stimulation (TENS) relieves pain by counterirritation on nociceptors (Halls, 2008). With two pairs of electrodes attached to a woman's back to coincide with the T10–L1 nerve pathways, low-intensity electrical stimulation is given continuously or is applied by the woman herself as a contraction begins. This stimulation blocks the afferent fibers, preventing pain from traveling to the spinal cord synapses from the uterus. As labor progresses and the pelvic division begins, the electrodes are moved to stimulate the S2–4 level. High-intensity stimulation is generally needed to control the pain at this stage.

TENS can be as effective as epidural anesthesia for pain relief in labor, but some women may object to being "tied down" to the equipment. Women with extreme back pain during labor may benefit the most from a TENS unit, because this type of pain is difficult to relieve with controlled breathing exercises. TENS is also discussed in Chapter 24 as it is helpful for the postoperative pain of a cesarean birth.

Acupressure and Acupuncture

Acupuncture is based on the concept that illness results from an imbalance of energy. To correct the imbalance, needles are inserted into the skin at designated susceptible body points (*tsubos*) located along meridians that course throughout the body to supply the organs of the body with energy. These points are not necessarily near the affected organ. Activation of these points apparently results in release of endorphins, so the system can be helpful, especially in the first stage of labor (Rosen, 2007).

Acupressure, in contrast, is the application of pressure or massage at these points. A common point used for a woman in labor is Co4 (Hoku or Hegu point) located between the first finger and thumb on the back of the hand. When a support person holds and squeezes a woman's hand in labor, he or she may be accidentally triggering this point.

Intracutaneous Nerve Stimulation

Intracutaneous nerve stimulation (INS) is a technique of counterirritation involving the intradermal injection of sterile water or saline along the borders of the sacrum to relieve low back pain during labor. Some women find the technique helpful; others prefer to bear back pain rather than submit to injections.

✔ Checkpoint Question 16.2

Susan asks you if she could use warm-water tub bathing during labor. Your best answer would be:

a. "No. No one is allowed to tub bathe during labor."
b. "Yes, as long as your membranes are not ruptured."
c. "No, because warm water can cause uterine infections."
d. "Yes, as long as you know that warm water has no effect."

Pharmacologic Measures for Pain Relief During Labor

Pharmacologic management of pain during labor and birth includes **analgesia,** which reduces or decreases awareness of pain, and **anesthesia,** which causes partial or compete loss of sensation. For the best results, be sure women are included in a selection that is right for them.

Virtually all medication given during labor crosses the placenta and has some effect on the fetus, which makes it important for a woman to receive as little systemic medication as possible. On the other hand, labor should not test a woman to the limit of her endurance, especially since local anesthesia is available. Be sure to caution women not to take acetylsalicylic acid (aspirin) for pain in labor. Aspirin interferes with blood coagulation, increasing the risk for bleeding in the newborn or mother.

Goals of Pharmacologic Management of Pain During Labor

Medication effectively used during labor must relax a woman and relieve her discomfort, yet have minimal systemic effects on her uterine contractions, her pushing effort, or her fetus. Whether a drug affects a fetus depends on its ability to cross the placenta. Drugs with a molecular weight of greater than 1000 cross poorly, whereas those with a molecular weight of less than 600 cross very readily. Drugs with highly charged molecules or molecules strongly bound to protein cross more slowly than others. Fat-soluble drugs cross most easily. A preterm fetus, which has an immature liver and is unable to metabolize or inactivate drugs, is generally more affected by drugs than a term fetus. If a drug causes a systemic response, such as hypotension, in a woman, it can result in a decreased oxygen (Po_2) gradient across the placenta and fetal hypoxia. If it causes confusion or disorientation, a woman may be unable to work effectively with contractions, prolonging labor. If a medication causes changes in a fetus, such as a decreased heart rate or central nervous system (CNS) depression, it may be difficult for the newborn infant to initiate respirations at birth, severely compromising the infant in the important first minutes of life.

For all these reasons, there is no perfect medicine to use to reduce the pain of labor. Because pain is a subjective sensation, some women are most aware of pain early in labor, whereas some report the second stage of labor as the most difficult. The point at which pain medication is needed, therefore, differs from one individual to another. It should be given as early in labor as an individual woman needs it. Once labor is well under way, medication to relieve discomfort can speed its progress: with pain gone, a woman can relax and work with, not against, her contractions. Unfortunately, no perfect analgesic agent exists for labor or birth that has no effect on labor, the mother, and the fetus.

Preparation for Medication Administration

The type of medication used during labor varies among different health care agencies and also changes based on new research as the effectiveness and safety of new drugs for use during labor are tested. To be safe, remember the criteria that a drug must fulfill to be used in pregnancy, or expand the rule of basic medication administration from "Never give any drug unless you know it is safe for your individual client" to "Never give a drug during labor unless you know it is safe for both of your clients: the mother and the fetus."

Medicines commonly used in labor and birth are shown in Table 16.1. Prepare a woman for the type of agent prescribed,

TABLE 16.1 ✻ Analgesics and Anesthetics Commonly Used in Labor and Birth

Type	Drug	Usual Dosage/Route	Effect on Mother	Effect on Labor Progress	Effect on Fetus or Newborn
Narcotic analgesic	Meperidine (Demerol)	25 mg IV, 50–100 mg IM q3–4 hr; also epidurally	Effective analgesic; feeling of well-being	Relaxation, possibly aiding progress during cervical relaxation. Slows labor contractions if given early.	Should be given 3 hr before birth to avoid respiratory depression in newborn. Decreases beat-to-beat variability in FHR.
	Nalbuphine (Nubain)	10–20 mg IM q3–6 hr, 0.3–3 mg/kg over 10–15 min IV	Slowing of respiratory rate; effective analgesic	Mild maternal sedation	Results in some respiratory depression
	Butorphanol (Stadol)	1–2 mg IM or IV q3–4 hr	Withdrawal symptoms if woman is opiate dependent	Possible slowing of labor if given early	Results in some respiratory depression
	Morphine sulfate	Intrathecally 0.2–1 mg; 5 mg epidurally	Pruritus; effective analgesia	Possible slowing of labor contractions.	Some respiratory depression
	Fentanyl (Sublimaze)	50–100 μg IM or 25–50 μg IV; also epidurally	Hypotension; respiratory depression	Slowing of labor if given early	May result in respiratory depression
Lumbar epidural block	Local anesthetic bupivacaine (Marcaine), ropivacaine (Naropin)	Administered for first stage of labor; with continuous block, anesthesia will last through birth; injected at L3–4; fentanyl or morphine possibly added	Rapid onset, in minutes; lasting 60–90 min; loss of pain perception for labor contractions and birth; possible maternal hypotension	Slowing of labor if given early; pushing feeling obliterated, resulting in possible prolonged second stage	May be some differences in response in first few days of life
Pudendal block	Local anesthetic lidocaine (Xylocaine)	Administered just before birth for perineal anesthesia; injected through vagina	Rapid anesthesia of perineum	None apparent	None apparent
Local infiltration of perineum	Local anesthetic lidocaine (Xylocaine)	Injected just before episiotomy incision	Anesthesia of perineum almost immediately	None apparent	None apparent
General intravenous anesthetic	Thiopental	Administered IV by anesthesiologist or nurse-anesthetist	Rapid anesthesia; also rapid recovery	Forceps required because abdominal pushing is no longer possible	Results in infant being born with CNS depression

how it will be administered (e.g., "You'll need to lie on your side"), and what she can expect to happen after administration (e.g., "I'll be taking your blood pressure frequently"). Women in labor are under stress. Experiencing surprising body sensations from a drug without preparation can be so frightening that it can defeat their individual coping abilities and any relaxation potential associated with it. When a woman struggles this way against medication administration because she does not understand the strange feeling it is causing, the risk of inadvertent problems increases.

What if... Susan tells you she wants epidural anesthesia for pain in labor but also wants to be wide awake? How would you advise her? You notice that Susan's husband grips her hand very tightly during contractions. What possible pain relief measure is her husband's tight pressure providing for her?

Narcotic Analgesics

Narcotics may be given during labor because of their potent analgesic effect, but all drugs in this category cause fetal CNS depression to some extent so are used cautiously (McDonald & Yarnell, 2007). Be sure to question an order for a narcotic if a woman is in preterm labor. Because of possible lung immaturity, a preterm infant may have extreme difficulty coping with the added insult of respiratory depression at birth.

Narcotic analgesics commonly used include meperidine hydrochloride (Demerol), nalbuphine (Nubain), fentanyl (Sublimaze), and butorphanol tartrate (Stadol). *Meperidine* is advantageous as an analgesic in labor because it has additional sedative and antispasmodic actions; these make it effective not only for relieving pain but also for helping to relax the cervix and provide a feeling of euphoria and well-being. It may be given either intramuscularly or intravenously. The dose is 25 to 100 mg, depending on a woman's weight and the route of administration. The drug begins to act about 30 minutes after intramuscular (IM) injection and about 5 minutes after intravenous (IV) administration. Its duration of action is 2 to 3 hours (Karch, 2009).

Meperidine also may be self-administered by a patient-controlled analgesic (PCA) pump for low-dose but frequent administration during labor. Intrathecal administration (injection into the cerebrospinal fluid [CSF]) is used less frequently.

Because meperidine crosses the placenta, it can cause respiratory depression in a fetus. The drug crosses the placenta minutes after either IV or IM administration to the woman. However, because the fetal liver takes 2 to 3 hours to activate the drug into the fetal system, the effect will not be registered in the fetus for 2 to 3 hours after maternal administration. For this reason, meperidine is given when the mother is more than 3 hours away from birth. This allows the peak action of the drug in the fetus to have passed by the time of birth.

It may be puzzling to see a sleepy baby delivered to a woman who was given meperidine 2 hours before birth and an alert baby delivered to a woman who had received meperidine within 1 hour of birth. In the second instance, the peak action or peak effect has not yet occurred in the infant. This newborn needs careful assessment for the next 4 hours until the drug reaches its peak.

Nalbuphine hydrochloride (Nubain) and *butorphanol tartrate* (Stadol) are both synthetic narcotic analgesics. The action of these agents is comparable to that of meperidine. Like meperidine, they may also leave a degree of respiratory depression in the newborn.

Whenever a narcotic is given during labor, a narcotic antagonist such as *naloxone* (Narcan) should be available for administration to the infant at birth (Box 16.3). Carefully observe an infant who receives naloxone in the immediate postpartum period, because the infant's respirations may become severely depressed again when the drug's effect wears off. If severe infant respiratory depression is anticipated, naloxone can be given to a woman just before birth. It readily crosses the placenta and, because it interferes with or competes for narcotic binding sites, may increase the chance for spontaneous respiratory activity in the newborn.

What if... Susan receives no narcotics during labor, yet her newborn is born very sleepy. Would you administer naloxone? Would asking Susan if she used recreational drugs be warranted?

Intrathecal Narcotics. *Intrathecal* administration refers to injection into the spinal cord. With intrathecal narcotic injection, a catheter is introduced into the spinal canal (the subarachnoid space), and a narcotic such as morphine or fentanyl citrate is injected into the canal by way of the catheter. Both drugs provide excellent pain relief for labor pain. They take effect in 15 to 30 minutes, and pain relief lasts 4 to 7 hours. A woman is able to feel the urge to push at the second stage of labor, allowing her to actively participate in the birth. Because intrathecal injections are not as effective in reducing the pain of the actual birth, they may be supplemented with a pudendal block in late labor.

BOX 16.3 ✻ Focus on Pharmacology

Naloxone Hydrochloride (Narcan)

Action: Naloxone hydrochloride is a narcotic antagonist that counteracts the effect of narcotic analgesics (Karch, 2009). It is used to counteract newborn respiratory depression when a mother has received a narcotic analgesic during labor.

Pregnancy category: B

Dosage: 0.01 mg/kg, administered either IV via umbilical vein, SC, or IM; repeated at 2- to 3-minute intervals until response is obtained.

Possible adverse effects: Hypotension, hypertension, tachycardia, diaphoresis, tremulousness

Nursing Implications

- Anticipate the need for newborn resuscitative measures; have resuscitative equipment and emergency drugs readily available.
- If no IV access is available, prepare for possible administration via endotracheal tube.
- If no response is seen after two or three doses, question whether respiratory depression is caused by narcotics or another reason.
- Continuously monitor all vital signs for changes.
- Remember that the pain-relieving effect of narcotics will be reversed; assess for pain in the neonate.

Possible side effects of intrathecal morphine are intense pruritus, nausea, and vomiting. The pruritus can be treated with IV diphenhydramine (Benadryl) if it becomes too uncomfortable.

Additional Drugs

Additional drugs, such as tranquilizers, may be administered during labor to reduce anxiety or potentiate the action of a narcotic. Examples include hydroxyzine hydrochloride (Vistaril) or a short-acting benzodiazepine such as midazolam (Versed). These drugs do not relieve pain, so the woman in labor needs pain management measures in addition to these drugs.

Regional Anesthesia

Regional anesthesia is the injection of a local anesthetic such as tetracaine (Pontacaine) or bupivacaine (Marcaine) to block specific nerve pathways (Cho & Penning, 2007). This achieves pain relief by blocking sodium and potassium transport in the nerve membrane, thereby stabilizing the nerve in a polarized resting state, so that it is unable to conduct sensations.

Various regional anesthetic injection sites are shown in Figure 16.2. Women with pre-eclampsia may have associated bleeding defects and need to be assessed carefully before regional anesthesia is administered.

Because regional anesthetics are not introduced into the maternal circulation, it was once believed that they had no effect on a fetus. However, research has demonstrated that there is some uptake of these drugs by a fetus, possibly resulting in fetal heart rate (FHR) decelerations and symptoms of flaccidity, bradycardia, and hypotension in the newborn (Subramanian, 2008). Effects are minimal compared with those of systemic anesthetic agents, however. Most important, regional anesthesia allows a woman to be completely awake and aware of what is happening during birth. They do not depress uterine tone, so the uterus remains capable of optimal contraction after birth, thereby helping to prevent postpartal hemorrhage.

It is rare that an infant is born with symptoms of toxicity from a regional anesthetic. If this should occur, an exchange transfusion at birth will remove the anesthetic from the infant's bloodstream. Gastric lavage also will remove a great deal of anesthetic, because anesthetics have a strong affinity for acid media such as stomach acid.

Epidural Anesthesia. The nerves in the spinal cord are protected by several tissue layers. The pia mater is the membrane adhering to the nerve fibers. Surrounding this is the *cerebrospinal fluid*. Next comes the arachnoid membrane and outside that, the *dura mater*. Outside the dura mater is a vacant space (the *epidural space*). Beyond it is the *ligamentum flavum,* yet another protective shield for the vulnerable spinal cord (see Fig. 16.2).

An anesthetic agent introduced into the CSF in the subarachnoid space is called a *spinal injection* or *spinal anesthesia*. An anesthetic agent placed just inside the ligamentum flavum in the epidural space is **epidural anesthesia.** Anesthetic agents placed in the epidural space at the L4–5, L3–4, or L2–3 interspace block not only spinal nerve roots in the space but also the sympathetic nerve fibers that travel with them. Therefore, these blocks provide pain relief for both labor and birth. Such a block may actually increase contraction strength and blood flow to the uterus. Because a woman no longer experiences pain, the release of catecholamines (epinephrine) with a β-blocking effect from a pain response is decreased, making this a very effective pain relief measure for labor (Anim-Somuah, Smyth, & Howell, 2009).

Women worry if they will experience a "spinal headache" after receiving anesthesia. These headaches are apparently caused by leakage of CSF or instillation of air into the CSF. With epidural anesthesia, the CSF space is not entered, so this problem should not occur (Box 16.4). Because the

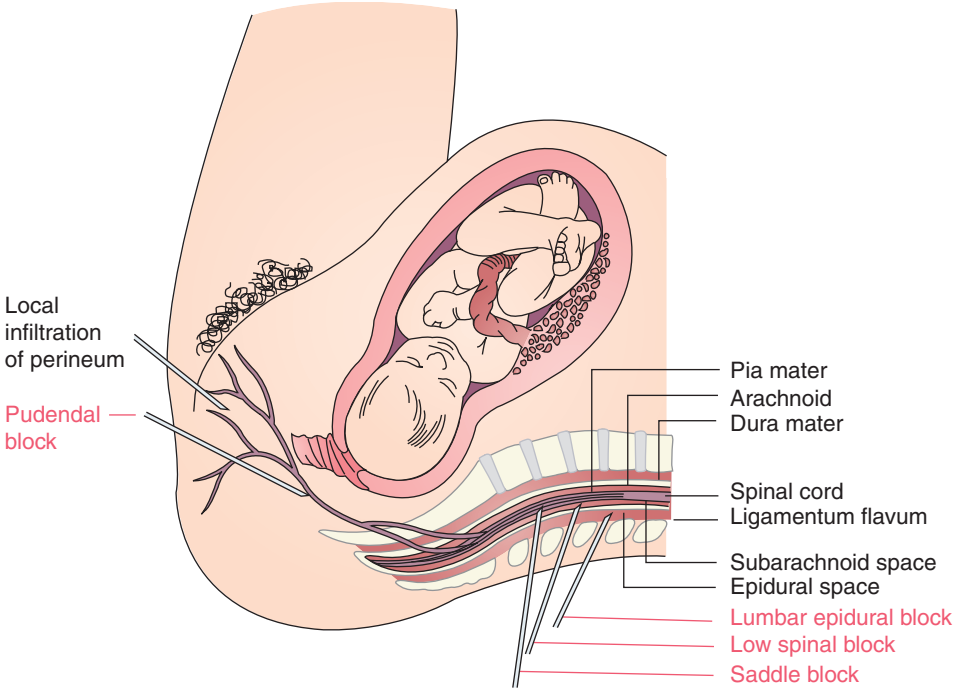

FIGURE 16.2 Anatomy of the spinal canal and sites of injection for regional anesthesia.

BOX 16.4 * Focus on Evidence-Based Practice

How often do postepidural headaches occur?
Theoretically, epidural anesthesia does not result in a postprocedure headache because such headaches are caused by loss of spinal fluid and with epidural anesthesia, the spinal fluid or subarachnoid space is not entered. A few women do report frontal or occipital headaches accompanied by photophobia, nausea, and vomiting following epidural anesthesia. To investigate the incidence of epidural postprocedure headaches, researchers reviewed the labor and birth charts of 18,337 women who received epidural anesthesia for labor or birth. Of these women, 167, or 0.91%, were identified as women who had had an accidental dural puncture. Of these women, 88% developed a postprocedure headache (147 women), or the overall incidence of headache following routine epidural administration to women in labor was 0.8%.

If a woman is worried about developing a "spinal headache," would you use the above study to assure her she will not develop a headache?

Sprigge, J. S., & Harper, S. J. (2008). Accidental dural puncture and post dural puncture headache in obstetric anaesthesia: presentation and management: a 23-year survey in a district general hospital. *Anaesthesia, 63*(1), 36–43.

injection technique is potentially frightening, however, women need continuous support during the process.

Epidural blocks, administered by an anesthesiologist or nurse-anesthetist, are suitable for almost all women. They are advantageous for women with heart disease, pulmonary disease, diabetes, and sometimes severe pregnancy-induced hypertension, because they make labor virtually pain free and thereby reduce stress from the discomfort of labor to a minimum. Because the woman does not feel contractions, her physical energy is preserved. Epidural blocks are acceptable for use in preterm labor because the drug has scant effect on a fetus and allows for a controlled and gentle birth with less trauma to an immature fetal skull. Because the woman receives no systemic medication, the infant responds more quickly after birth than if systemic narcotic analgesics were used.

The chief concern with epidural anesthesia is its tendency to cause hypotension because of its blocking effect on the sympathetic nerve fibers in the epidural space. This blocking leads to decreased peripheral resistance in the woman's circulatory system. Decreased peripheral resistance causes blood to flow freely into peripheral vessels, and a pseudohypovolemia develops, registering as hypotension. The combined use of fentanyl and bupivacaine can lower the risk for hypotension. In addition, the risk also can be reduced by being sure a woman is well hydrated with 500 to 1000 mL of IV fluid, such as Ringer's lactate, before the anesthetic is given. Ringer's lactate is preferable to a glucose solution, because too much maternal glucose can cause hyperglycemia with rebound hypoglycemia in the newborn. Be certain that a woman does not lie supine but remains on her side after an epidural block, to help prevent supine hypotension syndrome.

If hypotension should occur, raising the woman's legs and administering oxygen and additional IV fluid, along with an agent such as ephedrine to elevate blood pressure, may be necessary to stabilize cardiovascular status.

The use of an epidural block may prolong the second stage of labor, but whether this leads to an increase in cesarean births is controversial (Cho & Penning, 2007). Descent can slow, for example, taking 3 hours rather than 2 hours, but if there is no indication that this is detrimental to the fetus, it should not lead to a greater need for vacuum extraction or cesarean birth (Crombleholme, 2009). Relaxation of the levator ani muscle may impede internal rotation of the fetal head, further slowing labor or making the use of forceps necessary to effect rotation. This occurs primarily when the fetus is in an occipitoposterior position. Oxytocin may be given to shorten labor. Allowing an epidural to wear off by the second stage of labor, so that a woman can push with contractions, is another option. However, experiencing contractions at this point can be overwhelming for a woman and counteracts the original reason for giving the anesthetic: to reduce pain in labor.

In rare instances, the anesthetic enters the blood circulation. This occurrence is manifested as drowsiness, a metallic taste on the tongue, slurred speech, blurred vision, unconsciousness, and seizure leading to cardiac arrest. If such symptoms occur, it is an emergency situation. The woman needs oxygen and an anticonvulsant such as diazepam (Valium) or thiopental (Pentothal) IV, followed by prompt birth of the fetus.

Technique for Administration. Epidural anesthesia is begun when the cervix is dilated 3 to 5 cm. An IV infusion and equipment for blood pressure monitoring should be in place. Help position the woman on her side. Her back should not be flexed, because this increases the possibility of puncturing the dura and accidentally giving the anesthetic as a spinal, not epidural, injection. The lumbar area of the back is cleaned with an antiseptic solution. A local anesthetic is injected into the skin to form a wheal over the L3 and L4 vertebrae. A special 3- to 5-inch needle is then passed through the L3–4 interspace into the epidural space. After needle placement, a polyethylene catheter is passed through the needle into the space, and the needle is then withdrawn, leaving the catheter to be taped in place. A closed system (a syringe is attached) is established to prevent infection through the catheter (Fig. 16.3).

The anesthetist then injects a small test dose of a local anesthetic solution into the catheter. Five minutes later, the woman's legs are inspected for flushing and warmness, evidence that the anesthetic is in the epidural space (peripheral dilatation is beginning). Assess a woman's pulse and blood pressure at this time. If the anesthetic was accidentally placed in a blood vessel, toxic symptoms of hypotension, slurred speech, and rapid pulse will be present. After assurance that the anesthetic is epidural, the initial dose of anesthetic is given through the catheter. This produces anesthesia up to the level of the umbilicus in 10 to 15 minutes. The effect of epidural anesthesia is short lived (40 minutes to 2 hours). To keep a woman free from discomfort during the duration of labor, another dose of anesthetic, termed a "top-up," must be added, or anesthetic must be continually infused by an infusion pump. A nurse should be in continuous attendance while an epidural anesthetic is given. Be certain to review agency policy regarding nursing responsibility for catheter care before caring for a woman with a catheter in place (Pasero et al., 2007).

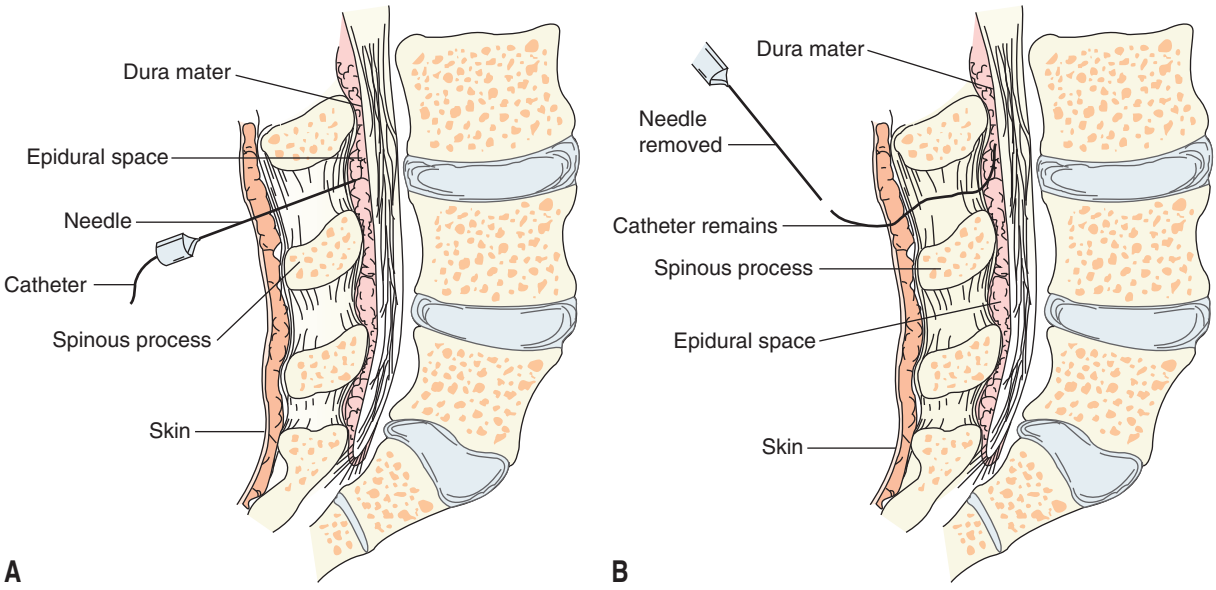

FIGURE 16.3 Epidural anesthesia. (**A**) A needle is inserted into the epidural space. (**B**) A catheter is threaded into the epidural space; the needle is then removed. The catheter allows medication to be administered intermittently or continuously to relieve pain during labor and childbirth.

Before an additional top-up dose is administered, ask the woman to both write and say out loud a phrase such as "I can do it" three times. If she is unable to do this, question the dose: lack of fine motor coordination and slurred speech indicate a slowly occurring toxic reaction.

Yet another technique used with epidural anesthesia is self-administered or patient-controlled epidural analgesia (PCEA). With this technique, an epidural catheter delivers an analgesic mixture whenever the client presses a button on a special pump (Topcu et al., 2007). A lockout period follows each self-administration, to avoid overdosage. This method of administration is advantageous because less anesthetic is required, compared with continuous epidural infusion (CEI), and gives a woman a feeling of empowerment as she controls her own pain management (Marshall & Baker, 2007). Epidural anesthesia can cause a temporary elevation in temperature although this is not serious (Goetzl et al., 2007). Keep in mind this may occur when evaluating a woman's temperature. To detect hypotension, continuously monitor blood pressure for the first 20 minutes after each new injection of anesthetic. Continue to monitor blood pressure throughout the time the anesthetic is in effect, to be certain that the systolic pressure does not fall to less than 100 mm Hg or decrease by 20 mm Hg or more in a hypertensive woman. A drop greater than this could be life-threatening to a fetus unless prompt, effective corrective measures are taken, such as repositioning and administering an antihypotensive agent. If such measures are instituted quickly, fetal outcome will not be compromised.

Epidural anesthesia may also be given in a "segmented" fashion. With this technique, after the test dose, only a small dose (about 4 mL) is given. This provides anesthesia for uterine contractions but not perineal relaxation. Close to birth, if the woman sits up and an additional dose is given, perineal anesthesia will result. Leaving the lower anesthesia for late in labor in this way allows for better internal rotation of the fetal head, because the perineal muscle is not lax and there is less chance that forceps for rotation will be necessary.

With an epidural block, a woman loses sensation of her bladder filling. Remind her to void every 2 hours, monitor intake and output, and observe and palpate for bladder distention to avoid overfilling. To assess after birth whether the anesthesia is wearing off, touch a woman's legs and ask if she feels your touch. Ask her to raise her knees and observe whether she can do this. Even after feeling in legs returns, walking may be difficult. Be certain to stay with a woman the first time she is out of bed following regional block anesthesia.

Spinal (Subarachnoid) Anesthesia. Spinal anesthesia is used less frequently today, in preference to lumbar epidural blocks. It may be used in an emergency, however, because the administration technique is simpler than that of an epidural and can be accomplished more rapidly.

For spinal anesthesia, a local anesthetic agent such as bupivacaine (Marcaine) or ropivacaine (Naropin) is injected using lumbar puncture technique into the subarachnoid space (into the CSF) at the third or fourth lumbar interspace. A narcotic agonist such as morphine or fentanyl may be added for additional pain relief. For administration, the woman is placed in a sitting position on the side of the birthing bed, with legs dangling and head bent. She is asked to bend her head forward so that her back curves and the intravertebral spaces open. Be sure to support her in this position, because she is "front-heavy" as a result of her pregnancy and could easily fall forward if not well supported.

After injection, the anesthetic normally rises to the level of T10. Anesthesia up to the umbilicus and including both legs will be achieved. Spinal anesthetic agents may be "loaded" or "weighted" with glucose to make them heavier than CSF. This helps prevent them from rising too high in the spinal

canal and interfering with the motor control of the uterus or with respiratory muscles.

After injection of the anesthetic, the anesthesiologist asks the woman to lie down again. It is important that she does lie down at this time, because if she sits up too long, the anesthetic will not rise high enough in the canal to achieve pain relief. On the other hand, she must not lie down before this time, or the anesthetic will rise too high in the canal. Lying with a pillow under the head also helps ensure that the anesthesia will be confined to the lower spinal canal.

Hypotension from sympathetic blockage in the lower extremities can occur immediately after administration. This leads to vasodilation and a decrease in central blood pressure. If hypotension occurs, placental blood perfusion could be compromised. Turn the woman to her left side to reduce vena cava compression. The anesthesiologist will quickly increase the rate of IV fluid administration to increase blood volume. A vasopressor (e.g., ephedrine) to increase blood pressure and oxygen also may be administered. Never place a woman in a Trendelenburg position to help restore blood pressure after spinal anesthesia. This could make the anesthetic rise high in her spinal column, causing uterine or respiratory function to cease.

To guard against hypotension, IV fluids such as lactated Ringer's solution are usually given before the injection to ensure hydration. Be certain the fluid is infusing well before the anesthesia is administered.

A late complication of spinal anesthesia is a postpartal dural puncture headache (PDPH) or "spinal headache." This occurs because of continuous leakage of CSF from the needle insertion site and possibly from the irritation of a small amount of air that enters at the injection site. The shift in pressure of the CSF causes strain on the cerebral meninges, initiating the pain. The incidence of such headaches is reduced if a small-gauge needle is used for the injection and the woman drinks a quantity of fluid afterward, because a high fluid intake rapidly provides replacement of spinal fluid. Although it is usually encouraged, asking a woman to remain flat may not be necessary because of the routine use of small needles in most settings.

If a headache does occur, it can be relieved by having the woman lie flat and administering an analgesic. Some women find a cold cloth applied to the forehead helpful. If a headache is incapacitating, it can be treated with a blood patch technique. For this, 10 mL of blood is withdrawn from an accessible vein and then immediately injected into the epidural space over the spinal injection site. The injected blood clots and seals off any further leakage of CSF.

✔ Checkpoint Question 16.3

Susan chooses to have epidural anesthesia. What are two risks associated with this?

a. Hypotension and prolonged second stage of labor.
b. Severe headache and coldness of all extremities.
c. Continued back pain and short first stage of labor.
d. Hypertension and a reduced red blood cell count.

Combined Spinal Epidural Technique. Spinal anesthesia has an advantage over epidural anesthesia in that the pain control is immediate after injection of the anesthetic. A disadvantage of spinal anesthesia is that the woman cannot ambulate afterward. To take advantage of the rapid onset of pain control but also allow for ambulation, combined spinal epidural (CSE) technique was originated (Simmons et al., 2009). To administer this, the anesthesiologist first inserts an epidural needle using usual epidural technique. A catheter is inserted into the epidural needle and taped in place. The anesthesiologist then inserts a very fine spinal needle into the subarachnoid space and the CSF. It is confirmed that the second needle is into the CSF if a drop of fluid falls from the end of the needle. A small dose of narcotic (e.g., fentanyl) is then added to the CSF, and the spinal needle is withdrawn.

The advantage of a CSE administration is immediate pain relief, whereas an epidural block alone would take 15 to 30 minutes to accomplish this. In addition, it allows the woman to be ambulatory, because the drug added to the CSF is a narcotic, not a local anesthetic. Possible complications that can occur from the CSE method include hypotension, pruritus, urinary retention, nausea and vomiting, and a PDPH (although all of these are rare). Additional anesthesia for the duration of labor is achieved by the epidural route.

Medication for Pain Relief During Birth

Stretching of the perineum causes the pain during birth. The simplest form of pain relief for birth is the natural **pressure anesthesia** that results from the fetal head pressing against the stretched perineum. This natural anesthesia is often adequate to allow an episiotomy to be performed without a woman feeling the cut. The pain she experiences as the fetal head is born, although intense and hot, occurs suddenly and is over quickly. Often, after the hours of hard contractions a woman has come through, this flash of pain seems almost nothing. For some women, however, additional medication is needed to reduce the pain of birth.

Local Anesthetics

Local anesthesia reduces the ability of local nerve fibers to conduct pain.

Local Infiltration. Local infiltration is the injection of an anesthetic such as lidocaine (Xylocaine) into the superficial nerves of the perineum. It is used when the fetal head is too low to allow for a pudendal block. The anesthetic is placed along the borders of the vulva. The effect lasts for approximately 1 hour, allowing for a pain-free birth and suturing of an episiotomy without additional anesthetic.

Pudendal Nerve Block. A **pudendal nerve block** (Fig. 16.4) is the injection of a local anesthetic such as bupivacaine (Marcaine) near the right and left pudendal nerves at the level of the ischial spine. The injection, made through the vagina with the woman in a lithotomy or dorsal recumbent position, provides relief of perineal pain in 2 to 10 minutes that lasts for approximately 1 hour. Anesthesia achieved with this method is sufficiently deep to allow the use of low forceps during birth and an episiotomy repair. Although the injection is only local, the FHR and the mother's blood pressure should be checked immediately after the injection, in case maternal hypotension occurs.

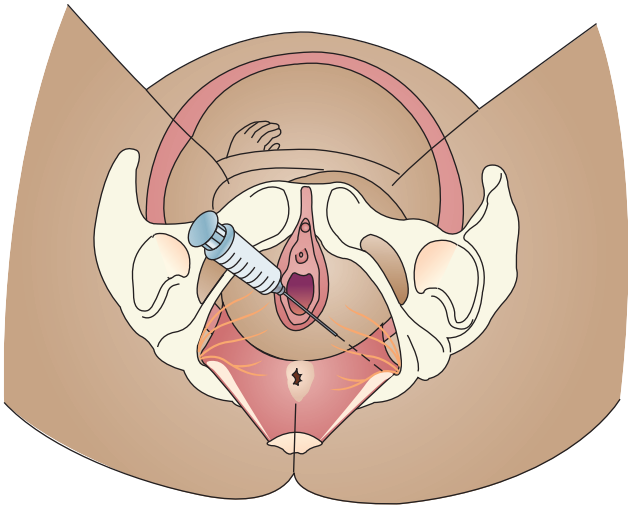

FIGURE 16.4 Pudendal nerve block.

General Anesthesia

General anesthesia is never preferred for childbirth, because it carries the dangers of hypoxia and possible inhalation of vomitus during administration. Pregnant women are particularly prone to gastric reflux and aspiration because of increased stomach pressure from the weight of the full uterus beneath it. The gastroesophageal valve also may be displaced and possibly functioning improperly. Despite these risks, general anesthesia may be necessary in emergency situations (e.g., premature separation of the placenta) when an immediate cesarean birth is required.

For complete and rapid anesthesia during childbirth, thiopental sodium (Pentothal), a short-acting barbiturate, is usually the drug of choice. It causes rapid induction of anesthesia and, because it has a short half-life, allows for good uterine contraction afterward, with minimal postpartal bleeding. After intravenous induction with thiopental sodium, the woman is intubated, and anesthesia is then maintained by administration of nitrous oxide and oxygen. Thiopental sodium crosses the placenta rapidly. Infants born of a woman anesthetized by this method may be slow to respond at birth and may need resuscitation. However, in view of the degree of barbiturate intoxication demonstrable in these infants, their ability to respond and alertness at birth are always surprising.

All women who receive a general anesthetic must be observed closely in the postpartal period, because most gases used for general anesthesia cause uterine relaxation, opening the possibility of uterine atony and postpartal hemorrhage. Some women comment that their throat feels raw or sore afterward from insertion of the endotracheal tube. Using an anesthetic throat spray or gargle, sipping cold liquids, or sucking on ice chips (as soon as this is safe after general anesthesia) may help to relieve the discomfort.

Preparation for the Safe Administration of General Anesthesia. To ensure safe anesthesia administration, an anesthesiologist or nurse anesthetist needs a minimum of six drugs readily available: (a) ephedrine, to use in the event blood pressure falls; (b) atropine sulfate, to dry oral and respiratory secretions to prevent aspiration; (c) thiopental sodium (Pentothal), for rapid induction of a general anesthetic; (d) succinylcholine (Anectine), to achieve laryngeal relaxation for intubation; (e) diazepam (Valium), to control seizures, a possible reaction to anesthetics; and (f) isoproterenol (Isuprel), to reduce bronchospasm should aspiration occur. In addition to these medications, an adult laryngoscope, an endotracheal tube, a breathing bag with a source of 100% oxygen, and a suction catheter and suction source should be at hand.

Aspiration of Vomitus. Inhalation of vomitus from pressure of the uterus on the stomach can be fatal if a woman's airway becomes occluded by the foreign matter. In addition, stomach contents have an acid pH that can cause chemical pneumonitis and secondary infection of the respiratory tract.

Some anesthesiologists may order IV ranitidine (Zantac) or an oral antacid such as cimetidine to be given before general anesthesia is administered, to reduce the level of acid in stomach contents should aspiration occur. Metoclopramide (Reglan) increases gastric emptying and may also be prescribed.

For general anesthesia administration, a woman should be placed on her back with a wedge under her right hip to displace the uterus from the vena cava. To reduce the occurrence of hypotension and to establish a line for emergency medications, IV fluid administration is begun. The woman is given a rapid-induction IV agent and is then intubated with a cuffed endotracheal tube. To prevent gastric reflux and aspiration before intubation is achieved, cricoid pressure (which seals off the esophagus by compressing it between the cricoid cartilage and the cervical vertebrae) must be applied as soon as the IV agent is begun until the cuff on the tube is in place.

The moments of induction of general anesthesia before the endotracheal tube is safely in place are critical ones for the anesthesiologist. Respect his or her need to concentrate until the task is achieved.

If aspiration of vomitus should occur in a birthing room, prompt attention is essential. The anesthesiologist suctions the woman's trachea to remove as much foreign material as possible. The woman is intubated, if she was not previously, and given 100% oxygen. IV isoproterenol to reduce bronchospasm and a corticosteroid to reduce inflammation may be given. Positive-pressure ventilation may be started. Blood gas analysis and a chest radiograph usually are obtained to determine the degree of aeration of which the woman is still capable.

Usually, the woman will receive mechanical ventilation until her overall clinical condition improves, as shown by the x-ray films and blood gas concentrations. She is critically ill at the time of aspiration and often will be transferred to an intensive care unit for the special care she needs to survive this emergency.

✔ Checkpoint Question 16.4

There is no reason to think that Susan will need a general anesthetic. If she did, what type of drug is usually prescribed to minimize the risk of aspiration of vomitus?

a. An anticonvulsant such as diazepam (Valium).
b. A nerve relaxant such as phenobarbital.
c. Metoclopramide (Reglan) to speed gastric emptying.
d. Oxytocin to increase the effectiveness of labor.

NURSING CARE TO PROMOTE THE COMFORT OF A WOMAN DURING LABOR

The best approach to pain management for women in labor is to always complement any pharmacologic intervention with a complementary or alternative therapy measure.

Nursing Diagnoses and Related Interventions

Nursing Diagnosis: Anxiety related to fear of pain from labor contractions

Outcome Evaluation: Client identifies beginning and ending of contractions; expresses confidence rather than confusion about ongoing process; states she feels less anxious.

In addition to causing local discomfort, pain can evoke a general stress response (fight-or-flight syndrome). This releases epinephrine, which causes peripheral and uterine vasoconstriction. This can increase the degree of pain experienced because of the resulting increase in tissue anoxia. Reducing anxiety through relaxation techniques such as planned breathing exercises, or through administration of medication to reduce anxiety, can reduce vasoconstriction and help reduce pain.

Reduce Anxiety With Explanations of the Labor Process. Planning with women about their options for pain relief during labor should begin prenatally (Box 16.5). During labor, use a standard method of pain assessment, such as a scale of 1 to 10, so that a woman can rate her pain. Evaluate whether pain relief is adequate—not only whether pain relief was offered, but whether it was effective.

Help women use natural methods based on the gate control theory (see Chapter 14) as well as pharmacology relief. Be sure to offer careful explanations of what is happening or what will happen during labor, because this can help alleviate anxiety and thereby reduce some discomfort.

Be sure to explain the characteristics of contractions and reinstruct as necessary (e.g., that labor contractions are rhythmic in nature and come and go repeatedly). Do not assume that a woman is aware of this simply because she is experiencing the contractions. Her pain may be so intense that she is unaware of any relief between contractions (Box 16.6). She may fear that things will worsen as labor progresses and that the pain will become continuous.

This on–off effect differentiates the pain of labor contractions from that of a toothache or headache, which is continuous. Sometimes, just knowing this can help a woman tolerate the pain even as it increases in intensity.

Do not assume everyone knows that the rupturing of membranes is painless, that a pink-stained show is normal, or that contractions change in character during the pelvic division of labor. A woman having her first child probably does not know these things. A woman having her second child may not remember, or she may find this time so different from the last time (even if it is well within normal limits) that she is frightened. Be certain to give explanations to a woman's husband or support person, as well; otherwise, he or she may start to convey anxiety back to the woman in labor.

Nursing Diagnosis: Ineffective coping related to combination of uterine contractions and anxiety

Outcome Evaluation: Client expresses confidence in her ability to maintain active participation during labor; demonstrates continued breathing techniques; expresses need to change position; and expresses confidence in the labor nurse and other health care providers.

BOX 16.5 Focus on Family Teaching

Learning More About Options for Pain Relief During Labor

Q. Susan tells you, "My friends have told me horrible stories about pain during labor. What can I do so I won't hurt so much?"

A. Here are some suggestions to help with pain relief:

- Ask your obstetrician or nurse-midwife early in pregnancy about pain management options. The options your care provider suggests may actually influence your decision as to whether this is the optimal care provider for you.
- Attend childbirth preparation classes during pregnancy, and conscientiously practice breathing or other relaxation exercises. These measures can be adequate all by themselves; if not, they complement pharmacologic methods of pain relief.
- Make a birth plan detailing what position you choose for labor and other options you want to use. This helps give you a greater sense of control.
- Be certain a support person will be with you during labor. Name a second person or investigate using a doula if you are uncertain whether your usual support person can fill this role.
- Late in pregnancy, if you are still concerned, let your primary care provider know. In addition to medication for pain relief during labor, medication to reduce anxiety is also available.
- On admission to the hospital, let the medical and nursing staff know that you are concerned. The most commonly used options today are oral, intramuscular, or intravenous administration of narcotics and injection of regional anesthesia by epidural block. Ask questions about any method suggested that you do not understand.
- Be aware that the choice of receiving analgesia or anesthesia is yours. On the other hand, if a complication occurs, be ready to compromise in the interest of safety for yourself or your child.

BOX 16.6 ✻ Focus on Communication

Suppose Susan stated early in labor that she did not want to use any medication for pain relief. As soon as her contractions became 30 seconds in length, however, she requested some analgesia. Her physician prescribed intramuscular meperidine. Her contractions are now 40 seconds in duration and only moderately strong. She looks increasingly uncomfortable with each contraction.

Less Effective Communication

Nurse: How are you feeling, Susan? Is there anything I can do for you?
Susan: I need something else for pain. I can't stand this any longer.
Nurse: Didn't the medicine I gave you work at all?
Susan: It's working for now, but it won't be enough by another half hour. I'll need something else by then.
Nurse: You won't be able to get anything for another 2 hours. I'm sorry.

More Effective Communication

Nurse: How are you feeling, Susan? Is there anything I can do for you?
Susan: I need something else for pain. I can't stand this any longer.
Nurse: On a scale of 0 to 10, with 0 being no pain and 10 being the worst pain ever, how would you rate your pain now?
Susan: It's about a 2 now, but it'll be a 10 in another half-hour when my contractions start to be constant. How will I be able to stand them when they don't let up at all.
Nurse: I'm sorry. I must not have explained that contractions always have a space in between them. Let's talk about that.

Because women in labor are under stress, they may not hear instructions as well as they normally would. First, assess the pain. Asking a woman to rate her pain on a scale of 0 to 10 is an effective method for pain assessment. Also, be certain to assess whether the woman has a clear understanding of the nature of labor contractions so that she is well prepared to manage them.

Help the Woman Identify Coping Strategies. Because pain is not a new phenomenon for a woman of childbearing age, it can be helpful to ask a woman to recall methods she usually uses to combat pain or anxiety such as meditation or applying a cool cloth. This can go a long way toward helping her collect her resources and decide on a pain relief strategy (see Focus on Nursing Care Planning Box 16.7).

Provide Comfort Measures. Usually, anyone can tolerate a little discomfort from a backache, being thirsty, having dry lips, or having a leg cramp. However, few people can tolerate having all of these discomforts simultaneously or feeling even one of them while experiencing labor contractions.

Assist a woman's support person to provide the usual comfort measures that are helpful for anyone with pain, such as reassurance or a change in position. For dry lips, ice chips to suck on, moistening the lips with a wet cloth, or using a moisturizing jelly may be helpful. A cool cloth to wipe perspiration from her forehead can prevent her from feeling overheated.

Be aware of what is happening to a woman's bedclothes and clothing, which will wrinkle rapidly and stick to her skin because she is perspiring. If a waterproof pad is used under her buttocks, it will become soiled with vaginal secretions and feel hot and sticky. However, never apply sanitary pads in labor. Although they absorb vaginal secretions well, they tend to slip out of place, possibly carrying pathogens from the rectal area forward to the vaginal opening. Instead, change the waterproof pad frequently. At least halfway through the first stage of labor, or more frequently as indicated by the woman's condition, change the sheets and give her a clean gown. She could bathe or take a shower if that would be helpful. These measures can help her feel clean and refreshed, with a ready-to-go-again feeling.

Think of comfort measures for the woman's support person as well. Is the chair by the side of the bed comfortable? Does he or she need to stretch or take a beverage or bathroom break? It is difficult for the support person to comfort a woman if he or she is uncomfortable because of spending hours sitting still in one position.

Nursing Diagnosis: Pain related to labor contractions

Outcome Evaluation: Client states pain is reduced to a tolerable level with techniques used and is able to handle or "work with" contractions; demonstrates ability to listen and respond to questions and instructions.

Encourage Comfortable Positioning. An upright, sitting, or walking position may be most comfortable for a woman in early labor. Contractions also are most efficient in this position. Before membranes have ruptured, therefore, a woman may be most comfortable either sitting in a chair or ambulating. After the membranes have ruptured and if the fetal head is not engaged, there may be danger in walking about, because the cord might prolapse and impede fetal circulation. If this is so, a woman should remain in bed at this time. Urge her not to lie on her back, to avoid supine hypotension syndrome.

Encouraging position changes from time to time is important. Assist a woman to find a satisfying position by moving bedclothes or monitor leads, if any are attached. If she wishes to walk and has no support person, walk with her. Pelvic rocking between contractions may relieve tense back muscles.

BOX 16.7 ✻ Focus on Nursing Care Planning

A Multidisciplinary Care Map for a Woman Requiring Comfort Measures During Labor and Birth

Susan Baranca is a primipara in early labor whom you admit to a birthing unit. She tells you her sister had epidural anesthesia for the birth of her baby 3 months ago. She told Susan that preparation for labor really was not necessary because an epidural block completely obliterated her pain in labor. Based on her sister's experience, Susan expected to be given epidural anesthesia as soon as she arrived at the hospital. As she is barely in labor, however, her physician asked her to wait until she is 4 cm dilated. When you enter her room, you find her lying on her back in a birthing bed, crying. Her husband is standing outside in the hallway at the nursing desk, shouting that his wife deserves better care than this.

Family Assessment ✻ Gravida 1, para 0; accompanied by husband who will act as support person and coach. Client works as clerk in clothing store; husband is law student at local university.

Client Assessment ✻ Contractions are of moderate intensity, every 6 to 7 minutes, 35 seconds' duration. Cervix dilated 3 cm, 60% effaced. Membranes intact. FHR 148; fetus in ROA position. Attended childbirth education classes but did not practice breathing exercises.

Nursing Diagnosis ✻ Pain related to effects of uterine contractions and pressure on pelvic structures

Outcome Criteria ✻ Client confirms that discomfort is controlled with either nonpharmacologic or pharmacologic methods; responds to questions and instructions; identifies need for additional pain relief measures if required during labor.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Activities of Daily Living		
Nurse	Assess what birth plan the woman wants to follow. Inspect the client's suprapubic area and palpate for bladder distention.	Remind client she does not need to remain in bed. Encourage client to void every 2 hours.	Ambulation can increase comfort. A full bladder contributes to the client's discomfort and may impede fetal descent, possibly prolonging labor.	Client ambulates in early labor. Has no signs of bladder distention; voids every 2 hours during labor.
		Consultations		
Physician/nurse	Locate which health care provider is on call to provide anesthetic pain relief in labor.	Notify nurse-anesthetist concerning client's wish to receive an epidural block as soon as possible.	Respecting client's wishes is a prime mode of encouraging self-efficacy.	Pain management team supports client's wish for pharmacologic intervention; encourages nonpharmacologic measures until epidural anesthetic is appropriate.
		Procedures/Medications		
Nurse	Assess how client's husband views his role in labor.	Allow client's husband to take occasional breaks. Stay with the client during this time to provide support.	Occasional relief breaks allow a support person to conserve energy and provide continued support throughout labor.	Client allows health care providers to substitute for husband so husband can take occasional breaks.

(continued)

BOX 16.7 ✻ Focus on Nursing Care Planning (continued)

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
		Nutrition		
Nurse	Determine when patient last ate.	Provide client with ice chips as desired.	Ice chips or hard candy can relieve mouth dryness from breathing exercises.	Client states she has no mouth discomfort.
		Patient/Family Education		
Nurse	Assess what couple learned in preparation for childbirth classes about pain control in labor.	Provide information on epidural anesthesia; update the couple on labor progress.	An epidural is the pain control method chosen; frequent updates on progress help alleviate anxiety and fears that may exacerbate pain.	Couple confirm that they are certain epidural anesthesia is their method of choice; receive frequent updates on labor progress.
		Psychosocial/Spiritual/Emotional Needs		
Nurse	Assess level of client's pain by both verbal and nonverbal indicators. Use 1-to-10 scale and evaluate response to techniques used.	Teach breathing exercises for use during early labor until client receives epidural relief.	Pain is a subjective experience, so only the woman can know her level of pain. Breathing exercises can be an effective way to reduce the pain of labor.	Client rates her level of pain from labor contractions not above 3 on a 1-to-10 scale.
Nurse	Assess what nonpharmacologic measures (e.g., music, room temperature) client thinks would help complement epidural block and aid comfort.	Provide a comfortable environment: clean sheets, comfortable room temperature, cool washcloth to forehead, closed room door. Refrain from intervening with client during a contraction.	A comfortable environment aids in relaxation, promoting effective coping. Interrupting the client's breathing can make the technique ineffective as a pain relief measure.	Client reports she feels environment is comfortable and complements other pain relief measures.
		Discharge Planning		
Nurse	Ask client and husband to evaluate their labor experience.	Review with client pain relief measures used and determine which were most effective.	Reviewing a possibly traumatic experience helps to put it into perspective among life events.	Client and support person state that labor and birth was at worst a tolerable experience; at best, a highlight of their lives.

Position changes are also essential in the second stage of labor. Depending on medical protocols and barring any medical contraindications, a woman might prefer to sit, stand, kneel on hands and knees, lie in dorsal recumbent or lateral recumbent positions, or squat (see Chapter 15). Keep in mind that maintaining these positions often requires assistance from one or two support people.

Assist the Woman With Prepared Childbirth Method. Depending on the type of childbirth preparation a woman and her support person have had, the method used may include breathing exercises, distraction by focusing on an external object, acupressure, therapeutic touch, music therapy, guided imagery, self-hypnosis, or a combination of these methods (see Chapter 14). Biofeedback is not well documented in labor but also may be effective.

Often, with the discomfort and stress of labor, it is easy for a woman to forget what was learned in the relaxed, fun setting of an antepartal class. As necessary, review previously learned breathing techniques with the woman. Urge her to begin these early in labor, even before contractions become strong. It is

not essential for women to use complex breathing patterns in labor; even a woman who has had no prior training in breathing exercises can use a simple breathing pattern to alleviate discomfort with just a little guidance from a nurse.

Massage is another pain relief method that can be taught to a woman and her support person during labor. It may be especially useful if a woman is experiencing back pain from labor, because rubbing or massaging the sacral area often alleviates back pain. Firm counterpressure on the lower back, thighs, feet, hands, or shoulders can provide a relaxing distraction from the sensation of internal pressure and pain.

Provide Pharmacologic Pain Relief. Helping a woman decide if and when medication for pain relief should be given requires an in-depth understanding of the available drugs, their effects on the mother and the fetus, and their mechanism and duration of action. It also requires sympathetic listening and counseling skills. Many women come into labor wishing to avoid drugs entirely. Once in labor, they may change their minds but hesitate to say so, especially if their partners also believe that a birth without the use of drugs is ideal. Other women come into labor asking to receive something immediately to avoid experiencing any pain. In both instances, provide information about the use of drugs and their ultimate effects. Maintain a supportive presence to help a woman make the best decision for herself and her baby. Some women require analgesia or anesthesia because of a complication. Helping these women and their support persons understand why the medication is necessary calls for equal care and skill. As a rule, record a baseline FHR and maternal blood pressure and pulse before administering medication; reassess 15 minutes later for fetal and maternal safety.

✔ Checkpoint Question 16.5

Susan, still in early labor, tells you that she is not having much pain. You assess that her contractions are also not strong. What position usually promotes efficient uterine contractions in early labor?

a. Sitting or standing.
b. Lying supine.
c. Lying prone.
d. Side-lying.

Key Points for Review

- Pain in labor occurs because of anoxia to uterine cells, stretching of the cervix and perineum, and pressure of the presenting part of the fetus on maternal tissues.
- Each person perceives pain differently. Only a woman herself can describe the extent of her pain.
- Usually, the better prepared a woman is for childbirth, the less analgesia and anesthesia is necessary.
- Encourage complementary and alternative therapies such as reducing anxiety, providing changes in position, increasing knowledge, and supporting prepared childbirth exercises in conjunction with prescribed analgesics.
- Be certain to ask about allergy to a medication before administering it during labor. Women under stress may omit mentioning this unless directly asked.
- Women may lose their ability to use controlled breathing after systemic narcotic administration because of a "lightheaded" feeling. They may need additional support during this time to be able to continue with a breathing technique until the analgesic agent begins to have an effect.
- Regional anesthesia (e.g., epidural anesthesia) is extremely effective in relieving labor pain. Be certain the woman is well hydrated with IV fluid and that her blood pressure is within normal limits before administration of the anesthetic agent.
- During regional or general anesthesia administration, if a woman must lie supine, she should have a wedge positioned under her right buttock to help prevent supine hypotension syndrome. If hypotension should occur after epidural anesthesia administration, elevating a woman's legs is an emergency measure to help relieve hypotension.
- If a narcotic analgesic is used, naloxone (Narcan) must be available for possible newborn resuscitation.
- General anesthesia is not administered for an uncomplicated labor, because it has risks for both the mother and the infant, but may still be used in an emergency.

CRITICAL THINKING EXERCISES

1. Susan, the patient you met at the beginning of the chapter, did not attend any preparation for childbirth classes because she planned to rely totally on a regional block for pain relief. If you had met her during pregnancy, instead of when she was beginning labor, would you have supported this plan? Are there any complementary and alternative therapies that she could have planned for in addition to relying on a regional block?
2. Suppose Susan says she wants a general anesthetic for labor or she will leave the hospital. Her physician has said that he cannot justify a general anesthetic for uncomplicated labor. You find Susan crying because her doctor will not give her anything for pain. How would you handle this situation?
3. Suppose Susan seems well prepared for labor but, after an injection of meperidine early in labor, grows angry with her husband and refuses to use breathing exercises because she feels "so lightheaded" from the medicine. How would you help her at this point?
4. Examine the National Health Goals related to comfort in labor. Most government-sponsored funds for nursing research are allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to the Baranca family and also advance evidence-based practice?

CRITICAL THINKING SCENARIO

Open the accompanying CD-ROM or visit http://thePoint.lww.com and read the Patient Scenario included for this chapter, then answer the questions to further sharpen your skills and grow more familiar with NCLEX style questions related to comfort measures for labor and birth. Confirm your answers are correct by reading the rationales.

Chapter 17

Nursing Care of a Postpartal Family

KEY TERMS

- afterpains
- diastasis recti
- en face position
- engorgement
- engrossment
- Homans' sign
- involution
- letting-go phase
- lochia
- postpartal depression
- rooming-in
- sitz bath
- taking-hold phase
- taking-in phase
- uterine atony

OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe the psychological and physiologic changes that occur in a postpartal woman.
2. Identify National Health Goals related to the postpartal period that nurses can help the nation achieve.
3. Use critical thinking to analyze ways that postpartum nursing care can be more family centered.
4. Assess a woman and her family for physiologic and psychological changes after childbirth.
5. Formulate nursing diagnoses related to physiologic and psychological transitions of the postpartal period.
6. Identify expected outcomes for a postpartal woman and family related to the changes during this period.
7. Plan nursing care such as measures to aid uterine involution or encourage bonding.
8. Implement nursing care to aid the progression of physiologic and psychological transitions occurring in a postpartal woman and family such as teaching about breastfeeding.
9. Evaluate outcome criteria for the achievement and effectiveness of care.
10. Identify areas related to care of the postpartal family that could benefit from additional nursing research or application of evidence-based practice.
11. Integrate knowledge of the physiologic and psychological changes of the postpartal period with the nursing process to achieve quality maternal and child health nursing care.

As the nurse working in a postpartum unit, you care for Mike and Joan Cooper, who have just become parents of an 8-lb 2-oz baby girl. Joan is on maternity leave from her job as a court reporter. Mike plans to take off a week from work to spend time with Joan and the new baby.

As you prepare them for discharge, you notice they seem overwhelmed with the amount of information they have been provided. Joan says, trying to get the baby to nurse, "He's so big and my breasts are so small, will he get enough milk? I was hoping by breastfeeding I wouldn't have to worry about birth control for a while, but I'm having so much trouble maybe that won't work out." Mike pulls you aside and says, "Sometimes, I see my wife crying for no reason. Why isn't she as happy as I am?"

Previous chapters discussed caring for the pregnant woman and her family during the antepartal and intrapartal periods. This chapter adds information about caring for a postpartal woman and family. Nurses are able to play major roles in assessment, comfort promotion, and education during this period as they help a new family adjust to the many physiologic and psychological changes that occur during this period.

What additional postpartal teaching does the Cooper family need?

The postpartal period, or *puerperium* (from the Latin *puer,* for "child," and *parere,* for "to bring forth"), refers to the 6-week period after childbirth. It is a time of maternal changes that are both retrogressive (involution of the uterus and vagina) and progressive (production of milk for lactation, restoration of the normal menstrual cycle, and beginning of a parenting role). Protecting a woman's health as these changes occur is important for preserving her future childbearing function and for ensuring that she is physically well enough to incorporate her new child into her family. The period is popularly termed the *fourth trimester of pregnancy.*

The physical care a woman receives during the postpartal period can influence her health for the rest of her life. The emotional support she receives can influence the emotional health of her child and family so much that it can be felt into the next generation (McGarry et al., 2009). National Health Goals related to the postpartal period that nurses can help the nation achieve are shown in Box 17.1.

Nursing Process Overview

For a Postpartal Woman and Family

Assessment

During the puerperium, assessment of a woman is accomplished by health interview, physical examination, and analysis of laboratory data. It is important to ensure that physical changes, such as uterine involution, are occurring by evaluating uterine size and consistency and lochia flow amount.

Assessment of a woman's psychological adjustment begins with her reaction at birth (Was she disappointed or happy with the appearance of her baby? Is she glad to be through with the pregnancy or still longing to be back in it?) and continues with every contact made with the family during and after a hospital stay. Assess the extent and quality of the woman's interaction with her child (Does she hold the infant and talk to him or her?), her overall mood (Do you observe her crying? Does she have long periods of staring into space or not talking?), and her ability to begin infant care. Observe also for self-care. A woman who feels good about herself, even though she is exhausted from childbirth, usually will try to maintain her appearance. On the other hand, if she is depressed, she probably has little energy to do things such as comb her hair or worry about her appearance.

Nursing Diagnosis

Nursing diagnoses during the postpartal period usually are concerned either with a family's inability to accept and bond with a new child or with physiologic considerations. Examples might include:

- Health-seeking behaviors related to care of newborn
- Risk for impaired parenting related to disappointment in the sex of the child
- Fear related to lack of preparation for child care
- Risk for deficient fluid volume related to postpartal hemorrhage

BOX 17.1 ✻ Focus on National Health Goals

The first hour after birth is an extremely dangerous one because of the possibility of hemorrhage. It is also the optimal period when breastfeeding should begin. National Health Goals that involve this time period include:

- Reduce the maternal mortality rate to no more than 3.3/100,000 live births from a baseline of 7.1/100,000.
- Reduce the proportion of births occurring within 24 months of a previous birth to 6% from a baseline of 11%.
- Increase to at least 75% the proportion of mothers who breastfeed their babies in the early postpartum period from a baseline of 64% and increase the proportion of mothers who still breastfeed at 6 months to 29% from a baseline of 50% (http://www.nih.gov).

Nurses can help the nation achieve these goals by maintaining close observation in the immediate postpartal period to detect maternal hemorrhage, encouraging and supporting women who breastfeed, and ensuring that women receive reproductive life planning information if desired.

Areas that could benefit from additional nursing research include discovering effective means to encourage women to maintain breastfeeding and effective ways to teach women to monitor their own health in the postpartal period, particularly because, with early discharge, they may be at home when uterine hemorrhage occurs.

Outcome Identification and Planning

Be certain that outcomes established during this time are realistic in light of a woman's changed life pattern. Most postpartal families remain in the hospital for a relatively short time, only 48 to 72 hours. The postpartum stay in an alternative birth center can be as short as 4 hours. That means outcomes must be devised that can be accomplished and evaluated during this short period of client contact. If an outcome cannot be evaluated within this short timeframe, follow-up home care or ambulatory visits may be necessary.

When planning care in the postpartal period, try to arrange procedures to allow optimal time for family infant–interaction and yet provide adequate time for a woman to rest, to prevent exhaustion. Prevention of exhaustion can improve coping ability and plans for self-care. After adequate instruction, a woman should be prepared to monitor her own health after she returns home.

Planning should also include ample time for health teaching. An important part of teaching related to care of the newborn is preparation for the unexpected and the need for flexibility, because parents do not yet know what their new life will be like (whether their child will sleep deeply or fitfully at night, whether their child will become hungry at long or short intervals) or how tired they will become after being awakened frequently during the night.

Brainstorming—practicing to produce at least three different methods of reaching a particular goal—is excellent practice for parenting. A helpful Internet site to recommend to parents who feel a need for additional knowledge or support during this time is the Postpartal Support International web site (http://www.postpartum.net).

Implementation

All interventions in the postpartal period should be family centered, to enhance family functioning and bonding.

Interventions also should be geared toward increasing a woman's self-esteem and allowing her to view herself as a new mother and her new infant as part of her family. Teaching new mothers is important, but it is also important to explore what they already know about child care and what they think would be a sensible solution to a problem. Giving advice only solves an immediate problem; helping a woman learn good problem-solving technique improves her ability to handle the many challenges that will arise with childrearing.

Outcome Evaluation

If a woman fails to make an adequate adjustment to her new life changes, she may have difficulty integrating an infant into the family. This could affect a child's mental health, self-esteem, and ability to form a sense of trust.

Evaluation in the postpartal period involves being certain not only that a woman and her baby are safe but also that the woman knows how to maintain her own health. Such follow-up evaluation can be done by telephone, during home visits, or during postpartal and well-child assessments.

Examples of expected outcomes include:

- Parents spontaneously make at least one positive comment about their child's characteristics before hospital discharge.
- Client states that she believes she will be able to manage newborn care with the support of her significant other.
- Client's lochial flow is no more than one saturated perineal pad (50 mL) every 3 hours.
- Client states she is tired but feels able to manage her newborn and family care.

PSYCHOLOGICAL CHANGES OF THE POSTPARTAL PERIOD

A transition is a movement or passage from one position or concept to another or a pause between what was and what is to be. It represents the internal process experienced by people when change occurs. In a classic presentation of what transition entails, Bridges (1994) stated that change is something that happens to people, and transition is how they respond to that change.

People move through several predictable stages during transition: first is the act of ending old ways of thinking or believing (letting go); next, there is a neutral zone, during which the old way is gone but the new way is not yet comfortable; and finally, there is a new beginning, during which new ideas and concepts are put into action (Bridges, 1994). The postpartum period is a time of transition, during which a couple gives up concepts such as "childless" or "parents of one" and moves to the beginning of new parenthood. The immediate postpartal period is a neutral time during which a couple tries out the new role and attempts to "fit" their expectations for that role. Nurses can help couples acknowledge the extent of the change, so that they can gain closure on their previous lifestyle. Opening channels for communication, anticipating new needs, and highlighting potential gains that will occur because of the change are important actions.

Phases of the Puerperium

In her classic work on maternal behavior, Reva Rubin, a nurse, divided the puerperium into three separate phases (Rubin, 1977). She viewed the first of these as a **taking-in phase,** or a time when the new parents review their pregnancy and the labor and birth. The subsequent phases, called the **taking-hold phase** and the **letting-go phase,** are times of renewed action and forward movement. At the time these phases of the puerperium were identified, women were hospitalized for 5 to 7 days after childbirth and moved in a paced manner from one step to the next. Today, with hospitalization as short as a few hours, women appear to move through these phases much more quickly and may even be experiencing two different phases at once.

Taking-In Phase

The taking-in phase, the first phase experienced, is a time of reflection. During this 2- to 3-day period, a woman is largely passive. She prefers having a nurse minister to her (such as bringing her a bath towel or a clean nightgown) and make decisions for her, rather than do these things herself. This dependence results partly from her physical discomfort because of afterpains or hemorrhoids; partly from her uncertainty in caring for her newborn; and partly from the extreme exhaustion that follows childbirth.

As a part of thinking and pondering about her new role, the woman usually wants to talk about her pregnancy, especially about her labor and birth. She holds her new child with a sense of wonder and asks: Is birth really over? Could this child really have been inside me? Could I be this lucky? During the taking-in phase, she rests to regain her physical strength and to calm and contain her swirling thoughts. Encouraging her to talk about the birth helps her integrate it into her life experiences (Box 17.2).

Taking-Hold Phase

After a time of passive dependence, a woman begins to initiate action. She prefers to get her own washcloth and to make her own decisions. Women who give birth without any anesthesia may reach this second phase in a matter of hours after birth.

During the taking-in period, a woman may have expressed little interest in caring for her child. Now, she begins to take a strong interest. As a rule, therefore, it is always best to give a woman brief demonstrations of baby care and then allow her to care for her child herself—with watchful guidance.

Although a woman's actions suggest strong independence during this time, she often still feels insecure about her ability

BOX 17.2 ✻ Focus on Communication

Joan Cooper gave birth 6 hours ago. You want to assess her for postpartal pain, so you enter her hospital room. She is wearing a hospital gown and sitting in the chair by her bed.

Less Effective Communication

Nurse: How are you feeling, Mrs. Cooper?
Mrs. Cooper: Like I'm still rushing around. I called my husband as soon as my water broke. He hit a truck on the way home, though, so he couldn't get here in time. I tried to call—
Nurse: Do you have any pain?
Mrs. Cooper: It's not bad. I tried to call my mother, but she couldn't come over because she didn't have a car. Our neighbor—
Nurse: Okay, then let me check your stitches.

More Effective Communication

Nurse: How are you feeling, Mrs. Cooper?
Mrs. Cooper: Like I'm still rushing around. I called my husband as soon as my water broke. He hit a truck on the way home, though, so he couldn't get here in time. I tried to call—
Nurse: Do you have any pain?
Mrs. Cooper: It's not bad. I tried to call my mother, but she couldn't come over because she didn't have a car. Our neighbor—
Nurse: Go on. I didn't mean to interrupt.
Mrs. Cooper: Our neighbor said he'd drive me but then discovered his wife had his car keys. It was a three-ring circus of problems.
Nurse: A three-ring circus?
Mrs. Cooper: Finally, my husband made it home, but then there was such a bad accident on the freeway we had to drive all the way around the lake. I thought I'd have the baby in the middle of the bridge!
Nurse: That must have been terrifying for you.

Most women are interested in discussing their labor and birth experience in the days immediately after birth as a part of a "taking-in" phase. Repeating the story of how worried they were when labor started, how much pain they had, or how scared they were when their membranes broke helps them put these sensations into perspective and integrate them into their life experiences. Communication that encourages women to elaborate on a story is therapeutic; communication that discourages story-telling is not. Once you have talked about what concerned her most, returning to a discussion and assessment of her pain would be appropriate.

to care for her new child. She needs praise for the things she does well such as supporting the baby's head or beginning breastfeeding to give her confidence. This positive reinforcement begins in the health care facility and continues after discharge, at home, and at postpartum and well-baby visits.

Do not rush a woman through the phase of taking-in or prevent her from taking hold when she reaches this point. For many young mothers, learning to make decisions about their child's welfare is one of the most difficult phases of motherhood. It helps if a woman has practice in making such decisions in a sheltered setting, such as a hospital, rather than first taking on that level of responsibility after she is home alone.

Letting-Go Phase

In the third phase, called letting-go, a woman finally redefines her new role. She gives up the fantasized image of her child and accepts the real one; she gives up her old role of being childless or the mother of only one or two (or however many children she had before this birth). This process requires some grief work and readjustment of relationships, similar to what occurred during pregnancy. It is extended and continues during the child's growing years. A woman who has reached this phase is well into her new role.

✔ Checkpoint Question 17.1

Which of the following actions would alert you that Joan Cooper, 2 days postpartum, is entering a postpartal taking-hold phase?

a. She tells you she has painful contractions for 8 hours.
b. She sleeps as if exhausted from the effort of her labor.
c. She urges her baby to stay awake so that she can breastfeed.
d. She says that she has not selected a name for her baby as yet.

Development of Parental Love and Positive Family Relationships

During pregnancy, almost every woman worries about her ability to be a "good" mother, and this concern does not evaporate as soon as the baby is born. Some women seem able to recognize a newborn's needs immediately and to give care with confident understanding right from the start. More often, however, a woman enters into a relationship with her newborn tentatively and with qualms and conflicts that must be addressed before the relationship can be meaningful. This is because parental love is only partly instinctive. A major portion develops gradually, in stages such as planning the pregnancy, hearing the pregnancy confirmed, feeling the child move in utero, birthing, seeing the baby, touching the baby, and, finally, giving total care to the child. Factors such as a difficult labor or transport and separation from the newborn may lead to symptoms of a traumatic stress disorder that slows the process or interferes with the ability to bond warmly (Tam & Chung, 2007).

Many women may not experience maternal feelings for their infants until days or even weeks after giving birth. Some fathers admit they have difficulty "claiming" or bonding with an infant (feeling fatherly toward the new child) until as late as 3 months after the birth, when the child begins to smile or coo and interact more directly with them. The ability of both parents to reach out to their child can be strengthened by allowing them to touch and spend as much time as possible with the new child during the first few hours of life.

Forming a strong bond with a child is not a problem only for first-time parents. Experienced parents can have just as much difficulty—they know they love 4-year-old Johnny and 2-year-old Sue at home, but worry that their hearts may not be big enough to love a third child, too.

FIGURE 17.1 A mom and dad begin interaction with their newborn immediately after birth: a very special moment in their life. (© Kathy Sloane.)

FIGURE 17.2 A nurse encourages a father as he interacts and bonds with his newborn. (© Caroline Brown, RNC, MS, DEd.)

Because of these mixed feelings, parents may not show genuine warmth the first time they hold their infant. Although a woman carried the child inside her for 9 months, she now approaches her newborn as she would a stranger. The first time she holds the infant, she may touch only the blanket and never make close physical contact. If she unfolds the blanket to examine the baby or count the fingers or toes, she may use only her fingertips for touch (Fig. 17.1).

Gradually, as a woman holds her child more, she begins to express more warmth, touching the child with the palm of her hand rather than with her fingertips. She smoothes the baby's hair, brushes a cheek, plays with toes, and lets the baby's fingers clasp hers. Soon, she feels comfortable enough to press her cheek against the baby's or kiss the infant's nose or mouth; she has become a mother tending to her child. This identification process is termed *claiming* or *bonding.* Looking directly at her newborn's face, with direct eye contact (termed an **en face position**), is a sign a woman is beginning effective interaction. Many fathers can be observed staring at a newborn for long intervals in this same way. Often termed **engrossment,** this action alerts caregivers to how actively the father, as well as the mother, is beginning bonding (Fig. 17.2). The length of time parents take to bond with a child depends on the circumstances of the pregnancy and birth, the wellness and ability of the child to meet the parent's expectations, reciprocal actions by the newborn, and the opportunities the parents have to interact with the child. Freedom from stringent health agency rules helps good parent–child relationships to develop. To help parents sort out their feelings about being a mother or father and about their new responsibility, provide a supportive presence and offer anticipatory guidance as necessary.

✔ Checkpoint Question 17.2

You observe Joan Cooper holding her newborn. Which position would best reassure you that she is relating well to her newborn?

a. She looks directly at her infant's face and talks to him.
b. She holds the infant over her shoulder to burp him.
c. She sits in a rocking chair and rocks the new infant.
d. She lies in bed and places the infant on her stomach.

Rooming-In

The more time a woman has to spend with her baby, the sooner she may feel competent in child care, and the more likely she may be to form a sound mother–child relationship (Moore, Anderson, & Bergman, 2009). If her infant stays in the birthing room with her (called **rooming-in**) rather than in a central nursery, she can become better acquainted with her child and begin to feel more confident in her ability to care for him or her after discharge (Fink, 2007). In many settings, the father can stay overnight in the room, or room-in, as well.

There are two types of rooming-in: complete, in which the mother and child are together 24 hours a day, and partial, in which the infant remains in the woman's room for most of the time, perhaps from 8:00 AM to 9:00 PM, but then the infant is taken to a small nursery near the woman's room or returned to a central nursery for the night. With both complete and partial rooming-in, the father and siblings can hold and feed the infant when they visit.

Sibling Visitation

Separation from children is often as painful for a mother as it is for her children. Waiting at home, separated from their mother and listening only to telephone reports of what a new brother or sister looks like, can be very difficult for older children. They may picture the new baby as much older than he or she actually is. "He is eating well" may produce an image of a child sitting at a table using a fork and spoon. "He weighs 8 pounds" can be meaningless information. A chance to visit the hospital and see the new baby and their mother reduces feelings that their mother cares more about the new baby than about them. It can help to relieve some of the impact of separation. It helps to make the baby a part of the family (Fig. 17.3).

Assess to be sure that siblings are free of contagious diseases such as upper respiratory tract illnesses or recent exposure to chickenpox before they visit. Then, have them wash their hands and, if they choose, hold or touch the newborn with parental assistance.

You may need to caution a woman that the opinions of a new brother or sister expressed by her older children may not

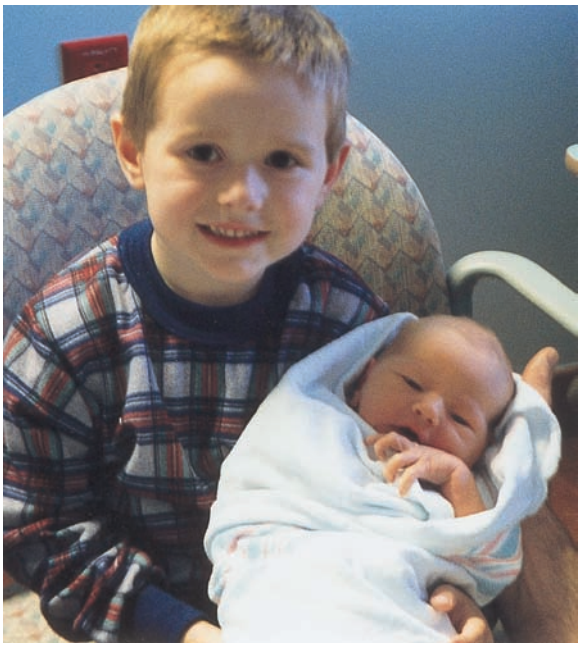

FIGURE 17.3 Sibling visiting is important to bring a family together.

be complimentary. This baby with little hair is not their idea of a "pretty baby." If they thought the new baby would be big enough to play with, they may not believe that he is a "big baby." However, seeing the baby, even if the baby's appearance is not what the other children expected, is helpful in establishing strong relationships and should be encouraged.

Maternal Concerns and Feelings in the Postpartal Period

Traditionally, it is assumed that the bulk of a woman's concerns in the postpartal period center on the care of her new infant. Based on this, classes in the postpartal period have traditionally focused on teaching how to breastfeed and bathe infants. Although these acts are concerns for many mothers, they are not necessarily every new mother's chief concern. A woman has come through a tremendous psychological experience during pregnancy and the birth of a child. She is in the middle of a complete role change. It can be expected, therefore, that some of her attention and interest during this time will be directed inward as she tries to view herself in this new role.

Typical issues identified by postpartal women include breast soreness; regaining their figure; regulating the demands of housework, their partner, and their children; coping with emotional tension and sibling jealousy; and fatigue.

Abandonment

Many mothers, if given the opportunity, admit to feeling abandoned and less important after giving birth than they did during pregnancy or labor. Only hours before, they were the center of attention, with everyone asking about their health and well-being. Now, suddenly, the baby seems to be everyone's chief interest. Relatives ask about the baby; the gifts are all for the baby. Even a woman's obstetrician, who has made her feel so important for the last 9 months, may ask during a visit, "How's that healthy 8-pound boy?" It can make a woman feel confused by a sensation very close to jealousy. And how can a good mother be jealous of her own baby?

You can help a woman move past these feelings by verbalizing the problem: "How things have changed! Everyone's asking about the baby today and not about you, aren't they? How does that make you feel?" These are welcome words for a woman to hear. It is reassuring to know that the sensation she is experiencing, although uncomfortable, is normal.

When a newborn comes home, a father may express much the same feelings. He may become resentful of the time the mother spends with the infant. Perhaps the two used to sit at the table after dinner and discuss their day or the future, and now she hurries away to feed the baby. She used to watch the late show with him at night; now she goes to bed earlier, because she knows she will be up again at 2:00 AM.

Examination of competitive feelings—both motherhood and fatherhood involve some compromise in favor of the baby's interests—should start during the pregnancy or early in the postpartal period. Making infant care a shared responsibility can help alleviate these feelings and make both partners feel equally involved in the baby's care.

Disappointment

Another common feeling parents may experience is disappointment in the baby. All during pregnancy, they pictured a chubby-cheeked, curly-haired, smiling girl or boy. They have instead a skinny baby, without any hair, who seems to cry constantly. It can be difficult for parents to feel positive immediately about a child who does not meet their expectations in this way. It can cause parents to remember their adolescence, when they felt gangly and unattractive, or to experience feelings of inadequacy all over again.

You can never change the sex, size, or look of a child, but in the short time you care for a postpartal family, you can help to change the feelings of a mother or father about their infant. Handle the child warmly, to show that you find the infant satisfactory or even special. Comment on the child's good points, such as long fingers, lovely eyes, and good appetite. During periods of crisis such as childbearing, it is possible for a key person such as a nurse to offer support to tip a scale toward acceptance or at least help a person involved to take a clearer look at his or her situation and begin to cope with the new circumstances.

Postpartal Blues

During the postpartal period, as many as 50% of women experience some feelings of overwhelming sadness (Buultjens & Liamputtong, 2007). They may burst into tears easily or feel let down or irritable. This temporary feeling after birth has long been known as the "baby blues." This phenomenon may be caused by hormonal changes, particularly the decrease in estrogen and progesterone that occurs with delivery of the placenta. For some women, it may be a response to dependence and low self-esteem caused by exhaustion, being away from home, physical discomfort, and the tension engendered by assuming a new role, especially if a woman is not receiving support from her partner. The syndrome is evidenced by tearfulness, feelings of inadequacy, mood lability, anorexia, and sleep disturbance.

Anticipatory guidance and individualized support from health care personnel are important to help the parents

understand that this response is normal. You can assure a woman that sudden crying episodes may occur; otherwise, she may have difficulty understanding what is happening to her. Her support person also needs assurance, or he can think the woman is unhappy with him or their new baby or is keeping some terrible secret about the baby from him.

It is also important to give the woman a chance to verbalize her feelings: "I know there's absolutely no reason for me to be crying, but I cannot stop." Allowing her to make as many decisions as possible can help give her a sense of control over her life and help her move past these strange postpartal emotions.

Remember, however, that not all postpartal women cry because they have baby blues. A woman sometimes has other reasons to feel sad during this time. Perhaps problems at home have become overwhelming. Her husband may have been laid off from his job just when they most need the money. One of her parents may be ill, or her house may have been damaged by a disaster such as a flood. Keeping lines of communication open is important to help differentiate between problems that can be handled best with discussion and concerned understanding and those that should be referred to a social service department or a community health agency.

Thirty percent of women experience a more serious level of sadness after birth or **postpartal depression** (Lipscomb & Novy, 2007). Serious depression requiring formal counseling or psychiatric care also can occur in women during this time (Engqvist et al., 2007). Because these are deeper level concerns, postpartal depression and psychosis are discussed in Chapter 25.

PHYSIOLOGIC CHANGES OF THE POSTPARTAL PERIOD

Retrogressive physiologic changes that occur during the postpartal period include those related specifically to the reproductive system as well as other systemic changes (Box 17.3).

Reproductive System Changes

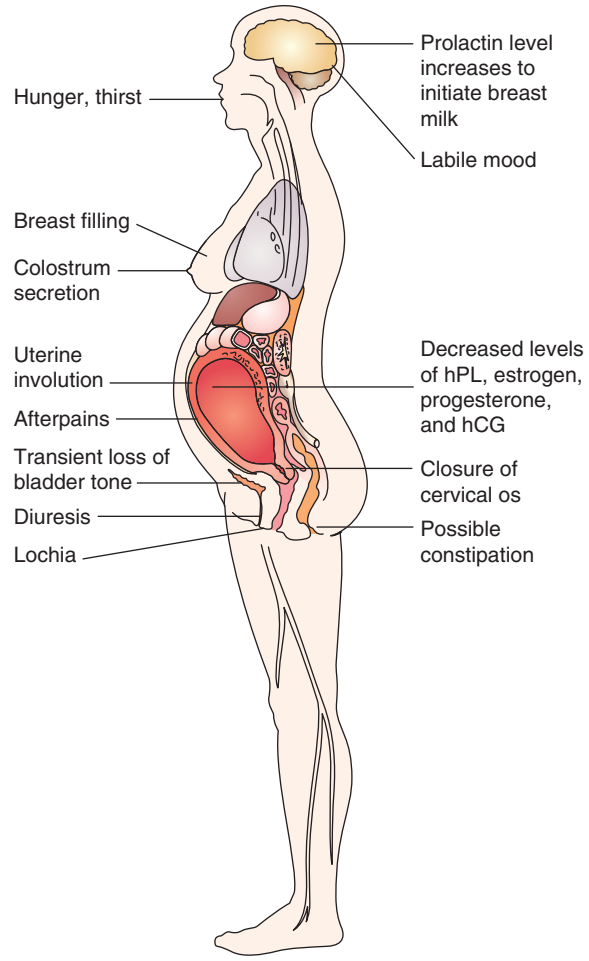
Involution is the process whereby the reproductive organs return to their nonpregnant state. A woman is in danger of hemorrhage from the denuded surface of the uterus until involution is complete (Poggi, 2007).

The Uterus

Involution of the uterus involves two main processes. First, the area where the placenta was implanted is sealed off to prevent bleeding. Second, the organ is reduced to its approximate pregestational size.

The sealing of the placenta site is accomplished by rapid contraction of the uterus immediately after delivery of the placenta. This contraction pinches the blood vessels entering the 7-cm-wide area left denuded by the placenta and stops bleeding. With time, thrombi form within the uterine sinuses and permanently seal the area. Eventually, endometrial tissue undermines the site and obliterates the organized thrombi, covering and healing the area so completely that the process leaves no scar tissue within the uterus and does not compromise future implantation sites.

Box 17.3 Assessment
Assessing the Postpartal Woman



The same contraction process reduces the bulk of the uterus. Devoid of the placenta and the membranes, the walls of the uterus thicken and contract, gradually reducing the uterus from a container large enough to hold a full-term fetus to one the size of a grapefruit. A few cells of the uterine wall are broken down into their protein components by an autolytic process. These components are then absorbed by the bloodstream and excreted by the body in urine. The main mechanism that reduces the bulk of the uterus, however, is contraction, a phenomenon that can be compared with a rubber band which has been stretched for many months and now is regaining its normal contour. None of the rubber band is destroyed; the shape is simply altered. For this reason, the postpartal period, like pregnancy, is not a period of illness, of necrosing cells being evacuated, but primarily a period of healthy change (Pavone, Purinton, & Petersen, 2007).

Although the uterus will never completely return to its prepregnancy state, its reduction in size is dramatic. Immediately after birth, the uterus weighs about 1000 g. At the end of the first week, it weighs 500 g. By the time involution is complete (6 weeks), it weighs approximately 50 g, similar to its prepregnancy weight.

Because uterine contraction begins immediately after placental delivery, the fundus of the uterus may be palpated through the abdominal wall, halfway between the umbilicus and the symphysis pubis, within a few minutes after birth. One hour later, it will have risen to the level of the umbilicus, where it remains for approximately the next 24 hours. From then on, it decreases one fingerbreadth per day—on the first postpartal day, it will be palpable one fingerbreadth below the umbilicus; on the second day, two fingerbreadths below the umbilicus; and so on. Because a fingerbreadth is about 1 cm, this can be recorded as 1 cm below the umbilicus, 2 cm below it, and so forth. In the average woman, by the ninth or tenth day, the uterus will have contracted so much that it is withdrawn into the pelvis and can no longer be detected by abdominal palpation (Fig. 17.4). The uterus of a breastfeeding mother may contract even more quickly, because oxytocin, which is released with breastfeeding, stimulates uterine contractions. However, breastfeeding alone is not sufficient to protect against postpartum hemorrhage.

The fundus is normally in the midline of the abdomen. Occasionally, it is found slightly to the right, because the bulk of the sigmoid colon forces it to that side during pregnancy and it tends to remain in that position. Assess fundal height shortly after a woman has emptied her bladder for most accurate results, because a full bladder can keep the uterus from contracting, pushing it upward and possibly deviating it from the midline, because of the laxness of the uterine ligaments.

Uterine involution may be delayed by a condition such as the birth of multiple fetuses, hydramnios, exhaustion from prolonged labor or a difficult birth, grand multiparity, or physiologic effects of excessive analgesia. Contraction may be difficult if there is retained placenta or membranes. Involution will occur most dependably in a woman who is well nourished and who ambulates early after birth (gravity may play a role).

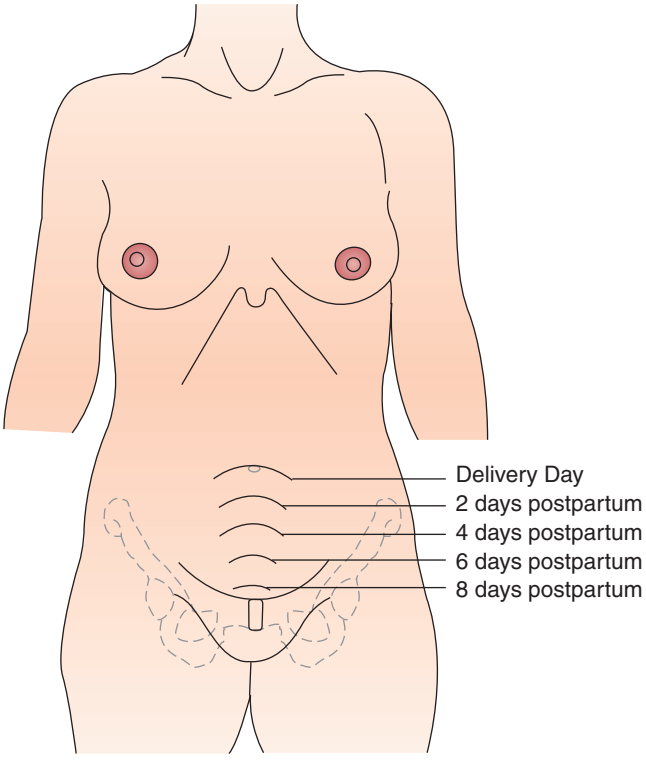


FIGURE 17.4 Uterine involution. The uterus decreases in size at a predictable rate during the postpartal period. After 10 days, it recedes under the pubic bone and is no longer palpable.

An estimation of the consistency of the postpartal uterus is as important as measurement of its height. A well-contracted fundus feels firm. It can be compared with a grapefruit in both size and tenseness. Whenever the fundus feels boggy (soft or flabby), it is not as contracted as it should be, despite its position in the abdomen.

The first hour after birth is potentially the most dangerous time for a woman. If her uterus should become relaxed during this time **(uterine atony),** she will lose blood very rapidly, because no permanent thrombi have yet formed at the placental site.

In some women, contraction of the uterus after birth causes intermittent cramping termed **afterpains,** similar to that accompanying a menstrual period. Afterpains tend to be noticed most by multiparas rather than primiparas and by women who have given birth to large babies or multiple births. In these situations, the uterus must contract more forcefully to regain its prepregnancy size and has difficulty maintaining a steady contracted state. These sensations are noticed most intensely with breastfeeding, when the infant's sucking causes a release of oxytocin from the posterior pituitary, increasing the strength of the contractions.

Lochia

The separation of the placenta and membranes occurs in the spongy layer or outer portion of the decidua basalis of the uterus. By the second day after birth, the layer of decidua remaining under the placental site (an area 7 cm wide) and throughout the uterus differentiates into two distinct layers. The inner layer attached to the muscular wall of the uterus remains, serving as the foundation from which a new layer of endometrium will be formed. The layer adjacent to the uterine cavity becomes necrotic and is cast off as a uterine discharge similar to a menstrual flow. This uterine flow, consisting of blood, fragments of decidua, white blood cells, mucus, and some bacteria, is known as **lochia.**

The portion of the uterus where the placenta was not attached is so fully cleansed by this sloughing process that it will be in a reproductive state in about 3 weeks' time. It takes approximately 6 weeks (the entire postpartal period) for the placental implantation site to be healed.

For the first 3 days after birth, a lochia discharge consists almost entirely of blood, with only small particles of decidua and mucus. Because of its mainly red color, it is termed *lochia rubra.* As the amount of blood involved in the cast-off tissue decreases (about the fourth day) and leukocytes begin to invade the area, as they do with any healing surface, the flow becomes pink or brownish (*lochia serosa*). On about the 10th day, the amount of the flow decreases and becomes colorless or white (*lochia alba*). Lochia alba is present in most women until the third week after birth, although it is not unusual for a lochia flow to last the entire 6 weeks of the puerperium. Characteristics of lochia are summarized in Table 17.1. Several rules for judging whether lochia flow is normal are summarized in Box 17.4.

TABLE 17.1 ✻ Characteristics of Lochia

Type of Lochia	Color	Postpartal Day	Composition
Lochia rubra	Red	1–3	Blood, fragments of decidua, and mucus
Lochia serosa	Pink	3–10	Blood, mucus, and invading leukocytes
Lochia alba	White	10–14 (may last 6 weeks)	Largely mucus; leukocyte count high

The Cervix

Immediately after birth, a uterine cervix is soft and malleable. Both the internal and external os are open. Like contraction of the uterus, contraction of the cervix toward its prepregnant state begins at once. By the end of 7 days, the external os has narrowed to the size of a pencil opening; the cervix feels firm and nongravid again.

In contrast to the process of uterine involution, in which the changes consist primarily of old cells being returned to their former position by contraction, the process in the cervix involves the formation of new muscle cells. Like the fundus, the cervix does not return exactly to its prepregnancy state. The internal os closes as before, but after a vaginal birth the external os usually remains slightly open and appears slitlike or stellate (star shaped), whereas previously it was round. Finding this pattern on pelvic examination suggests that childbearing has taken place.

The Vagina

After a vaginal birth, the vagina is soft, with few rugae, and its diameter is considerably greater than normal. The hymen is permanently torn and heals with small, separate tags of tissue. It takes the entire postpartal period for the vagina to involute (by contraction, as with the uterus) until it gradually returns to its approximate prepregnancy state. Thickening of the walls also appears to depend on renewed estrogen stimulation from the ovaries. Because a woman who is breastfeeding may have delayed ovulation, she may continue to have thin-walled or fragile vaginal cells that cause slight vaginal bleeding during sexual intercourse until about 6 weeks' time. Like the cervix, the vaginal outlet remains slightly more distended than before. If a woman practices Kegel exercises, the strength and tone of the vagina will increase more rapidly (see Chapter 12). This may be important for the sexual enjoyment of both a woman and her partner.

The Perineum

Because of the great amount of pressure experienced during birth, the perineum feels edematous and tender immediately after birth. Ecchymosis from ruptured capillaries may show on the surface. The labia majora and labia minora typically remain atrophic and softened after birth, never returning to their prepregnancy state.

Systemic Changes

The same body systems that were involved in pregnancy are also involved in postpartal changes as the body returns to its prepregnancy state.

The Hormonal System

Pregnancy hormones begin to decrease as soon as the placenta is no longer present. Levels of human chorionic gonadotropin (hCG) and human placental lactogen (hPL) are almost negligible by 24 hours. By week 1, progestin, estrone,

Evaluating Lochia Flow

Q. Joan Cooper asks you, "How do I know if my lochia is normal?"

A. Several guidelines are helpful for evaluating lochia flow:

Evaluate the Amount: Lochia amount will vary from woman to woman. Mothers who breastfeed tend to have less lochial discharge than those who do not, because the natural release of the hormone oxytocin during breastfeeding strengthens uterine contractions. Conservation of fluid for lactation also may be a factor. Lochial flow increases on exertion, especially the first few times a woman is out of bed, but decreases again with rest. The increase in amount that occurs with ambulation is the result of vaginal discharge of pooled lochia, not a true increase in amount. However, lochia amount truly does increase with strenuous exercise, such as lifting a heavy weight or walking up stairs. Saturating a perineal pad in less than 1 hour is considered an abnormally heavy flow and should be reported.

Check the Consistency: Lochia should contain no large clots. Clots may indicate that a portion of the placenta has been retained and is preventing closure of the maternal uterine blood sinuses. In any event, large clots denote poor uterine contraction, which needs to be corrected.
