Skin/soft tissue	Vancomycin or linezolid or daptomycin	Vancomycin + piperacillin/tazobactam	
Catheter-related		Vancomycin	
Unknown		Piperacillin/tazobactam or ceftazidime/cefipime or imipenem/meropenem	}± vancomycin

[a]750 mg orally once daily.

[b]Imipenem, meropenem, and doripenem.

S. pneumoniae is the most common cause of community-acquired pneumonia, and it accounts for approximately 60% of all deaths. The steady prevalence of penicillin-resistant *S pneumoniae* requires empiric use of newer "respiratory" fluoroquinolones. Levofloxacin or moxifloxacin can be used as monotherapy, as they offer excellent coverage against penicillin-resistant pneumococci and aerobic gram-negative bacteria, as well as atypical pathogens, including *Legionella pneumophila, Mycoplasma pneumoniae*, and *Chlamydophila pneumoniae*.[44] Addition of a macrolide to a β-lactam empirical therapy improves outcome in severe pneumonia, and clarithromycin and azithromycin are effective against atypical pathogens and better tolerated than erythromycin.[45]

In nosocomial pneumonia, enteric gram-negative bacteria such as *Enterobacter* and *Klebsiella* species and *P. aeruginosa* are the major pathogens in addition to *S. aureus*. If *P. aeruginosa* infection is suspected, β-lactam antipseudomonal agents (ceftazidime or cefepime), antipseudomonal fluoroquinolone (ciprofloxacin or levofloxacin), or an aminoglycoside should be included in the regimen.[3,46] When *S. aureus* is likely to be methicillin-resistant, linezolid may be preferred to vancomycin because of the poor penetration of vancomycin into the lungs, as well as the worldwide emergence of glycopeptide intermediately resistant *S. aureus*.[47] Televancin, a bactericidal, lipoglycopeptide was evaluated in treatment of hospital-acquired pneumonia due to gram-positive organisms against vancomycin in two randomized trials.[48] MRSA was the most commonly isolated microorganism from both respiratory specimens and blood. Televancin was noninferior to vancomycin in terms of clinical responses. However, vancomycin dosing and the subsequent serum trough levels were slightly lower than the current practice. Further use in clinical settings will define its role.

Abdominal infections are frequent causes of sepsis and septic shock in the ICU and are associated with adverse outcomes. ICU mortality was higher in patients with abdominal infections than in those with other infections (29.4% vs 24.2%, p <0.001).[49] Microbiological cultures were positive in 67%, and polymicrobial infections were present in 40.1% of the patients. *E. coli* was isolated most frequently,

followed by *Pseudomonas* spp. and *Klebsiella* spp. among gram-negative isolates. *Enterococcus* was the most common gram-positive isolate.[49] Because of widespread resistance of *E. coli* to ampicillin/sulbactam, it is no longer recommended.[50] Emerging fluoroquinolone-resistant *E. coli* and the local prevalence of extended-spectrum *β*-lactamase-producing strains of *Klebsiella* species and *E. coli* should be considered in choosing empiric therapy. *Bacteroides fragilis*, the major pathogen, has shown uniform susceptibility to metronidazole, carbapenems, and *β*-lactam/*β*-lactamase inhibitors.[51] High resistance rates were observed for clindamycin and moxifloxacin (as high as 60% for clindamycin and >80% for moxifloxacin), with relatively stable low resistance (5.4%) for tigecycline.

In addition to surgical intervention, broad-spectrum antibiotics, such as a *β*–lactam/*β*-lactamase inhibitor combination agent (piperacillin/tazobactam) is appropriate in treating intraabdominal infections.[50] Carbapenems such as imipenem, meropenem, and doripenem are indicated in the treatment of resistant pathogens, including Enterobacteriaceae and *P. aeruginosa* in critically ill patients.[50]

Skin and soft tissue infections (SSTIs) range from cellulitis to rapidly progressive necrotizing fasciitis, which may be associated with septic shock and toxic shock syndrome. Staphylococci and streptococci long have been the leading causes of SSTIs, but severe SSTIs can be caused also by indigenous aerobes and anaerobes such as *Clostridium* species.[52] Early initiation of appropriate empiric broad-spectrum antimicrobial therapy is essential and should include coverage against MRSA due to the high prevalence of community-associated MRSA strains.[47,52] Vancomycin, daptomycin, and linezolid have comparable clinical efficacy and safety data for complicated skin and skin-structure infections caused by MRSA.[47,53] Daptomycin resulted in a 70% success rate for septic patients bacteremic with MRSA, vancomycin-resistant *Enterococcus* (VRE) *faecium* or coagulase-negative staphylococci.[54]

Combination therapy does not appear to be more effective than monotherapy in reducing organ failure or mortality in low risk patients.[10,55] However, multidrug resistance in sepsis due to gram-negative bacteremia was strongly associated with the receipt of inappropriate empiric therapy and a three-fold increase in the risk of hospital mortality.[40] As such, the greatest benefit of combination therapy appeared to be in patients with *Pseudomonas* or multidrug-resistant gram-negative bacteremia and in neutropenic patients with severe sepsis or septic shock.[3,55,56,57]

Empiric combination therapy should not be administered for longer than 3 to 5 days.[3] The antimicrobial regimen should be reassessed daily based on the microbiological and clinical data. This creates a potential de-escalation opportunity as part of good antibiotic stewardship to narrow down the spectrum when possible to prevent drug toxicities and the development of nosocomial super infections with *Candida* species, *Clostridium difficile*, or VRE.[3,58] Furthermore, improved patient care outcomes have been demonstrated with such de-escalation of antibiotic therapy.[59] De-escalation of antimicrobial therapy in patients admitted to the ICU with severe sepsis or septic shock had a protective factor.[60] The hospital mortality rate was 27.4% in patients in whom therapy was de-escalated, 32.6% in the category of “no change”, and 42.9% in the escalation group.[60]

Antifungal Therapy

Patients with candidemia are generally acutely sicker based on higher APACHE II scores, have presence of septic shock, and mechanical ventilation, and the mortality is significantly higher in comparison to patients with bacteremia (47% vs 28%, respectively).[17] Septic shock caused by *C. albicans* demonstrated 24.6% survival with initial appropriate therapy but only 4.6% survival without (ninefold decrease).[11] Of the patients with candidemia, delayed appropriate antifungal treatment, especially in presence of septic shock and failure to achieve timely source control were independently associated with a greater risk of hospital mortality.[15,61,62] Hence, accurate and rapid identification of candida is critical in prompt initiation of appropriate therapy.[3,34]

Treatment of invasive candidiasis involves echinocandins, triazoles, or a formulation of amphotericin B. The choice depends on the clinical status of the patient, the fungal species and its susceptibility, relative drug toxicity, presence of organ dysfunction that would affect drug clearance, and the patient's prior exposure to antifungal agents.

Empirical fluconazole therapy for suspected nosocomial bloodstream infections can be appropriate for hospitalized patients at high risk for fungal infections, including those receiving total parenteral nutrition, with bowel perforation, *Candida* colonization, malignancy, emergency surgery, or with persistent or new signs and symptoms of infections despite receiving broad-spectrum antibacterial therapy.[63,64] However, recent exposure to antibiotics and fluconazole have been associated with fluconazole-resistant *Candida* species.[18,65] A global survey evaluating Candida bloodstream infections reported a low overall fluconazole resistance (5% of ICU isolates and 4.4% of non-ICU isolates).[66] *C. glabrata* was the only species to exhibit resistance to both azoles and echinocandins. Of 1,669 bloodstream infection isolates of *C. glabrata* reported resistance to fluconazole was 9.7%, of which 8% to 9.3% were resistant to enchinocandins.[67]

Echinocandins are potent against all *Candida* species, including *C. glabrata, C. krusei*, and *Candida lusitaniae*, as well as *Aspergillus* species. IV caspofungin was equally effective but better tolerated than amphotericin B deoxycholate for invasive candidiasis.[68] In an international, randomized, double-blind trial, micafungin 100-mg was noninferior to caspofungin for the treatment of candidemia and other forms of invasive candidiasis (76.4% vs 72.3%).[69] All three echinocandins appear to be comparable in terms of efficacy, pharmacology, and adverse effects, and the guidelines do not make a distinction or a preferred agent.[64,70]

In general, suspected systemic mycotic infection leading to sepsis in nonneutropenic patients should be treated empirically with parenteral fluconazole or an enchinocandin.[64] However, an echinocandin is preferred for a patient with recent azole exposure or if the patient is clinically unstable because of its greater activity against fluconazole-resistant *Candida* species and non-*albicans* species, including *C. glabrata* and *C. krusei*.[64] In neutropenic patients, an echinocandin, or voriconazole is recommended. Azoles should be avoided for empiric therapy in patients who have received an azole for prophylaxis.[64]

Antiviral Therapy

Early antiviral treatment of suspected or confirmed influenza is recommended among persons with severe influenza or at higher risk for influenza complications. A neuramidase inhibitor such as oseltamivir or zanamivir is generally effective but susceptibility among the seasonal influenza virus should be considered.[3] While cytomegalovirus in the bloodstream has been associated with poor prognosis, the role of cytomegalovirus and other herpesviruses in septic patients in mildly immunocompromised state remains unclear.

Duration of Therapy

The average duration of antimicrobial therapy in a patient with sepsis is 7 to 10 days, and fungal infections can require 10 to 14 days.[3,46,64] However, the duration can be longer in patients with a slow clinical response, undrainable focus of infection, bacteremia with *S. aureus*, or neutropenia. In a neutropenic patient, therapy is usually continued until the patient is no longer neutropenic and has been afebrile for at least 72 hours. After the patient is hemodynamically stable, afebrile for 48 to 72 hours, has a normalizing WBC count, and is able to take oral medications, then a "step-down" from parenteral to oral antibiotics can be considered for the remaining duration of therapy.

PCT is a biomarker that increases in response to endotoxins and inflammatory cytokines that are released during systemic bacterial infections. Hence, PCT has been studied as a marker to initiate and discontinue antibiotics in patients with severe sepsis or septic shock and surgical intensive care patients.[71] However, aside from the shortened length of antibiotic therapy, the survival benefit has not been clearly defined.

Clinical Controversy…

The biomarkers such as PCT rise early in severe sepsis by pneumonia and bloodstream infections, and a growing body of evidence supports the use of PCT to differentiate bacterial from viral diagnoses, to help risk stratify patients, and to guide antibiotic therapy decisions in terms of initiating and optimizing duration of therapy.[71,72]

A meta-analysis of randomized controlled clinical trials or cohort studies investigating PCT guided therapy in ICU patients with severe sepsis and septic shock found no significant difference in both hospital mortality and 28-day mortality between PCT-guided therapy and standard treatment groups.[73] Duration of antimicrobial therapy was significantly reduced in favor of PCT group. However, the length of stay in the ICU and in hospital did not differ between groups. The Procalcitonin and Survival Study Group in Demark found no significant difference in ICU mortality between the PCT arm and the standard of care arm with a strategy of escalation of broad-spectrum antimicrobials and intensified diagnostics based on daily PCT measurements.[74] PCT-guided antimicrobial escalation leads to increased use of broad-spectrum antimicrobials, organ-related harm, and prolonged admission to the ICU. Further trials are needed to determine the safety and efficacy of antibiotic sparing PCT strategies in critically ill patients.

Hemodynamic Support

A high cardiac output and a low SVR characterize septic shock. Patients can have hypotension as a result of low SVR and abnormal distribution of blood flow in the microcirculation, resulting in compromised tissue perfusion. Because approximately half of patients with septic shock die of multiple organ system failure, they should be monitored carefully, and aggressive hemodynamic support should be initiated. The Surviving Sepsis Guidelines recommend a MAP of at least 65 mm Hg (8.6 kPa) in patients with septic shock.[3] A large, controlled trial randomized patients to either a high (MAP of 80-85 mm Hg [10.6-11.3 kPa]) or low (MAP of 65-70 mm Hg [8.6-9.3 kPa]) target and found no significant difference in mortality at 28 days.[75] Among patients with chronic hypertension, those in the high-target group had less renal dysfunction and need for renal-replacement therapy. However, the high-target group had an increased risk of new atrial fibrillation in comparison to the low-target group. Hence, the question of an ideal MAP for septic shock still remains unanswered.

Hemodynamic support can be divided into three main categories: fluid therapy, vasopressor therapy, and inotropic therapy.

Fluid Therapy

6 Septic patients have enormous fluid requirements as a result of peripheral vasodilation and capillary leakage. In approximately 50% of septic patients who initially present with hypotension, fluids alone will reverse hypotension and restore hemodynamic stability. Rapid fluid resuscitation improves the 28-day survival rate in patients with sepsis-induced hypoperfusion.[3] The goal of fluid therapy is to maximize cardiac output by increasing the LV preload, which will ultimately restore tissue perfusion. Fluid administration should be titrated to clinical end points such as heart rate, urine output, blood pressure, and mental status. Increased serum lactate, a by-product of cellular anaerobic metabolism, should normalize as tissue perfusion improves.

Isotonic crystalloids, such as 0.9% sodium chloride (normal saline) and lactated Ringer solution, are commonly used for fluid resuscitation. A patient in septic shock may require up to 10 L of crystalloid solution during the first 24-hour period. These solutions distribute into the extracellular compartment, and approximately 25% of the infused volume of crystalloid remains in the intravascular space, whereas the balance distributes to extravascular spaces. Although this could impair diffusion of oxygen to tissues, clinical impact is unproven.

The most commonly used colloids are 5% albumin, a naturally occurring plasma protein, and 6% hetastarch, a synthetic colloid formulation. These solutions offer more rapid restoration of intravascular volume because they produce greater intravascular volume expansion per quantity of volume infused. Colloids produce less peripheral edema than crystalloid, but there is no significant clinical impact. However, synthetic colloids cause dose-related acute kidney injury and increased bleeding.[3,76] The use of colloid solutions and blood products can be particularly important if there is significant blood loss associated with sepsis or if the patient had severe preexisting anemia.

There was no difference in 28-day mortality in critically ill patients given saline or albumin in the Saline versus Albumin Fluid Evaluation (SAFE) trial.[77] There was no significant difference in the mortality rate at 28 days for patients admitted to ICU with severe sepsis or septic shock given 20%

albumin or crystalloid solution (31.8% vs 32.0%) and at 90 days (41.1% vs 43.6%).[78]

Crystalloid solutions are generally recommended for fluid resuscitation because of the absence of any clear benefit with colloids solutions in addition to the lower cost of crystalloids. For initial fluid challenge, a minimum of 30 mL/kg of normal saline is recommended. More rapid administration and greater amounts of fluid may be needed in some patients. The fluid administration should be continued as long as there is hemodynamic improvement either based on changes in pulse pressure, stroke volume, arterial pressure, and heart rate.[3]

Patients receiving fluid challenges require close monitoring of volume status to avoid pulmonary and systemic edema. Aggressive volume expansion can cause an increase in pulmonary capillary pressure, leading to an increase in lung water and associated hypoxemia. In a retrospective cohort of 405 patients with severe sepsis and septic shock, fluid overload was seen in 67% at day 1, and 48% had persistent fluid overload, exhibiting pulmonary vascular congestion and/or pleural effusions and requiring medical interventions including thoracentesis and diuretics.[79] Fluid overload was also associated with increased hospital mortality (odds ratio, 1.92; confidence interval, 1.16-3.22).

Vasopressor and Inotropic Therapy

When fluid resuscitation alone provides inadequate arterial pressure and organ perfusion, vasopressors and inotropic agents should be initiated. Inotropic agents such as dopamine and dobutamine have been effective in improving cardiac output by increasing cardiac contractility. Vasopressors such as norepinephrine should be considered when a systolic blood pressure is less than 90 mm Hg (12.0 kPa) or MAP is less than 65 mm Hg (<8.6 kPa) after adequate LV preload and inotrope therapy. Although inotropes and vasopressors are effective in life-threatening hypotension and in improving cardiac index (CI), there are significant complications such as tachycardia and myocardial ischemia and infarction as a result of the change in myocardial oxygen consumption in patients with coexisting coronary disease. Thus, a catecholamine infusion should be titrated gradually to restore MAP without impairing stroke volume.

Fluids and vasoactive agents have a strong influence on mortality. Mortality was lowest when vasoactive agents were started within 1 to 6 hours after onset of septic shock, with more than 1 L of fluid in the initial hour.[80]

7 Agents commonly considered for vasopressor or inotropic support include dopamine, dobutamine, norepinephrine, phenylephrine, and epinephrine (**Table 119-5**). Norepinephrine should generally be considered to be the first-choice vasopressor in septic shock after failure to restore adequate blood pressure and organ perfusion with appropriate fluid resuscitation.[3] Norepinephrine is a potent α-adrenergic agent with less pronounced β-adrenergic activity. It increases MAP and SVR because of its vasoconstrictive effects on peripheral vascular beds. Doses of 0.01 to 3 µg/kg/min can reliably increase blood pressure with little changes in heart rate or CI. Despite the earlier concern of decreased renal blood flow associated with norepinephrine, data in humans and animals demonstrate a norepinephrine-induced renal blood flow as well as urine and cardiac output.[81] Norepinephrine is a more potent agent than dopamine in refractory septic shock. Norepinephrine

resulted in greater increases in arterial blood pressure in comparison to patients with septic shock who were treated with dopamine (93% with norepinephrine vs 31% with dopamine).[81] In a meta-analysis evaluation the randomized trials comparing norepinephrine and dopamine, dopamine was associated with a higher risk of death and more frequently associated with arrythmias.[82]

TABLE 119-5 Receptor Activity of Cardiovascular Agents Commonly Used in Septic Shock

Agent	α_1	α_2	β_1	β_2	Dopaminergic
Dopamine	++/+++	?	++++	++	++++
Dobutamine	+	+	++++	++	0
Norepinephrine	+++	+++	+++	+/++	0
Phenylephrine	++/+++	+	?	0	0
Epinephrine	++++	++++	++++	+++	0

α_1, α_1-adrenergic receptor; α_2, α_2-adrenergic receptor; β_1, β_1-adrenergic receptor; β_2, β_2-adrenergic receptor; 0, no activity; ++++, maximal activity; ?, unknown activity.

Dopamine is a natural precursor of norepinephrine and epinephrine, and it exhibits dose-dependent pharmacologic effects. It is an α- and β-adrenergic agent with dopaminergic activity. Doses greater than 5 µg/kg/min increase MAP and cardiac output, primarily because of the increase in heart rate and cardiac contractility through stimulation of β-adrenergic receptors. At higher doses, α-adrenergic effects predominate, resulting in arterial vasoconstriction. Because of combined vasopressor and inotropic effects, dopamine is more useful in patients with hypotension and compromised systolic function. However, it is also more arrhythmogenic and can cause more tachycardia.[3,81,82] It should be used with caution in patients who have underlying heart disease. Norepinephrine was more frequently used in 61,122 patients admitted with septic shock in US hospitals as initial vasopressor (77.6%) over dopamine, and patients who received dopamine experienced greater hospital mortality (25% norepinephrine vs 23.7% dopamine).[83]

Epinephrine is a nonspecific α- and β-adrenergic agonist. Ranging from 0.1 to 0.5 µg/kg/min, cardiac output is increased at lower doses, and vasoconstriction occurs predominantly at higher doses. Despite human and animal studies suggesting epinephrine impairing blood flow to the splanchnic system and increasing lactate level, clinical data demonstrating worse clinical outcomes as in mortality is lacking. The 2012 guidelines recommend epinephrine as the first alternative to patients intolerant to norepinephrine.[3]

Phenylephrine, a selective α-1-agonist, has rapid onset, short duration, and primary vascular effects, and it is least likely to produce tachycardia. Limited data suggest it can increase blood pressure modestly in fluid-resuscitated patients. Phenylephrine may decrease the stroke volume. Hence, it is only recommended when norepinephrine is associated with serious arrhythmias, cardiac output is known to be high, or as a salvage therapy when all other vasopressors have failed to achieve target MAP.[3,81]

During hypotension, endogenous vasopressin levels should increase and maintain arterial blood

pressure, as vasopressin is a direct vasoconstrictor without inotropic or chronotropic effects. However, there is a vasopressin deficiency in septic shock most likely caused by inadequate production. Low doses of vasopressin produce a significant increase in MAP in septic shock, and it may be beneficial to add vasopressin in severe sepsis and septic shock that is refractory to other vasopressors.[77] Although vasopressin 0.03 units/min can be used to increase MAP or reduce norepinephrine requirements, this has not been shown to improve mortality rates.[3,84]

Dobutamine is a β-adrenergic inotropic agent that many clinicians consider to be the preferred drug for improvement of cardiac output and oxygen delivery, particularly in early sepsis before significant peripheral vasodilation has occurred. Doses of 2 to 20 µg/kg/min increase the CI, ranging from 20% to 66%. However, heart rate often increases significantly.[81] Dobutamine should be considered in severely septic patients with low CI but adequate filling pressures and blood pressure.[3] A vasopressor such as norepinephrine and dobutamine can be used in combination to maintain both MAP and cardiac output.

In summary, for the septic patients with clinical signs of shock and significant hypotension unresponsive to aggressive fluid therapy, norepinephrine is the preferred agent for increasing MAP. In comparison to dopamine, it is less arrhythmogenic and studies have shown benefits in mortality. Epinephrine is an alternative to norepinephrine for refractory hypotension. Dopamine and epinephrine are more likely to induce or exacerbate tachycardia than norepinephrine. Phenylephrine is only recommended as a salvage therapy only if tachycardia or arrhythmia makes norepinephrine and epinephrine intolerable. In a septic patient with low CI after adequate fluid therapy and adequate MAP, dobutamine is the first-line agent for its strong inotropic effect, increasing cardiac output with minimal effect on SVR.

Initial Resuscitation

8 Initial resuscitation of patients in severe sepsis or sepsis-induced tissue hypoperfusion should begin within 6 hours of recognition of the syndrome. A randomized, controlled trial evaluated the timing of the goal-directed therapy involving adjustments of cardiac preload, afterload, and contractility to balance oxygen delivery with demand prior to admission to the ICU.[85] The goals during the first 6 hours included central venous pressure (CVP) of 8 to 12 mm Hg (1.1-1.6 kPa), MAP more than or equal to 65 mm Hg (≥8.6 kPa), urine output more than or equal to 0.5 mL/kg/h, and a central venous or mixed venous oxygen saturation ($Scvo_2$) more than or equal to 70% (≥0.70). During the first 6 hours of resuscitation, this early goal-directed therapy (EGDT) group had a central venous catheter placed and received more fluid than with traditional therapy (5 vs 3.5 L), dobutamine therapy to a maximum of 20 µg/kg/min, and red blood cell transfusions. The 28-day mortality rate was 30% in the EGDT group, in comparison to 46.5% in the traditional therapy group consisting of fluid resuscitation, followed by vasopressor therapy if required. Increased oxygen delivery from the red blood cell transfusions to achieve a hematocrit of ≥30% (≥0.30) in the EGDT group appeared to be the primary difference between the two groups. However, a decade later, new data challenges the effect of EGDT on patient outcomes.[86,87,88,89]

Clinical Controversy...

The benefit of EGDT is controversial. EGDT emerged over a decade ago, as a novel approach for reducing mortality due to sepsis.[85] The impressive 15.9% absolute reduction in 28-day mortality rate is the result of invasive monitoring to guide resuscitation with aggressive IV fluids, vasopressors, red cell transfusions, and inotropes. Three large multicenter, randomized trials of 4,183 patients were conducted to validate the effect of EGDT on morbidity and mortality. The Protocolized Care for Early Septic Shock (ProCESS) trial was conducted in the United States at 31 academic hospitals. The patients with septic shock were randomly assigned to one of the three treatment groups: EGDT with continuous monitoring of CVP and Scvo2, protocolized standard therapy without continuous monitoring, and usual care. The EGDT group was most likely to receive vasopressors, inotropes, and red cell transfusions. However, there was no significant change in 60-day mortality (21.0% EGDT vs 18.9% usual care).[87] The Australasian Resuscitation in Sepsis Evaluation (ARISE) trial in Australia and New Zealand enrolled patients from 51 urban and rural hospitals who were diagnosed with septic shock.[88] No significant difference in 90-day mortality (18.6% EGDT vs 18.8% usual care) was noted. The Protocolised Management of Sepsis (ProMISe) trial in England showed similar findings as the ProCESS and ARISE.89. There was no significant difference in the 90-day mortality (29.5% EGDT vs 29.2% usual care), but the patients in the EGDT group had higher organ failure at 6 hours and longer stays in the ICU. Furthermore a meta-analysis of 11 published randomized clinical trials of EGDT did not show improved survival for patients in the EGDT group but rather had an increase admission to ICU from the emergency room for an invasive monitoring.[90]

The 2012 Surviving Sepsis Campaign recommends implementation of hospital-based performance improvement efforts such as a core set (“bundle”) as they have been associated with improved patient outcomes. A 7.5-year study assessing the level of compliance with the 2004 Surviving Sepsis Campaign performance bundle and its effect on mortality in the United States, South America, and Europe reported lower mortality in high resuscitation compliance (29.0%) versus low compliance sites (38.6%).[91] In addition, hospital mortality rates dropped 0.7% per site for every three months of participation and the hospital and ICU length of stay decreased 4% for every 10% increase in site compliance. The 2012 guidelines have created the resuscitation bundle based on the time from of 3 hours and 6 hours with the recommended targets from the guidelines (**Table 119-6**).

TABLE 119-6 Initial Resuscitation bundle for Sepsis and Septic Shock

Within 3 hours

- Measure lactate level
- Obtain blood cultures x 2 prior to antibiotic administration
- Initiate empiric broad spectrum antibiotics
- Fluid resuscitation with crystalloid for hypotension or lactate >4mmol/L

Within 6 hours

- Vasopressors if not responsive to initial fluid resuscitation to maintain MAP >65 mm Hg (≥8.6 kPa)

- Measure for target CVP of ≥8 mm Hg (≥1.1 kPa), $SCVO_2$ of ≥70% (≥0.70) and normalization of lactate

CVP, central venous pressure; MAP, mean arterial pressure; $SCVO_2$, saturation of central venous oxygen.

Adapted from Dellinger RP, Levy MM, Rhodes A, et al. Surviving sepsis campaign: International guidelines for management of severe sepsis and septic shock: 2012. Crit Care Med 2013;41:580-637.

Adjunctive Therapies

ARDS and hypoxia are common in septic patients, even in those without pulmonary infection. Oxygen therapy is indicated to maintain oxygen saturation greater than 90% (0.90), and with progressive pulmonary insufficiency, the patient may require assisted ventilation.

9 Hyperglycemia and insulin resistance are frequently associated with sepsis regardless of the presence of diabetes prior to sepsis, and more severe hyperglycemia is associated with higher morbidity and mortality.[3] However, intensive insulin therapy is no longer the standard of care in critically ill patients. Patients receiving intensive insulin therapy (target serum glucose of 81-108 mg/dL [4.5-6 mmol/L]) had a higher incidence of severe hypoglycemia and increased mortality at 90 days compared with patients receiving conventional insulin therapy (target ≤180 mg/dL [≤10.0 mmol/L]).[92] Further analysis of patients with moderate (41-70 mg/dL [2.3-3.9 mmol/L]) and severe hypoglycemia (≤40 mg/dL [≤2.2 mmol/L]) reported death rate of 23.5% with moderate hypoglycemia and 35.4% with severe hypoglycemia.[93] Severe hypoglycemia in the absence of insulin therapy was also associated with a higher risk of death. The 2012 guidelines recommend blood glucose levels more than 180 mg/dL (>10 mmol/L) to initiate an insulin protocol with an upper target blood glucose level than 180 mg/dL (10 mmol/L) for the majority of critically ill patients to improve the outcome while reducing the risk of hypoglycemia.[3]

10 Cortisol levels vary widely in patients with septic shock, and some studies have suggested increased mortality associated with both low and high serum cortisol levels. Corticosteroids have been studied as adjunct therapy in patients with severe sepsis and septic shock to decrease the duration of shock and to decrease mortality.

A significant reduction in 28-day all–cause mortality and hospital mortality was reported in patients unresponsive to vasopressor therapy and receiving prolonged courses (>5 days) of low-dose corticosteroid therapy (<300 mg hydrocorortisone or equivalent/day) compared to placebo (38% vs 44%; relative risk 0.84).[94] There was no benefit for those patients without adrenal insufficiency. However, the large multicenter trial, the Corticosteroid Therapy of Septic Shock (CORTICUS) found no survival benefit among patients who received prolonged courses of hydrocortisone, but reported a trend in shock reversal for patients who received hydrocortisone.[95] The use of adrenocorticotropic hormone (ACTH) stimulation test to identify those patients who have a relative adrenal insufficiency did not predict the faster resolution of shock. The differences between the studies appear to arise

from the study design of considering the response of septic shock patients to fluid and vasopressor therapy prior to hydrocortisone therapy. The CORTICUS study included patients with septic shock regardless of their responsiveness to vasopressor therapy. The guidelines recommend using IV hydrocortisone only if hemodynamic stability is not achieved after adequate fluid resuscitation and vasopressor therapy, regardless of the state of adrenal insufficiency, negating the ACTH stimulation test.[3] The guidelines also suggest using continuous infusion of hydrocortisone rather than repetitive bolus injections to avoid increased hyperglycemia and hypernatremia. Data on optimal duration of hydrocortisone therapy and the comparative clinical trials comparing whether steroid should be abruptly discontinued or tapered are sparse. Patients should be tapered from steroid therapy when vasopressors are no longer required.[3]

Deep vein thrombosis prophylaxis with daily subcutaneous low-molecular weight heparin should be initiated in all patients admitted to the ICU with severe sepsis and septic shock.[3] There was no significant difference in asymptomatic venous thromboembolism (VTE) between the low-molecular heparin group versus unfractionated heparin twice daily group but the proportion of patients with pulmonary embolism on CT scan was much lower in the low-molecular weight heparin group.[3] In patients with creatinine clearance of less than 30 mL/min (0.5 mL/s), dalteparin did not accumulate while data on the low-molecular weight heparin products is lacking. Dalteparin or unfranctionated heparin is recommended for critically ill patients with acute renal injury.[3]

The systemic inflammatory events of sepsis may further predispose septic patients to VTE. A combination of pharmacologic therapy and intermittent pneumatic compression devices is recommended whenever possible. If heparin use is contraindicated, mechanical prophylactic treatment should be considered.[3] The incidence of venous thromboembolism (VTE) was 37.2% in patients admitted to the ICU with severe sepsis and septic shock despite thromboprophylaxis and resulted in increased ICU length of stay (18.2 vs 13.4 days).[96]

Stress ulcer prophylaxis should be initiated in all patients with severe sepsis and septic shock.[3] Proton pump inhibitors and H_2 receptor antagonists are equivalent in their ability to increase gastric pH. However, proton pump inhibitors may be more effective in GI bleeding protection over H_2 receptor antagonists.

PERSONALIZED PHARMACOTHERAPY

Patients presenting with severe sepsis and septic shock are critically ill and their management in an intensive care setting can be overwhelming. While it is critical to manage the complications involving multiple organ systems to ultimately sustain life during the initial hours, initial resuscitation of sepsis-induced tissue hypoperfusion and infection source identification are imperative as severe sepsis and subsequent multiorgan dysfunction arise from an uncontrolled infection and septic shock. Clinical presentation of each patient should be considered carefully and should prompt further evaluation of any underlying conditions, recent travel, injury, animal exposure, infection or use of antibiotics along with a complete physical examination to determine the possible source of infection. Based on the individual patients' findings and the most likely source of infection, the empiric regimen may be

completely different from one patient to another. A patient presenting with sepsis secondary to a community-acquired pneumonia may receive ceftriaxone and azithromycin where another patient presenting with secondary peritonitis as a consequence of perforation of the GI tract may require a broad-spectrum regimen such as ertapenem or piperacillin/tazobactam.[44,45,50] Catheter-related sepsis may require a removal of the line as well as initiating vancomycin. There is abundant evidence in the literature demonstrating a correlation between the prompt and appropriate antibiotics and the overall survival rate.[36,37] Severe sepsis and complications such as shock, ARDS, and DIC result from an acute infection. As such, prompt identification of the source of infection in an individual patient and customizing the empiric antibiotic regimen while maintain hemodynamic stability may be the key to controlling the multiorgan dysfunctions and overall mortality rate.

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

ACTH	adrenocorticotropic hormone
ARDS	acute respiratory distress syndrome
CI	cardiac index
CORTICUS	Corticosteroid Therapy of Septic Shock (trial)
CT	computed tomography
CVP	central venous pressure
DIC	disseminated intravascular coagulation
DO_2	oxygen delivery to tissues
EGDT	Early goal-directed therapy
GI	gastrointestinal
HIV	human immunodeficiency virus
ICU	intensive care unit
IL	interleukin
IL-1RA	interleukin-1 receptor antagonist
LV	left ventricular
MAP	mean arterial pressure
MODS	multiple-organ dysfunction syndrome
MRSA	methicillin-resistant *Staphylococcus aureus*
PAF	platelet activating factor
PCT	procalcitonin
$Scvo_2$	central venous oxygen saturation
SIRS	systemic inflammatory response syndrome
SSTIs	skin and soft tissue infections
SVR	systemic vascular resistance

TNF	tumor necrosis factor
VO_2	oxygen consumption
VRE	vancomycin-resistant enterococci
VTE	venous thromboembolism
WBC	white blood cell

Chapter 120: Superficial Fungal Infections

Thomas E. R. Brown; Linda D. Dresser

INTRODUCTION

KEY CONCEPTS

- 1 Vulvovaginal candidiasis (VVC) is a fungal infection of the vagina that can be classified as uncomplicated or complicated. This classification is useful in determining appropriate pharmacotherapy.
- 2 *Candida albicans* is the major pathogen responsible for VVC. The number of cases of non-*C. albicans* species appears to be increasing.
- 3 Signs and symptoms of VVC are not pathognomonic, and reliable diagnosis must be made with laboratory tests including vaginal pH, saline microscopy, and 10% potassium hydroxide (KOH) microscopy.
- 4 *C. albicans* is the predominant species causing all forms of mucosal candidiasis. Important host and exogenous risk factors have been identified that predispose an individual to the development of mucosal candidiasis. In oropharyngeal and esophageal candidiasis, the key risk factor is impaired host immune system.
- 5 Topical antimycotic agents such as nystatin or clotrimazole are the first choice for treating oropharyngeal candidiasis (OPC). Systemic therapy can be used in patients who are not responding to an adequate trial of topical treatment or are unable to tolerate topical agents and in those at high risk for systemic candidiasis. Fluconazole and itraconazole remain first line antimycotic agents.
- 6 For esophageal candidiasis, topical agents are not of proven benefit; fluconazole or itraconazole solution is the first choice.
- 7 Optimal antiretroviral therapy is important for the prevention of recurrent and refractory candidiasis in patients with human immunodeficiency virus (HIV) infection.

- 8 Primary or secondary prophylaxis of fungal infection is not recommended routinely for HIV-infected patients; use of secondary prophylaxis should be individualized for each patient.
- 9 Topical antimycotic agents are first-line treatment for fungal skin infections. Oral therapy is preferred for the treatment of extensive or severe infection and those with tinea capitis or onychomycosis.
- 10 New topical antifungal agents efinaconazole and tavaborole are recommended for mild-moderate toenail fungal infections.

Superficial mycoses are among the most common infections in the world and the second most common vaginal infections in North America. Mucocutaneous candidiasis can occur in three forms—oropharyngeal, esophageal, and vulvovaginal disease—with oropharyngeal and vulvovaginal disease being the most common. Over the past 15 to 20 years, the occurrence rates of some fungal infections have increased dramatically. The prevalence of fungal skin infections varies throughout different parts of the world, from the most common causes of skin infections in the tropics to relatively rare disorders in the United States. This chapter reviews the pharmacotherapy of vulvovaginal candidiasis (VVC), oropharyngeal and esophageal candidiasis, and common dermatophyte infections.

VULVOVAGINAL CANDIDIASIS

1 Vulvovaginal candidiasis refers to infections in individuals with or without symptoms who have positive vaginal cultures for *Candida* species. Depending on episodic frequency, VVC can be classified as either sporadic or recurrent.[1] This classification is essential to understand the pathophysiology, as well as the pharmacotherapy, of VVC. Furthermore, VVC may be defined as uncomplicated, which refers to sporadic infections that are susceptible to all forms of antifungal therapy regardless of the duration of treatment, or complicated, in which consideration of factors affecting the host, microorganism, and pharmacotherapy all have an essential role in successful treatment.[1] Complicated VVC includes recurrent VVC, severe disease, non-*Candida albicans* candidiasis, and host factors, including diabetes mellitus, immunosuppression, and pregnancy.[1]

Epidemiology

There is minimal information on the incidence and prevalence of VVC. Healthcare workers are not required to report cases of VVC; therefore, estimates are derived from self-reported histories. Epidemiologic data are limited because VVC usually is diagnosed without microscopy and/or cultures, and antifungal nonprescription preparations are available for self-treatment.[1] By 25 years of age, approximately 50% of college women will have had at least one episode of VVC.[1] It is rare before menarche and increases dramatically at about 20 years of age, with the peak incidence between age 30 and 40 years. It is associated with the initial act of sexual intercourse. As many as 75% of women experience one bout of symptomatic VVC in their lifetime. Between 40% and 50% of women who experience one episode of VVC experience a second episode, and 5% experience recurrent VVC.[2,3] Black women appear to be at higher risk than white women of developing VVC (62.8% vs 55%,

respectively).[4] The incidence after menopause remains unknown. However, one study of 149 healthy postmenopausal women with vulvar conditions reported significantly more women taking hormone replacement therapy (HRT) were prone to developing VVC than those who were not taking HRT (culture-positive, clinical VVC in 49% on HRT versus 1% on those not on HRT).[5]

Costs from VVC can be direct (medical visits and self-treatment) and indirect (nonmedical expenses, eg, time losses from work, costs of travel, and time required in obtaining treatment). There are an estimated 6 million visits to healthcare providers each year, resulting in more than $1 billion spent annually on these medical visits and self-treatment.[6] These costs could reach $3.1 billion by 2014.[7]

Pathophysiology

2 *C. albicans* is the major pathogen responsible for VVC, accounting for 80% to 92% of symptomatic episodes. The remainder are caused by non-*C. albicans* species, with *Candida glabrata* dominating.[8] The number of cases of non-*C. albicans* candidiasis appears to be increasing, possibly related to the use of nonprescription vaginal antifungal preparations and short-course therapy and/or the increased use of long-term maintenance therapy in preventing recurrent infections.[1]

Candida species can act as commensal members of the vaginal flora. Asymptomatic colonization with *Candida* species has been found in 10% to 20% of women of reproductive age.[8,9] *Candida* organisms are dimorphic; blastospores are responsible for colonization (transmission and spread), whereas germinated *Candida* forms are associated with tissue invasion and symptomatic infections.[10] To colonize the vagina, *Candida* species must be able to attach to the mucosa. The attachment process is complex. Not only are candidal surface structures important for attachment, but appropriate receptors for attachment must be present in the epithelial tissue. Not all women have the same range of receptors, which may explain variation in colonization.[9] Changes in the host's vaginal environment or response are necessary to induce a symptomatic infection. Unfortunately, in most cases of symptomatic VVC, no precipitating factor can be identified.[10]

Risk Factors

Several factors predispose a woman to VVC. VVC is not considered to be a sexually transmitted disease, although sexual factors can be important. There is a dramatic increase in the frequency of VVC when women become sexually active. In addition, oral-genital contact can increase the risk.[1] However, current guidelines do not recommend the treatment of asymptomatic partners.[8] Contraceptive agents, including the diaphragm with spermicide, the contraceptive sponge, and the intrauterine device, increase the risk of VVC. An in vitro study demonstrated that four different isolates of *Candida* species were capable of adhering to the contraceptive vaginal ring.[11] Oral contraceptive users demonstrated increased risk of candidiasis; however, these reports were with the higher-dose oral contraceptive pills, and the risk may not be as great with the lower-estrogen-dose oral contraceptives.[12]

Antibiotic use can increase the risk of VVC, but it is significant in only a small number of women. The

mechanism by which antibiotics can increase the risk of VVC is unknown; colonization, however, is a prerequisite.[1] A small pilot study showed that 3 days of antibiotics increased the prevalence of asymptomatic vaginal colonization of *Candida* and the incidence of symptomatic VVC.[13] Diet (excess refined carbohydrates), douching, and tight-fitting clothing often are listed as important risk factors; however, no association has been established between these factors and increased risk of VVC.[1]

Clinical Presentation

3 These signs and symptoms of VVC (**Table 120-1**) are not pathognomonic, and a reliable diagnosis cannot be made without laboratory tests.[1,8] Self-diagnosis has a sensitivity of 35%, a specificity of 89%, and a positive predictive value of 62%.[4] More than 50% of women who had self-diagnosed VVC did not have yeast as the causative agent.[14] This limits the value of self-diagnosis and the success of self-treatment. The American College of Obstetricians and Gynecologists (ACOG) recommends that whenever possible women requesting treatment for VVC should be examined and evaluated. They only recommend self-diagnosis in compliant women with multiple confirmed prior cases of VVC who report the same symptoms. They further recommend that if these individuals fail to improve on a short course of therapy, they be evaluated for a further diagnosis.[15] Therefore, in most instances the diagnosis should be based on both clinical presentation and investigations, including vaginal pH, saline microscopy, and 10% potassium hydroxide (KOH) microscopy. The vaginal pH remains normal in VVC, and microscopic investigations should detect blastospores or pseudohyphae. *Candida* cultures usually are not required in the diagnosis of uncomplicated VVC; however, they are recommended when an individual presents with classic signs and symptoms of VVC, has a normal vaginal pH, but microscopy is inconclusive or recurrence is suspected.[8]

TABLE 120-1 Clinical Presentation of Vulvovaginal Candidiasis

General	Often involves both the vulva and the vagina
Symptoms	Intense vulvar itching, soreness, irritation, burning on urination, and dyspareunia
Signs	Erythema, fissuring, curdy "cheese"-like discharge, satellite lesions, edema
Laboratory tests	Vaginal pH—normal, saline and 10% KOH microscopy—blastospores or pseudohyphae
Other diagnostic tests	*Candida* cultures not recommended unless classic signs and symptoms with normal vaginal pH and microscopy are inconclusive or recurrence is suspected

KOH, potassium hydroxide.

TREATMENT

Goals of Therapy

The goal of therapy is complete resolution of symptoms in patients who have symptomatic VVC. A test of the cure is not necessary if symptoms resolve.[8] Antimycotic agents used in the treatment of VVC do not meet the definition of being fungicidal agents because of their slower killing rate. At the end of therapy, the number of viable organisms drops below the detectable range. However, by 6

weeks after a course of therapy, 25% to 40% of women will have positive yeast cultures and remain asymptomatic.[1] Asymptomatic colonization with *Candida* species does not require therapy.

General Approaches to Treatment

The approach to therapy is to remove or improve any predisposing factors if they can be identified. A pharmacologic antimycotic agent should have limited local and systemic side effects, a high cure rate, and easy administration. Additionally, it would be advantageous to use a therapy that is able to resolve symptoms within 24 hours, that has broad antimycotic activity (to cover increasing rates on non-*C. albicans* species), that prevents recurrence, and that can be used over a shortened period of time, such as 1 to 3 days. Many topical azoles medications (such clotrimazole, miconazole, etc.) are available without a prescription, and although this may increase public access to these medications, there is concern that having them available without a prescription may lead to inappropriate use. Patient actors who visited 60 pharmacies found that vaginal antimycotics were more likely to be supplied to appropriate individuals as more information was exchanged, if interactions involved a pharmacist, and if questions regarding specific symptoms were used.[16]

Patients should be advised to avoid harsh soaps and perfumes that can cause or worsen vulvar irritation. The genital area must be kept clean and dry by avoiding constrictive clothing and frequent or prolonged exposure to hot tub use.[3] Douching is not recommended for either prevention or treatment.[14] Cool baths can soothe the skin.[3] The oral use of lactobacillus remains unclear. The addition of oral lactobacillus to single dose oral fluconazole VVC treatment augmented the cure rate compared to the use of fluconazole alone.[17] A mixture of oral consumption of bee-honey and yogurt showed some efficacy with mycotic cure rates of 76.9% compared to cure rates with antifungal agents of 91.5%.[18] Daily ingestion of 240 mL yogurt containing *Lactobacillus acidophilus* decreased colonization and symptomatic infections of VVC in women with recurrent infections.[19] However, a subsequent study showed that the addition of oral lactobacillus to itraconazole therapy in the treatment of recurrent VVC did not confer any additional benefit. Treatment using classic homeopathy was less effective than the use of itraconazole in recurrent VVC.[20] The use of probiotic remains controversial. A Cochrane Collaborative protocol has been developed to determine the role of probiotics in the treatment of VVC in nonpregnant women.[21]

Treatment of VVC will be considered to have positive outcomes if the symptoms of VVC are resolved within 24 to 48 hours and no adverse medication events are experienced. Self-assessment of symptom relief is appropriate for most cases of VVC. If symptoms remain unresolved or recur, then further testing and treatment can be required.

Pharmacologic Treatments

Uncomplicated Vulvovaginal Candidiasis

Cure rates for uncomplicated VVC are between 80% and 95% with topical or oral azoles and between 70% and 90% with nystatin preparations. **Table 120-2** lists available topical and oral preparations for

the treatment of uncomplicated VVC. There are many topical nonprescription preparations for the treatment of VVC. No significant differences in in vitro activity or clinical efficacy exist between the topical azole agents.[1,3,8,15] The selection of a topical azole antimycotic agent should be based primarily on an individual patient's preference as to product formulation. Some topical products can cause vaginal burning, stinging, or irritation; conversely, the vehicle used in topical creams or gels can provide initial symptomatic relief.[1] Of note, most topical preparations can decrease the efficacy of latex condoms and diaphragms.

TABLE 120-2 Treatment for Uncomplicated Vulvovaginal Candidiasis

Active Ingredient	Preparation	Regimen
Nonprescription/Topical Vaginal Products		
Butoconazole	2% cream	One applicator × 3 days
	1% cream	One applicator × 7-14 days
Clotrimazole	100 mg tablet	One 100 mg tablet × 7 days
	2% cream	One applicator × 3 day
	100 mg suppository	One 100 mg suppository × 7 days
Miconazole[a]	200 mg suppository	One 200 mg suppository × 3 days
	1,200 mg ovule	One ovule × 1 day
Ticonazole	6.5% cream	One applicator × 1 day
Prescription/Topical		
Nystatin	100,000 unit tablet	One tablet × 14 days
Butoconazole	2% cream	One applicator x 1 day
Terconazole	0.4% cream	One applicator × 7 days
	0.8% cream	One applicator × 3 days
	80 mg suppository	One suppository × 3 days
Oral Products		
Fluconazole	150 mg	One tablet × 1 day

[a]The FDA warns of the possible increase in the anticoagulant effects of warfarin with concomitant use.

Oral azoles (such as fluconazole or itraconazole) have been used in the treatment of VVC. Patients may prefer oral therapy because of its convenience.[22] A Cochrane review of 19 trials analyzing 22 oral versus topical antifungal comparisons concluded that there were no differences between the routes of administration in short-term mycologic cure rates. There was a significant difference between long-term cure rates in favor of long-term follow up; however, the authors stated that the clinical significance of this finding is uncertain.[1,23]

In the treatment of uncomplicated VVC, the duration of therapy is not critical. Cure rates with different lengths of treatment have not demonstrated that one duration of therapy is significantly better.[2223,24] Shorter-duration therapies (eg, clotrimazole 1-day therapy) consist of higher concentrations of azoles that maintain the local therapeutic effect for up to 72 hours and allow for resolution of signs and symptoms.[25] A review of 14 trials that examined 1-day treatments showed less than 7% difference in short-term cure rates or improvement between any two treatments in any two studies and no significant differences in short- or long-term clinical cure rates among 1-day regimens.[24] Table 120-2 lists the therapeutic options recommended by the Centers for Disease Control and Prevention for the treatment of uncomplicated VVC.[26]

Clinical Controversy...

Although there are a few clinical trials evaluating the use of lactobacillus formulations. The use of probiotics alone or in combination with an anti-mycotic agent remains unclear.

Complicated Vulvovaginal Candidiasis

Complicated VVC occurs in patients who are immunocompromised or have uncontrolled diabetes mellitus.[1] These individuals need a more aggressive treatment plan.[15] Current recommendations are to lengthen therapy to 10 to 14 days regardless of the route of administration.[15] Therapeutic options include those listed in Table 120-2; however, regimens should be continued for 10 to 14 days. A study of oral fluconazole therapy in women with complicated VVC demonstrated that cure rates increased from 67% with single-dose therapy to 80% when the 150 mg dose of fluconazole was repeated 72 hours after the initial dose.[27]

VVC during pregnancy can be considered complicated because consideration of host factors such as hormonal changes that can affect normal flora are essential in selecting therapeutic regimens. Topical agents are considered to be safe throughout pregnancy. A systematic review of 10 trials demonstrated that imidazole topical agents (such as fluconazole) were more effective than nystatin. Two of the trials showed that treatment for 7 days was more effective than treatments of 4 days or less.[28] Oral agents are contraindicated in pregnancy because of the concern for fetal complications. A prospective assessment of pregnancy outcomes in 226 women exposed to fluconazole in the first trimester did not indicate increased risk of congenital abnormalities or other adverse outcomes.[29] A Danish registry based cohort found that oral fluconazole may increase the risk of tetratology of Fallot.[30] The ACOG recommends avoiding oral therapy, and recommends a topical imidazole therapy for 7 days.[14]

Recurrent Vulvovaginal Candidiasis

Recurrent vulvovaginal candidiasis (RVVC) is defined as having more than four episodes of VVC within a 12-month period.[1,7] The prevalence of RVVC is higher than once thought, as high as 7% to 8%.[31] A proper diagnosis should be obtained to rule out other infections or nonmycotic contact dermatitis. RVVC is best treated in two stages: an initial intensive stage followed by prolonged antifungal

therapy to achieve mycologic remission. Ninety percent of women randomly receiving 150 mg fluconazole daily for 10 days followed by 6 months of either fluconazole 150 mg weekly or placebo were symptom free for the 6 months following initial treatment (during the weekly fluconazole therapy), and there were 50% fewer symptomatic episodes in the 6 months following weekly suppressive therapy.[32] The Infectious Diseases Society of America recommends 10 to 14 days of induction therapy with a topical or oral azole, followed by 150 mg of fluconazole once weekly for 6 months for recurring *Candida* VVC.[33] Future directions in pharmacotherapy include the development of anti-Candida vaccines. Clinical investigations have begun to determine the effectiveness of these vaccines in preventing RVVC.[34]

ANTIFUNGAL-RESISTANT VULVOVAGINAL CANDIDIASIS

Resistance to azole antimycotics should be considered in individuals who have persistently positive yeast cultures and fail to respond to therapy despite adherence to prescribed regimens.[1] These infections can be treated with boric acid or 5-flucytosine.[35,36] Boric acid is administered as a 600 mg intravaginal capsule daily for 14 days of induction therapy, followed by a maintenance regimen of one capsule intravaginally twice weekly. Boric acid should not be administered orally, as it is toxic. 5-Flucytosine cream is administered vaginally, 1,000 mg inserted nightly for 7 days. The prevalence of *C. glabrata* with VVC is higher in those with diabetes, 68% had isolates for *C. glabrata* compared with 28.8% for *C. albicans*. Those with *C. glabrata* had significantly higher mycological cure rates with 600 mg of boric acid suppositories for 14 days compared with a single dose of fluconazole 150 mg.[37]

OROPHARYNGEAL AND ESOPHAGEAL CANDIDIASIS

Oropharyngeal candidiasis (OPC), or *thrush*, is a common and localized infection of the oral mucosa caused by the yeast *Candida*. *C. albicans*, a common oral commensal organism, is the most frequent infecting species. OPC is also referred to as *candidiasis* (or the more correct but less commonly used term *candidosis*). The infection may extend into the esophagus, causing esophageal candidiasis.

Epidemiology and Etiology

Candida is a commensal fungus found in the oral cavity in up to 65% of healthy individuals with higher prevalence in healthy children and young adults.[38,39] *Candida* carriage increases under immunocompromised conditions and also among hospitalized patients.[39] Even in the era of highly active antiretroviral therapy (HAART) up to 80% of human immunodeficiency virus (HIV)-infected persons may demonstrate oral yeast colonization.[40] The organism is capable of transition to a pathogen causing symptomatic mucosal infections in association with predisposing host factors.[39] *C. albicans* is the predominant colonizing *Candida* species (70%-80%), but any of the non-*C. albicans* species such as *C. glabrata* and *C. tropicalis* which may account for 5% to 8%, respectively, can be colonizers.[40] Colonization rates are influenced by the severity and nature of the underlying medical illness and the duration of hospitalization, as well as age (highest in infants younger than 18 months of age and in adults older than 60 years of age). A variety of host and exogenous factors (**Table**

120-3) can lead to the transformation of asymptomatic colonization to symptomatic disease, such as oropharyngeal and esophageal candidiasis. *C. albicans* is the most common species causing all forms of mucosal candidiasis in humans. Less frequently, non-*C. albicans* species can be pathogenic and cause disease. These include *C. glabrata*, *Candida tropicalis*, *Candida krusei*, and *Candida parapsilosis*.[41,42] *Candida krusei*, although relatively uncommon, generally is recovered from mucosal surfaces of neutropenic patients with hematologic malignancies.[42] Another species, *Candida dubliniensis*, has been identified in both HIV-infected and noninfected patients, and may cause ~15% of infections previously ascribed to *C. albicans*.[42] In patients with cancer, non-*C. albicans* species account for almost half of all *Candida* infections.

TABLE 120-3 Risk Factors for the Development of Oropharyngeal and/or Esophageal Candidiasis

Local Factors	Potential Mechanisms
Use of steroids and antibiotics	Suppression of cellular immunity and inhibition of phagocytosis by steroids, including chronic use of inhaled and topical steroids Alteration of endogenous oral flora by broad-spectrum antibiotics, especially when used with steroids, creates a milieu for proliferation of *Candida* species because of reduced environmental and nutritional competition
Dentures	Enhanced adherence of *Candida* species to the acrylic material of dentures, reduced saliva flow under surfaces of denture fittings, improperly fitted dentures, and poor oral hygiene provide a milieu conducive to the survival of microorganisms
Xerostomia caused by drugs (eg, tricyclic antidepressants and phenothiazine), chemotherapy, radiotherapy to the head/neck, and various diseases (eg, Sjögren's syndrome, HIV, and cancer of the head/neck), as well as bone marrow transplant recipients	Reduced dilutional and cleansing effect caused by low secretion rate and low pH in saliva: Saliva and mucosa secretions have defense factors, such as lactoferrin, sialoperoxidase, isozyme, histidine-rich polypeptide, secretory IgA antibodies, specific anti-*Candida* antibodies that help prevent adhesion and overgrowth of *Candida* species
Smoking	
Disruption of oral mucosa caused by chemotherapy and radiotherapy, ulcers, endotracheal intubation trauma, and burns	Oral mucositis induced by radiation and breaks in the physical barrier of the oral epithelium, which is protective against invasion by microorganisms; altered rate of mucosa regeneration by cancer chemotherapy, which increases vulnerability to infection
Systemic Factors	**Potential Mechanisms**
Drugs (eg, cytotoxic agents, corticosteroids, and immunosuppressants after organ	Reduced immunity because of drug-induced neutropenia or cell-mediated immunity; potent

Local Factors	Potential Mechanisms
transplant), omeprazole, and environmental chemicals (eg, benzene and pesticides)	inhibition of gastric acid by PPIs can facilitate the growth of *Candida* species; PPIs also can inhibit the cytotoxic effect of lymphocytes and reduce salivary secretion
Neonates or the elderly	Immature immune system of neonates who usually acquire infection during birth to a mother with vaginal candidiasis or from exposure to infected bottle nipples or to skin of adult caregiver Elderly—unclear if this is the direct effect of age per se or contribution from dentures or underlying comorbidity
HIV infection/AIDS	Depletion of CD4 T lymphocytes especially below 200-300 cells/mm^3 (0.2×10^9-0.3×10^9/L); anti-*Candida* protective mechanism of T lymphocytes at a mucosal level is unclear but can be caused by altered cytokines, especially interferon-γ, that inhibit transformation of *Candida* blastoconidia to the more invasive hyphal phase
Diabetes	Higher than normal numbers of *C. albicans* cultured from saliva of diabetic patients; can be related to the elevated glucose levels and reduced chemotactic factor in saliva, altered neutrophil function, and reduced saliva volume and flow
Malignancies (eg, leukemia and head/neck cancer)	Use of intensive radiotherapy and chemotherapy can disrupt oral mucosa and cause xerostomia; prolonged use of broad-spectrum antibiotics in neutropenic patients can alter the normal oral flora; because of the prolonged neutropenia, the principal immune defect, seen especially in leukemic patients, the initial oropharyngeal candidiasis can become systemic or invasive
Nutritional deficiencies (eg, iron, folate, and vitamins B1, B2, B6, B12, and C)	Can be related to dietary restriction or GI absorption problems; deficiencies can serve to enhance the pathogenic potential of the *Candida* inhabitants, alter host defense mechanisms, or change epithelial barrier integrity

AIDS, acquired immunodeficiency syndrome; GI, gastrointestinal; HIV, human immunodeficiency virus; IgA, immunoglobulin A; PPI, proton pump inhibitor.

OPC is the most common opportunistic infection in patients with HIV disease, and it may be the first clinical manifestation of the HIV infection in the majority of untreated patients. OPC occurs in 50% to

90% of HIV-infected patients at some point during the progressive course of the disease to acquired immunodeficiency syndrome (AIDS),[38,41,42] although significant reductions in the incidence have been observed after the introduction of HAART. The absolute CD4 T-cell count is the primary risk factor for development of OPC with the greatest risk at CD4 T-cell levels less than 200 cells/mm^3 (less than 0.2 × 10^9/L). Also, the HIV viral load is a predictor of OPC development; OPC is thought to increase with HIV viral loads greater than 10,000 copies/mL (greater than 10 × 10^6/L). This finding correlates with the observation that initiation of antiretroviral therapy and subsequent increase in CD4 T-cell counts does not fully account for the decrease in OPC incidence.[41] Regardless of the CD4 T-cell count, or HIV viral load OPC is predictive for the development of AIDS-related illnesses if left untreated.[38,42]

In non-HIV diseases, such as cancer, the incidence of OPC varies depending on the type of malignant neoplastic disease, level of immune suppression, and type and duration of treatment, but it is less common than in HIV-infected patients. OPC was initially reported in ~25% of patients with solid tumors and up to 60% in those with hematologic malignancies or bone marrow transplant recipients.[43] Rates of OPC have decreased significantly in these patients because of widespread use of antifungal prophylaxis. Incidence in other patient populations predisposed to OPC such as the hospitalized patient administered broad-spectrum antibiotics or denture and other oral appliance users is not well quantified, however, do represent at-risk individuals where the clinical pharmacist has an important patient-care role.[39,43]

OPC can predispose patients to develop more invasive disease, including esophageal candidiasis.[43] The esophagus is the second most common site of GI candidiasis. The prevalence of esophageal candidiasis has increased mainly because of the number of individuals with AIDS, as well as the increased numbers of other severely immunocompromised patients, especially those with hematologic malignancies.[42] Esophageal candidiasis is the first opportunistic infection in 3% to 10% of HIV-infected patients and is the second most common AIDS-defining disease after *Pneumocystis jiroveci* pneumonia.[42] The mean incidence of esophageal candidiasis among HIV-infected patients is less than OPC and ranges from 15% to 20%.[42] The risk of esophageal candidiasis is increased in HIV-infected patients when the CD4 T-cell count has dropped below 100 to 200 cells/mm^3 (0.1 × 10^9 to 0.2 × 10^9/L), as well as in those with OPC.[43,44] However, the absence of OPC does not necessarily exclude the possibility of esophageal disease. Like OPC, the presence of esophageal candidiasis can help predict HIV disease progression and prognosis.[43] The incidence of esophageal candidiasis in non-HIV-infected immunocompromised patients is not well established. *C. albicans* is the most common cause of esophageal candidiasis, accounting for ~80% of cases, with the rest being caused by non-*C. albicans* species.[41]

The introduction of HAART appears to have resulted in a significant decline in the incidence of OPC and esophageal candidiasis.[41,42,45] In addition, the widespread use of the azole agents for treatment and prophylaxis has led to a decline in the prevalence of mucosal candidiasis while leading to the emergence of refractory infections that are more challenging to treat.

Pathophysiology

The pathogenesis of OPC is most clearly elucidated in the setting of HIV infection. There appear to be several levels of immune defense against the development of OPC in HIV-infected persons, and they involve both systemic and local immunity. The primary line of host defense against *C. albicans* is cell-mediated immunity (CMI) at the mucosal surfaces, which is mediated by CD4 T cells.[38] The efficacy of the CD4 T cells is reduced when the number of cells drops below a protective threshold, and protection against infection becomes dependent on secondary or local immune mechanisms.[38,41] When the number of CD4 T cells drops too low, recruitment of these cells to the oral cavity is impaired. The CD4 T-cell count is the hallmark predictor for development of OPC. However, HIV viral load may have a stronger association with OPC than CD4 cell number.[41,46] The possibility that HIV plays a strong role in susceptibility to infection is supported clinically by the observation that OPC is more common in HIV-infected persons than in those with similar immunosuppression, such as lymphoma and bone marrow transplant. When the primary line of defense fails, the secondary host defenses become crucial. These include the CD8 T cells, salivary cytokines, and other innate immune cells, such as the neutrophils, macrophages, and epithelial cells (with anti-*Candida* activity). Deficiencies or dysfunction in any of these can result in increased susceptibility to OPC. The problem with the CD8 T cells is caused more by a dysfunction of the microenvironment, specifically, reduction in the E-cadherin adhesion molecule that promotes migration of the cells through mucosal tissues.[42] The role of humoral immunity by antibodies as a protective mechanism is unclear and controversial. The changeover of the role of *Candida* species from commensal to pathogenic in the human host usually occurs when breakdown in these host defenses occurs. The pathogenesis of OPC is still not completely understood. It is important to develop a better understanding of the pathogenesis and role of host defenses, including the mechanism of CD8 T-cell activity, reduced adhesion molecules, and whether other cofactors, such as HIV viral load, HAART, and injection drug use, play a role. Immunotherapeutic modalities can then be developed to eliminate the susceptibility factors and significantly reduce OPC in the at-risk populations.

Significant differences exist in the virulence among *Candida* species in mucosal candidiasis. One virulence factor is the ability of the organism to adapt and survive in response to changes in the host environment.[41] The genes required for virulence are regulated in response to the environmental signals indigenous to the host environment (eg, temperature, pH, osmotic pressure, iron and calcium ion concentrations, oxygenation, and carbon and nitrogen availability). The ability of *C. albicans* to undergo reversible morphologic transition between the budding pseudohyphal and the more invasive hyphal growth forms is also a determinant of virulence, and genes are recognized to play a role.[38] Other virulence factors are the adhesive ability of *C. albicans* to epithelial cells and proteins and its ability to invade host cells by means of phospholipase and proteinase enzymes. This may be one of the factors leading to OPC in non-HIV-infected individuals. Other components of the pathogenesis in the absence of HIV that have been postulated are the ability of the *Candida* species to adhere to buccal epithelial cells. A close correlation between adhesion of *Candida* species and their ability to cause infection has been demonstrated in animal model studies.[47] This is hypothesized to be a key element in the development of OPC in patients with altered microflora, including those receiving broad-spectrum antimicrobial therapy.

Risk Factors

4 Several host and exogenous factors contribute to the ability of *Candida* species to cause infection (see Table 120-3). Local and systemic factors, as well as characteristics of the organism itself, can increase the susceptibility of an individual to *Candida* infections.[38] Endocrine disorders besides diabetes mellitus, such as hypothyroidism, hypoparathyroidism, and hypoadrenalism, also can predispose patients to *Candida* species overgrowth. Patients with primary immune deficiencies such as lymphocytic abnormalities, phagocytic dysfunction, immunoglobulin A (IgA) deficiency, viral-induced immune paralysis, and severe congenital immunodeficiencies are also at risk for OPC as well as disseminated candidiasis. Oral mucosal disease, such as lichen planus, can be preexistent causes of candidiasis. Smoking may be a predisposing risk factor. In many cases, multiple concurrent predisposing factors to candidiasis can exist, for example, xerostomia with mucositis and a break in the epithelial surface or immunosuppression, such as might occur in a leukemic patient receiving radiation and chemotherapy. The severity and extent of *Candida* infections increase with the number and severity of predisposing risk factors.[39]

Clinical Presentation and Diagnosis

OPC can manifest in several major forms (**Table 120-4**).[38,39] The clinical signs and symptoms of OPC and the locations of the lesions can be quite diverse (**Table 120-5**). A presumptive diagnosis of OPC usually is made by the characteristic appearance on the oral mucosa, with resolution of signs and symptoms after antifungal therapy. Pseudomembranous candidiasis, commonly known as *oral thrush*, is the classic and most common form seen in immunosuppressed and immunocompetent hosts. Erythematous and hyperplastic candidiasis and angular cheilitis occur less commonly in the HIV-infected population. Dysphagia, odynophagia, and retrosternal chest pain are common complaints of esophageal candidiasis, which is usually, but not always, accompanied by the presence of OPC. Clinical symptomatology, along with a therapeutic trial of antifungal, can provide a reliable presumptive diagnosis of esophageal candidiasis. If antifungal therapy does not lead to resolution, more invasive tests such as upper GI endoscopy can be undertaken.

TABLE 120-4 Clinical Classification of Oropharyngeal Candidiasis

Types	Population at Risk	Clinical Signs and Appearance
Pseudomembranous (thrush)	Neonates, patients with HIV or cancer, the debilitated elderly, patients on broad-spectrum antibiotics or steroid inhalers, patients with dry mouth from various causes, and smokers	Classic "cottage cheese" appearance, yellowish white, soft plaques (or milk curds) overlying areas of erythema on the buccal mucosa, tongue, gums, and throat; plaques are easily removed by vigorous rubbing but can leave red or bleeding sites when removed; lesions on the tongue dorsum give it a bald, depapillated appearance
Erythematous (atrophic)	Patients with HIV, patients on broad-spectrum antibiotics or steroid	Sensitive and painful erythematous mucosa with few, if any, white plaques; lesions are generally on the dorsal surface of the tongue

Types	Population at Risk	Clinical Signs and Appearance
	inhalers	or the hard palate, occasionally on the soft palate, but any part of the mucosa can be involved; appear as flat red patches on the palate or atrophic patches on the tongue dorsum with loss of papillae. Can be acute or chronic
Hyperplastic (candidal leukoplakia)	Smokers; uncommon in patients with HIV	Thick white and adherent keratotic plaques commonly seen on the buccal mucosa and lateral border of the tongue; can also be seen on the lips and the bottom of the mouth; plaques cannot be easily scraped off or only partially removed; this condition is distinct from oral hairy leukoplakia, and it can progress to severe dysplasia or malignancy
Angular cheilitis	Patients with HIV, denture wearers	Painful red, ulcerative, cracking, or fissuring lesion at one or both comers of the mouth because of an inflammatory reaction; usually lesions are small and rather punctate, but occasionally they can extend in a linear fashion from the angles onto the facial skin
Denture stomatitis (chronic atrophic)	Denture wearers who tend to be elderly and have poor oral hygiene	Red, flat lesions on the mucosa beneath the denture and extend right up to the denture border; more commonly located beneath a maxillary denture, although they can be encountered beneath a mandibular denture
Central papillary atrophy (median rhomboid glossitis)	Uncommon (<1% prevalence), men more commonly infected than women (3:1)	Rhomboid-shaped hypertrophic or atrophic plaque in the mid-doral tongue. Lesions may not resolve completely

HIV, human immunodeficiency virus.

TABLE 120-5 Clinical Presentation of Oropharyngeal and Esophageal Candidiasis

Oropharyngeal Candidiasis	Esophageal Candidiasis
General	**General**
The clinical features can be quite diverse (see Table 98-4)	This usually occurs as an extension of OPC; however, the esophagus can be the only site involved; the distal two-thirds, rather than the proximal one-third, is the most common site
Symptoms	**Symptoms**

Oropharyngeal Candidiasis	Esophageal Candidiasis
Symptoms are diverse and range from none to a sore, painful mouth, burning tongue, metallic taste, and dysphagia and odynophagia with involvement of the hypopharynx	Typically, the symptoms are dysphagia, odynophagia, and retrosternal chest pain but can be asymptomatic in some patients; although rare, epigastric pain can be the dominant symptom
Signs	**Signs**
	Constitutional signs, including fever, occasionally occur; physical findings can range from a few to numerous white or beige plaques of variable size
Signs are variable and can include diffuse erythema and white patches on the surfaces of the buccal mucosa, throat, tongue, or gums; constitutional signs are absent	Plaques can be hyperemic or edematous, with ulceration in more severe cases
	Most advanced cases can occur with increased mucosal friability and narrowing of lumen
	Uncommon complications include perforation and aortic–esophageal fistula formation
Laboratory tests	**Laboratory tests**
Scraping of an active lesion for microscopic examination can help confirm the diagnosis (presence of pseudohyphae and budding yeast) but is usually not necessary	The best test is upper GI endoscopy (more useful than barium swallow); helps exclude other causes of esophagitis (eg, viral, aphthous ulcers); diagnosis is confirmed by the histologic presence of *Candida* species in biopsy lesions taken during endoscopy
Cultures are not necessary because isolation of *Candida* species does not distinguish between colonization and true infection; cultures can be taken in patients responding poorly to therapy to determine the infecting species and to predict likely drug resistance	Cultures to look for drug-resistant *Candida* species are warranted in patients who require endoscopy

GI, gastrointestinal; OPC, oropharyngeal candidiasis.

TREATMENT

Desired Outcomes

The primary desired outcome in the management of OPC is a clinical cure, that is, elimination of clinical signs and symptoms. Even when the patient is relatively asymptomatic, it is important to treat the initial episode of OPC to avoid progression to more extensive disease. In the most severe cases, the patient's quality of life can be impaired; this can result in decreased fluid and nutritional intake. Lack of appropriate treatment of OPC can lead to more extensive oral disease, especially in patients who are immunocompromised. The most serious complication of untreated OPC is extension of the

infection to esophageal candidiasis. Because esophageal candidiasis is more debilitating, the patient's quality of life is more affected. It is important to initiate appropriate antifungal therapy for both OPC and esophageal candidiasis. Preventing or minimizing the number of future recurrences of both types of candidiasis is an equally important outcome. The approach depends largely on the underlying predisposing conditions. Mycologic cure is not a necessary treatment outcome because it may not be feasible or realistic, given that *Candida* species exist commonly as part of the normal mouth flora.

Minimizing toxicities and drug–drug interactions of systemic antifungal agents, as well as maximizing adherence by ensuring that the patient understands the importance of therapy and the directions to take the medication appropriately, are important secondary outcomes of therapy.

General Approach to Treatment

The management of OPC should be individualized for each patient, taking into consideration the underlying immune status, other concurrent mucosal and medical diseases, concomitant medications, and exogenous infectious sources. In HIV-infected patients with inadequately controlled disease, antifungal treatment produces only a transient clinical response, and the relapse rates are higher than in other patient populations. These patients usually require frequent courses of antifungal treatment. Therefore, in patients with HIV disease, treatment with effective HAART is paramount because this would provide the best prophylaxis against recolonization and recurrence of symptoms.[39,41,48]

Whenever feasible, it is desirable to minimize all predisposing factors, such as administration of corticosteroids, chemotherapeutic agents, and antimicrobials, as well as institute proper oral hygiene and resolve concurrent conditions, such as denture stomatitis. Selection of an appropriate antifungal agent for treatment of candidiasis requires consideration of several factors, including the patient's drug adherence, adequate saliva for dissolution of solid topical medications, risk of caries from sucrose- or dextrose-containing preparations, potential drug interactions, coexisting medical conditions (eg, liver disease), location and severity of the infection, and the need for long-term maintenance therapy. Another factor that could affect drug selection is overuse of fluconazole, leading to the emergence of fluconazole-resistant species of *C. albicans*, and in some cases to all azoles, and other intrinsically more resistant species, such as *C. krusei*, *C. glabrata*, and *C. tropicalis*.

5 Topical antimycotic therapies should be the first choice for milder forms of infections.[48] The efficacy of antimycotic agents for OPC varies in different patient populations. Until the polyene antimycotic agents became available in the 1950s, gentian violet, an aniline dye, was used to treat OPC. Problems with gentian violet include fungal resistance, skin irritation, and especially the unaesthetic staining of the oral mucosa. In resource limited areas gentian violet remains a therapeutic option. A 0.00165% gentian violet solution does not stain the oral mucosa and has potent antifungal activity.[49] Topical agents, such as nystatin and clotrimazole, have been the standard of treatment for uncomplicated OPC and generally are effective for treatment in otherwise healthy adults and infants with no underlying immunodeficiencies. Topical agents are available in an assortment of formulations, including oral rinses (suspension), troches, powder, vaginal tablets, creams and most recently as a mucoadhesive tablet[43,48,50] (**Table 120-6**).

TABLE 120-6 Therapeutic Options for Mucosal Candidiasis

Initial Episodes of OPC:[a] Treat for 7-14 Days	Common/Significant Side Effects
Clotrimazole 10 mg troche: hold 1 troche in mouth for 15-20 minutes for slow dissolution 5 times daily (B-2)	Altered taste, mild nausea, vomiting
Nystatin 100,000 units/mL suspension: 5 mL swish and swallow 4 times daily (B-2)	Mild nausea, vomiting, diarrhea
Miconazole 50 mg mucoadhesive buccal tablets 50 mg daily (A-1)	Diarrhea, headache, nausea, dysgeusia, upper abdominal pain, and vomiting
Fluconazole 100 mg tablets:[b] 100-200 mg daily (A-1)	GI upset, hepatitis not common
Itraconazole 10 mg/mL solution:[c] 200 mg daily (A-2)	GI upset, not common: hepatotoxicity, CHF, pulmonary edema with long-term use[e]
Posaconazole 40 mg/mL suspension: 400 mg daily with a full meal (A-2)	GI upset, fever, headache, increased hepatic transaminases not common
Fluconazole-Refractory OPC: Treat for ≥14 Days	
Itraconazole 10 mg/mL solution: 200 mg daily (A-3)	See above
Voriconazole 200 mg tablets: 200 mg twice daily (>40 kg), taken on empty stomach (A-3)	GI upset, rash, reversible visual disturbance (altered light perception, photopsia, chromatopsia, photophobia), increased hepatic transaminases, hallucinations, or confusion
Posaconazole 40 mg/mL suspension: 400 mg twice daily × 3 days, then 400 mg daily × 28 days (A-2)	See above
Amphotericin B 100 mg/mL suspension:[d] 1-5 mL swish and swallow 4 times daily (B-2)	Oral: nausea, vomiting, diarrhea with higher dose
Amphotericin B deoxycholate 50 mg injection: 0.3-0.7 mg/kg/day IV daily (B-2)	IV: fever, chills, sweats, nephrotoxicity, electrolyte disturbances, bone marrow suppression
Caspofungin 50 mg IV daily (B-2)	Fever, headache, infusion-related reactions (<5%) (eg, rash, facial swelling, pruritus, vasodilation), hypokalemia, increased hepatic transaminases, anemia, neutropenia
Micafungin 150 mg IV daily (B-2)	Similar to caspofungin
Anidulafungin 200 mg IV daily (B-2)	Similar to caspofungin
Esophageal Candidiasis:[a] Treat for 14-21 Days	

Initial Episodes of OPC:[a] Treat for 7-14 Days	Common/Significant Side Effects
Fluconazole 100 mg tablets: 200-400 mg (3-6 mg/kg) daily (A-1)	See above
Echinocandin: see above (B-2)	See above
Amphotericin B deoxycholate 50 mg injection: 0.3-0.7 mg/kg/day IV daily (B-2)	See above
Posaconazole 40 mg/mL suspension: 400 mg twice daily (A-3)	See above
Itraconazole 10 mg/mL solution:[c] 200 mg daily (A-3)	See above
Voriconazole 200 mg tablets: 200 mg twice daily (>40 kg) (A-3)	See above
Voriconazole and echinocandins (A-1): generally reserved for refractory cases	See above
Fluconazole-Refractory EC: Treat for 21-28 Days	
Itraconazole 10 mg/mL solution: 200 mg daily (A-2)	See above
Posaconazole 40 mg/mL suspension: 400 mg twice daily (A-3)	See above
Voriconazole 200 mg tablets: 200 mg twice daily (>40 kg), taken on empty stomach (A-3)	See above
Caspofungin 50 mg IV daily (B-2)	See above
Micafungin 150 mg IV daily (B-2)	Similar to caspofungin
Anidulafungin 100 mg IV on day 1, then 50 mg IV daily (B-2)	Similar to caspofungin
Amphotericin B deoxycholate: 0.3-0.7 mg/kg/day IV, or lipid-based amphotericin 3-5 mg/kg/day IV (B-2)	See above

CHF, congestive heart failure; GI, gastrointestinal; OPC, oropharyngeal candidiasis.

[a]Initial episodes of OPC can be adequately treated first with topical agents before resorting to systemic therapy (B-2), but systemic therapy is required for effective treatment of esophageal candidiasis. (A-2) Suppressive therapy is recommended for patients with frequent or severe recurrences (A-1).

[b]Fluconazole is more effective than ketoconazole (A-1).

[c]Solution is more effective than capsule (A-1); solution is better taken on an empty stomach.

[d]Suspension is not marketed; can be prepared extemporaneously by pharmacy.[50]

[e]See discussion under onychomycosis.

Recommendation grades:

Strength of recommendation: **A**—Both strong evidence for efficacy and substantial clinical benefit to support recommendation for use. *Should always be offered*. **B**—Moderate evidence for efficacy but only limited clinical benefit, to support recommendation for use. *Should generally be* offered. **C**—Evidence for efficacy is insufficient to support recommendation for or against use; or evidence for efficacy might not outweigh adverse consequences or cost of the treatment under consideration. *Optional*. **D**—Moderate evidence for lack of efficacy or adverse outcome supports a recommendation against use. *Should generally not be offered*.

Quality of evidence: **1**—Evidence from at least one properly designed randomized, controlled trial. **2**—Evidence from at least one well-designed trial without randomization, from cohort or case-controlled analytic studies (preferably from more than one center), or from multiple time-series studies, or dramatic results from uncontrolled experiments. **3**—Evidence from opinions of respected authorities based on clinical experience, descriptive studies, or reports of expert committees. (UR) Evidence currently unrated.

Topical agents require frequent applications because of the short contact time with the oral mucosa; the ideal contact time is 20 to 30 minutes. Sufficient saliva is needed to dissolve clotrimazole troches, and this can be problematic for patients with xerostomia. Also, the rough surface of the tablet can become irritating to the oral soft tissue. Troches also contain dextrose, which has cariogenic potential. Nystatin suspension might be a better choice for patients with xerostomia, but it is difficult to maintain adequate contact time with the oral mucosa. Some patients complain of the unpleasant taste of nystatin, which can cause nausea and vomiting; this is especially problematic in cancer patients experiencing chemotherapy-induced nausea. The high sucrose content of nystatin suspension is cariogenic in dentate patients, and it should be used with caution in diabetic patients.[39,43] Miconazole 50 mg mucoadhesive tablets are the first buccal adherent miconazole product approved for the local treatment of OPC in adults and adolescents older than age 16 years.[51] This product offers the advantage of a once-daily formulation that is tasteless, odorless, and sugar free.[50] Topical creams, such as clotrimazole, ketoconazole, miconazole, and nystatin (usually mixed with a steroid), are more appropriate for application three times daily to the corners of the mouth in treating angular cheilitis, the inflammation, drying, and cracking of the corners of the mouth.[48]

Systemic therapy is necessary in patients with OPC that is refractory to topical treatment, those who cannot tolerate topical agents, moderate-to-severe disease, and those at high risk for disseminated systemic or invasive candidiasis. Effective treatment of esophageal candidiasis generally requires the use of systemic antifungal agents. However, these agents have the disadvantage of producing more side effects (see Table 120-6) and drug–drug interactions (see Chapter e99). Fluconazole is inexpensive and generally well tolerated, and its absorption is unaffected by food or gastric acidity.

Ketoconazole requires gastric acidity for absorption, which can be problematic in AIDS patients with achlorhydria; hence, it is best given with an acidic beverage. Ketoconazole is not recommended today with the availability of more effective triazoles. Itraconazole capsules also have the same absorption problem and are no longer recommended. In contrast, itraconazole solution has enhanced absorption and is best taken in a fasting state; in addition, the solution provides the benefit of both topical effects to the oral mucosa and systemic effects and is beneficial to patients with mucositis or swallowing problems. Whenever possible, it is generally beneficial to limit the use of systemic azole agents to prevent unnecessary drug exposure and to minimize the potential for occurrence of drug-resistant candidiasis, particularly from fluconazole resistance.

When patients become unresponsive to topical agents or fluconazole and itraconazole, alternative agents are available.[43,44,48,52,53] These include amphotericin B and newer triazoles such as voriconazole and posaconazole and echinocandins (caspofungin, micafungin, and anidulafungin) (see discussion below). Although posaconazole is now available in three formulations; the original suspension as well as oral tablets and an intravenous product, only the suspension has an FDA indication for the treatment of OPC.[54]

Clinical Controversy...

The optimal strategy for the management of recurrent oral mucosal candidiasis is unclear. Primary and secondary prophylaxis is not routinely recommended in HIV infected patients. The decision to use secondary prophylaxis should be made on an individual case basis.

Oropharyngeal Candidiasis: Human Immunodeficiency Virus-Infected Patients

It is appropriate to start therapy with topical agents for initial or recurrent episodes of OPC, provided that clinical symptoms are not severe and that there is minimal risk of esophageal involvement.[42,48] Clinical responses with the resolution of signs and symptoms generally occur within 5 to 7 days of initiating treatment. Clotrimazole appears to be the most effective topical agent and demonstrates comparable clinical response rates with both fluconazole and itraconazole.[42,48] However, topical therapy is associated with more frequent relapses than with fluconazole.[44,48] This may be of limited clinical significance in patients receiving effective HAART because of their decreased susceptibility to opportunistic infection. In practice, nystatin suspension is still used frequently in initial episodes of OPC, although it is the least effective agent and is associated with frequent treatment failures and early relapses, especially in patients with advanced HIV disease or neutropenia.[39,43] Miconazole mucoadhesive tablets (MMT) 50 mg once daily was noninferior to clotrimazole troches 10 mg five times daily for the treatment of OPC in HIV infected patients (61% vs 65%, respectively for intention to treat cure rate), (68% vs 74%, respectively per protocol) populations at the test of cure visit. Safety and tolerability was also similar between treatment groups.[51]

Systemic oral azoles should be reserved for use in the more severe episodes of OPC unresponsive to topical agents or in patients with concurrent esophageal involvement.[43,48] In clinical practice, fluconazole usually is the systemic azole agent of choice because of its proven efficacy, favorable absorption, safety, and drug-interaction profiles, and it is relatively inexpensive. Fluconazole is

superior to ketoconazole and itraconazole capsules.[42,48] A fluconazole regimen of 100 to 200 mg/day for 7 to 14 days is recommended.[48] A single dose of fluconazole 750 mg orally is as effective as fluconazole 150 mg orally for 14 days, which warrants further evaluation, given the potential advantages of adherence and cost-effectiveness.[52] Itraconazole oral solution with an improved absorption profile compared with the capsule formulation is as effective as fluconazole, with comparable clinical and mycologic response and relapse rates.[43,48] However, it carries a higher risk of drug interactions because it is a potent inhibitor of the cytochrome P450 (CYP) enzymes, and it is associated with more nausea than fluconazole. Posaconazole is an extended-spectrum triazole with potent in vitro activity against both *C. albicans* and non-*C. albicans* species. It is equivalent to fluconazole in terms of efficacy, safety, and tolerability.[53] Posaconazole has joined itraconazole solution and voriconazole as the azole alternatives to fluconazole in the management of moderate-to-severe OPC.[47] Other agents that are effective are amphotericin B and the echinocandins (caspofungin, micafungin, and anidulafungin). They are better reserved for refractory OPC, however, because of their greater toxicity. They are also more expensive and are less convenient to use.

Oropharyngeal Candidiasis: Non-Human Immunodeficiency Virus-Infected Patients

This patient population includes patients with hematologic malignancy (eg, leukemias) or blood and bone marrow transplantation (BMT) with a long duration of neutropenia and chronic graft-versus-host disease, patients with solid tumors, patients with solid-organ transplants who are receiving immunosuppressive therapy, and patients with diabetes mellitus, as well as patients on prolonged courses of antibiotics or corticosteroids and the debilitated elderly. Factors to consider in deciding whether to use topical or systemic antifungal therapy include the severity and extent of mucosal involvement (oropharyngeal vs esophageal), predisposing risk factors, and risk for dissemination. Patients who develop neutropenia (eg, leukemic and BMT patients) are usually at high risk for disseminated and invasive fungal disease, and treatment of oral candidiasis is more aggressive. Patients with cell-mediated immune deficits but normal or near-normal granulocyte function and number (eg, solid tumors, solid-organ transplants, or diabetic patients) are at low risk for dissemination of infection.

Specific antifungal therapy can be unnecessary for asymptomatic patients at relatively low risk for disseminated candidiasis, such as those who are not granulocytopenic or who are expected to have a short duration of granulocytopenia.[43] Many of these infections will clear spontaneously after recovery of the granulocytes or discontinuation of antibiotic and/or immunosuppressive therapy. However, antifungal therapy usually is required for patients who have persistent infection or significant symptoms, usually pain, or who are granulocytopenic with a relatively high risk of fungal dissemination. Topical agents can be given a first therapeutic trial depending on the severity of infection and the degree of immunosuppression. Although both nystatin and clotrimazole can be effective in treating OPC, nystatin suspension does not effectively reduce the incidence of either oropharyngeal or systemic *Candida* infections in immunocompromised patients receiving chemotherapy or radiation; its use often is associated with treatment failures and early relapses.[48] Clotrimazole appears to be more effective in reducing colonization and treating acute episodes in cancer patients who are immunocompromised. MMTs were superior to miconazole oral gel in

achieving a complete response in patients with head and neck cancer.[55] MMT has not been studied against clotrimazole in this patient population specifically but is approved for use in adults with OPC.

Systemic azole agents are used for treating OPC in patients who have failed or who are unable to take topical therapy.[43,48,53] The preceding discussion on the relative efficacy of fluconazole, itraconazole, and ketoconazole in HIV-infected patients can be extrapolated to the non-HIV-infected population. Oral fluconazole 100 to 200 mg daily is used more commonly because of more extensive experience with its use, and it is more effective and has a more favorable absorption and side-effect profile compared with other available azoles.[48] If the oral route is not feasible for reasons such as severe chemotherapy-induced mucositis, fluconazole can be administered IV. In patients unresponsive to azoles, IV amphotericin B in relatively low doses of 0.1 to 0.3 mg/kg/day can be tried.[48] Because of the higher risk for dissemination in patients who are severely neutropenic (less than 0.1×10^9 neutrophils/L) or clinically unstable (hypotensive or febrile), some clinicians prefer to initiate therapy with IV amphotericin B at 0.6 mg/kg/day, with therapy continued until the neutropenia has resolved or an echinocandin.[48] The echinocandins caspofungin, micafungin, and anidulafungin have all been found to be effective for treatment of OPC, thus offering another option, with fewer adverse effects in the patient with refractory disease.[48]

Topical therapy with clotrimazole or nystatin for 7 days is usually adequate for treating mucocutaneous candidiasis in most solid-organ transplant patients.[43] Use of topical therapy will reduce the number of systemic drugs that these patients receive and hence minimize the risk of drug–drug interactions. Failure to respond to topical agents warrants the use of fluconazole. Low-dose amphotericin B solution as "swish and swallow" (100 mg/mL, 1 mL four times daily) for 7 to 10 days is reserved for the unusual cases of treatment failure.

Patients who develop OPC because of prolonged antibiotic use or aerosolized corticosteroids use can be managed successfully by discontinuation of the offending agent, and the infection usually will resolve. If there is a strong desire to treat because of discomfort or need to hasten symptom resolution or an inability to stop the offending agent, therapy with a topical agent, either miconazole MT, clotrimazole or nystatin, is effective in most cases. The advantage of systemic azoles is the convenience of less frequent dosing. Symptoms usually improve in 3 or 4 days. Infants should be given smaller amounts more frequently (eg, nystatin 100,000 units every 2-3 hours) to ensure better contact time. For denture-related OPC, or candidal stomatitis, effective therapy requires treatment of both the mouth and the dentures to avoid relapse. The dentures must be brushed vigorously and disinfected every night by soaking in antiseptic solution, such as chlorhexidine gluconate 0.25% or a product such as Polident or Efferdent.[43,48] Topical antifungal therapy of the oral cavity is required. Consistent proper oral hygiene and care of the dentures can help prevent relapse.

Esophageal Candidiasis: Human Immunodeficiency Virus-Infected Patients

6 Treatment of esophageal candidiasis has not been as well studied as OPC. Because of the significant morbidity of esophageal candidiasis and the absence of evidence supporting the efficacy of topical antifungals, treatment requires systemic antifungal agents.[3] Fluconazole is superior to

ketoconazole and itraconazole capsules with respect to endoscopic cure and clinical response and usually produces a more rapid onset of action and resolution of symptoms. Fluconazole is as effective as itraconazole solution, with reported response rates of greater than 80% to 90%.[39,43] However, itraconazole solution causes more nausea and drug interactions because of inhibition of the CYP enzymes. Amphotericin B, voriconazole, posaconazole, and the echinocandins are also effective in esophageal candidiasis, but they are generally reserved for patients with advanced or inadequately controlled HIV disease where the candidiasis tends to recur or becomes refractory to azole therapy.[56,57,58,59]

Esophageal Candidiasis: Non-Human Immunodeficiency Virus-Infected Patients

As in the case of HIV-infected patients, treatment of esophageal candidiasis requires systemic therapy. Patients can be started on fluconazole 200 to 400 mg/day for 14 to 21 days.[48] Higher fluconazole doses (up to 400 mg/day) have been suggested for patients with severe symptoms or those who are neutropenic.[60] Other agents currently recommended if fluconazole is not an option are an echinocandin or amphotericin B at 0.3 to 0.7 mg/kg. Itraconazole solution, posaconazole, and voriconazole are effective alternatives that may be considered for those not responding adequately to fluconazole. An echinocandin or IV amphotericin B may be selected over fluconazole for initial therapy in neutropenic patients who present with severe symptoms or who are at high risk for dissemination of *Candida* species, such as those receiving other aggressive immunosuppressive therapy (eg, corticosteroids, total-body irradiation, or antithymocyte globulin) and who have documented evidence of esophageal candidiasis or who have failed an initial empirical trial of oral nonabsorbable agents or systemic azoles.[48] Therapy should be continued at least until the neutropenia resolves. For patients whose symptoms have resolved and who are afebrile and clinically stable, therapy should be discontinued, and the patients should be monitored closely for infection recurrence. In high-risk patients, particularly those with persistent fever and neutropenia, the potential presence of clinically occult, diffuse GI or disseminated candidiasis should be considered. The echinocandins and newer azole agents (voriconazole and posaconazole) offer less toxic alternatives or oral agents and are preferred in patients who are intolerant of amphotericin B deoxycholate or who have preexisting renal impairment.[43,60,61] There are limited data on the clinical efficacy of anidulafungin compared with fluconazole, 95% versus 89% cure rates, respectively, in the non-HIV-infected patients.[60]

Antifungal-Refractory Oral Mucosal Candidiasis

Treatment failure is generally defined as persistence of signs and symptoms of OPC or esophageal candidiasis after an appropriate trial of antifungal therapy.[42] Treatment of refractory oral mucosal candidiasis is frequently unsatisfactory, and clinical response is usually short-lived, with rapid and periodic recurrences. The key risk factors for occurrence of refractory candidiasis are advanced stage of AIDS with low CD4 cell counts (less than 50 cells/mm^3 [less than 0.05×10^9/L]) and repeated or prolonged courses of various systemic antifungal agents, in particular systemic azoles.[43,48] Frequent or prolonged use of fluconazole can be associated with fluconazole-refractory candidiasis because of selection of more resistant non-*C. albicans* species. An important initial management strategy is to

assess and optimize the antiretroviral therapy of the patient with refractory OPC to help improve the immune function. With the widespread use of HAART, fluconazole-refractory OPC is now less commonly encountered. It is also important to identify and rectify potentially correctable causes of clinical failures of mucosal candidiasis, such as poor drug adherence, adequate dosing, reduced drug absorption associated with hypochlorhydria, and drug–drug interactions.

There have been few controlled studies that assess the effectiveness of antifungal agents. Doubling of the fluconazole dosage to 400 or 800 mg/day can be effective in some patients with infection caused by *Candida* species of intermediate resistance, although the response may be only transient.[44] Fluconazole oral suspension can be beneficial in some patients because of increased salivary concentrations obtained when the suspension is taken with the swish and swallow technique.[48] Patients with fluconazole-refractory mucosal candidiasis can be treated with itraconazole oral suspension because it can be effective in 64% to 80% of patients; however, the benefit is short-lived if chronic suppressive therapy is not maintained.[42,48] Posaconazole suspension has been reported to be successful in ~74% of patients with refractory oral or esophageal candidiasis; voriconazole may also be efficacious in these patients. Amphotericin B oral suspension is another alternative for azole-refractory patients.[44,48] It has broad-spectrum activity against many fungal species and low likelihood of *Candida* species resistance. There are limited data and experience on its use in immunosuppressed patients, and results from small studies have yielded mixed results.[62] Amphotericin B suspension is no longer available commercially in the United States, but it can be prepared extemporaneously by the pharmacy.[62]

Clinical Controversy…

There are several alternatives to fluconazole refractory candidiasis, no drug of choice has been definitively identified, selection will depend on disease severity, route of administration effect on cytochrome P450 enzymes and side effect profile.

Until recently, IV amphotericin B deoxycholate has been the alternative for patients with endoscopically proven disease who have failed fluconazole or itraconazole therapy. Patients with severe disease unresponsive to other agents require IV amphotericin B 0.3 to 0.7 mg/kg/day for 7 to 10 days to achieve clinical response; higher dose or longer treatment duration can be needed in more severe disease.[44,48] After response, suppressive therapy with amphotericin B is required to increase disease-free intervals. Patients who fail to respond to amphotericin B and require greater than 1 mg/kg/day might be candidates for liposomal amphotericin B preparations because of renal and/or bone marrow toxicities, although at a markedly higher cost. Flucytosine usually is not used as monotherapy because of rapid development of resistance but can be used in combination with an azole or amphotericin B.[44] Less toxic agents that are also effective are voriconazole and the echinocandins.[60,61] Voriconazole, a triazole antifungal available in both oral and IV preparations, appears to be as effective as fluconazole for esophageal candidiasis, and it has shown success in treatment of fluconazole-refractory disease.[59] However, voriconazole has more side effects and multiple pharmacokinetic drug interactions compared to fluconazole.[59] Caspofungin, micafungin, and anidulafungin are approved for this indication. All three echinocandins have similar efficacy and tolerability profile as fluconazole, although caspofungin and anidulafungin have higher relapse rates

compared with fluconazole.[48,61] Because the echinocandins require IV administration and are expensive, they are primarily used in patients who are refractory to the triazoles or have serious triazole-related adverse effects. As a class, the echinocandins have a favorable adverse effect profile. They are less toxic than amphotericin B (see Table 120-6) and have less impact on the CYP enzymes than either itraconazole or voriconazole. Immunomodulation with adjunctive granulocyte-macrophage colony-stimulating factor and interferon have been used for refractory oral candidiasis in very limited numbers of patients.[48]

Antifungal Prophylaxis

7 Ensuring that the HIV-infected patient is receiving appropriate antiretroviral therapy to enhance the immune system is perhaps the most important measure in preventing future episodes of mucosal candidiasis (oropharyngeal, esophageal, and vulvovaginal).[48] Initial success of treatment often is followed by symptomatic recurrences, especially in patients with advanced or poorly controlled HIV disease. Long-term suppressive therapy with fluconazole is effective in preventing recurrences or new infections of OPC in HIV disease and in patients with cancer.[48] However, the indications for antifungal prophylaxis and the best long-term management strategy still have not been well established. Fluconazole does not provide complete protection, and breakthrough infections can occur.[44] The reduced risk of recurrence of OPC also has not been demonstrated to improve survival. In addition, chronic exposure to azole therapy is a concern in that it might lead to the development of refractory disease or emergence of azole resistance.[48] However, in a randomized trial of continuous versus episodic fluconazole therapy, continuous therapy did not result in a higher rate of refractory OPC or esophageal disease.[63] HIV specialists do not recommend primary or secondary prophylaxis for OPC.[44] The rationale includes effectiveness of therapy for acute episodes of OPC, low incidence of serious invasive fungal disease, low mortality associated with mucosal candidiasis, potential for drug interactions, potential for emergence of drug resistance, and the prohibitive long-term cost of prophylaxis.

8 The decision to use secondary prophylaxis should be individualized for each patient. Secondary prophylaxis can be considered in patients with multiple recurrent episodes of symptomatic OPC or when the disease is sufficiently severe and affecting the quality of life.[44] Patients with a history of one or more episodes of documented esophageal candidiasis and a CD4 T-cell count still less than 200 cells/mm^3 (less than 0.2 × 10^9/L) despite being on HAART are candidates for secondary prophylaxis. Oral fluconazole 100 mg daily is the usual regimen recommended for OPC and esophageal candidiasis,[44,48] although 200 mg three times weekly also appears to be effective.[63] Once-weekly oral fluconazole (200 mg) is also effective for preventing OPC recurrences in those with less-advanced AIDS.[44] Itraconazole solution 200 mg daily orally is an alternative as suppressive therapy for OPC.[48]

Patients with malignant neoplastic diseases who are receiving irradiation, cytotoxic, and/or immunosuppressive therapy are at high risk for fungal infections in addition to bacterial and viral infections. Prophylaxis of *Candida* infection is controversial, and the results of studies have been conflicting and difficult to evaluate. In the hematopoietic stem cell transplant (HSCT) population,

fluconazole prophylaxis is recommended prior to engraftment. Cross-resistance to other azoles may occur among *Candida* species; this should be a treatment consideration in a patient who develops a breakthrough fungal infection. Micafungin is an alternative to fluconazole prophylaxis of candidiasis.[64] The value of antifungal prophylaxis in these patients needs to be considered in the broader context of not only reducing colonization and the risk of superficial candidiasis but also, more importantly, reducing the risk for invasive candidiasis and improving survival. Management of these infections in this patient population is discussed further in Chapter 100.

Evaluation of Therapeutic Outcomes

Efficacy end points for oropharyngeal and esophageal candidiasis include rapid relief of symptoms and prevention of complications without early relapse after completion of the course of therapy.[44,48] Sterilization of the oral cavity is not a feasible end point because mycologic eradication is rarely achievable, especially in HIV-positive patients. Symptomatic relief of presenting signs and symptoms (see Table 120-5) generally occurs within 48 to 72 hours of starting therapy, with complete resolution by 7 to 10 days. Patients should be advised about the time course and told to return for reassessment when signs and symptoms recur. It is usually unnecessary for the patient to be reassessed soon after finishing the treatment course. However, HIV patients should be questioned and examined for the occurrence of mucosal candidiasis as part of their regular follow-up. The frequency of monitoring can be more often in neutropenic patients because of concern for dissemination of candidiasis. During the period of neutropenia, temperature should be monitored daily, as well as signs of dissemination.

Efficacy of the antifungal agent is partly influenced by patient adherence to the medication regimen. Patients must be counseled on proper administration and dosing, in particular for topical agents (**Table 120-7**).[60] Safety end points include monitoring for occurrence of the relevant drug side effects and drug interactions (see Table 120-6). Mild GI intolerance can occur with topical therapy, but serious adverse effects are rare. It is still prudent to monitor for hypersensitivity reactions, especially rash and pruritus that might occur with any medication. GI intolerance is more associated with the oral azoles. Hepatotoxicity can occur when azole therapy is prolonged beyond 7 to 10 days or high doses are used. Periodic monitoring of liver enzymes (alanine transaminase and aspartate amino-transferase) should be considered, especially if prolonged therapy (longer than 21 days) is anticipated. Patients who are receiving IV amphotericin B require daily monitoring by a pharmacist.

TABLE 120-7 Patient Counseling Tips for Managing Oropharyngeal Candidiasis

1. Clean the oral cavity prior to administering the topical antifungal agent. Daily fluoride rinses can help reduce the risk of caries when using an agent containing sucrose or dextrose.

2. Use the topical antifungal agent after meals, as saliva flow and mouth movements can reduce the contact time.

3. Troches should be slowly dissolved in the mouth, not chewed or swallowed whole, over 15-20 minutes, and the saliva swallowed.

4. Suspension should be swished around the mouth in the oral cavity to cover all areas for as

long as possible, ideally at least 1 minute, then gargled and swallowed.

5. Remove dentures while medication is being applied to the oral tissues.
6. Use a suspension or buccal mucoadhesive tablet instead of a troche if xerostomia is present; if a troche is preferred, the patient should rinse or drink water prior to dosing. For xerostomia, suggest nonpharmacologic measures for symptomatic relief (eg, ice chips, sugarless gum or hard candy, citrus beverages).
7. Dentures should be removed and disinfected overnight using an antiseptic solution (eg, chlorhexidine 0.12%-0.2%). Disinfect oral tissues in addition to dental prosthesis.
8. Complete treatment course even though symptomatic improvement can occur in 48-72 hours.
9. Maintain good oral hygiene. Brush teeth daily (twice daily) and floss, rinse mouth, or brush teeth after eating sweets.
10. Stop smoking; avoid alcohol.

Data from reference 52.

MYCOTIC INFECTIONS OF THE SKIN, HAIR, AND NAILS

Superficial cutaneous mycoses affect up to 20% to 25% of the global population.[65] The usual pathogens are the dermatophytes classified by genera: *Trichophyton*, *Epidermophyton*, and *Microsporum*. Less frequently infection is caused by nondermatophyte fungi (eg, *Malassezia furfur*) and Candida species. Dermatophytes have the ability to penetrate keratinous structures of the body and therefore infections are limited to hair, nails and skin. These infections affect both male and female genders and all races. Reservoirs of mycotic infections include humans, animals, and soil.[65,66] Individuals can develop an infection if they come in contact with a reservoir in addition to having a conducive environment for mycotic growth (ie, moist conditions).[67] Risk factors for the development of an infection include prolonged exposure to sweat or soaking in water, maceration, intertriginous folds, sharing personal belongings such as combs, close living quarters (dormitories, barracks).[66,67]

Mycotic infections of the skin have a classic appearance that consists of a central clearing surrounded by an advancing red, scaly, elevated border, also referred to as an "active" border.[67,68] The central clearing of the lesion may distinguish dermatophytoses from other skin eruptions such as psoriasis or lichen planus which have a more uniform inflammatory presentation.[68] Infections of the nail can appear chalky and dull yellow or white and become brittle and crumbly.

Diagnosis usually is based on patient history, as well as the physical examination.[69] Diagnostic tests include direct microscopic examination of a specimen after the addition of KOH or fungal cultures. The KOH test is quick, inexpensive, and easy to perform, whereas cultures are more expensive and take longer to obtain results. Diagnostic tests are recommended when systemic therapy is likely to be

prescribed.[69]

9 A general approach to treatment of superficial mycotic infections includes keeping the infected area dry and clean and limiting exposure to the infected reservoir. Topical agents generally are considered to be first-line therapy for infections of the skin. Oral therapy is preferred when the infection is extensive or severe or when treating tinea capitis or onychomycosis. Table 120-8 lists specific treatments for each mycotic infection. Superficial mycotic infections are categorized by the pattern and site of infection.[66] The most commonly occurring infections in North America are detailed in the following sections.

TABLE 120-8 Treatment of Mycoses of the Skin, Hair, and Nails

	Topical[a,b]	Oral[c]
Tinea pedis	Butenafine, daily Sertaconazole, twice daily Luliconazole daily	Fluconazole 150 mg 1 per week × 1-4 weeks
Tinea manuum	Naftifine cream daily, gel daily Ciclopirox, twice daily Clotrimazole, twice daily	Ketoconazole 200 mg daily × 4 weeks
Tinea cruris	Luliconazole, daily	Itraconazole 200-400 mg/day × 1 week
Tinea corporis	Naftifine cream daily, Econazole, daily Haloprogin, twice daily Ketoconazole cream, daily Luliconazole daily Miconazole, twice daily Naftifine cream, daily; Oxiconazole, twice daily Sulconazole, twice daily Terbinafine, twice daily Tolnaftate, twice daily Triacetin cream, solution, 3 times daily	Terbinafine 250 mg/day × 2 weeks Fluconazole 150 mg once weekly × 4 weeks

	Topical[a,b]	Oral[c]
Tinea capitis	Undecylenic acid, various preparations: apply as directed Shampoo only in conjunction with oral therapy or for treatment of asymptomatic carriers	Terbinafine 250 mg/day × 4-8 weeks Fluconazole 150 mg/week × 4 weeks
Tinea barbae	Ketoconazole twice weekly × 4 weeks Selenium sulfide daily × 2 weeks	Ketoconazole 200 mg daily × 4 weeks Itraconazole 100-200 mg/day × 4-6 weeks Griseofulvin 500 mg/day × 4-6 weeks
Pityriasis versicolor	Clotrimazole, twice daily Econazole, daily Haloprogin, twice daily Ketoconazole, daily Miconazole, twice daily Oxiconazole cream only, twice daily Sulconazole, twice daily Tolnaftate, three times daily	Ketoconazole Fluconazole Itraconazole 200 mg daily × 3-7 days
Onychomycosis	Ciclopirox 8% nail lacquer: apply solution at night for up to 48 weeks (fingernails and toenails) Efinaconazole 10% topical solution daily for 48 weeks (toenails) Tavaborole 5% topical solution daily for 48 weeks (toenails)	Terbinafine 250 mg/day × 6 weeks (fingernail), 12 weeks (toenail) Itraconazole 200 mg twice daily × 1 week/month for 2 months (fingernail); 200 mg daily × 12 weeks (toenail) Fluconazole 50 mg daily or 300 mg once weekly for ≥6 months (fingernail) or 12 months (toenail)

[a]Other products are available, including combination products.

[b]Length of therapy depends on mycotic sensitivity and severity of infection.

[c]Only capsule formulation studied; give with food for increased absorption.

Tinea Pedis

Tinea pedis is the most common dermatophytoses (affecting ~70% of adults). It is better known as "athlete's foot" and occurs in hot weather, with exposure to surface reservoirs (locker room floors),

and with use of occlusive footwear.[67] Tinea pedis has three common presentations. The most common is the interdigital form which is characterized by fissuring, maceration and scaling of the spaces between the toes (most frequently the fourth and fifth toes). Patients often complain of itching and burning. The "moccasin-like" distribution presentation is usually caused by *Trichophyton* rubrum. In this form the plantar surface becomes chronically scaly and thickened with accompanying erythema of the soles, heels, and sides of the foot. The third presentation, vesiculobulous tinea pedis, is characterized by the formation of vesicles, pustules and occasionally bullae typically on the soles of the foot. Contact dermatitis, pustular psoriasis and eczema would be in the differential diagnosis. Disruption of skin integrity with tinea pedis is a risk factor for streptococcal cellulitis as a complication.[68] Treatment with topical therapy for 2 to 4 weeks often is adequate for mild infections; however, severe infections or involvement of the nails require oral therapy[67] (see Table 120-8). A new 2% gel formulation of naftifine has been approved by the FDA for the treatment of interdigital tinea pedis. In clinical trials of naftifine 2% gel for tinea pedis (interdigital and moccasin-type) found that there was continued improvement even after the therapy was completed with clinical and mycological cure rates increasing from 5.4% and 39.1%, respectively at the 2 weeks end of treatment time point to 21.5% and 62% at week 6.[70] This finding suggests a depot effect of naftifine gel which is supported by the results of studies demonstrating the epidermal level of naftifine at application site remains relatively constant over several weeks post-treatment.[71] Naftifine is not approved for moccasin-type tinea pedis but is the only agent formally studied for this indication in a randomized double-blind vehicle controlled trial. Naftifine 2% gel resulted in a complete cure rate at week 6 of 19.6% compared to 0.7% for vehicle treated patients. Treatment effectiveness at week 6 was 51% for the naftifine versus 6% for the vehicle group.[70] Luliconazole 1% cream once daily for 2 weeks was approved for the topical management of interdigital tinea pedis, tinea cruris and tinea corporis in patients 18 years or older. Similar to naftifine, luliconazole 1% cream applied once daily for interdigital tinea pedis resulted in continued improvement even after therapy was completed.[72] Recurrence of infection occurs in up to 70% of individuals especially if there is concomitant onychomycosis. Prolonged treatment with either topical or systemic therapy may be required.[65,66] Other nonpharmacologic measures such as disinfecting footwear, avoidance of walking barefoot in public places, controlling hyperhidrosis, wearing absorbent socks and nonocclusive shoes should be advised.[67]

Tinea Manuum

Tinea manuum is a superficial fungal infection of one or infrequently both hands, and can involve the feet (tinea pedis). The infection presents with dry and hyperkeratotic palmar surface of the hand. The fingernails, when involved, may present with vesicles and scaling. Contact dermatitis, eczema, psoriasis and callus formation should be in the differential diagnosis.[68] Treatment of this infection is similar to tinea pedis (see Table 120-8). Emollients that contain lactic acid also can be useful.[65] Relapse or recurrence is frequent especially if tinea pedis or onychomycosis is present.[68]

Tinea Cruris

Tinea cruris is an infection of the proximal thighs and buttocks.[68] It is referred to as "jock itch" and is more common in males. Tinea cruris and tinea pedis often occur concurrently. High humidity and warm temperatures along with wet or tight-fitting clothes contribute to the development of tinea cruris. The scrotum and penis often are spared from infection. The lesions are red, scaling with raised borders. Pustules or vesicles and maceration are usually found along the active border. Itching and burning are the most common patient complaint. The differential diagnosis would include candida infection, erythrasma, mechanical intertrigo, psoriasis, and seborrheic dermatitis.[68] Treatment with topical therapy is recommended and should continue for 1 to 2 weeks after symptom resolution. Severe infections can require oral therapy (see Table 120-8). Relief of pruritus and burning can be facilitated by the use of short-term (2 or 3 days) topical steroids (2.5% hydrocortisone).[67] The feet of the patient should also be examined as a source of infection. Non-pharmacological measures such as keeping the area dry or avoiding prolonged exposure to moisture are important patient counselling points.[68]

Tinea Corporis

Tinea corporis, also known as ringworm, is an infection of the glabrous skin of the trunk, extremities, or face.[68] Lesions of tinea corporis may be singular or multiple and appear as round, scaly lesions with central clearing and a raised border with sharp margination. The border may exhibit pustules. The degree of pruritis is variable. The differential diagnosis includes nummular eczema, contact dermatitis, psoriasis, pityriasis rosea, tinea versicolor, granuloma annulare and Lyme disease.[68] Prior use of topical corticosteroid preparations may alter the appearance such that the central clearing and raised borders are no longer apparent impacting diagnosis. Diagnosis should be confirmed with KOH examination of skin scrapings of the edge of the lesion. Therapy is similar to that for tinea pedis, tinea manuum, and tinea cruris (see Table 120-8). If the infection is very widespread systemic antifungal therapy may be necessary.[68]

Tinea Capitis

Tinea capitis is a mycotic infection involving the scalp, hair follicles, and adjacent skin that primarily affects children.[68,73] Approximately, 90% to 95% of tinea capitis cases are due to *Trichophyton tonsurans*. Inanimate objects such as hats, brushes, or pillowcases are often the source of transmission particularly in the setting of poor hygiene. Viable organisms can be recovered from shed hairs for up to a year.[68] The lesions are characterized by irregular, frequently well-demarcated areas of alopecia with scaling. The alopecia is a result of infected hairs breaking off a few millimeters from the scalp; sometimes called "black dot alopecia." A "kerion" is a sterile, inflammatory scalp mass, often accompanied with cervical and occipital lymphadenopathy, due to a cell-mediated immune response to the infecting pathogen and is another manifestation of tinea capitis. The differential diagnosis will be influenced by the appearance of the lesions. For lesions that are predominantly scaly in inflamed consider seborrheic dermatitis, atopic dermatitis or psoriasis. If alopecia is the primary presenting feature rule out alopecia areata, traction alopecia and trichotillomania (obsessive hair pulling). The diagnosis of tinea capitis can be made in children based on the presence of at least 3 clinical features: scalp scaling, scalp pruritis, occipital adenopathy and diffuse patchy or discrete

alopecia.[74] However, given the broad differential diagnoses and the need for prolonged treatment required diagnosis should be confirmed with microscopic examination or fungal culture. Treatment should consist of oral therapy, as well as the cleaning of combs and brushes, which can be contaminated (see Table 120-8). Topical therapy will not penetrate into hair follicles. Daily shampooing is recommended for removal of scales. An antifungal shampoo (eg, selenium sulfide 1%, ketoconazole 2%) in addition to oral therapy is recommended to eliminate the shedding of viable spores.[75] Some children and adults can be asymptomatic carriers, thereby facilitating spread of the infection. Family members who culture positive for *T. tonsurans* should be treated with an antifungal shampoo (eg, ketoconazole, selenium sulfide, or povidone-iodine).[68]

Tinea Barbae

Tinea barbae affects the hairs and follicles of beards and mustaches of adult men and hirsute women.[68] Tinea barbae will present with scaling, follicular pustules and erythema. The differential diagnosis included bacterial folliculitis, contact dermatitis, perioral dermatitis, pseudofolliculitis barbae and herpes simplex. One clue to the diagnosis of tinea barbae is that hair removal with shaving is painless. Treatment is similar to that for tinea capitis (see Table 120-8). Removal of the beard or mustache is recommended.[67]

Pityriasis Versicolor

Hyper- and hypopigmented scaly patches characterize pityriasis versicolor, which is also known as *tinea versicolor*. It is caused by yeasts of the *Malassezia* genus which with the exception of *Malassezia pachydermatis*, are all lipophilic. The seborrheic areas (scalp, face, back and front of the trunk) of the human body are always colonized by one or more *Malassezia* spp., such as *M. globosa*, *M. sympodialis*, *M. sloffiae*, and *M. restricta* are the most common colonizers; *M. globosa* and *M. furfur* are most frequent clinical infection isolates. This is not considered a contagious infection given the source is normal flora. It is more common in adults and in areas with tropical ambient temperatures. The lesions are found on the trunk, face and extremities.[64] Lesions are described as well-demarcated and scaling thin plaques with various degrees of pigmentation. Most patients are asymptomatic or may complain of mild pruritis. Many are concerned about the cosmetic appearance and possible contagion.[76] Topical treatment usually is adequate unless there is extensive involvement, recurrent infections, or failure of topical therapy. Ketoconazole 2% shampoo was significantly more effective than selenium sulfide 2.5% shampoo (89% vs 35% cure rate).[77] Oral imidazole antifungal agents (ketoconazole, itraconazole, or fluconazole) are safe and effective options for oral therapy of extensive pityriasis versicolor. Recurrence of infection after cessation of treatment may be as high as 60% in the first year and 80% the second year. Suppressive maintenance therapy either orally or topically may be used in these cases although data is lacking to definitively identify the most optimal drug, dose or route.[76]

Onychomycosis (Tinea Unguium)

Onychomycosis is a fungal infection of the nail apparatus and is the most common single cause of

nail dystrophy, affecting up to 8% of the general population and accounting for up to 50% of all nail problems.[78] Onychomycosis more commonly affects the toenails (2%-14% of adults), ~4 to 19 times more frequently than fingernails, with prevalence increasing with age.[78] This can be because of the slower growth of toenails (three times slower than fingernails), making it easier for fungi to establish infection. Onychomycosis has a significant impact on quality of life, both functional and psychosocial. In addition, the affected nails can disrupt the integrity of the surrounding skin, potentially increasing the risk of secondary bacterial infections.[78,79]

Onychomycosis is due to infection by dermatophytes (tinea unguium), yeasts and nondermatophyte fungi.[80] Dermatophytes are the most frequent causes of onychomycosis (~90% in toenail and ~50% in fingernail infections).[77] The dermatophytes responsible for causing >90% of cases of onychomycosis are *Trichophyton rubrum* (71%) and *Trichophyton mentagrophytes* (20%).[73] Less common fungi causing onychomycosis are the nondermatophytic molds (2.3%-11%) and yeasts (5.6%). *C. albicans* is the most commonly isolated yeast and typically affects fingernails rather than toenails.[77,81] Risk factors for dermatophytic onychomycosis are increasing age (especially older than 40 years), family history and genetic factors, immunodeficiency (eg, HIV, renal transplant, immunosuppressive therapy, and defective polymorphonuclear chemotaxis), diabetes mellitus, psoriasis, peripheral vascular disease, smoking, prevalence of tinea pedis, frequent nail trauma, and sporting activities such as swimming.[81,82] These risk factors also appear to apply to recurrence of onychomycosis. Mold onychomycosis does not seem to be associated with systemic or local predisposing factors, but there is a risk of systemic dissemination in immunosuppressed patients.[77] *Candida* onychomycosis seems to always occur in immunosuppressed patients.[81]

Onychomycosis can present in in a variety of clinical forms. The five major clinical patterns are i) lateral distal subungual onychomycosis (DLSO), ii) white superficial onychomycosis (WSO), iii) proximal subungual onychomycosis (PSO), iv) endonyx onychomycosis, and v) total dystrophic onychomycoisis (TDO).[78,79] In DSO, the most common type, the nail plate, the nail bed, and, in advanced cases, the matrix are all affected, and *T. rubrum* is the most common etiologic cause. The worst case of onychomycosis is progression of the infection to total dystrophic onychomycosis, characterized by almost complete destruction of the nail plate. WSO is usually caused by *T. mentagrophytes*, where the infection is localized to the surface of the nail plate. In PSO, the fungi (usually *T. rubrum*) invade the nail through the proximal nail fold and spread to the nail plate and matrix. Although PSO is relatively uncommon in the general population, it occurs most frequently in severely immunocompromised patients and is often considered a marker for AIDS.[82,83] In endonyx onychomycosis the fungus directly invades the nail plate keratin instead of the nail plate margin.[78] Because of the multifactorial etiology of onychomycosis, it is important to differentiate onychomycosis from other causes of nail dystrophies (eg, psoriasis, lichen planus, chronic trauma, eczema, yellow nail syndrome, lamellar onychoschizia, periungual squamous cell carcinoma, malignant melanoma, and myxoid cyst) so that the patient receives appropriate therapy and is not subjected to prolonged treatment with unnecessary drugs.[79] Besides clinical history and physical examination, proper diagnosis of onychomycosis can include the combination of direct microscopy of scrapings from the appropriate nail area to look for fungal hyphae and fungal cultures, and, if necessary, histologic examination.[78,79,81] **Table 120-9** provides a differential diagnosis for fungal nail

diseases.[84]

TABLE 120-9 Differential Diagnosis of Fungal Nail Infections

Diagnosis	Features Consistent with Diagnosis
Psoriasis	Nail pitting, rash elsewhere on body, family history of psoriasis
Lichen planus	Nail atrophy, scarring at proximal aspect of the nail
Periungual squamous cell carcinoma	Single nail affected, pain, warty nail fold change, or ooze from the edge of nail
Yellow nail syndrome	Multiple nails turn yellow, grow slowly, increased longitudinal and transverse curvature, intermittent pain and shedding, associated with chronic sinusitis, bronchiectasis, lymphedema
Trauma	Single nail affected, homogeneous alteration of nail color and altered shape of nail

Data from Reference 24.

TREATMENT

General Approach

Onychomycosis merits proper assessment and treatment consideration because it is a debilitating disease and can exert a negative impact on quality of life (eg, cosmetic and psychosocial effects, pain, discomfort, and decreased ambulation).[78,79] It is reasonable to not treat persons with minimal toenail involvement and no associated symptoms.[84] Although definitive data are lacking regarding the risk of progression of untreated disease, it can lead to complications such as cellulitis or reduced mobility, which can further compromise peripheral circulation in those with diabetes or peripheral vascular disease; additionally, infected nails can serve as a source of transmission of fungi to other areas of the body, as well as to other people, such as close household contacts, or in communal bathing places.[78,85] Treatment decisions should be made on an individual basis. The primary end point of treatment is eradication of the organism, with secondary end points being clinical cure and improvement. Assessment of clinical success (cure or improvement) requires follow-up for several months after the end of treatment because of the slow growth rate of nails, especially toenails (1 mm/mo).[78] Successful eradication of the fungus does not always result in normalization of the nails because they can have been dystrophic prior to infection. This can cause patient dissatisfaction, especially if this is not explained before starting treatment.[79] There are several factors that must be taken into account on a patient-by-patient basis to ensure appropriate treatment decisions (**Table 120-10**). The impact of patient adherence on the success of treatment cannot be overemphasized. Patients need to be educated about their disease, expectations of treatment, and prevention of recurrence, and various strategies have been suggested to improve treatment success.[79]

TABLE 120-10 Factors That May Impact Treatment Decisions and Outcomes

- Type and severity of onychomycosis
- Causative organism—dermatophyte vs molds or yeast
- Infection of the finger vs toenail
- Extent of disease—involvement of matrix, one or two lateral edges, number of nails
- Thickness of nail plate
- Other sites of mycotic infection (palms, soles, toe webs)
- Other nail alterations affecting outcome (onycholysis, paronychia, dermatophytoma, etc.)
- Other nail diseases and symptoms
- Age and underlying medical conditions (diabetes, poor perfusion, immunocompromised)
- Drug interactions and adverse effects
- Cost of therapy

Data from references 67, 76, 78, and 79.

In general, onychomycosis of the toenail is more difficult to treat than fingernails, requires longer treatment duration, and is associated with a higher recurrence. The treatment options for onychomycosis include oral and topical therapies, mechanical or chemical nail avulsion, or a combination of these. Mechanical or chemical nail avulsion is used primarily as adjunct to oral therapy in patients with total dystrophic onychomycosis, in whom there is severe onycholysis and extensive nail thickening or longitudinal spikes. This is to enhance penetration of the antifungal agent to the entire nail plate and unit.[78,79,85]

Topical Therapy

Diffusion of topically applied drugs is impeded by the hard keratin and compact structure of the dorsal nail plate. The hydrophilic nature of the nail plate also inhibits absorption of most lipophilic molecules.[78]

10 Conventional topical antifungal products are available as creams, ointments, powders, and solutions. Because these formulations do not penetrate through the nail plate to the nail bed, they are most appropriately used when the nail plate has been removed.[80,85] Even then cure rates are still low and variable and are influenced by patient adherence.[80,81] Efinaconazole is a new triazole antifungal formulated as a topical solution with a novel applicator and tavaborole, a novel boron-based molecule that is the latest development in the management of onychomycosis.[85,86]

The most often recommended topical therapies for onychomycosis include amorolfine, ciclopirox, and the newer agents efinaconazole and tavaborole.[85] Amorolfine 5% and ciclopirox 8% solution (Penlac), are available as nail lacquers, the latter being the only one approved in the United States for the treatment of mild-to-moderate onychomycosis caused by *T. rubrum* without lunula involvement.[79,85] The volatile vehicle, used to deliver the drug, evaporates and leaves an occlusive film with a high drug concentration on the nail surface.[78,85] Ciclopirox, a hydroxypyridine, has a broad spectrum of antifungal activity (dermatophytes, *Candida* species, and some molds) and requires treatment for 1 year. Although ciclopirox was significantly better than vehicle alone, the mycologic cure rate was only 32% with ciclopirox versus 10% for vehicle alone after 48 weeks of treatment; the overall treatment cure (mycologic cure with 0%-10% involvement of the target nail) was 9% versus 0.9% for drug and vehicle, respectively.[85] Concomitant nail debridement accompanied treatment in most ciclopriox studies. Higher mycologic cure rates of 45% to 65% have been reported in open-label trials involving 6 to 12 months of treatment.[86] Amorolfine appears to produce higher mycologic and treatment cure rates than ciclopirox but is not approved for use in the United States or Canada.[80,85] Efinaconazole is a triazole antifungal approved as a 10% topical solution for the treatment of DLSO. Efinaconazole was evaluated in two phase III randomized controlled trials enrolling adult patients with mild to moderate DLSO of the great toenail. Patients were treated with once daily administration for 48 weeks without concomitant nail debridement. At 4 weeks post-treatment there was significantly greater mycological cure rates in the eficonazole group (55.2%) versus the vehicle controls (16.8%).[86]

Tavaborole 5% solution is a novel boron-based antifungal agent approved for the treatment of toenail onychomycosis involving 20% to 60% of the nail without spikes and lunula involvement. Tavaborole 5% solution applied to the affected great toenail once daily for 48 weeks was compared to vehicle in two phase III trials. Complete cure was achieved in 6.5% of tavaborole treated patients versus 0.5% vehicle controls in trial 1 and 9.1% versus 1.5% respectively in trial 2. Mycologic cure rates were significantly higher with tavaborole compared to vehicle control at 31.1% and 35.9% versus 7.2% and 12.2% in trials 1 and 2, respectively.[87] Unfortunately no studies comparing any of the approved agents head to head have been conducted. Most experts consider topical therapy a feasible option when the infection is superficial involving the nail plate without matrix involvement, such as WSO, involves a partial area of the nail plate not exceeding 50% (owing to difficulty of applying treatment to the margin of the nail), is limited to a few (three or four) nails, is in the very early stages of DSO when infection is still confined to the distal edge of the nail, or when systemic therapy is contraindicated.[78,79] Combining topical therapy with debridement of the affected nail (thus diminishing the amount of nail requiring treatment) may increase the likelihood of successful treatment, although there is no strong supporting evidence and this practice has not been a consistent component of clinical trials.[84,85,86] Topical therapy is not associated with systemic adverse effects or drug interactions. Any adverse effect will be localized to the application site, such as mild erythema in the adjacent skin area.

Clinical Controversy…

Treatment of onychomycosis is associated with a high failure rate of 20% to 50%. There appears to be

a sound pharmacologic rationale behind the use of topical therapy and concomitant nail debridement to improve overall efficacy. However, this approach had not been consistently employed in clinical trials making it unclear if nail debridement should be routinely performed nor is it possible to compare outcomes between studies that have included debridement to those that have not.

Systemic Therapy

Oral antifungal therapy is considered to be more effective than topical for treating onychomycosis. Terbinafine and itraconazole (capsule), the current first-line agents for treatment, have yielded higher efficacy rates using shorter treatment periods (generally 3 months or shorter) for toenail and fingernail onychomycosis compared with the traditional agents, such as griseofulvin and ketoconazole, which are rarely used nowadays. Terbinafine, an allylamine, exerts fungicidal activity and demonstrates the greatest in vitro activity against dermatophytes compared with the other oral antifungals; it has good activity against nondermatophyte molds and only marginal activity against *Candida* species.[78,85] Like other azoles, itraconazole is fungistatic, has a broad antifungal spectrum, and is very active against dermatophytes, nondermatophytes, and *Candida* species.[78] Both agents have lipophilic and keratinophilic properties, which explains their excellent penetration (appearing in the nail plate within days of treatment initiation) and accumulation in the nails, achieving concentrations far exceeding the minimal inhibitory concentration (MIC) of most dermatophytes. Nail terbinafine concentrations are detected within 1 week of starting therapy, whereas itraconazole can be detected 1 (fingernails) to 2 weeks (toenails) after starting therapy.[81] Both drugs are slowly eliminated from the nail, with effective drug concentrations persisting in nails for 30 to 36 weeks after completion of treatment with terbinafine and for 27 weeks with itraconazole.[83] The persistence of drug in the nails explains in part the long-term protection against relapses after the end of treatment and also permits use of intermittent (pulse) dosing.

The treatment of toenail onychomycosis requires a 12-week course, whereas a 6-week course is adequate for fingernail onychomycosis with either drug.[83,85] In general, cure rates of 80% to 90% for fingernail infection and 70% to 80% for toenail infection can be expected.[79] Terbinafine is approved for daily dosing (see Table 120-8).[79,83] Various terbinafine pulse regimens have been evaluated;[78] in some trials, pulse dosing was less effective than continuous dosing, and it did not provide clear safety advantages.[81] Pulse terbinafine had similar efficacy to continuous therapy had better outcomes compared with pulse itraconazole treatment.[88] Itraconazole pulse therapy is the preferred method over continuous dosing for fingernail infections, and it is licensed as twice-daily dosing for a 1-week cycle per month for 2 consecutive months (ie, two pulses), or as daily therapy for 6 weeks (see Table 120-8).[83] Although itraconazole pulse therapy is not approved by the U.S. Food and Drug Administration (FDA), three or four pulses are effective for toenail infections; otherwise, half the dose is taken daily for 3 months (see Table 120-8).[83] In addition to lower drug cost, the potential advantages of itraconazole pulse therapy compared with continuous therapy are a lower risk of adverse drug effects and improved patient adherence.

Terbinafine is generally considered by most experts as the first-line agent for onychomycosis;

itraconazole is the alternative. It is more effective than itraconazole by continuous or pulse dosing.[78,79] Mycologic cure rates for terbinafine range from 77% to 100% depending on the study.[81,89,90] In a cumulative meta-analysis of randomized, controlled trials, mycologic cure rates for terbinafine, itraconazole pulse, itraconazole continuous, fluconazole, and griseofulvin were 76%, 63%, 59%, 60%, and 48%, respectively.[91] An earlier meta-analysis and systematic review also reported that continuous terbinafine was the most effective therapy for toenail onychomycosis.[9192,93] In addition, terbinafine was reported to achieve high cure rates in high-risk immunosuppressed patients, such as diabetics and organ transplant recipients, comparable to the immunocompetent population, with no significant adverse effects or drug interactions. It also appears to be effective in HIV patients and nondermatophyte infections.[78,94] A pharmacoeconomic analysis of oral and topical (ciclopirox) therapies showed that from a managed-care perspective, terbinafine was the most cost-effective therapy in terms of highest success rate, lowest relapse rate, and highest number of disease-free days for both fingernail and toenail infections.[95] The cost per cure with the use of oral terbinafine (based on cure rates from clinical trials) ranged from $2,439 to $7,944, depending on disease severity.[96] Compared with the amount of money a patient would consider reasonable to spend on treatment, the current charges for a course of systemic therapy are considerably higher.[96,97]

Both terbinafine and itraconazole generally are well tolerated. The more common adverse effects reported with terbinafine are GI (eg, diarrhea, dyspepsia, nausea, and abdominal pain), dermatologic (eg, rash, urticaria, and pruritus), and headache; less common adverse effects are taste disturbances, fatigue, inability to concentrate, and asymptomatic liver enzyme abnormalities.[81,85] Terbinafine can cause transient decrease in absolute lymphocyte counts; hence, monitoring of complete blood counts can be useful, especially in immunocompromised patients.[98] Although uncommon, severe adverse effects have been reported with terbinafine, including erythema multiforme, Stevens-Johnson's syndrome, toxic epidermal necrolysis, pancytopenia, lupus erythematosus, psoriasis, hair loss, and hepatotoxicity. Although the incidence of severe hepatotoxicity is considered rare, the FDA issued a public health advisory in 2001 regarding the association of terbinafine tablets with 16 possible cases of liver failure, including 2 liver transplants and 11 deaths.[99] Terbinafine thus is not recommended for patients with chronic or active liver disease, although hepatotoxicity can occur in patients with no preexisting liver disease or serious underlying medical condition. Prior to initiating terbinafine treatment, it is recommended to obtain appropriate nail specimens for laboratory testing to confirm the diagnosis of onychomycosis. Liver function parameters (serum transaminases) should be assessed at baseline and periodically during treatment with terbinafine.[98,99]

The common adverse effects of itraconazole are similar to those of terbinafine, such as GI disturbance, dermatologic disorders, and headache; less common adverse effects include dizziness, fatigue, fever, decreased libido, and asymptomatic liver enzyme abnormalities (1%-5% with continuous dosing and ~2% with pulse dosing).[83,100] Although still considered rare, 24 serious cases of liver failure, including transplantation and death, have been reported with the use of itraconazole, resulting in an FDA public health advisory warning.[99] Some of these patients did not have preexisting liver disease or serious underlying medical conditions, and some developed within the first week of treatment. Itraconazole should be avoided in patients with elevated liver enzymes or active liver disease or in those who have experienced other drug-induced liver toxicity. Liver function parameters

(serum transaminases) should be assessed prior to and periodically during treatment. However, some experts have suggested that frequent monitoring is not as necessary if pulse therapy is used because symptomatic hepatotoxicity has not been reported with pulse therapy.[100] In addition, there is an FDA warning on the risk of developing congestive heart failure (CHF) associated with the use of itraconazole, possibly related to its potential negative inotropic effect.[78,89] Therefore, itraconazole should not be used in patients with evidence of ventricular dysfunction, such as CHF. Symptomatic assessment for the development of CHF also should be included as part of therapy monitoring. Before a patient is subjected to several months of itraconazole treatment, it is important to confirm the diagnosis of onychomycosis.

In contrast to the azoles, terbinafine does not inhibit the CYP 3A4 isoenzymes, but it is a potent inhibitor of the CYP2D6 isoenzymes, which are responsible for metabolism of tricyclic antidepressants and other psychotropic drugs.[78,83,98] The most significant drug interactions with terbinafine are decreased clearance of 33% by cimetidine and increased clearance of 100% by rifampin. Other drug interactions of variable clinical significance are tricyclic antidepressants, cyclosporine, caffeine, theophylline, and terfenadine. Itraconazole and its major metabolite can inhibit the CYP3A4 isoenzymes and result in numerous clinically significant drug interactions where coadministration with several drugs are contraindicated (eg, alprazolam, midazolam, triazolam, pimozide, lovastatin, simvastatin, cisapride, and terfenadine).[78,83,98]

Fluconazole is also active against dermatophytes, *Candida* species, and some nondermatophytes;[78,83] however, it does not have current FDA-approved indication for treatment of onychomycosis. The overall mycologic cure rate of fluconazole is 48%, which is lowest compared with all other oral agents.[91] The most effective dose and treatment duration have not been clearly established, with a variety of dosing regimens used, ranging from 50 mg daily to 300 mg once weekly for 6 to 12 months (see Table 120-8).[87,98] The advantages of fluconazole include a relatively good safety profile and fewer drug interactions compared with itraconazole.[83,98]

These three oral antifungal agents have superseded the use of griseofulvin and ketoconazole as treatments of choice for onychomycosis.[78,79] Griseofulvin has a narrow antifungal spectrum, low clinical efficacy, especially for toenail infections, high relapse rates, and the need for prolonged treatment duration (up to 12-18 months for toenails). Use of ketoconazole is also associated with high relapse rates, and the prolonged treatment duration carries an increased risk of hepatotoxicity.

Treatment Response and Recurrence

Treatment failures and recurrence rates of infection following initial cure are high, ranging from 20% to 50%.[78,79,84] Recurrence could be either a relapse (original infection not completely cured) or reinfection (new infection after achieving a cure of the original). Factors associated with poor response to systemic therapy include a compromised immune system (AIDS), reduced blood flow (diabetes, peripheral vascular disease, vasculitis, connective tissue disease, and CHF), coexisting nail disease (psoriasis), nail factors (slow growth, thick nails, and severe disease), drug-resistant organisms because of extensive prior drug exposure, and reduced bioavailability (absorption problems, poor

compliance, and drug interactions).[83,84] To improve treatment outcomes and reduce recurrence, patients should be counseled on the importance of proper foot hygiene, for example, wearing breathable footwear and 100% cotton socks with frequent changes, keeping the nails short and clean, keeping the feet dry, protecting the feet in shared bathing areas, treating tinea pedis, and controlling other predisposing medical conditions.[84]

The use of combination therapy (topical–oral) has been suggested to provide antifungal synergy, broader antifungal spectrum, increased cure rates, suppression of resistant mutants and enhancement of tolerability and safety.[78] Combination therapy could shorten treatment duration of therapy, as this approach provides complementary mechanisms of attack.[78] Ciclopirox, amorolfine and topical imidazoles have all been studied in combination with systemic antifungal agents (eg, tioconazole 28% with griseofulvin 1 g for 1 year; amorolfine 5% with pulsed itraconazole; amorolfine 5% with oral terbiafine) and reported favorable results. Conversely, a study of combination amorolfine 5% or ciclopriox 8% nail lacquer with pulsed oral terbinafine did not offer any advantage over pulsed oral terbinafine monotherapy.[101] To date, no specific combination has been approved or endorsed for use.

Clinical Controversy...

The optimal dosing regimen of terbinafine therapy in onychomycosis remains unclear. Either continuous, or pulse therapy can be used, Selection should be based on cost and adherence to therapy.

Chapter 121: Invasive Fungal Infections

Peggy L. Carver

INTRODUCTION

KEY CONCEPTS

- 1 Systemic mycoses can be caused by pathogenic fungi and include histoplasmosis, coccidioidomycosis, cryptococcosis, blastomycosis, paracoccidioidomycosis, and sporotrichosis, or infections by opportunistic fungi such as *Candida albicans*, *Aspergillus* species, *Trichosporon*, *Candida glabrata*, *Fusarium*, *Alternaria*, and *Mucor*.
- 2 The diagnosis of fungal infection generally is accomplished by careful evaluation of clinical symptoms, results of serologic tests, and histopathologic examination and culture of clinical specimens. Rapid, accurate diagnostic laboratory tests are currently under development.
- 3 Histoplasmosis is caused by *Histoplasma capsulatum* and is endemic in parts of the central United States along the Ohio and Mississippi River valleys. Although most patients experience asymptomatic infection, some can experience chronic, disseminated disease.
- 4 Asymptomatic patients with histoplasmosis are not treated, although patients who do not have acquired immune deficiency syndrome (AIDS) patients with evident disease are treated with either oral ketoconazole or IV amphotericin B; AIDS patients are treated with amphotericin B and then receive lifelong suppression.
- 5 Blastomycosis is caused by *Blastomyces dermatitidis*. In the immunocompetent host, acute pulmonary blastomycosis can be mild and self-limited and may not require treatment. However, consideration should be given to treating all infected individuals to prevent extrapulmonary dissemination. All persons with moderate to severe pneumonia, disseminated infection, or those who are immunocompromised require antifungal therapy.
- 6 Coccidioidomycosis is caused by *Coccidioides immitis* and is endemic in some parts of the southwestern United States. It can cause nonspecific symptoms, acute pneumonia, or chronic pulmonary or disseminated disease. Primary pulmonary disease (unless severe) frequently is not treated, whereas extrapulmonary disease is treated with amphotericin B, and meningitis is treated with fluconazole.
- 7 Cryptococcosis is caused by *Cryptococcus neoformans*, which occurs primarily in immunocompromised patients, and *Cryptococcus gattii*, which occurs primarily in nonimmunocompromised patients. Patients with acute meningitis are treated with amphotericin B with flucytosine. Patients infected with human immunodeficiency virus (HIV) often require long-term suppressive therapy with fluconazole or itraconazole.
- 8 A variety of *Candida* species (including *C. albicans*, *C. glabrata*, *Candida tropicalis*, *Candida parapsilosis*, and *Candida krusei*) can cause diseases such as mucocutaneous, oral, esophageal, vaginal, and hematogenous candidiasis, as well as candiduria. Candidemia can be treated with a variety of antifungal agents; the optimal choice depends on previous patient exposure to antifungal agents, potential drug interactions and toxicities of each agent, and local epidemiology of intensive care unit (ICU) or hematology–oncology centers.
- 9 Aspergillosis can be caused by a variety of *Aspergillus* species that can cause superficial infections, pneumonia, allergic bronchopulmonary aspergillosis (BPA), or invasive infection. Voriconazole has emerged as the drug of choice of most clinicians for primary therapy of most patients with invasive aspergillosis (IA). Combination therapy, while widely used, lacks clinical trial data to support its use.

1 Advances in medical technology including organ and bone marrow transplantation, cytotoxic chemotherapy, the widespread use of indwelling IV catheters, and the increased use of potent broad-spectrum antimicrobial agents all have contributed to the dramatic increase in the incidence of fungal infections worldwide.[1,2,3] Problems remain in the diagnosis, prevention, and treatment of fungal infections.[1,4,5,6] The Infectious Diseases Society of America (IDSA) publishes guidelines regarding the prophylaxis and treatment of many commonly encountered fungal infections.[7,8,9,10,11,12]

MYCOLOGY

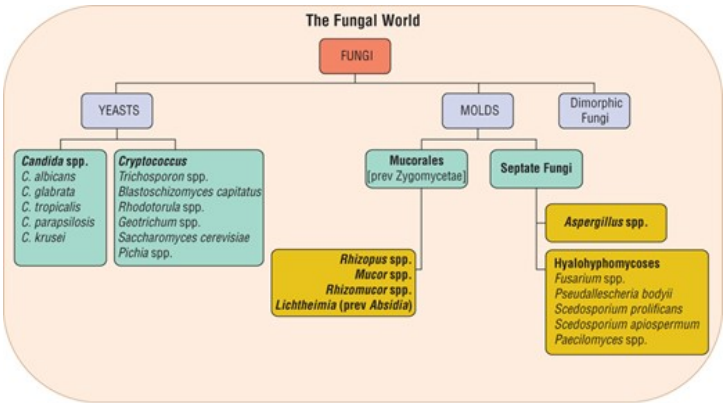
Fungi are eukaryotic organisms with a defined nucleus enclosed by a nuclear membrane; a cytoplasmic membrane containing lipids, glycoproteins, and sterols, mitochondria, golgi apparatus, and ribosomes bound to endoplasmic reticulum; and a cytoskeleton with microtubules,

microfilaments, and intermediate filaments. Fungi have rigid cell walls composed of chitin, cellulose, or both that stain with Gomori methenamine silver or periodic acid–Schiff reagent. Most fungi, except *Candida* species, are too weakly Gram-positive to be seen well on Gram stain. *Cryptococcus neoformans* has a polysaccharide capsule surrounding the cell wall.[1]

Morphologically, pathogenic fungi can be grouped as either filamentous molds or unicellular yeasts (**Fig. 121-1**). *Molds* grow as multicellular branching, threadlike filaments (hyphae) that are either septate (divided by transverse walls) or coenocytic (multinucleate without cross walls). Yeasts are oval or spherically shaped unicellular forms that generally produce pasty or mucoid colonies on agar medium similar to those observed with bacterial cultures. Yeasts have rigid cell walls and reproduce by budding, a process in which daughter cells arise from pinching off a portion of the parent cell.

FIGURE 121-1

Morphologically, pathogenic fungi can be grouped as either filamentous molds or unicellular yeasts. *Molds* grow as multicellular branching, thread-like filaments (hyphae) that are either septate (divided by transverse walls) or coenocytic (multinucleate without cross walls).



Many pathogenic fungi, termed *dimorphic fungi*, exist as either a yeast or a mold, depending on pathogen, site of growth (in the host or in the laboratory setting), and temperature. Usually yeasts are the parasitic form that invades human or animal host tissue, whereas molds are the free-living form found in the environment. For example, *Histoplasma capsulatum* exists as a yeast in humans and as a mold in the laboratory.[1]

Clinical Versus Microbial Resistance

Host factors contribute greatly to clinical outcome. A patient may respond clinically to treatment with an antifungal agent despite resistance to that agent in vitro because the patient's own immune system may eradicate the infection, or the agent may reach the site of infection in high concentrations.[13] Thus, in vitro susceptibility does *not* necessarily equate with in vivo clinical success, and in vitro resistance might *not* always correlate with treatment failure.

It is important to distinguish between clinical resistance and microbial resistance. *Clinical resistance* refers to failure of an antifungal agent in the treatment of a fungal infection that arises from factors other than microbial resistance, such as failure of the antifungal agent to reach the site of infection or inability of a patient's immune system to eradicate a fungus whose growth is retarded by an antifungal agent.[13,14]

Microbial resistance can refer to *primary* or *secondary* resistance, as determined by in vitro susceptibility testing using standardized methodology. *Primary* or *intrinsic resistance* refers to resistance recorded prior to drug exposure in vitro or in vivo. *Secondary* or *acquired resistance* develops on exposure to an antifungal agent and can be either reversible, owing to transient adaptation, or acquired as a result of one or more genetic alterations. It is possible for a patient to respond clinically to treatment with an antifungal agent, despite resistance to that agent in vitro, because the patient's own immune system may eradicate the infection, or the agent reaches the site of infection in high concentrations.[6]

Susceptibility Testing of Antifungal Agents

Most laboratories do not routinely perform susceptibility tests on fungal isolates, but standardized methods for performing these tests are being developed and are now available for testing selected yeasts. As the prevalence of nosocomial and community-acquired fungal infections become more prominent, the need for in vitro susceptibility testing increases. Susceptibility testing occasionally is indicated, for example, in a patient with prolonged fungemia with a presumed susceptible isolate, and is most helpful in dealing with infections caused by non-*albicans* species of *Candida*.[5,6,7]

Clinical breakpoints (CBPs) are antimicrobial concentrations (MICs) obtained from susceptibility testing, which are used to define isolates as susceptible, intermediate, or resistant. No CBPs have been established for posaconazole or amphotericin B versus *Candida*, or for antifungal agents and filamentous fungi such as *Aspergillus*.[6] CBPs can be used to differentiate strains for which there is a high likelihood of treatment success (organisms which are clinically susceptible, or (S), from those for which treatment is more likely to fail (clinically resistant [R]). (**Tables**

121-1 and **121-2**). A clinically intermediate (I) or susceptible dose-dependent (SDD) category can be assigned to pathogens for which the level of antimicrobial agent activity is associated with uncertain therapeutic effect, implying that infections due to the isolate may be appropriately treated in body sites where the drugs are physically concentrated or when a high dosage of drug can be used. Although CBPs are designed to guide therapy, they do not distinguish between fungal isolates with or without resistance mechanisms, nor do they always allow for early detection of resistant isolates. **Table 121-3** shows the currently approved Interpretive CBPs for *Candida* species.

TABLE 121-1 General Patterns of Susceptibility and Interpretive Breakpoints of *Candida* Species[a]

	Patterns of Susceptibility								
	Azoles			***Echinocandins***			***Amphotericin***		
***Candida* Species**	**Fluconazole**	**Itraconazole**	**Voriconazole**	**Posaconazole**	**Isavuconazole**	**Caspofungin**	**Micafungin**	**Anidulafungin**	**Amphotericin B**
C. albicans	+++ S	+++ S	+++ S	S	S	+++	+++	+++	+++
C. tropicalis	+++ S	+++ S	+++ S	+++ S	S	+++ S	+++ S	+++ S	+++ S
C. parapsilosis	S	S	S	S	S	S[d]	S[d]	S[d]	S
C. glabrata	++ S-DD to R[b]	++ S-DD to R[c]	++	S	S	S	S	S	S-I[e]
C. krusei	R	S-DD to R[c]	S	S	S	S	S	S	S-I[e]
C. lusitaniae	S	S	S	S	S	S	S	S	S to R[f]

For antifungal drugs and pathogens for which susceptibility breakpoints have been established (fluconazole, itraconazole, voriconazole): S, susceptible; S-DD, susceptible-dose dependent (see the text); I, intermediate; R, resistant; NA, not applicable (has not been established for this antifungal against this pathogen).

[a]Except for amphotericin B, interpretations are based on the use of a broth sensitivity test.

[b]Approximately 15% of C. glabrata isolates are resistant to fluconazole.

[c]Approximately 46% of C. glabrata isolates and 31% of C. krusei isolates are resistant to itraconazole.

[d]Most isolates of C. parapsilosis have reduced susceptibility to echinocandins.

[e]A significant proportion of C. glabrata and C. krusei isolates has reduced susceptibility to amphotericin B.

[f]Although frank resistance to amphotericin B is not observed in all isolates, it is well described for isolates of C. lusitaniae

TABLE 121-2 General Patterns of In Vitro Susceptibility of Non-*Candida* Fungal Pathogens[a]

	Patterns of Susceptibility								
	Azoles			***Echinocandins***			**Amphotericin B**		
Pathogen	**Fluconazole**	**Itraconazole**	**Voriconazole**	**Posaconazole**	**Isavuconazole**	**Caspofungin**	**Micafungin**	**Anidulafungin**	**Amphotericin B**
Aspergillus									
A. fumigatus	No	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Yes

Resistance to Antifungal Agents

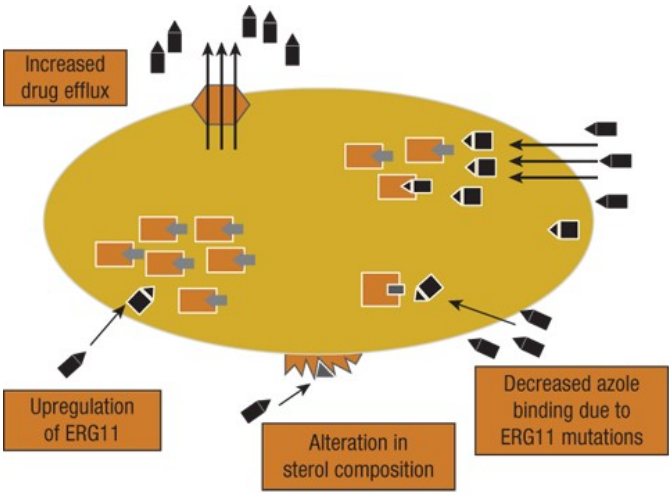
Understanding mechanisms of resistance is an important process in the optimization of antifungal therapy. The most exhaustive and definitive accounts of antifungal resistance have been described in *Candida* species, in particular *Candida albicans* and, to a lesser extent, *Candida glabrata*, *Candida tropicalis*, and *Candida krusei*, as well as in a few *C. neoformans* isolates.[13,14] *C. glabrata* isolates are increasingly resistant to both azole and echinocandin antifungal agents.

There are four different mechanisms that result in azole resistance: (a) mutations or upregulation of *ERG11* (an enzyme involved in the ergosterol biosynthesis pathway), (b) expression of multidrug efflux transport pumps that decrease antifungal drug accumulation within the fungal cell, (c) alteration of the structure or concentration of antifungal drug target proteins, and (d) alteration of membrane sterol proteins (**Fig. 121-2**). Although detailed analysis of each of the elucidated mechanism of resistance is beyond the scope this chapter, interested readers are referred to several recent publications which have comprehensively summarized this topic.[13,14]

FIGURE 121-2

Mechanisms of azole resistance. Four different mechanisms result in azole resistance: (a) mutations or upregulation of *ERG11*, the target enzyme

of azoles, (b) expression of multidrug efflux transport pumps that decrease antifungal drug accumulation within the fungal cell, (c) alteration of the structure or concentration of antifungal drug target proteins, and (d) alteration of membrane sterol proteins.



The most commonly reported mechanisms of azole resistance among *C. albicans* isolates include reduced permeability of the fungal cell membrane to azoles, modification or overproduction of the target fungal enzymes (cytochrome P450, CYP) resulting in decreased binding of the azole to the target site, alterations in sterol synthesis, and activation of efflux pumps capable of actively pumping azoles from the target pathogen.

Fluconazole resistance is observed most frequently in *C. glabrata*, which may appear S-DD, or resistant, and in *C. krusei*, for which fluconazole resistance is universal.

Azole resistance among *Aspergillus* spp. (specifically *A. fumigatus*) is predominantly mediated by specific point mutations in TR/L98H in the CYP51A gene promoter region, causing amino acid changes and tandem repeats, and often results in cross-resistance with azole antifungals.

With the increase in echinocandin use, there has been an increase in the number of reports of echinocandin-resistant isolates from patients failing therapy. Echinocandin exposure and previous episodes of *C. glabrata* are predictors of FKS gene mutations in *Candida*.[15,16,17]

Although, to date, the rate of amphotericin B resistance remains low, the exact incidence remains difficult to quantify and the response to antifungal agents difficult to characterize. As such, no consensus for therapy has been formulated at this time, although clinicians should keep in mind that *C. glabrata*, *Candida guilliermondii*, *C. krusei*, and *Candida lusitaniae* may have a higher propensity to developing resistance than other species.

Acquired resistance of *Aspergillus* species during long-term azole exposure to azoles, while still relatively uncommon, is emerging, and varies widely between geographic centers. Acquisition of primary-resistant isolates is also increasing, due to the agricultural use of azoles.[18,19] Cross-resistance of azole-resistant strains of *Aspergillus* to amphotericin B has not been described.

PATHOGENESIS AND EPIDEMIOLOGY

Systemic mycoses caused by primary or pathogenic fungi include histoplasmosis, coccidioidomycosis, cryptococcosis, blastomycosis, paracoccidioidomycosis, and sporotrichosis. Primary pathogens can cause disease in both healthy and immunocompromised individuals, although disease generally is more severe or disseminated in the immunocompromised host. In contrast, mycoses caused by opportunistic fungi such as *C. albicans*, *Aspergillus* species, *Trichosporon*, *Torulopsis (Candida) glabrata*, *Fusarium*, *Alternaria*, and *Mucor* generally are found only in the immunocompromised host.[1]

Most fungal infections are acquired as a result of accidental inhalation of airborne conidia. For example, *H. capsulatum* is found in soil contaminated by bat, chicken, or starling excreta, and *C. neoformans* is associated with pigeon droppings. Although some fungi, including *C. albicans*, *C. neoformans*, and *Aspergillus* species, are ubiquitous pathogens with worldwide distribution, other fungi have regional distributions associated with specific geographic environments.[1]

IFIs are a major cause of morbidity and mortality in the immunocompromised patient.[20,21] In patients with hematologic malignancies and following hematopoietic stem cell transplantation (HSCT), there has been a shift in the most commonly encountered IFIs from *Candida* spp. to *Aspergillus* spp. *Candida* species (primarily *C. albicans*) are the fourth most commonly isolated bloodstream isolate and account for 78% of all

nosocomial fungal infections.

Nosocomially acquired fungal infections can arise from either exogenous or endogenous flora. Endogenous flora can include normal commensal organisms of the skin, GI, genitourinary, or respiratory tract. *C. albicans* is found as a normal commensal of the GI tract in 20% to 30% of humans. A complex interplay of host and pathogen factors influences the acquisition and development of fungal infections. Intact skin or mucosal surfaces serve as primary barriers to infection. Alterations in the balance of normal flora caused by the use of antibiotics or alterations in nutritional status can allow the proliferation of fungi such as *Candida*, increasing the likelihood of systemic invasion and infection.[1]

Patients with decreased neutrophil counts or decreased neutrophil function are at higher risk of infections, particularly infections caused by *Candida* and *Aspergillus* species. Fungal cells sometimes can persist within macrophages without being killed, perhaps because of resistance to the effects of lysosomal enzymes.[1]

Risk Factors for Fungal Infections

Increasing use of aggressive and intensive cancer chemotherapeutic regimens, immunosuppressive therapy for autoimmune disorders, and transplantation have led to an increase in the number of susceptible hosts, contributing to the changing epidemiology of fungal infections. Infection epidemiology can drastically vary depending on patients' underlying concomitant conditions, comorbidities, confounding risk factors and geographical area.

A clinical indicator for a patient's immunologic status is the quantitation of absolute neutrophil count (ANC). Neutropenia, defined as an ANC less than equal to 500/mm^3 (less than equal to 0.5 × 10^9/L), dramatically escalates the risk of acquiring and opportunistic infection. However, recent studies have demonstrated that the shift in fungemic pathogens occur in both neutropenic and nonneutropenic patients.

There is an increased prevalence of fungemia in the general in-patient setting and in critically-ill, neutropenic, and transplant patients.[22,23,24,25,26] Major risk factors for *Candida* blood stream infections (BSIs) in ICU patients include the use of central venous catheters (CVCs), receipt of multiple antibiotics or parenteral nutrition (PN), extensive surgery and burns, renal failure and hemodialysis, mechanical ventilation, and prior fungal colonization.[27]

Diagnosis and Rapid Diagnostic Tests

2 Traditionally, the diagnosis of invasive fungal infections (IFIs) is accomplished by careful evaluation of clinical symptoms, results of serologic tests, and histopathologic examination and culture of clinical specimens. While traditional direct microscopy, culture and histological techniques constitute the 'gold standard' for diagnosis, obtaining biopsies from sterile body sites for these studies is a highly invasive approach that may not be possible in severely ill patients. Also, histopathology lacks sensitivity and selectivity, as several filamentous fungi may exhibit undistinguishable morphologies. Further, the finding of a positive culture from a sterile site may indicate transient colonization and not true infection, especially for opportunistic fungi. Fungi may require special laboratory conditions, with additional time (up to 4 days) required in order to obtain species identification and the results of susceptibility testing. Some species, such as *C. glabrata*, tend to grow more slowly; initial identification of yeast from blood averages 100 hours (~4 days) in most institutions.[28] Several rapid, accurate diagnostic laboratory tests, including matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF), peptide nucleic acid (PNA) in situ hybridization (PNA-FISH), PCR, galactomannan, and T2 magnetic resonance assays, have been developed which have the potential to enhance sensitivity and speed of diagnosis of IFIs.[29,30]

New laboratory methods that allow for early differentiation of IFIs due to *Aspergillus* species versus zygomycetes and other moulds would be helpful in allowing clinicians in the earlier initiation of appropriate antifungal therapy. These underscore the need for rapid diagnosis and identification of clinically significant isolates to species level, and the need for susceptibility testing.[31]

TREATMENT

Invasive Mycoses

Strategies for the prevention or treatment of invasive mycoses can be classified broadly as prophylaxis, early empirical therapy, empirical therapy, and secondary prophylaxis or suppression.[1] In patients undergoing cytotoxic chemotherapy, antifungal therapy is directed primarily at the prevention or treatment of infections caused by *Candida* and *Aspergillus* species. Prophylactic therapy with topical, oral, or IV antifungal agents is administered prior to and throughout periods of granulocytopenia (absolute neutrophil count less than 1,000 cells/L [less than 1 × 10^9/L]). The potential benefits of prophylactic therapy must be weighed against the potential risks inherent in each regimen, including safety, efficacy, cost, the prevalence of infection, and the potential consequences (eg, resistance) of widespread use.

Early empirical therapy is the administration of systemic antifungal agents at the onset of fever and neutropenia. Empirical therapy with systemic antifungal agents is administered to granulocytopenic patients with persistent or recurrent fever despite the administration of appropriate antimicrobial therapy.

Secondary prophylaxis (or suppressive therapy) is the administration of systemic antifungal agents (generally prior to and throughout the period of granulocytopenia) to prevent relapse of a documented invasive fungal infection that was treated during a previous episode of granulocytopenia.

Although these treatment classifications also have been applied to the treatment of fungal infections in acquired immunodeficiency syndrome (AIDS), patients with AIDS rarely acquire systemic infections caused by *Candida* or *Aspergillus* species, unless they become granulocytopenic because of disease or drugs.

HISTOPLASMOSIS

In humans, histoplasmosis is caused by inhalation of dust-borne microconidia of the dimorphic fungus *H. capsulatum*. Although there exist two dimorphic varieties of *H. capsulatum*, the small-celled (2-5 microns) form (var. *capsulatum*) occurs globally, whereas the large-celled (8-15 microns) form (var. *duboisii*) is confined to the African continent and Madagascar. In tissues stained by conventional techniques, *H. capsulatum* appears as an oval or round, narrow-pore, budding, unencapsulated yeast.[32]

Epidemiology

3 Although histoplasmosis is found worldwide, certain areas of North and Central America are recognized as endemic areas. In the United States, most disease is localized along the Ohio and Mississippi River valleys, where more than 90% of residents may be affected. Precise reasons for this endemic distribution pattern are unknown but are thought to include moderate climate, humidity, and soil characteristics. *H. capsulatum* is found in nitrogen-enriched soils, particularly those heavily contaminated by avian or bat guano, which accelerates sporulation. Blackbird or pigeon roosts, chicken coops, and sites frequented by bats, such as caves, attics, or old buildings, serve as "microfoci" of infections; once contaminated, soils yield *Histoplasma* for many years. Although birds are not infected because of their high body temperature, bats (mammals) may be infected and can pass yeast forms in their feces, allowing the spread of *H. capsulatum* to new habitats. Air currents carry the spores for great distances, exposing individuals who were unaware of contact with the contaminated site.[32]

Pathophysiology

At ambient temperatures, *H. capsulatum* grows as a mold. The mycelial phase consists of septate branching hyphae with terminal micro- and macroconidia that range in size from 2 to 14 microns in diameter. When soil is disturbed, these conidia become aerosolized and reach the bronchioles or alveoli.[32]

Animal studies demonstrate that within 2 to 3 days after reaching lung tissue, the conidia germinate, releasing yeast forms that begin multiplying by binary fission. During the next 9 to 15 days, organisms are ingested but not destroyed by large numbers of macrophages that are recruited to the infected site, resulting in small infiltrates. Infected macrophages migrate to the mediastinal lymph nodes and other sites within the mononuclear phagocyte system, particularly the spleen and liver. At this time, the onset of specific T-cell immunity in the nonimmune host activates the macrophages, rendering them capable of fungicidal activity. Tissue granulomas form, many of which develop central caseation and necrosis over the next 2 to 4 months. Over a period of several years, these foci become encapsulated and calcified, often with viable yeast trapped within the necrotic tissue.[32]

Cellular immunity, as measured by histoplasmin skin-test reactivity, wanes in the absence of occasional reexposure. Although exposure to heavy inocula can overcome these immune mechanisms, resulting in severe disease, reinfection occurs frequently in endemic areas. In the immune individual, the reactions of acquired immunity begin 24 to 48 hours after the appearance of yeast forms, resulting in milder forms of illness and little proliferation of organisms. Although viable organisms can be found within granulomas years after initial infection, the organisms appear to have little ability to proliferate within the fibrous capsules, except in immunocompromised patients.[32]

Clinical Presentation

The outcome of infection with *H. capsulatum* depends on a complex interplay of host, pathogen, and environmental factors.[10,32] Host factors include the degree of immunosuppression and the presence of immunity (from prior infection). Environmental factors include inoculum size, exposure within an enclosed area, and duration of exposure. Hematogenous dissemination from the lungs to other tissues probably occurs in all infected individuals during the first 2 weeks of infection before specific immunity has developed but is nonprogressive in most cases, which leads to the development of calcified granulomas of the liver and/or spleen. Progressive pulmonary infection is common in patients with underlying centrilobular emphysema.

Acute and chronic manifestations of histoplasmosis appear to result from unusual inflammatory or fibrotic responses to the pathogen, including pericarditis and rheumatologic syndromes during the first year after exposure, with chronic mediastinal inflammation or fibrosis, broncholithiasis, and enlarging parenchymal granulomas later in the course of disease.

Acute Pulmonary Histoplasmosis

In the vast majority of patients, low-inoculum exposure to *H. capsulatum* results in mild or asymptomatic pulmonary histoplasmosis. The course of disease generally is benign, and symptoms usually abate within a few weeks of onset. Patients exposed to a higher inoculum during an acute primary infection or reinfection can experience an acute, self-limited illness with flu-like pulmonary symptoms, including fever, chills, headache, myalgia, and a nonproductive cough. Patients with diffuse pulmonary histoplasmosis can have diffuse radiographic involvement, become hypoxic, and require ventilatory support. A low percentage of patients present with arthritis, erythema nodosum, pericarditis, or mediastinal

granuloma.

Chronic Pulmonary Histoplasmosis

Chronic pulmonary histoplasmosis generally presents as an opportunistic infection imposed on a preexisting structural abnormality, such as lesions resulting from emphysema. Patients demonstrate chronic pulmonary symptoms and apical lung lesions that progress with inflammation, calcified granulomas, and fibrosis. Patients with early, noncavitary disease often recover without treatment. Progression of disease over a period of years, seen in 25% to 30% of patients, is associated with cavitation, bronchopleural fistulas, extension to the other lung, pulmonary insufficiency, and often death.

Disseminated Histoplasmosis

In patients exposed to a large inoculum and in immunocompromised hosts, successful containment of the organism within macrophages may not occur, resulting in a progressive illness characterized by yeast-filled phagocytic cells and an inability to produce granulomas. This disease, termed *disseminated histoplasmosis*, is characterized by persistent parasitization of macrophages. The clinical severity of the diverse forms of disseminated histoplasmosis (**Table 121-4**) generally parallels the degree of macrophage parasitization observed.

TABLE 121-4 Clinical Manifestations and Therapy of Histoplasmosis

Type of Disease and Common Clinical Manifestations	Approximate Frequency (%)[a]	Therapy/Comments
Nonimmunosuppressed Host		
Acute pulmonary histoplasmosis		
Asymptomatic or mild to moderate disease	50-99	*Asymptomatic, mild, or symptoms <4 weeks:* No therapy generally required. Itraconazole (200 mg three times daily for 3 days and then 200 mg once or twice daily for 6-12 weeks) is recommended for patients who continue to have symptoms for 11 months *Symptoms >4 weeks:* Itraconazole 200 mg once daily × 6-12 weeks[b]
Self-limited disease	1-50	*Self-limited disease:* Amphotericin B[c] 0.3-0.5 mg/kg/day × 2-4 weeks (total dose 500 mg) or ketoconazole 400 mg orally daily × 3-6 months can be beneficial in patients with severe hypoxia following inhalation of large inocula; antifungal therapy generally not useful for arthritis or pericarditis; NSAIDs or corticosteroids can be useful in some cases
Mediastinal granulomas	1-50	Most lesions resolve spontaneously; surgery or antifungal therapy with amphotericin B 40-50 mg/day × 2-3 weeks or itraconazole 400 mg/day orally × 6-12 months can be beneficial in some severe cases; mild to moderate disease can be treated with itraconazole for 6-12 months
Moderately severe to severe diffuse pulmonary disease		Lipid amphotericin B 3-5 mg/kg/day followed by itraconazole 200 mg twice daily for 3 days then twice daily for a total of 12 weeks of therapy; alternatively, in patients at low risk for nephrotoxicity, amphotericin B deoxycholate 0.7-1 mg/kg/day can be utilized; methylprednisolone (0.5-1 mg/kg daily IV) during the first 1-2 weeks of antifungal therapy is recommended for patients who develop respiratory complications, including hypoxemia or significant respiratory distress
Inflammatory/fibrotic disease	0.02	*Fibrosing mediastinitis:* The benefit of antifungal therapy (itraconazole 200 mg twice daily × 3 months) is controversial but should be considered, especially in patients with elevated ESR or CF titers ≤1:32; surgery can be of benefit if disease is detected early; late disease cannot respond to therapy *Sarcoid-like:* NSAIDs or corticosteroids[d] can be of benefit for some patients *Pericarditis:* Severe disease: corticosteroids 1 mg/kg/day or pericardial drainage procedure
Chronic cavitary pulmonary histoplasmosis	0.05	Antifungal therapy generally recommended for all patients to halt further lung destruction and reduce mortality *Mild–moderate disease:* Itraconazole 200 mg three times daily for 3 days and then one or two times daily for at least 1 year; some clinicians recommend therapy for 18-24 months due to the high rate of relapse; itraconazole plasma concentrations should be obtained after the patient has been receiving this agent for at least 2 weeks *Severe disease:* Amphotericin B 0.7 mg/kg/day for a minimum total dose of 25-35 mg/kg is effective in 59%-100% of cases and should be used in patients who require hospitalization or are unable to take itraconazole because of drug interactions, allergies, failure to absorb drug, or failure to improve clinically after a minimum of 12 weeks of itraconazole therapy

Type of Disease and Common Clinical Manifestations	Approximate Frequency (%)[a]	Therapy/Comments
Histoplasma endocarditis		Amphotericin B (lipid formulations may be preferred, due to their lower rate of renal toxicity) plus a valve replacement is recommended; if the valve cannot be replaced, lifelong suppression with itraconazole is recommended
CNS histoplasmosis		Amphotericin B should be used as initial therapy (lipid formulations at 5 mg/kg/day, for a total dosage of 175 mg/kg may be preferred, due to their lower rate of renal toxicity) for 4-6 weeks, followed by an oral azole (fluconazole or itraconazole 200 mg two or three times daily) for at least a year; some patients may require lifelong therapy; response to therapy should be monitored by repeat lumbar punctures to assess *Histoplasma* antigen levels, WBC, and CF antibody titers; blood levels of itraconazole should be obtained to ensure adequate drug exposure
Immunosuppressed Host		
Disseminated histoplasmosis	0.02-0.05	*Disseminated histoplasmosis:* Untreated mortality 83%-93%; relapse 5%-23% in non-AIDS patients; therapy is recommended for all patients
Acute (Infantile)		*Nonimmunosuppressed patients:* Ketoconazole 400 mg/day orally × 6-12 months or amphotericin B 35 mg/kg IV
Subacute		*Immunosuppressed patients (non-AIDS) or endocarditis or CNS disease:* Amphotericin B >35 mg/kg × 3 months followed by fluconazole or itraconazole 200 mg orally twice daily × 12 months
Progressive histoplasmosis (immunocompetent patients and immunosuppressed patients without AIDS)		*Moderately severe to severe:* Liposomal amphotericin B (3 mg/kg daily), amphotericin B lipid complex (ABLC, 5 mg/kg daily), or deoxycholate amphotericin B (0.7-1 mg/kg daily) for 1-2 weeks, followed by itraconazole (200 mg twice daily for at least 12 months) *Mild to moderate:* Itraconazole (200 mg twice daily for at least 12 months)
Progressive disease of AIDS	25-50[e]	Amphotericin B 15-30 mg/kg (1-2 g over 4-10 weeks)[f] or itraconazole 200 mg three times daily for 3 days then twice daily for 12 weeks, followed by lifelong suppressive therapy with itraconazole 200-400 mg orally daily; although patients receiving secondary prophylaxis (chronic maintenance therapy) might be at low risk for recurrence of systemic mycosis when their $CD4^+$ T-lymphocyte counts increase to >100 cells/μL (>0.1 × 10^9/L) in response to HAART, the number of patients who have been evaluated is insufficient to warrant a recommendation to discontinue prophylaxis

AIDS, acquired immunodeficiency syndrome; CF, complement fixation; ESR, erythrocyte sedimentation rate; HAART, highly active antiretroviral therapy; NSAIDs, nonsteroidal antiinflammatory drugs; PO, orally.

[a]As a percentage of all patients presenting with histoplasmosis.

[b]Itraconazole plasma concentrations should be measured during the second week of therapy to ensure that detectable concentrations have been achieved. If the concentration is below 1 mcg/mL (mg/L; 1.4 μmol/L), the dose may be insufficient or drug interactions can be impairing absorption or accelerating metabolism, requiring a change in dosage. If plasma concentrations are greater than 10 mcg/mL (mg/L; 14 μmol/L), the dosage can be reduced.

[c]Deoxycholate amphotericin B.

[d]Effectiveness of corticosteroids is controversial.

[e]As a percentage of AIDS patients presenting with histoplasmosis as the initial manifestation of their disease.

[f]Liposomal amphotericin B (AmBisome) may be more appropriate for disseminated disease.

Data from references 10 and 32.

Acute (infantile) disseminated histoplasmosis is characterized by massive involvement of the mononuclear phagocyte system by yeast-engorged macrophages. Classically, this severe type of infection is seen in infants and young children and (rarely) in adults with Hodgkin's disease or other lymphoproliferative disorders. In infants or children, acute disseminated histoplasmosis is characterized by unrelenting fever, anemia, leukopenia or thrombocytopenia, enlargement of the liver, spleen, and visceral lymph nodes, and GI symptoms, particularly nausea, vomiting, and diarrhea. The chest roentgenogram often demonstrates remnants of the initiating acute pulmonary lesion. Untreated disease is uniformly fatal in 1 to 2 months. A less severe "subacute" form of the disease, which occurs in both infants and immunocompetent adults, is characterized by focal destructive lesions in various organs, weight loss, weakness, fever, and malaise. Untreated disease generally is fatal in approximately 10 months.

Most adults with disseminated histoplasmosis demonstrate a mild, chronic form of the disease. Untreated patients often are ill for 10 to 20 years,

demonstrating long asymptomatic periods interrupted by relapses of clinical illness characterized primarily by weight loss, weakness, and fatigue. Chronic disseminated histoplasmosis can be seen in patients with lymphoreticular neoplasms (Hodgkin's disease) and patients undergoing immunosuppressant chemotherapy for organ transplantation or for rheumatic diseases. Although CNS involvement occurs in 10% to 20% of patients with severe underlying immunosuppressive conditions, focal organ involvement is uncommon. The disease is characterized by the development of focal granulomatous lesions, often with bone marrow involvement resulting in thrombocytopenia, anemia, and leukemia. Fever, hepatosplenomegaly, and GI ulceration are common.

Histoplasmosis in HIV-Infected Patients

Adult patients with AIDS demonstrate an acute form of disseminated disease that resembles the syndrome seen in infants and children. Progressive disseminated histoplasmosis (PDH), which is defined as a clinical illness that does not improve after at least 3 weeks of observation and that is associated with physical or radiographic findings and/or laboratory evidence of involvement of extrapulmonary tissues, can occur as the direct result of initial infection or because of the reactivation of dormant foci. In endemic areas, 50% of AIDS patients demonstrate PDH as the first manifestation of their disease. PDH is characterized by fever (75% of patients), weight loss, chills, night sweats, enlargement of the spleen, liver, or lymph nodes, and anemia. Pulmonary symptoms occur in only one third of patients and do not always correlate with the presence of infiltrates on chest roentgenogram. A clinical syndrome resembling septicemia is seen in approximately 25% to 50% of patients.[10]

Diagnosis

The diagnosis of histoplasmosis is made on the basis of histopathology, cultures, antigen detection, and serologic tests for *Histoplasma*-specific antibodies. Detection of single, ovoid cells 2 to 5 microns in diameter with narrow-based budding by direct examination or by histologic study of blood smears or tissues should raise strong suspicion of infection with *H. capsulatum* because colonization does not occur as with *Aspergillus* or *Candida* infection. In patients with acute self-limited histoplasmosis, extensive testing to verify the diagnosis may not be necessary.[32,33]

In most patients, serologic evidence (complement fixation test or immunodiffusion testing) remains the primary method in the diagnosis of histoplasmosis. Detection of *Histoplasma* antigen by enzyme immunoassay (EIA) in the urine, blood, or bronchoalveolar lavage fluid of infected patients provides rapid diagnostic information and is particularly useful in patients who are severely ill. The highest sensitivity is obtained by testing both urine and serum.[34] *Histoplasma* EIA has also been used to monitor the course of therapy and to detect relapses in patients with AIDS, and the clearance of antigen from serum and urine correlates with clinical efficacy during maintenance therapy.[35]

TREATMENT

Non-HIV-Infected Patient

Table 121-4 summarizes the recommended therapy for the treatment of histoplasmosis. In general, asymptomatic or mildly ill patients and patients with sarcoid-like disease do not benefit from antifungal therapy. In the vast majority of patients, low-inoculum exposure to *H. capsulatum* results in *mild* or *asymptomatic* pulmonary histoplasmosis. The course of disease generally is benign, and symptoms usually abate within a few weeks of onset. Therapy can be helpful in symptomatic patients whose conditions have not improved during the first month of infection. Fever persisting more than 3 weeks can indicate that the patient is developing progressive disseminated disease, which can be aborted by antifungal therapy. Whether antifungal therapy hastens recovery or prevents complications is unknown because it has never been studied in prospective trials.

Fluconazole remains a second-line agent for the treatment of histoplasmosis. Clinical data regarding the use of newer azoles such as voriconazole and posaconazole are limited. While both have activity against *Histoplasma*, posaconazole appears to be more active than itraconazole in the immune compromised and nonimmune compromised mouse model of infection, while voriconazole has not been tested in animal models. Both agents have been used successfully in a few patients. Of note, the echinocandins have no activity against *Histoplasma*.

Patients with mild, self-limited disease, chronic disseminated disease, or chronic pulmonary histoplasmosis who have no underlying immunosuppression usually can be treated with either oral itraconazole or IV amphotericin B. The goals of therapy are resolution of clinical abnormalities, prevention of relapse, and eradication of infection whenever possible, although chronic suppression of infection can be adequate in immunosuppressed patients, including those with HIV disease.[10]

HIV-Infected Patient

In AIDS patients, intensive 12-week primary antifungal therapy (induction and consolidation therapy) is followed by lifelong suppressive (maintenance) therapy with itraconazole. Amphotericin B dosages of 50 mg/day (up to 1 mg/kg per day) should be administered IV to a cumulative dose of 15 to 35 mg/kg (1-2 g) in patients who require hospitalization. Amphotericin B can be replaced with itraconazole 200 mg orally twice daily when the patient no longer requires hospitalization or IV therapy to complete a 12-week total course of induction therapy. In patients who do not require hospitalization, itraconazole therapy for 12 weeks can be used.

Fluconazole 800 mg/day orally as induction, followed by 400 mg/day, was effective in 88% of patients, but relapses occurred in approximately one third of patients, and in vitro resistance developed in approximately 50% of patients who relapsed.

In regions experiencing high rates of histoplasmosis (greater than 5 cases/100 patient-years), itraconazole 200 mg/day is recommended as

prophylactic therapy in HIV-infected patients. Fluconazole is not an acceptable alternative because of its inferior activity against *H. capsulatum* and its lower efficacy for the treatment of histoplasmosis.[10]

Although patients receiving secondary prophylaxis (chronic maintenance therapy) might be at low risk for recurrence of systemic mycosis when their $CD4^+$ T lymphocyte counts increase to greater than 100 cells/μL (greater than 0.1×10^9/L) in response to highly active antiretroviral therapy (HAART), the number of patients who have been evaluated is insufficient to warrant a recommendation to discontinue prophylaxis.

Evaluation of Therapeutic Outcomes

Response to therapy should be measured by resolution of radiologic, serologic, and microbiologic parameters and by improvement in signs and symptoms of infection. Although investigators are limited by the lack of standardized criteria to quantify the extent of infection, degree of immunosuppression, or treatment response, response rates (based on resolution or improvement in presenting signs and symptoms) of greater than 80% have been reported in case series in AIDS patients receiving varied dosages of amphotericin B. Rapid responses are reported, with the resolution of symptoms in 25% and 75% of patients by days 3 and 7 of therapy, respectively.

After the initial course of therapy for histoplasmosis is complete, lifelong suppressive therapy with oral azoles or amphotericin B (1-1.5 mg/kg weekly or biweekly) is recommended because of the frequent recurrence of infection. Relapse rates in AIDS patients not receiving maintenance therapy range from 50% to 90%.[10]

Antigen testing can be useful for monitoring therapy since concentrations decrease with therapy and increase with relapse.

BLASTOMYCOSIS

North American blastomycosis is a systemic fungal infection caused by *Blastomyces dermatitidis*, a dimorphic fungus that infects primarily the lungs. Patients, however, can present with a variety of pulmonary and extrapulmonary clinical manifestations. Pulmonary disease can be acute or chronic and can mimic infection with tuberculosis, pyogenic bacteria, other fungi, or malignancy. Blastomycosis can disseminate to virtually every other body organ, and approximately 40% of patients with blastomycosis present with skin, bone and joint, or genitourinary tract involvement without any evidence of pulmonary disease.[8,36]

Pulmonary infection probably occurs by inhalation of conidia, which convert to the yeast form in the lung. A vigorous inflammatory response ensues, with neutrophilic recruitment to the lungs followed by the development of cell-mediated immunity and the formation of noncaseating granulomas.

Epidemiology

Blastomycosis was renamed *North American blastomycosis* in 1942, when Conant and Howell named a similar fungus endemic to South America, *Blastomyces braziliensis*, and the disease it caused *South American blastomycosis*. Although the disease is now recognized to be endemic to the southeastern and south central states of the United States (especially those bordering on the Mississippi and Ohio River basins) and the midwestern states and Canadian provinces bordering the Great Lakes, numerous cases of North American blastomycosis have been diagnosed in Africa, northern parts of South America, India, and Europe. Endemic areas have been defined primarily by analysis of sporadic cases and epidemics or clusters of disease because the lack of a dependable skin or laboratory test makes wide-scale epidemiologic testing to determine the incidence of infection unfeasible at present.[8,36] Although initial review of sporadic cases suggested that males with outdoor occupations that exposed them to soil were at greatest risk for blastomycosis, there is no sex, age, or occupational predilection for blastomycosis.[8,36]

Although *B. dermatitidis* generally is considered to be a soil inhabitant, attempts to isolate the organism in nature frequently have been unsuccessful. *B. dermatitidis* has been isolated from soil containing decayed vegetation, decomposed wood, and pigeon manure, frequently in association with warm, moist soil of wooded areas that is rich in organic debris.[8,36]

Pathophysiology and Clinical Presentation

Colonization does not occur with *Blastomyces*[8,36] *Acute pulmonary blastomycosis* generally is an asymptomatic or self-limited disease characterized by fever, shaking chills, and productive, purulent cough, with or without hemoptysis, in immunocompetent individuals. The clinical presentation can be difficult to differentiate from other respiratory infections, including bacterial pneumonia, on the basis of clinical symptoms alone.

Sporadic (nonepidemic) pulmonary blastomycosis can present as a more chronic or subacute disease, with low-grade fever, night sweats, weight loss, and productive cough that resembles tuberculosis rather than bacterial pneumonia. *Chronic pulmonary blastomycosis* is characterized by fever, malaise, weight loss, night sweats, chest pain, and productive cough. Patients often are thought to have tuberculosis and frequently have evidence of disseminated disease that can appear 1 to 3 years after the primary pneumonia has resolved. Reactivation of disease can occur in the lungs or as the focus of new infection in other organs.

In approximately 40% of patients, dissemination is not accompanied by reactivation of pulmonary disease. The most common sites for disseminated disease include the skin and bony skeleton, although less commonly the prostate, oropharyngeal mucosa, and abdominal viscera

are involved. CNS disease, while exceedingly uncommon, is associated with the highest mortality rate.

Laboratory and Diagnostic Tests

The simplest and most successful method of diagnosing blastomycosis is by direct microscopic visualization of the large, multinucleated yeast with single, broad-based buds in sputum or other respiratory specimens following digestion of cells and debris with 10% potassium hydroxide.[8,36] Histopathologic examination of tissue biopsies and culture of secretions also should be used to identify *B. dermatitidis*, although it can require up to 30 days to isolate and identify a small inoculum.

No reliable skin test exists to determine the incidence and prevalence of disease in endemic populations, and reliable serologic diagnosis of blastomycosis has long been hampered by the lack of specific and standardized reagents. Serologic response does not always correlate with clinical improvement, although some investigators have noted that a decline in the number of precipitins or CF titers can offer evidence of a favorable prognosis in patients with established disease.

Acute pulmonary blastomycosis generally is an asymptomatic or self-limited disease characterized by fever, shaking chills, and productive, purulent cough, with or without hemoptysis, in immunocompetent individuals. The clinical presentation can be difficult to differentiate from other respiratory infections, including bacterial pneumonia, on the basis of clinical symptoms alone. Sporadic (nonepidemic) cases of pulmonary blastomycosis can present as a more chronic or subacute disease with low-grade fever, night sweats, weight loss, and productive cough that resembles tuberculosis rather than bacterial pneumonia.

TREATMENT

Non-HIV-Infected Patient

5 In the immunocompetent host, acute pulmonary blastomycosis can be mild and self-limited and may not require treatment. However, consideration should be given to treating all infected individuals to prevent extrapulmonary dissemination. All individuals with moderate to severe pneumonia, disseminated infection, or those who are immunocompromised require antifungal therapy.

In patients with mild to moderate pulmonary blastomycosis, itraconazole is effective; however, in patients with moderately severe to severe pulmonary disease, the clinical presentation of the patient, the immune competence of the patient, and the toxicity of the antifungal agents are the main determinants of the choice of antifungal therapy. All immunocompromised patients and patients with progressive pulmonary disease or with extrapulmonary disease should be treated (**Table 121-5**). In the case of disease limited to the lungs, cure might have occurred without treatment before the diagnosis is made. Regardless of whether or not the patient receives treatment, however, he or she must be followed carefully for many years for evidence of reactivation or progressive disease.[8,36]

TABLE 121-5 Therapy of Blastomycosis

Type of Disease	Preferred Treatment
Pulmonary[a]	
Moderately severe to severe disease	Lipid formulation of amphotericin B 3-5 mg/kg IV daily or amphotericin B[b] 0.7-1 mg/kg IV daily (total dose 1.5-2.5 g) × 1-2 weeks or until improvement is noted, followed by itraconazole[c,d] 200 mg orally three times daily for 3 days, then 200 mg twice daily, × total of 6-12 months
Mild to moderate disease	Itraconazole[c,d] 200 mg orally three times daily for 3 days, then 200 mg twice daily, for a total of 6 months[c]
CNS disease	*Induction:* Lipid formulation of amphotericin B 5 mg/kg IV daily × 4-6 weeks, followed by an oral azole as consolidation therapy *Consolidation:* Fluconazole[d] 800 mg orally daily, or itraconazole[d] 200 mg two or three times orally daily, or voriconazole[d] 200-400 mg orally twice daily, for ≥12 months and until resolution of CSF abnormalities
Disseminated or Extrapulmonary Disease	
Moderately severe to severe disease	Lipid formulation of amphotericin B 3-5 mg/kg IV daily or amphotericin B[b] 0.7-1 mg/kg IV daily × 1-2 weeks or until improvement is noted, followed by itraconazole[c,d] 200 mg orally three times daily for 3 days, then 200 mg twice daily × 6-12 months. Treat osteoarticular disease with 12 months of antifungal therapy Most clinicians prefer to step-down to itraconazole[d] therapy once the patient's condition improves
Mild to moderate	Itraconazole[c,d] 200 mg orally three times daily for 3 days, then 200 mg once or twice daily × ≥12 months. Treat osteoarticular disease with 12 months of antifungal therapy
Immunocompromised Host (Including Patients with AIDS, Transplants, or Receiving Chronic Glucocorticoid Therapy)	
Acute disease	Lipid formulation of amphotericin B 3-5 mg/kg IV daily or amphotericin B[b] 0.7-1 mg/kg IV daily × 1-2 weeks or until improvement is noted, then give suppressive therapy for a total of at least 12 months of therapy
Suppressive therapy	Itraconazole[c,d] 200 mg orally three times daily for 3 days, then 200 mg twice daily for a total of at least 12 months of therapy; lifelong suppressive therapy with oral itraconazole[d] 200 mg daily may be required for immunosuppressed patients

Type of Disease	Preferred Treatment
	in whom immunosuppression cannot be reversed, and in patients who experience relapse despite appropriate therapy

AIDS, acquired immunodeficiency syndrome.

[a]In the immunocompetent host, acute pulmonary blastomycosis can be mild and self-limited and may not require treatment.

[b]Desoxycholate amphotericin B.

[c]Serum levels of itraconazole should be determined after the patient has received itraconazole for ≥2 weeks, to ensure adequate drug exposure.

[d]Azoles should not be used during pregnancy.

Data from reference 8.

Some authors recommend azole therapy for the treatment of self-limited pulmonary disease, with the hope of preventing late extrapulmonary disease; however, data supporting the efficacy of these regimens are lacking.[8,36] Itraconazole 200 to 400 mg/day demonstrated 90% efficacy as a first-line agent in the treatment of nonlife-threatening non-CNS blastomycosis, and for compliant patients who completed at least 2 months of therapy, a success rate of 95% was noted. No therapeutic advantage was noted with the higher (400 mg) dosage as compared with patients treated with 200 mg.

All patients with disseminated blastomycosis, as well as those with extrapulmonary disease, require therapy. Due to its adverse effects, variable oral absorption, and lack of CNS penetration, ketoconazole is now reserved as an alternative therapy for mild to moderate pulmonary and non-CNS disease. However, older studies demonstrate that ketoconazole 400 mg/day orally for 6 months cures more than 80% of patients with chronic pulmonary and nonmeningeal disseminated blastomycosis. Amphotericin B is more efficacious but more toxic and therefore is reserved for noncompliant patients and patients with overwhelming or life-threatening disease, CNS infection, and treatment failures.[8,36] Lipid preparations of amphotericin B have largely replaced conventional amphotericin B for treatment of blastomycosis, despite their higher cost, due to their decreased renal toxicity. Surgery has only a limited role in the treatment of blastomycosis.

HIV-Infected Patient

For unclear reasons, blastomycosis is an uncommon opportunistic disease among immunocompromised individuals, including AIDS patients; however, blastomycosis can occur as a late (CD4 lymphocytes less than 200 cells/mm^3 [less than 0.2 × 10^9/L]) and frequently fatal complication of HIV infection. In this population, overwhelming disseminated disease with frequent involvement of the CNS is common.[8,36] Following induction therapy with amphotericin B (total cumulative dose of 1 g), HIV-infected patients should receive chronic suppressive therapy with an oral azole antifungal.[8,36]

COCCIDIOIDOMYCOSIS

Epidemiology

Coccidioidomycosis is caused by infection with *Coccidioides immitis*, a dimorphic fungus found in the southwestern and western United States, as well as in parts of Mexico and South America. In North America, the endemic regions encompass the semiarid areas of the southwestern United States from California to Texas known as the Lower Sonoran Zone, where there is scant annual rainfall, hot summers, and sandy, alkaline soil. *C. immitis* grows in the soil as a mold, and mycelia proliferate during the rainy season. During the dry season, resistant arthroconidia form and become airborne when the soil is disturbed.

Although generally considered to be a regional disease, coccidioidomycosis has increased in importance in recent years because of the increased tourism and population in endemic areas, the increased use of immunosuppressive therapy in transplantation and oncology, and the AIDS epidemic. Although there is no racial, hormonal, or immunologic predisposition for acquiring primary disease, these factors affect the risk of subsequent dissemination of disease (**Table 121-6**).[37]

TABLE 121-6 Factors for Severe, Disseminated Infection with Coccidioidomycosis

Race (Filipinos > African Americans > Native Americans > Hispanics > Asians)

Pathophysiology

When individuals come in contact with contaminated soil during ranching, dust storms, or proximity to construction sites or archaeologic excavations, arthroconidia are inhaled into the respiratory tree, where they transform into spherules, which reproduce by cleavage of the cytoplasm to produce endospores. The endospores are released when the spherules reach maturity. Similar to histoplasmosis, an acute inflammatory response in the tissue leads to infiltration of mononuclear cells, ultimately resulting in granuloma formation.[37]

Clinical Presentation of Coccidioidomycosis

Coccidioidomycosis encompasses a spectrum of illnesses ranging from primary uncomplicated respiratory tract infection that resolves spontaneously to progressive pulmonary or disseminated infection.[37] Initial or primary infection with *C. immitis* almost always involves the lungs. Although approximately one third of the population in endemic areas is infected, the average incidence of symptomatic disease is only approximately 0.43%.

Signs and Symptoms

Primary Coccidioidomycosis ("*Valley Fever*"): Approximately 60% of infected patients have an asymptomatic, self-limited infection without clinical or radiological manifestations. The remaining 40% of patients exhibit nonspecific symptoms that are often indistinguishable from ordinary upper respiratory infections, including fever, cough, headache, sore throat, myalgias, and fatigue that occur 1 to 3 weeks after exposure to the pathogen. More commonly, a diffuse, mild erythroderma or maculopapular rash is observed. Patients can have pleuritic chest pain and peripheral eosinophilia.

A fine, diffuse rash can appear during the first few days of the illness. Primary pneumonia can be the first manifestation of disease, characterized by a productive cough that can be blood-streaked, as well as single or multiple soft or dense homogeneous hilar or basal infiltrates on chest roentgenogram. *Chronic, persistent pneumonia or persistent pulmonary coccidioidomycosis* (primary disease lasting more than 6 weeks) is complicated by hemoptysis, pulmonary scarring, and the formation of cavities or bronchopleural fistulas.

Necrosis of pulmonary tissue with drainage and cavity formation occurs commonly. Most parenchymal cavities close spontaneously or form dense nodular scar tissue that can become superinfected with bacteria or spherules of *C. immitis*. These patients often have persistent cough, fevers, and weight loss.

Disseminated disease occurs in less than 1% of infected patients. The most common sites for dissemination are the skin, lymph nodes, bone, and meninges, although the spleen, liver, kidney, and adrenal gland also can be involved. Occasionally, miliary coccidioidomycosis occurs, with rapid, widespread dissemination, often in concert with positive blood cultures for *C. immitis*. Patients with AIDS frequently present with miliary disease. Coccidioidomycosis in AIDS patients appears to be caused by reactivation of disease in most patients. Dissemination also is more likely if infection occurs during pregnancy, especially during the third trimester or in the immediate postpartum period.[37]

CNS infection occurs in approximately 16% of patients with disseminated coccidioidomycosis. Patients can present with meningeal disease without previous symptoms of primary pulmonary infection, although disease usually occurs within 6 months of the primary infection. The signs and symptoms are often subtle and nonspecific, including headache, weakness, changes in mental status (lethargy and confusion), neck stiffness, low-grade fever, weight loss, and occasionally, hydrocephalus. Space-occupying lesions are rare, and the main areas of involvement are the basilar meninges.

Diagnosis

The diagnoses of coccidioidomycosis generally utilizes identification or recovery of *Coccidioides* spp. from clinical specimens and detection of specific anticoccidioidal antibodies in serum or other body fluids.

TREATMENT

General Guidelines

6 Therapy for coccidioidomycosis is difficult, and the results are unpredictable. Guidelines[11] are available for treatment of this disease; however, optimal treatment for many forms of this disease still generates debate. The efficacy of antifungal therapy for coccidioidomycosis often is less certain than that for other fungal etiologies, such as blastomycosis, histoplasmosis, or cryptococcus, even when in vitro susceptibilities and the sites of infections are similar. The refractoriness of coccidioidomycosis can relate to the ability of *C. immitis* spherules to release hundreds of endospores, maximally challenging host defenses.[37] Fortunately, only approximately 5% of infected patients require therapy.

Goals of Therapy

Desired outcomes of treatment are resolution of signs and symptoms of infection, reduction of serum concentrations of anticoccidioidal antibodies, and return of function of involved organs. It would also be desirable to prevent relapse of illness on discontinuation of therapy, although current therapy is often unable to achieve this goal.

Specific Agents Used for the Treatment of Coccidioidomycosis

Azole antifungals, primarily fluconazole and itraconazole, have replaced amphotericin B as initial therapy for most chronic pulmonary or disseminated infections. Amphotericin B is now usually reserved for patients with respiratory failure because of infection with *Coccidioides* species, those with rapidly progressive coccidioidal infections, or women during pregnancy. Therapy often ranges from many months to years in duration, and in some patients, lifelong suppressive therapy is needed to prevent relapses. Specific antifungals (and their usual dosages) for the treatment of coccidioidomycosis include IV amphotericin B (0.5-1.5 mg/kg per day), ketoconazole (400 mg/day orally), IV or oral fluconazole (usually 400-800 mg/day, although dosages as high as 1,200 mg/day have been used without complications), and itraconazole (200-300 mg orally twice daily or three times daily, as either capsules or solution).[37] If itraconazole is used, measurement of serum concentrations can be helpful to ascertain whether oral bioavailability is adequate.

Amphotericin B generally is preferred as initial therapy in patients with rapidly progressive disease, whereas azoles generally are preferred in patients with subacute or chronic presentations. The lipid formulations of amphotericin B have not been studied extensively in coccidioidal infection but can offer a means of giving more drugs with less toxicity. Fluconazole probably is the most frequently used medicine given its tolerability, although high relapse rates have been reported in some studies. Relapse rates with itraconazole therapy can be lower than those with fluconazole.[37]

The usefulness of newly available antifungal agents of possible benefit for the treatment of refractory coccidioidal infections has not been adequately assessed and they are not yet FDA approved for use in this population. Case reports have suggested that voriconazole can be effective in selected patients. Caspofungin has been effective in treating experimental murine coccidioidomycosis, but in vitro susceptibility of isolates varies widely, and there is only one report regarding its value. Posaconazole was shown to be an effective treatment in a small clinical trial and in patients with refractory infections. Its efficacy relative to other triazole antifungals is unknown.

Clinical Controversy...

Although there is continued disagreement among experts in endemic areas whether antifungal therapy in patients with uncomplicated early coccidioidal infection might shorten the course of illness or reduce the development of more serious complications, prospective randomized trials addressing this question are lacking. The excellent tolerability of oral azoles has lowered the threshold for deciding to treat primary infection, and clinicians should treat patients with significantly debilitating illness, those with extensive pulmonary disease, and with who are frail due to advanced age, concurrent diabetes or comorbidities.[11]

Combination therapy with members of different classes of antifungal agents has not been evaluated in patients, and there is a hypothetical risk of antagonism. However, some clinicians feel that outcome in severe cases is improved when amphotericin B is combined with an azole antifungal. If the patient improves, the dosage of amphotericin B can be slowly decreased while the dosage of azole is maintained.[37]

Primary Respiratory Infection

Although most patients with symptomatic primary pulmonary disease recover without therapy, management should include followup visits for 1 to 2 years to document resolution of disease or to identify as early as possible evidence of pulmonary or extrapulmonary complications.

Patients with a large inoculum, severe infection, or concurrent risk factors (eg, HIV infection, organ transplant, pregnancy, or high doses of corticosteroids) probably should be treated, particularly those with high CF titers, in whom incipient or occult dissemination is likely. Because some racial or ethnic populations have a higher risk of dissemination, some clinicians advocate their inclusion in the high-risk group. Common indicators used to judge the severity of infection include weight loss (greater than 10%), intense night sweats persisting more than 3 weeks, infiltrates involving more than one half of one lung or portions of both lungs, prominent or persistent hilar adenopathy, CF antibody titers of greater than 1:16, failure to develop dermal sensitivity to coccidial antigens, inability to work, or symptoms that persist for more than 2 months.[37]

Commonly prescribed therapies include currently available oral azole antifungals at their recommended doses for courses of therapy ranging from 3 to 6 months.[37] In patients with diffuse pneumonia with bilateral reticulonodular or miliary infiltrates, therapy usually is initiated with amphotericin B; several weeks of therapy generally are required to produce clear evidence of improvement. Consolidation therapy with oral azoles can be considered at that time. The total duration of therapy should be at least 1 year, and in patients with underlying immunodeficiency, oral azole therapy should be continued as secondary prophylaxis.

Infections of the Pulmonary Cavity

Many pulmonary infections that are caused by *C. immitis* are benign in their course and do not require intervention. In the absence of controlled clinical trials, evidence of the benefit of antifungal therapy is lacking, and asymptomatic infections generally are left untreated. Symptomatic patients can benefit from oral azole therapy, although recurrence of symptoms can be seen in some patients once therapy is discontinued. Surgical resection of localized cavities provides resolution of the problem in patients in whom the risks of surgery are not too high.[37]

Extrapulmonary (Disseminated) Disease

Nonmeningeal Disease

Almost all patients with disease located outside the lungs should receive antifungal therapy; therapy usually is initiated with 400 mg/day of an oral azole. Amphotericin B is an alternative therapy and can be necessary in patients with worsening lesions or with disease in particularly critical locations such as the vertebral column. Approximately 50% to 75% of patients treated with amphotericin B for nonmeningeal disease achieve a sustained remission, and therapy usually is curative in patients with infections localized strictly to skin and soft tissues without extensive abscess formation or tissue damage. The efficacy of local injection into joints or the peritoneum, as well as intraarticular or intradermal administration, remains poorly studied. Amphotericin B appears to be most efficacious when cell-mediated immunity is intact (as evidenced by a positive coccidioidin or spherulin skin test or low CF antibody titer). Controlled trials that document these clinical impressions are lacking, however.[37]

Meningeal Disease

Fluconazole has become the drug of choice for the treatment of coccidioidal meningitis. A minimum dose of 400 mg/day orally leads to a clinical response in most patients and obviates the need for intrathecal amphotericin B. Some clinicians will initiate therapy with 800 or 1,000 mg/day, and itraconazole dosages of 400 to 600 mg/day are comparably effective. It is also clear, however, that fluconazole only leads to remission rather than cure of the infections; thus suppressive therapy must be continued for life. Ketoconazole cannot be recommended routinely for the treatment of coccidioidal meningitis because of its poor CNS penetration following oral administration. Patients who do not respond to fluconazole or itraconazole therapy are candidates for intrathecal amphotericin B therapy with or without continuation of azole therapy. The intrathecal dose of amphotericin B ranges from 0.01 to 1.5 mg given at intervals ranging from daily to weekly. Therapy is initiated with a low dosage and is titrated upward as patient tolerance develops.[37]

CRYPTOCOCCOSIS

Epidemiology

Cryptococcosis is a noncontagious, systemic mycotic infection caused by the ubiquitous encapsulated soil yeast *Cryptococcus*, which is found in soil, particularly in pigeon droppings, although disease occurs throughout the world, even in areas where pigeons are absent. Infections caused by *C. neoformans* var. *grubii* (serotype A) are seen worldwide among immunocompromised hosts, followed by *C. neoformans* var. *neoformans* (serotype D). On the other hand, *Cryptococcus gattii* (serotypes B and C) is geographically more restricted and in contrast to *C. neoformans*, rarely infects immunosuppressed patients, is not associated with HIV infection, and the infections are more difficult to treat. *C. gattii* is not associated with birds; its main reservoir was thought to be limited to certain species of eucalyptus tree. Until recently, it was most common in tropical and subtropical areas, such as Australia, South America, Southeast Asia, and central Africa, with the highest incidence in Papua New Guinea and Northern Australia, although infections occur in nontropical areas such as North America and Europe. *C. gattii* emerged on Vancouver Island, British Columbia, Canada, in 1999, and subsequently spread to the Vancouver lower mainland, Washington state, and Oregon.[38]

Infection is acquired by inhalation of the organism. The incidence of cryptococcosis has risen dramatically in recent years, reflecting the increased numbers of immunocompromised patients, including those with malignancies, diabetes mellitus, chronic renal failure, and organ transplants and those receiving immunosuppressive agents. In most developed countries, widespread use of HAART has significantly decreased the incidence of cryptococcosis; however, the incidence and mortality of this infection are still extremely high in areas with limited access to HAART and a high incidence of HIV.[39]

Disease can remain localized in the lungs or can disseminate to other tissues, particularly the CNS, although the skin also can be affected. Hematogenous spread generally occurs in the immunocompromised host, although it also has been seen in individuals with intact immune systems.

Clinical Presentation of Cryptococcosis

Primary cryptococcosis in humans almost always occurs in the lungs, although the pulmonary focus usually produces a subclinical infection.[38,39] Symptomatic infections usually are manifested by cough, rales, and shortness of breath that generally resolve spontaneously. Cryptococcus can present as part of an immune reconstitution inflammatory syndrome (IRIS), a paradoxical worsening of preexisting infectious processes following the initiation of HAART in HIV-infected individuals. In non-AIDS patients, the symptoms of cryptococcal meningitis are nonspecific. Headache, fever, nausea, vomiting, mental status changes, and neck stiffness generally are observed. Less common symptoms include visual disturbances (photophobia and blurred vision), papilledema, seizures, and aphasia. In AIDS patients, fever and headache are common, but meningismus and

photophobia are much less common than in non-AIDS patients. Approximately 10% to 12% of AIDS patients have asymptomatic disease, similar to the rate observed in non-AIDS patients.[39,40] Intracerebral mass lesions (cryptococcomas) are more common in *C. gattii* than in *C. neoformans*, presumably due to their different host immune responses.[38]

Laboratory Tests

With cryptococcal meningitis, the CSF opening pressure generally is elevated. There is a CSF pleocytosis (usually lymphocytes), leukocytosis, a decreased glucose concentration, and an elevated CSF protein concentration. There is also a positive cryptococcal antigen (detected by LA). The test is rapid, specific, and extremely sensitive, but false-negative results can occur. False-positive tests can result from cross-reactivity with rheumatoid factor and *Trichosporon beigelii. C. neoformans* can be detected in approximately 60% of patients by India ink smear of CSF, and it can be cultured in more than 96% of patients. Occasionally, large volumes of CSF are required to confirm the diagnosis.

The CSF parameters in patients with AIDS are similar to those seen in non-AIDS patients, with the exception of a decreased inflammatory response to the pathogen, resulting in a strikingly low number of leukocytes in CSF and extraordinarily high cryptococcal antigen titers.

TREATMENT

The choice of treatment for disease caused by *C. neoformans* depends on both the anatomic sites of involvement and the host's immune status, and thus, treatment recommendations are divided into three specific risk groups: (a) HIV-infected individuals, (b) transplant recipients, and (c) non–HIV-infected and nontransplant hosts (**Table 121-7**).[9] The management of cryptococcosis includes systemic antifungal therapy, control of elevated intracranial pressure (ICP), and supportive care. When possible, immune defects should be addressed. Although no randomized clinical trials have been performed to address this, outcomes of treatment for CNS cryptococcosis (without mass lesions or hydrocephalus) appear to be similar for disease due to either *C. neoformans* or *C. gattii*.[38]

TABLE 121-7 Therapy of Cryptococcosis[a,b]

Type of Disease and Common Clinical Manifestations	Therapy/Comments
Nonimmunocompromised Patients (Non–HIV-Infected, Nontransplant)	
Meningoencephalitis *without* neurological complications, in patients in whom CSF yeast cultures are negative after 2 weeks of therapy Follow all regimens with suppressive therapy	*Induction:* Amphotericin B[c] IV 0.7-1 mg/kg/day *plus* flucytosine 100 mg/kg/day orally in four divided doses × ≥4 weeks A lipid formulation of amphotericin B may be substituted for amphotericin B in the second 2 weeks *Consolidation:* Fluconazole 400-800 mg orally daily × 8 weeks *Maintenance:* Fluconazole 200 mg orally daily × 6-12 months
Meningoencephalitis *with* neurological complications	*Induction:* Same as for patients without neurologic complications, but consider extending the induction therapy for a total of 6 weeks. A lipid formulation of amphotericin B may be given for the last 4 weeks of the prolonged induction period *Consolidation:* Fluconazole 400 mg orally daily × 8 weeks
Mild-to-moderate pulmonary disease (Nonmeningeal disease)	Fluconazole 400 mg orally daily × 6-12 months
Severe pulmonary cryptococcosis	*Same as CNS disease × 12 months*
Cryptococcemia (nonmeningeal, nonpulmonary disease)	*Same as CNS disease × 12 months*
Immunocompromised Patients	
Severe pulmonary cryptococcosis	*Same as CNS disease × 12 months*
HIV-infected Patients	
Primary therapy; induction and consolidation[g] Follow all regimens with suppressive therapy	*Preferred regimen*: *Induction:* Amphotericin B[d] IV 0.7-1 mg/kg IV daily *plus* flucytosine 100 mg/kg/day orally in four divided doses for ≥2 weeks *Consolidation:* Fluconazole 400 mg [6 mg/kg] orally daily × ≥8 weeks Liposomal amphotericin B 3-4 mg/kg IV daily, or amphotericin B lipid complex (ABLC) 5 mg/kg IV daily, for ≥2 weeks can be substituted for amphotericin B[d] in patients with or at risk for renal dysfunction *Alternative regimens, in order of preference:* Amphotericin B[d] IV 0.7-1 mg/kg IV daily × 4-6 weeks *or* liposomal amphotericin B 3-4 mg/kg IV daily[f] × 4-6 weeks *or* ABLC 5 mg/kg IV daily × 4-6 weeks

Type of Disease and Common Clinical Manifestations	Therapy/Comments
	or Amphotericin B[d] IV 0.7 mg/kg IV daily, *plus* fluconazole 800 mg (12 mg/kg) orally daily × 2 weeks, followed by fluconazole 800 mg (12 mg/kg) orally daily × ≥8weeks *or* Fluconazole ≥800 mg (1,200 mg/day is preferred) orally daily *plus* flucytosine 100 mg/kg/day orally in four divided doses × 6 weeks *or* Fluconazole 800-1,200 mg/day orally daily × 10-12 weeks (a dosage ≥1,200 mg/day is preferred when fluconazole is used alone)[e] *or* Itraconazole 200 mg orally twice daily × 10-12 weeks (use of itraconazole, which produces minimal concentrations of active drug in the CSF is discouraged)[i] Preferred: Fluconazole 200 mg orally daily × ≥1 year *or*
Suppressive/maintenance therapy[h]	Itraconazole[i] 200 mg orally twice daily × ≥1 year *or* Amphotericin B[j] IV 1 mg/kg weekly × ≥1 year
Organ Transplant Recipients	
Mild-moderate non-CNS disease or mild-to-moderate symptoms without diffuse pulmonary infiltrates	Fluconazole 400 mg (6 mg/kg) orally daily × 6-12 months *Induction:* Liposomal amphotericin B 3-4 mg/kg IV daily,[f] or ABLC 5 mg/kg IV daily *plus* flucytosine 100 mg/kg/day orally in four divided doses × ≥2 weeks
CNS disease, moderately severe or severe CNS disease or disseminated disease without CNS disease, or severe pulmonary disease without evidence of extrapulmonary or disseminated disease	If induction therapy does not include flucytosine, consider a lipid formulation of amphotericin B for ≥4-6 weeks of induction therapy. Consider the use of a lipid formulation of amphotericin B lipid formulation (6 mg/kg IV daily) in patients with a high-fungal burden disease or relapse of disease *Consolidation:* Fluconazole 400-800 mg (6-12 mg/kg) per day orally for 8 weeks *Maintenance:* Fluconazole 200-400 mg per day orally for 6-12 months

HIV, human immunodeficiency virus; IT, intrathecal.

[a]When more than one therapy is listed, they are listed in order of preference.

[b]See the text for definitions of induction, consolidation, suppressive/maintenance therapy, and prophylactic therapy.

[c]Deoxycholate amphotericin B.

[d]In patients with significant renal disease, lipid formulations of amphotericin B can be substituted for deoxycholate amphotericin B during the induction.

[e]Or until cerebrospinal fluid (CSF) cultures are negative.

[f]Liposomal amphotericin B has been given safely up to 6 mg/kg daily; could be considered in treatment failure or in patients with a high fungal burden.

[g]Initiate HAART therapy 2-10 weeks after commencement of initial antifungal treatment.

[h]Consider discontinuing suppressive therapy during HAART in patients with a CD4 cell count ≥100 cells/μL (≥0.1 × 10^9/L) and an undetectable or very low HIV RNA level sustained for ≥3months (with a minimum of 12 months of antifungal therapy). Consider reinstitution of maintenance therapy if the CD4 cell count decreases to <100 cells/μL (<0.1 × 10^9/L).

[i]Drug level monitoring is strongly advised.

[j]Use is discouraged except in azole intolerant patients, since it is less effective than azole therapy, and is associated with a risk of IV catheter-related infections.

Data from reference 9.

Nonimmunocompromised Patients

7 Prior to the introduction of amphotericin B, cryptococcal meningitis was an almost uniformly fatal disease; approximately 86% of patients died within 1 year. The use of large (1-1.5 mg/kg) daily doses of amphotericin B resulted in cure rates of approximately 64%. When amphotericin B is combined with flucytosine, a smaller dose of amphotericin B can be employed because of the in vitro and in vivo synergy between the two antifungal agents. Resistance develops to flucytosine in up to 30% of patients treated with flucytosine alone, limiting its usefulness as monotherapy.[41] Combination therapy with amphotericin B and flucytosine will sterilize the CSF within 2 weeks of treatment in 60% to 90% of patients, and most immunocompetent patients will be treated successfully with 6 weeks of combination therapy.[39] However, because of the need for prolonged IV therapy and the potential for renal and hematologic toxicity with this regimen, alternative regimens utilizing lipid formulations of amphotericin B and the use of shorter (2 weeks) courses of amphotericin B followed by consolidation therapy with fluconazole for 8 weeks, then maintenance therapy with a lower dosage of fluconazole for 6 to 12 months has been advocated.[9,40,42]

For asymptomatic, immunocompetent hosts with isolated mild to moderate pulmonary disease and no evidence of CNS disease, careful observation can be warranted; in the case of symptomatic infection, fluconazole for 6 to 12 months is warranted. In individuals with non-CNS cryptococcemia, a positive serum cryptococcal antigen titer (greater than 1:8), cutaneous infection, a positive urine culture, or prostatic disease, the clinician must decide whether to follow the regimen for isolated pulmonary disease or the more aggressive regimen for patients with CNS (disseminated) disease.[9]

Pilot studies evaluating combination therapy with fluconazole plus flucytosine as initial therapy yielded unsatisfactory results, and this approach is discouraged even in "low-risk" patients. Ketoconazole has been used successfully in the treatment of cutaneous cryptococcosis, but it is not useful in the treatment of CNS disease, probably because of its poor penetration into the CNS.[9]

Despite low CSF concentrations of amphotericin B (2%-3% of those observed in plasma), the use of intrathecal amphotericin B is not recommended for the treatment of cryptococcal meningitis except in very ill patients or in patients with recurrent or progressive disease despite aggressive therapy with IV amphotericin B. The dosage of amphotericin B employed is usually 0.5 mg administered through the lumbar, cisternal, or intraventricular (through an Ommaya reservoir) route two or three times weekly. Side effects of intrathecal amphotericin B include arachnoiditis and paresthesias. Intrathecal amphotericin B therapy should be administered in combination with IV amphotericin B.[42]

The recommended management of raised ICP in cryptococcal meningitis (without hydrocephalus, a mass lesion, or a shift on computed tomography [CT] scan) has been repeated CSF removal by spinal tap. Those who do not respond and have ongoing raised ICP should have ophthalmologic monitoring for possible vision loss, and should be considered for ventriculoperitoneal shunt surgery. Neither corticosteroids (in the absence of IRIS) nor acetazolamide is recommended for management of raised ICP. Symptomatic, medically refractory mass lesions that may be compressing vital structures should be considered for surgical therapy.[38]

Immunocompromised Patients

Immunocompromised hosts with isolated severe pulmonary and extrapulmonary disease (including cryptococcemia) without CNS disease should be treated similarly to nonimmunocompromised patients with CNS disease. Immunocompromised patients with CNS infection require more prolonged therapy; treatment regimens are based on those used in the HIV-infected population and follow induction therapy with amphotericin B and consolidation therapy with 6 to 12 months of suppressive therapy with fluconazole.[9]

Organ Transplant Recipients

Cryptococcosis has been documented in an average of 2.8% of solid-organ transplant recipients. The median time to disease onset is 21 months after transplantation; 68.5% of the cases occur greater than 1 year after transplantation.

Induction therapy for solid organ transplant recipients with cryptococcal meningoencephalitis consists of liposomal amphotericin B or amphotericin B lipid complex (ABLC) plus flucytosine for at least 2 weeks. Fluconazole maintenance therapy should be continued for at least 6 to 12 months. Immunosuppressive management should include sequential or stepwise reduction of immunosuppressants, with consideration of lowering the corticosteroid dose first.[43] Amphotericin B should be used with caution in transplant recipients and is not recommended as first-line therapy in this patient population due to the risk of nephrotoxicity in this population that frequently has reduced renal function. If used, the tolerated dosage of amphotericin B is uncertain, but 0.7 mg/kg daily is suggested with frequent renal function monitoring. Regardless of the agent utilized, all antifungal dosages need to be carefully monitored.[43]

HIV-Infected Patients

Primary antifungal prophylaxis for cryptococcosis is not routinely recommended in HIV-infected patients in the United States and Europe. However, in areas with limited HAART availability, high levels of antiretroviral drug resistance, and a high burden of disease, clinicians may wish to consider the use of either prophylactic therapy or a preemptive strategy with serum cryptococcal antigen testing for asymptomatic antigenemia.[9]

Early studies confirmed the benefit of early high-dose amphotericin B use, the usefulness of flucytosine added to amphotericin B for induction therapy, and the slight superiority of fluconazole over itraconazole for consolidation therapy.

Amphotericin B combined with flucytosine during the two-week induction phase of therapyis the initial treatment of choice. In patients who cannot tolerate flucytosine, amphotericin B alone is an acceptable alternative. After the initially successful 2-week induction period, consolidation therapy with fluconazole can be administered for 8 weeks or until CSF cultures are negative. In patients in whom fluconazole cannot be given, itraconazole is an acceptable, albeit less effective, alternative. Combination therapy with fluconazole plus flucytosine is effective; however, it is recommended as an alternative to the preceding therapies because of its potential for toxicity. Lipid formulations of amphotericin B are effective, but the optimal dosage is unknown.[9]

In HIV-infected patients, mortality is highly associated with elevated ICP (CSF opening pressure greater than 250 mm H_2O [greater than 2.5 kPa]). At the initiation of antifungal therapy, lumbar drainage should remove enough CSF to reduce the opening pressure by 50%. Patients initially should undergo daily lumbar punctures to maintain CSF opening pressure in the normal range. When the CSF pressure is normal for several days, the procedure can be suspended. Adjunctive steroid treatment is not recommended because therapy has resulted in mixed results and its impact on outcome is unclear. Similarly, neither mannitol nor acetazolamide therapy provides any clear benefit in the management of elevated ICP.[9]

Suppressive (Maintenance) Therapy for Cryptococcal Meningitis in the HIV-Infected Patient

Relapse of *C. neoformans* meningitis occurs in approximately 50% of AIDS patients after completion of primary therapy. Persistence of asymptomatic urinary *C. neoformans* has been documented in a high percentage of AIDS patients despite seemingly adequate courses of therapy for primary meningeal disease. The prostate appears to act as a sequestered reservoir of infection in these patients, resulting in systemic relapse.

Patients appear to be at low risk for recurrence of cryptococcosis when they have successfully completed a course of initial therapy for cryptococcosis, remain asymptomatic with regard to signs and symptoms of cryptococcosis, have received antifungal therapy for greater than 3 of the previous 6 months, have a serum cryptococcal antigen titer less than 1:512, or have a sustained increase (eg, greater than 6 months) in their $CD4^+$ T-lymphocyte counts to greater than 100 to 200 cells/µL (greater than 0.1×10^9-0.2×10^9/L) and an HIV viral load of less than 50 copies/mL (50×10^3/L).[9,40,42]

After the completion of induction/consolidation phases of therapy, long-term chronic suppression with fluconazole (200 mg orally daily) should be continued for a minimum of one year. Maintenance therapy can be discontinued after one year in patients who have successfully completed primary therapy, are free of symptoms and signs of active cryptococcosis, and have been receiving HAART with a sustained CD4 cell count greater than 100 cells/mL (greater than 0.100×10^6/L) and an undetectable viral load.[9]

Evaluation of Therapeutic Outcomes

Once the CNS is involved, the usual course is weeks to months of progressive deterioration, with 80% of untreated patients dying within the first year. The prognosis of cryptococcal meningitis depends largely on the underlying predisposing factors of the host. Although cryptococcal antigen is positive in 90% of patients with cryptococcal meningitis, fewer than one half of the patients with cryptococcal meningitis develop antibody to capsular polysaccharide. Those who produce antibody have a slightly improved prognosis. In contrast, the presence of headache is a favorable symptom, presumably because it leads to an earlier diagnosis. A favorable outcome is also associated with a normal mental status on diagnosis and a CSF white blood cell (WBC) count of less than 20 cells/mm^3 (20×10^6/L). A poor outcome is predicted, however, by the presence of one or more underlying diseases (including hematopoietic disorders and AIDS), corticosteroid or immunosuppressive therapy, pretreatment serum cryptococcal antigen titers of 1:32, and posttherapy serum antigen titers of 1:8. In non-AIDS patients, the cryptococcal antigen titer can be followed during therapy to assess response to antifungal therapy. In AIDS patients, decreasing titers are not necessarily predictive of success, and titers rarely become negative at the completion of therapy.

CANDIDA INFECTIONS

Candida species are yeasts that exist primarily as small (4-6 microns), unicellular, thin-walled, ovoid cells that reproduce by budding. On agar medium, they form smooth, white, creamy colonies resembling staphylococci. Although there are more than 150 species of *Candida*, eight species—*C. albicans*, *C. tropicalis*, *Candida parapsilosis*, *C. krusei*, *Candida stellatoidea*, *C. guilliermondii*, *C. lusitaniae*, and *C. glabrata*—are regarded as clinically important pathogens in human disease.[17] Yeast forms, hyphae, and pseudohyphae can be found in clinical specimens.

Pathophysiology

8 *C. albicans* is a normal commensal of the skin, female genital tract, and entire GI tract of humans. Therefore, the mere presence of hyphae or pseudohyphae in a clinical specimen is insufficient for the diagnosis of invasive disease. The majority of infections with *C. albicans* are acquired

endogenously, although human-to-human transmission also can occur. Although the term *fungemia* refers to the presence of fungi in the blood, the most commonly isolated organism is *C. albicans*. Candidiasis can cause mucocutaneous or systemic infection, including endocarditis, peritonitis, arthritis, and infection of the CNS. (Mucocutaneous infections caused by *Candida* are discussed in further detail in Chapter 98.)

Adherence of *C. albicans* is important in the pathogenesis of oral candidiasis and subsequent colonization of the GI tract. Because evidence suggests that the GI tract is often the portal of entry for *Candida* in disseminated disease, factors that alter the adherence of *Candida* are crucial in the development of local and systemic infection. *C. tropicalis* adheres to intravascular catheters at a higher rate than *C. albicans*, a factor that may help to account for the increased incidence of systemic infections caused by this pathogen.

CANDIDEMIA AND ACUTE HEMATOGENOUSLY DISSEMINATED CANDIDIASIS

Epidemiology

Candidemia has increased substantially in the past 2 decades, and the fourth most common bloodstream infection (BSI) in US hospitals.[44] It is associated with high mortality, increased length of hospital stay, and significant economic burden.[44,45,46,47,48,49,50,51,52,53,54] Although patients with neutropenia are at high risk for IFIs, the use of antifungal prophylaxis and prompt initiation of antifungal therapy in persistently febrile patients with neutropenia who do not respond to antibioticshas resulted in a reduction in the frequency of *Candida* BSIs in this population.[7] In fact, most BSIs due to *Candida* species now occur in nonneutropenic patients who have been hospitalized in ICUs, especially adult ICUs and neonatal ICUs.

The most commonly encountered clinical species of *Candida* include *C. albicans*, *C. glabrata, C. tropicalis, C. parapsilosis*, *C. lusitaniae*, *C. krusei*, *and C. guilliermondii.* While *C. albicans* is still the most common species of *Candida* causing candidemia, its relative frequency is decreasing, while the frequency of the other, non-*albicans* species, including *C. glabrata*, *C. tropicalis*, *C. krusei*, and *C. parapsilosis*, have increased.[44,52,55,56,57] The change in species is of concern clinically, as certain pathogens, such as *C. krusei* and *C. glabrata*, are intrinsically more resistant to commonly used triazole drugs.[58,59] Although risk factors for the development of *Candida* BSIs in ICU patients can be identified, factors that lead to the acquisition of specific species are still unclear.[27]

Patients' characteristics influence the distribution of *Candida* species: *C. glabrata* infections are more common in the elderly, *C. krusei* in immunocompromised patients, while *C. parapsilosis* is most common in children and neonates. *C. lusitaniae* infections are a cause of breakthrough fungemia in cancer patients; *C. parapsilosis* has emerged as the second most common pathogen, following *C. albicans*, in neonatal ICU patients, where it is often associated with central lines and PN, and fungemias in patients outside the United States, in particular in South America. Fungemia caused by *C. glabrata* is observed more commonly in adults older than 65 years of age.[32]

Pathophysiology

Candida generally is acquired via the GI tract, although organisms also can enter the bloodstream via indwelling IV catheters. Immunosuppressed patients, including those with lymphoreticular or hematologic malignancies, diabetes, and immunodeficiency diseases and those receiving immunosuppressive therapy with high-dose corticosteroids, immunosuppressants, antineoplastic agents, or broad-spectrum antimicrobial agents, are at high risk for IFIs (**Table 121-8**). Major risk factors include the use of CVCs, total PN, receipt of multiple antibiotics, extensive surgery and burns, renal failure and hemodialysis, mechanical ventilation, and prior fungal colonization. Patients who have undergone surgery (particularly surgery of the GI tract) are increasingly susceptible to disseminated candidal infections.[20,46]

TABLE 121-8 Risk Factors for Invasive Candidiasis

Colonization
Corrected colonization index (CCI) ≥0.4[a]
Colonization index (CI) ≥0.8[a]
Candida spp. cultured from sites other than blood
Candiduria
Antibiotic use
Number of antibiotics prior to infection (per additional antibiotics)
Use of two or more antibiotics
Use of broad-spectrum antibiotics in previous 10 days
Surgery
Surgery on ICU admission
Gastro-abdominal surgery

Abdominal drainage

Elective surgery

Cardiopulmonary bypass time >120 minutes

Hickman catheter

Foreign devices

Central venous catheter

Triple lumen catheter in patients who have undergone surgery

Bladder catheter

Renal failure and dialysis

Prior hemodialysis

Hemofiltration procedures

Increased serum creatinine[b]

New-onset hemodialysis within 3 days of admission to ICU

Acute renal failure

Underlying disease/baseline characteristics

Total PN

Diabetes mellitus

Apache II (per point)

Signs of severe sepsis

Diarrhea at any time

Mechanical ventilation ≥10 days

Hospital-acquired bacterial infection

Bacterial peritonitis by ICU day 11

GI disease

ICU length of stay

Transferred from other hospital

Use of corticosteroids

Profound neutropenia (ANC < 100/mm^3 [<0.100 $\times 10^9$/L])

[a]CI = the ratio of number of nonblood distinct body sites (dbs) heavily colonized with identical strains to the total number of dbs; CCI = the product of the CI and the ratio of the number of dbs showing heavy growth (≥10^5 CFU/mL [≥10^8 CFU/L]) to the total of dbs growing *Candida* spp.

[b]Serum creatinine >1.2 mg/dL (>106 μmol/L) in females, >1.6 mg/dL (>141 μmol/L) in males.

Data from reference 27.

Clinical Presentation of Hematogenous Candidiasis

Dissemination of *C. albicans* can result in infection in single or multiple organs, particularly the kidney, brain, myocardium, skin, eye, bone, and joints.[60] In most patients, multiple micro- and macroabscesses are formed. Infection of the liver and spleen is becoming recognized as a particularly common and difficult-to-treat site of infection that characteristically occurs in patients undergoing chemotherapy for acute leukemia or lymphoma.

Laboratory Tests

The interpretation of positive surveillance cultures of the skin, mouth, sputum, feces, or urine is hampered by their occurrence as commensal pathogens and in distinguishing colonization from invasive disease. A rapid presumptive identification of *C. albicans* can be made by incubation of *Candida* in serum; formation of a germ tube (the beginning of hyphae, which arise as perpendicular extensions from the yeast cell, with no constriction at their point of origin) within 1 to 2 hours offers a positive identification of *C. albicans*. Unfortunately, *C. dubliniensis* also can produce a germ tube, and a negative germ tube test does not rule out the possibility of *C. albicans*, but further biochemical tests must be performed to differentiate between other non-*albicans* species.

The PNA fluorescence in situ hybridization (FISH) method uses fluorescein-labeled PNA probes that target *C. albicans* 26S rRNA for the identification of *C. albicans*. The test has excellent sensitivity (99%-100%) and specificity (100%) in the direct identification of *C. albicans* from blood cultures.[61]

Matrix-assisted laser desorption/ionization time-of-flight intact cell mass spectrometry (MALDI-TOF-ICMS) and T2 Magnetic Resonance Assays, are promising tools for the rapid detection and identification of pathogenic *Candida* species.[29,30,61]

TREATMENT

The list of risk factors for invasive candidiasis in critically ill patients is extensive, and trying to decipher which patients may benefit from antifungal prophylaxis or empirical therapy based on risk factors in an ICU is exceedingly difficult. In addition, the number of risk factors present in ICU patients changes over time, and the majority of ICU patients will have more than one risk factor. Clinically useful, practical predictive algorithms and "scoring systems" to identify high-risk patients early during their ICU admission have not proved successful thus far. To maximize its clinical utility as a decision-making tool, the ideal algorithm would identify high-risk populations (ones with a rate of invasive candidiasis of 10%-15%), providing clinicians with a means of administering prophylaxis to a minimal number of patients, while preventing the maximal number of invasive candidiasis cases.[27]

Hematogenous Candidiasis

There is a high rate of mortality in nonneutropenic patients with fungal blood cultures. Delays in the initiation of antifungal therapy significantly increase mortality.[62,63] Treatment of candidiasis should be guided by knowledge of the infecting species, the clinical status of the patient, and when available, the antifungal susceptibility of the infecting isolate. Therapy should be continued for 2 weeks after documented clearance of blood cultures, with resolution of all signs and symptoms of infection. All patients should undergo dilated fundiscopic exam within the 1st week of therapy. Susceptibility testing of the infecting isolate is a useful adjunct to species identification during selection of a therapeutic approach, since it can be used to identify isolates that are unlikely to respond to fluconazole or amphotericin B.[7] However, this is not currently available at many institutions.

Clinical Controversy… Role of Catheter Removal

Although it is common practice in today's standard of care to place indwelling catheters in patients for the administration of medications and parenteral nutrition (TPN), catheter-related infections are a common complication. These foreign bodies (especially triple lumen catheters) double as entry ports for normal skin flora or other nosocomial pathogens, and they provide a readily available site for the binding of pathogens via microbiotic biofilms. Their subsequent role as a source of BSIs is facilitated by frequent use, TPN, and the potential for contamination of catheters by medical staff who are colonized with *Candida* species.

Most consensus recommendations urge removal of all existing tunneled CVCs and implantable devices, particularly in patients with fungemia caused by *C. parapsilosis*, which is very frequently associated with catheters, as it has been associated with reduced mortality in adults, and a shorter duration of candidemia.[7] Arguments against the removal of all catheters in patients with candidemia include the prominent role of the gut as a source for disseminated candidiasis, the significant cost and potential for complications, and the problems that can be encountered in patients with difficult vascular access.[7,64,65] However, in an individual patient it is often difficult to determine the relative contribution of gut versus catheter as the primary source of fungemia.[66,67,68,69] The evidence for this recommendation is weakest in cancer patients with severe neutropenia and mucositis (eg, acute leukemia, stem cell transplant), in whom candidemia is almost always primarily of gut origin, and removal of CVCs is least likely to have an impact on mortality.[66,67,68,69]

Nonimmunocompromised Patient

Prophylaxis

In ICUs, the use of fluconazole for prophylaxis or empirical therapy has increased exponentially in the past decade. However, studies that demonstrated benefit in the prevention of invasive candidal BSIs did so either by using highly selective criteria or by studying patients in an unusually high-risk ICU setting, and the role of antifungal prophylaxis in the surgical ICU remains extremely controversial. For a study to demonstrate efficacy in clinical trials, the baseline rate of invasive candidiasis must be greater than 10%, and that prophylaxis must result in greater than fourfold reduction of disease.[7] Although ICU-specific, a greater than 10% rate of invasive candidiasis is generally found only in the setting of high-risk transplant patients (eg, patients undergoing liver transplantation), or in patients with one or more of the following risk factors

by day 3 of their ICU stay: new-onset dialysis, receipt of broad-spectrum antibiotics, the presence of diabetes, and in patients receiving PN.[70,71] Prophylactic antifungals are indicated in patients with recurrent intestinal perforations and/or anastomotic leak as these patients are at extremely high risk for invasive candidiasis (35%) and the use of empiric fluconazole has been shown to significantly decrease the incidence of infection to 4%.[27]

"Empirical" Therapy (Also Known as Preemptive Therapy)

The term "preemptive" antifungal therapy is often used to describe early antifungal therapy given to high-risk patients with persistent signs and symptoms and clinical, laboratory, or radiologic surrogate markers of infection but without mycological evidence of infection, or those heavily colonized with *Candida*. Few data are available for assessing the role of antifungals as empirical therapy for *suspected* fungemia in patients who do not yet exhibit a positive blood culture, or for isolates other than *C. albicans*. The empiric use of fluconazole did not significantly decrease the incidence of invasive candidiasis; thus, its use is not recommended at this time.[72]

Initial Antifungal Therapy in Non-neutropenic Patients with Documented Candidemia, in Whom the Species is Not Yet Identified and Results of Antifungal Susceptibility Testing are Not Known

Several large randomized studies in non-neutropenic patients have demonstrated that azoles (fluconazole or voriconazole), echinocandins, and deoxycholate amphotericin B (d-AmB) are similarly effective for the therapy of documented candidemia; however, fewer adverse effects are observed with azole therapy.[45] Similarly, echinocandins are at least as effective as amphotericin B or fluconazole in (primarily nonneutropenic) adult patients with candidemia with fewer drug-related adverse events. Although the use of combination therapy (high-dose fluconazole plus amphotericin B) was demonstrated to be superior to treatment with fluconazole alone, it was associated with a higher rate of nephrotoxicity, and the routine use of combination therapy in this patient population is not yet recommended.[7]

For empiric therapy in non-neutropenic adults, IDSA guidelines (**Table 121-9**) recommend use of an echinocandin or fluconazole as initial therapy. Echinocandins are recommended for patients with moderately severe to severe illness, and patients with recent azole exposure. Patients may be transitioned to fluconazole if their *Candida* isolates are known/likely to be susceptible to fluconazole (eg, *C. albicans*, *C. parapsilosis*) in patients who are clinically stable. Fluconazole may be used initially in patients who are less critically ill, with no recent azole exposure, who are not at high risk for *C. glabrata* or with central nervous system or endocardial disease.[7,45]

TABLE 121-9 Antifungal Therapy of Invasive Candidiasis[7,34]

Type of Disease and Common Clinical Manifestations	Therapy/Comments
Prophylaxis of Candidemia	
Nonneutropenic patients[a]	Not recommended except for severely ill/high-risk patients in whom fluconazole IV/PO 400 mg daily should be used (see the text)
Neutropenic patients[a]	The optimal duration of therapy is unclear but at a minimum should include the period at risk for neutropenia: Fluconazole IV/PO 400 mg daily *or* itraconazole solution 2.5 mg/kg every 12 hours orally *or* micafungin 50 mg (1 mg/kg in patients under 50 kg) IV daily
Solid-organ transplantation, liver transplantation	*Patients with two or more key risk factors[b]:* Amphotericin B IV 10-20 mg daily *or* liposomal amphotericin B (AmBisome) 1 mg/kg/day *or* fluconazole 400 mg orally daily
Empirical (Preemptive) Antifungal Therapy	
Suspected disseminated candidiasis in febrile nonneutropenic patients	None recommended; data are lacking defining subsets of patients who are appropriate for therapy (see the text)
Initial Antifungal Therapy (Documented Candidemia with Unknown Candida Species)	
Febrile neutropenic patients with prolonged fever despite 4-6 days of empirical antibacterial therapy	*Treatment duration:* Until resolution of neutropenia An echinocandin[d] is a reasonable alternative; voriconazole can be used in selected situations (see the text)
Less critically ill patients with no recent azole exposure	An echinocandin[d] or fluconazole (loading dose of 800 mg [12 mg/kg], then 400 mg [6 mg/kg] daily)
Additional mold coverage is desired	Voriconazole
Antifungal Therapy of Documented Candidemia and Acute Hematogenously Disseminated Candidiasis, Unknown Species	
Nonimmunocompromised host[c]	*Treatment duration:* 2 weeks after the last positive blood culture and resolution of signs and symptoms of infection *Remove existing central venous catheters when feasible plus fluconazole (loading dose of 800 mg [12 mg/kg], then 400 mg [6 mg/kg] daily) or an echinocandin[d]*

Type of Disease and Common Clinical Manifestations	Therapy/Comments
Patients with recent azole exposure, moderately severe or severe illness, or who are at high risk of infection due to *C. glabrata* or *C. krusei*	An echinocandin[d] Transition from an echinocandin to fluconazole is recommended for patients who are clinically stable and have isolates (eg, *C. albicans*) likely to be susceptible to fluconazole
Patients who are less critically ill and who have had no recent azole exposure	Fluconazole
Antifungal Therapy of Specific Pathogens	
C. albicans, C. tropicalis, and *C. parapsilosis*	Fluconazole IV/PO 6 mg/kg/day *or* an echinocandin[d] or amphotericin B IV 0.7 mg/kg/day *plus* fluconazole IV/orally 800 mg/day; amphotericin B deoxycholate 0.5-1 mg/kg daily or a lipid formulation of amphotericin B (3-5 mg/kg daily) are alternatives in patients who are intolerant to other antifungals; transition from amphotericin B deoxycholate or a lipid formulation of amphotericin B to fluconazole is recommended in patients who are clinically stable and whose isolates are likely to be susceptible to fluconazole (eg, *C. albicans*); voriconazole (400 mg [6 mg/kg] twice daily × two doses then 200 mg [3 mg/kg] twice daily thereafter) is efficacious, but offers little advantage over fluconazole; it may be utilized as step-down oral therapy for selected cases of candidiasis due to *C. krusei* or voriconazole-susceptible *C. glabrata*
	Patients intolerant or refractory to other therapy[e]: Amphotericin B lipid complex IV 5 mg/kg/day Liposomal amphotericin B IV 3-5 mg/kg/day Amphotericin B colloid dispersion IV 2-6 mg/kg/day
C. krusei	Amphotericin B IV ≤1 mg/kg/day *or* an echinocandin[d]
C. lusitaniae	Fluconazole IV/orally 6 mg/kg/day
C. glabrata	An echinocandin[d] (transition to fluconazole or voriconazole therapy is not recommended without confirmation of isolate susceptibility) *Treatment duration:* Until resolution of neutropenia
Neutropenic host[f]	*Remove existing central venous catheters when feasible, plus:* Amphotericin B IV 0.7-1 mg/kg/day (total dosages 0.5-1 g) *or patients failing therapy with traditional amphotericin B:* Lipid formulation of amphotericin B IV 3-5 mg/kg/day *Treatment duration:* Until calcification or resolution of lesions
Chronic disseminated candidiasis (hepatosplenic candidiasis)	*Stable patients:* Fluconazole IV/orally 6 mg/kg/day *Acutely ill or refractory patients:* Amphotericin B IV 0.6-0.7 mg/kg/day *Asymptomatic disease:* Generally no therapy is required
Urinary candidiasis	*Symptomatic or high-risk patients[g]*: Removal of urinary tract instruments, stents, and Foley catheters, +7-14 days therapy with fluconazole 200 mg orally daily *or* amphotericin B IV 0.3-1 mg/kg/day

PO, orally.

[a]Patients at significant risk for invasive candidiasis include those receiving standard chemotherapy for acute myelogenous leukemia, allogeneic bone marrow transplants, or high-risk autologous bone marrow transplants. However, among these populations, chemotherapy or bone marrow transplant protocols do not all produce equivalent risk, and local experience should be used to determine the relevance of prophylaxis.

[b]Risk factors include retransplantation, creatinine of more than 2 mg/dL (177 µmol/L), choledochojejunostomy, intraoperative use of 40 units or more of blood products, and fungal colonization detected within the first 3 days after transplantation.

[c]Therapy is generally the same for acquired immunodeficiency syndrome (AIDS)/non-AIDS patients except where indicated and should continued for 2 weeks after the last positive blood culture and resolution of signs and symptoms of infection. All patients should receive an ophthalmologic examination. Amphotericin B can be switched to fluconazole (IV or oral) for the completion of therapy. Susceptibility testing of the infecting isolate is a useful adjunct to species identification during selection of a therapeutic approach because it can be used to identify isolates that are unlikely to respond to fluconazole or amphotericin B. However, this is not currently available at most institutions.

[d]Echinocandin = caspofungin 70 mg loading dose, then 50 mg IV daily maintenance dose, or micafungin 100 mg daily, or anidulafungin 200 mg loading dose, then 100 mg daily maintenance dose.

[e]Often defined as failure of ≥500 mg amphotericin B, initial renal insufficiency (creatinine ≥2.5 mg/dL [≥221 µmol/L] or creatinine clearance <25 mL/min [< 0.42 mL/s]), a significant increase in creatinine (to 2.5 mg/dL [221 µmol/L] for adults or 1.5 mg/dL [133 µmol/L] for children), or severe acute administration-related toxicity.

[f]Patients who are neutropenic at the time of developing candidemia should receive a recombinant cytokine (granulocyte colony-stimulating factor or granulocyte–monocyte colony-stimulating factor) that accelerates recovery from neutropenia.

[g]Patients at high risk for dissemination include neutropenic patients, low-birth-weight infants, patients with renal allografts, and patients who will undergo urologic manipulation.

Data from reference 7.

Among the lipid-associated formulations of amphotericin B, only liposomal amphotericin B (AmBisome) and ABLC (Abelcet) have been approved for use in proven cases of candidiasis; however, patients with invasive candidiasis also have been treated successfully with amphotericin B colloid dispersion (ABCD, Amphotec or Amphocil). The lipid-associated formulations are less toxic but as effective as amphotericin B deoxycholate.

Antifungal Therapy for Specific *Candida* Species

C. krusei infections should be treated with large doses of amphotericin B (greater than equal to 1 mg/kg per day) or with caspofungin. *C. tropicalis*, and *C. parapsilosis* can be treated with either amphotericin B at or fluconazole.[7] Amphotericin B resistance remains relatively rare despite more than 45 years of clinical use, although it has been reported in *C. lusitaniae* (now *Clavispora lusitaniae*) and *C. guilliermondii*. *Candida rugosa* often is considered to be "polyene tolerant," and these isolates are believed to be selected owing to the wide use of amphotericin B.

Immunocompromised Patients

In immunocompromised patients, the optimal agent, dose, and duration of therapy are unclear, and patients must be monitored carefully with serial blood cultures and careful physical examinations, particularly of the retina. Patients who are neutropenic at the time of developing candidemia should receive a recombinant cytokine (granulocyte colony-stimulating factor or granulocyte-monocyte colony-stimulating factor) that accelerates recovery from neutropenia.[7]

Prophylaxis

Recognition of the role of the GI tract in invasive *Candida* infections has led to efforts to decrease infections by prophylactic administration of topical or systemically absorbed antifungal agents in immunocompromised patients. The use of systemically absorbable agents such as azole antifungal agents appears to decrease the risk of IFIs.[7]

Several antifungal agents, including fluconazole (400 mg/day), posaconazole (200 mg three times daily), micafungin or caspofungin (50 mg daily) administered from the start of the conditioning regimen until day 75, can reduce the frequency of invasive *Candida* infections and decrease mortality in patients undergoing allogeneic bone marrow transplantation.[7,21,73]

Similarly, in less risk-selected patients with hematologic malignancies who are undergoing remission-induction chemotherapy, fluconazole, posaconazole, or caspofungin, during induction chemotherapy for the duration of neutropenia, are effective in preventing systemic infection and death caused by *Candida* species.[7]

For solid-organ transplant recipients, fluconazole or liposomal amphotericin B is recommended as postoperative antifungal prophylaxis for liver, pancreas, and small bowel transplant recipients at high risk of candidiasis.[7,20]

Widespread use of prophylactic fluconazole in all ICU patients is not warranted and may lead to an increase in resistance and adverse events. If utilized, prophylactic fluconazole should target high-risk patients with a presumed risk of invasive candidiasis of 10% to 15%.[7,27]

Empirical Therapy for Febrile Neutropenic Patients

Many clinicians advocate early institution of empirical IV amphotericin B in patients with neutropenia and persistent (greater than 5-7 days) fever.[21] However, the potential toxicities (particularly nephrotoxicity) of this agent preclude its routine use in all patients. Suggested criteria for the empirical use of amphotericin B include: (a) fever of 5 to 7 days' duration that is unresponsive to antibacterial agents, (b) neutropenia of more than 7 days' duration, (c) no other obvious cause for fever, (d) progressive debilitation, (e) chronic adrenal corticosteroid therapy, and (f) indwelling intravascular catheters. In patients who fail therapy with amphotericin B, lipid formulations of amphotericin B can be used. Lipid formulations of amphotericin B can be used as alternatives to amphotericin B deoxycholate for empirical therapy. Although they do not appear to be substantially more effective, there is less drug-related toxicity (**Table 121-10**).[74]

TABLE 121-10 Comparative Trials for Initial Antifungal Therapy in the Febrile Neutropenic Host

Year Published	Study Drugs	Study Design	Results and Comments
1982	Placebo versus amphotericin B	Randomized	Favored amphotericin B
1989	Placebo versus amphotericin B	Randomized	Favored amphotericin B
1996	Fluconazole versus amphotericin B	Randomized	Defervescence: equivalence; safety analysis favored fluconazole
1998	Fluconazole versus amphotericin B	Randomized	Composite: equivalence; secondary analysis favored fluconazole
2000	Fluconazole versus amphotericin B	Randomized	Composite: equivalence; safety analysis favored fluconazole
1999	Liposomal amphotericin B versus amphotericin B	Randomized, double blind	Composite: equivalence; secondary analysis favors liposomal amphotericin B
2000	Liposomal amphotericin B versus amphotericin B lipid complex	Randomized, double blind	Liposomal amphotericin B had superior safety versus amphotericin B lipid complex and a similar therapeutic success rate
2001	Itraconazole versus amphotericin B	Randomized, open label	Composite: equivalence; secondary analysis favors itraconazole
2002	Voriconazole versus liposomal amphotericin B	Randomized, open label	Composite: equivalence; secondary analysis variable (voriconazole failed to meet criteria for noninferiority); fewer breakthrough infections with voriconazole
2004	Caspofungin versus liposomal amphotericin B	Randomized, double blind	Composite: equivalence; secondary analysis favored caspofungin for treatment of baseline infections
2005	Liposomal amphotericin B loading regimen (10 mg/kg/day × 14 day) vs standard dosing (3 mg/kg/day)	Randomized, prospective, double blind	Loading regimen did not demonstrate any benefit in overall response or survival and was associated with higher rates of nephrotoxicity and hypokalemia

Data from reference 74.

Itraconazole and fluconazole have demonstrated efficacy equivalent to that of d-AmB in patients with hematologic malignancy (not treated with allogeneic HSCT). However, as fluconazole is not active against filamentous fungi, its use in patients at high risk for these pathogens should be avoided. If itraconazole is used, the IV formulation should be used because the bioavailability of the oral formulations (including the solution) is unreliable; however, it is no longer available. Voriconazole and caspofungin were compared with liposomal amphotericin B in large randomized, multicenter trials of empirical antifungal therapy in febrile neutropenic patients. Voriconazole did not fulfill the protocol-defined criteria for noninferiority; however, it was superior in reducing documented breakthrough infections, infusion-related toxicity, and nephrotoxicity. Patients who received voriconazole had more frequent episodes of transient visual disturbances and hallucinations. Caspofungin demonstrated equivalent efficacy but was superior in the successful treatment of baseline IFIs.[74,75]

Specific Therapy

Amphotericin B, the azoles, and the echinocandins have roles in the treatment of hematogenous candidiasis, and the choice of therapy is guided by weighing the greater activity of amphotericin B for some non-*albicans* species (eg, *C. krusei*) against the lower toxicity and ease of administration of fluconazole and the echinocandins.[7]

Most clinicians recommend amphotericin B in total dosages of 0.5 to 1 g administered over approximately 1 to 2 weeks in patients with *Candida* endophthalmitis and in all neutropenic patients with candidemia. Longer courses of therapy can be needed in some patients.[17] Fluconazole and amphotericin B appear similarly effective for the treatment of *C. albicans* BSIs in the neutropenic patient; controlled data, however, are lacking. In patients with uncomplicated *C. albicans* fungemia who have not received systemic prophylaxis with antifungal azoles, therapy with fluconazole 400 to 800 mg/day IV can be considered. However, in patients who have undergone allogeneic HSCT, the role of fluconazole is becoming more limited because of its widespread use for antifungal prophylaxis. In this setting, particularly if the patient has been treated previously with an azole antifungal agent, the possibility of microbiologic resistance must be considered. Infections with fluconazole-resistant *Candida* species, including *C. glabrata*, *C. krusei*, and fluconazole-resistant *C. albicans*, or with *Aspergillus* species are more likely.

Clinical Controversy… Treatment of Candidemia in Non-Neutropenic Adults Once the *Candida* Species Is Identified

Expert opinion is divided regarding the optimal therapy of infections caused by *C. glabrata*.[76,77] Since *C. glabrata* often demonstrate reduced susceptibility to fluconazole, treatment with echinocandins, or amphotericin B at a dosage of 0.7 mg/kg/day is often recommended as initial therapy although there are successful treatment outcomes reported in response to fluconazole therapy of 6 to 12 mg/kg/day, and may be suitable in less critically ill patients.[76,77] The severity of illness and choice of antifungal predict response in patients with *C. glabrata* fungemia, and the choice of antifungal (fluconazole or an echinocandin) does not influence mortality. Failure is associated with admission to an intensive care unit. When fluconazole is dosed appropriately, (Table 121-9) *C. glabrata* fluconazole susceptibility breakpoints are predictive of clinical and microbiological response. Echinocandin therapy is independently associated with treatment success, but not survival, in invasive candidiasis due to *C. glabrata*.[77]

Amphotericin B, at a dosage of 1 mg/kg/day, is recommended for the management of systemic *C. krusei* infections. *C. tropicalis* and *C.*

parapsilosis may be treated with either amphotericin B at 0.6 mg/kg/day or fluconazole at 6 mg/kg/day. Candidemia due to *C. parapsilosis* has increased in frequency among pediatric populations and appears to be associated with a lower mortality rate than other species of *Candida*. Since many, but not all isolates of *C. lusitaniae* are resistant to amphotericin B, fluconazole at 6 mg/kg/day is the preferred agent for treatment of this species.

In patients with *C. parapsilosis* candidemia, guidelines[7] recommend the use of fluconazole, since MICs of echinocandins tend to be higher for *C. parapsilosis*. However, a meta-analysis of 5 randomized, blinded, comparative trials for treatment of candidemia or invasive candidiasis concluded that the overall treatment success of echinocandins versus other agents was similar: 76.5% versus 73%.[78,79] In patients with *Candida glabrata* candidemia, guidelines recommend the use of an echinocandin.[7] Treatment should be continued for 2 weeks, in the absence of metastatic complications of disease. It is important to note when counting days of therapy that the days of treatment 'begin' on the first day of documented clearance of *Candida* species from bloodstream, with the use of an effective antifungal agent to which the species is susceptible.

Updated IDSA and European guidelines have recently been published.[7,31,80] In the European Guidelines, important recommendations include the recommendation for daily blood cultures until negative, and that patients can be switched to oral therapy after 10 days of IV therapy. They also recommend the use of amphotericin or echinocandins preferentially if catheters cannot be removed.[31,80,81]

CANDIDURIA

Within the urinary tract, most common lesions are either *Candida* cystitis or hematogenously disseminated renal abscesses. *Candida* cystitis often follows catheterization or therapy with broad-spectrum antimicrobial agents. The diagnosis of *Candida* cystitis can be problematic because of the frequent presence of *Candida* pseudohyphae and yeast cells in urine specimens secondary to urethral colonization. The usefulness of urine colony counts or antibody coating techniques is questionable. The recovery of 10,000 organisms or visualization of both yeast and pseudohyphae from fresh midstream urine or from bladder urine obtained by single catheterization (not indwelling) is suggestive of genitourinary candidiasis. In most patients, the infection is asymptomatic and clears spontaneously without specific antifungal therapy.

Initial therapy of candidal cystitis should focus on removal of urinary catheters whenever possible. Changing the catheter will eliminate candiduria in only 20% of patients, whereas discontinuation will eradicate *Candida* in 40% of patients. Asymptomatic candiduria rarely requires therapy. Therapy should be used in symptomatic patients and in neutropenic patients, as well as in patients with renal allografts and those who will undergo urologic manipulation, because of the risk of dissemination.[82,83]

Fluconazole 200 mg/day for 14 days hastens the time to a negative urine culture as compared with placebo treatment, but 2 weeks after the end of therapy, the frequency of a negative urine culture remains the same with both treatments.[83] Short courses of therapy are not recommended; treatment should include removal of catheters and stents whenever possible plus 7 to 14 days of therapy. Bladder irrigation with amphotericin B (50 mg in 500 mL sterile water instilled twice daily into the bladder via a three-way catheter) is only transiently effective. Minimal quantities (less than 3%) of amphotericin B are absorbed systemically from the bladder.[83,84]

ASPERGILLOSIS

Saprophytic molds belonging to the *Aspergillus* spp. can be found around the world, of which, *Aspergillus fumigatus* is the most commonly observed pathogen, followed by *Aspergillus flavus*. Guidelines for the prophylaxis and empiric treatment of IA in neutropenic hosts can be referred to for more comprehensive details.[85]

IA is the second most common IFI, with increasing incidence over the last 20 years along with the advances in the treatment of hematological malignancies. The infection most commonly affects immunocompromised patients and patients with acute myeloid leukemia (AML) and those who undergo allogeneic HSCT who have prolonged durations (more than 10 days) of neutropenia are at highest risk. In the highest risk group, IA rates can reach 25%. The frequency of IA and infections caused by other molds has increased over the past 2 decades. Despite heightened awareness of the profiles of patients at risk, for *Aspergillus* infections, and despite the advent of liposomal formulations of amphotericin B, IA continues to be associated with extremely high mortality rates.[12,86] The crude mortality approaches 80% to 90% in patients with AIDS and bone marrow transplant patients. Major target sites for primary invasive disease include the lungs and sinuses; frequently, secondary infections involve the central nervous system. The appropriate duration of treatment is based on the extent of the infection, response to therapy, and host factors.[12]

Epidemiology

Aspergillus is a ubiquitous mold that grows well on a variety of substrates, including soil, water, decaying vegetation, moldy hay or straw, and organic debris. Although more than 300 species of *Aspergillus* have been characterized, three species are most commonly pathogenic: *A. fumigatus*, *A. flavus*, and *Aspergillus niger*. The varying degrees of pathogenicity of each species depend on their relative geographic prevalence, conidial size and shape, thermotolerance, and production of mycotoxins. For example, transport of *A. fumigatus* conidia into the lungs is facilitated by their smaller diameter in comparison with *A. flavus* and *A. niger*.

9 The term *aspergillosis* may be broadly defined as a spectrum of diseases attributed to allergy, colonization, or tissue invasion caused by members of the fungal genus *Aspergillus*. A single satisfactory classification system for these disease entities is difficult because different

populations of patients can develop the same type of infection. For example, osteomyelitis can result from local trauma or hematogenous dissemination in an immunocompromised host. Colonization in normal hosts can lead to allergic diseases ranging from asthma to allergic BPA or, rarely, invasive disease.[87]

Pathophysiology

Aspergillosis generally is acquired by inhalation of airborne conidia that are small enough (2.5-3 microns) to reach alveoli or the paranasal sinuses. Each conidiophore releases 10^4 conidia that remain suspended for long periods and are viable for months in dry locations. Although some authors advocate monitoring of hospital air for *Aspergillus* conidia, guidelines for interpreting results do not exist. The use of high-efficiency particulate air (HEPA) filters in operating rooms and laminar flow rooms and removal of immunocompromised patients from hospital renovation sites can be helpful in preventing infection in this population.

Superficial or locally invasive infections of the ear, skin, or appendages often can be managed with topical antifungal therapy. Skin infections in patients with burn wounds, although uncommon, can progress to deep-tissue invasion despite the use of topical or parenteral antifungal agents. Risk factors for deep infection include extensive thermal injuries, malnutrition, cirrhosis, and previous infection with *Pseudomonas aeruginosa*.[88,89,90]

Allergic manifestations of *Aspergillus* range in severity from mild asthma to allergic BPA. BPA, which is almost always caused by *A. fumigatus*, is characterized by severe asthma with wheezing, fever, malaise, weight loss, chest pain, and a cough productive of blood-streaked sputum. Following recurrent episodes of severe asthma, the disease usually progresses to fibrosis and bronchiectasis with granuloma formation. When *Aspergillus* conidia become trapped in the viscous mucus of asthmatic patients, BPA develops. The fungus grows, releasing toxins and antigens. The resulting host sensitization results in a variety of immune reactions. Early in the course of disease, an immunoglobulin E (IgE)-mediated (type I) immune reaction results in bronchospasm, eosinophilia, and immediate skin reactivity. The ensuing fibrosis and pulmonary infiltrates appear to be mediated by circulating or precipitating antibody complexes of IgG antibody, followed by granuloma formation and mononuclear infiltration because of a type IV delayed hypersensitivity reaction. Therapy is aimed at minimizing the quantity of antigenic material released in the tracheobronchial tree. Management of acute asthma attacks minimizes trapping of *Aspergillus* by bronchial secretions, and administration of parenteral corticosteroids clears lung infiltrates.[88,89,90] Antifungal therapy generally is not indicated in the management of allergic manifestations of aspergillosis, although some patients have demonstrated a decrease in their corticosteroid dose following therapy with itraconazole.[91]

Aspergilloma

In the nonimmunocompromised host, *Aspergillus* infections of the sinuses most commonly occur as saprophytic colonization (aspergillomas or "fungus balls") of previously abnormal sinus tissue. An aspergilloma is composed of intertwined *Aspergillus* hyphae matted together with fibrin, mucus, and cellular debris. Infection usually is localized in the maxillary sinus and rarely is associated with local invasion of adjacent bone or brain tissue. Sinus aspergillosis also can present as allergic sinusitis with nasal drainage of brownish mucous plugs. Therapy with corticosteroids and surgery generally is successful. In the immunocompromised host, subacute, chronic, or fulminant invasive disease can be seen, and a combination of antifungal and surgical therapy generally is required.[85]

Pulmonary aspergillomas are fungus balls arising in preexisting cavities because of tuberculosis, histoplasmosis, lung tumors, or radiation fibrosis, although occasionally no previous pulmonary disease is present. The diagnosis of aspergilloma generally is made on the basis of chest radiographs, on which aspergillomas appear as a solid rounded mass, sometimes mobile, of water density within a spherical or ovoid cavity and separated from the wall of the cavity by an airspace of variable size and shape. Patients generally experience chest pain, dyspnea, and sputum production. Hemoptysis is observed in 50% to 80% of patients, probably because of ulceration of the epithelial lining of the cavity with formation of granulation tissue, and hemoptysis is the cause of death in up to 26% of patients with aspergilloma. A poor prognosis is associated with increasing size or number of aspergillomas, immunosuppression (including corticosteroids), increasing *Aspergillus*-specific titers, underlying sarcoidosis, and HIV infection. Although *Aspergillus* can be cultured in only 50% to 60% of patients, precipitating antibodies are positive in virtually 100% of patients.

Invasive disease occurs rarely, and therapy therefore is controversial. There are no controlled clinical trials with which to guide therapy, and recommendations for treatment have been generated from uncontrolled trials and case reports.[85] Concern regarding the risk of severe hemorrhage has led some clinicians to use aggressive surgical excision of aspergillomas or pulmonary resection in patients with hemoptysis. Complications, including bronchopulmonary fistulas, hemorrhage, empyema, and persistent airspace problems, have led to the recommendation that surgical intervention be reserved for patients with severe (greater than 500 mL/24 h) hemoptysis, however. Bronchial artery embolization has been used to occlude the vessel that supplies the bleeding site in patients experiencing hemoptysis. Unfortunately, bronchial artery embolization generally is unsuccessful or only temporarily effective. Collateral circulation eventually develops, supplying blood flow to the affected area, and hemoptysis often recurs; consequently, reembolization is often unsuccessful. Bronchial artery embolization should be used as a temporizing procedure in a patient with life-threatening disease who might respond to more definitive therapy if hemoptysis is stabilized. Mild to moderate hemoptysis should be managed conservatively. Although IV amphotericin B generally is not useful in eradicating aspergillomas, inhaled or intracavitary instillation of amphotericin B has been employed successfully in a limited number of patients. Itraconazole has been efficacious in uncontrolled studies; however, the dose and duration of therapy have not been standardized. Hemoptysis generally ceases when the aspergilloma is eradicated.[85]

Invasive Aspergillosis

IA remains a disease of very high mortality: for example, in HSCT recipients with a diagnosis of invasive aspergillosis, the 3-month post HSCT mortality rate is 53.8% for autologous transplant recipients but approaches 90% for allogeneic HSCT recipients. However, the overall 1-year survival rate is only about 20% for autologous and allogeneic HSCT recipients with proven or probable invasive mold infections.[92,93,94]

Although exposure to *Aspergillus* conidia is nearly universal, impaired host defenses are required for the development of invasive disease. Phagocytes (neutrophils, monocytes, and macrophages) rather than antibodies or lymphocytes constitute the primary host defense system against invasive disease with aspergillosis. Macrophages prevent germination of conidia and also eradicate conidia, providing the first line of defense against invasive disease. Administration of corticosteroids appears to impair the killing of conidia by macrophages and to impair mobilization of neutrophils. Neutrophils halt hyphal growth and dissemination and kill mycelia, constituting a second line of defense. Prolonged neutropenia appears to be the most important predisposing factor to the development of IA, accounting for the high frequency of disease in patients with acute leukemia.[87]

Invasive disease with *Aspergillus* can arise de novo or from any of the allergic or colonizing forms of aspergillosis. Predisposing factors to the development of IA include glucocorticoid therapy, particularly following chronic administration or with higher dosages (30-200 mg/day of prednisone), cytotoxic agents, and recent or concurrent therapy with broad-spectrum antimicrobial agents. Patients with chronic hepatitis, alcoholism, diabetes mellitus, chronic granulomatous disease, leukopenia (less than 1,000 cells/mm^3 [less than 1×10^9/L]), leukemia (particularly acute lymphocytic or myelogenous leukemia), lymphoma, and acute rejection of an organ transplant are also at a higher risk of invasive disease. Although rare, IA has been reported in apparently normal hosts.[87] Aspergillosis is an uncommon fungal infection in patients with AIDS. AIDS patients may be at less risk for aspergillosis than other fungal infections because the primary cellular defect in AIDS patients is in the T-lymphocytes, whereas neutrophils and macrophages constitute the primary lines of defense to infection with aspergillosis.

Clinical Presentation

The lung is the most common site of invasive disease.[87] In the immunocompromised host, aspergillosis is characterized by vascular invasion leading to thrombosis, infarction, necrosis of tissue, and dissemination to other tissues and organs in the body. If bone marrow function returns, cavitation of the pulmonary lesion generally occurs, and the spread of infection can be halted. The progressive nature of the disease and its refractoriness to therapy are, in part, caused by the organism's rapid growth and its tendency to invade blood vessels.

Signs and Symptoms

Patients with IPA generally have blunted or non-specific signs and symptoms of infection due to impaired inflammatory responses.[95] Patients often present with classic signs and symptoms of acute pulmonary embolus: pleuritic chest pain, fever, hemoptysis, and friction rubs. The CNS, liver, spleen, heart, GI tract, pericardium, and other body sites are involved in a substantial minority of cases. In neutropenic patients with *Aspergillus* pneumonia, hyphae invade the walls of bronchi and surrounding parenchyma, resulting in an acute necrotizing, pyogenic pneumonitis. As a result, patients often present with classic signs and symptoms of acute pulmonary embolus: pleuritic chest pain, fever, hemoptysis, and friction rubs.

Diagnosis

The diagnosis of aspergillosis is complicated by the presence of *Aspergillus* as a normal commensal in the human GI tract and respiratory secretions, and establishment of a definitive diagnosis of disease is difficult. Demonstration of *Aspergillus* by repeated culture and microscopic examination of tissue provides the most firm diagnosis. A definitive diagnosis of invasive pulmonary aspergillosis (IPA) can be made by obtaining a biopsy of lung tissue; however, thrombocytopenia often limits clinicians' ability to perform this procedure. The appearance of *Aspergillus* in tissues varies with increasing host resistance from the normal vegetative hyphae found with necrotic tissue and exudate in the alveoli of immunocompromised hosts to the compact, tangled filaments (*granules*) observed in fungal balls. Identification of *Aspergillus* generally is based on the appearance of 2- to 4-micron-wide septate hyphae that are dichotomously branched at 45° angles. Sporulation is observed rarely in tissue. Although growth on Sabouraud dextrose or brain-heart infusion agar can be used for primary culture, bronchoscopy or bronchoalveolar lavage cultures are positive in only 40% of histopathologically identified specimens. Blood, CSF, and bone marrow cultures are rarely positive for *Aspergillus*.

Currently, the diagnosis is determined with the use of high resolution CT, in which IPA will manifest early on as "halo sign" (an area of low attenuation surrounding a nodular lung lesion, caused by edema or bleeding surrounding an ischemic area). In late IA nodular lesions, diffuse pulmonary infiltrates, consolidation, or ground glass opacities can be observed, and CT scans may demonstrate the crescent sign (an air crescent near the periphery of a lung nodule caused by contraction of infarcted tissue), while chest radiographs can demonstrate wedge-shaped, pleural-based infiltrates or cavities.[95] These signs are not specific to IPA, however, as bacteria and other fungal infections may produce similar findings. CT abnormalities are best documented in neutropenic marrow transplant recipients and commonly precede plain chest radiograph abnormalities.

Diagnostic Tests

New laboratory methods that allow for early differentiation of IFIs due to *Aspergillus* species versus zygomycetes and other moulds would be helpful in allowing clinicians in the earlier initiation of appropriate antifungal therapy. Although PCR-based testing is being performed in some centers, and appears promising, no FDA-approved method is commercially available.

The galactomannan test is an enzyme-linked immunosorbent assay (ELISA) (Platelia *Aspergillus* EIA test; Bio-Rad Laboratories) that detects galactomannan, an antigen released from *Aspergillus* hyphae upon invasion of host tissue. The clinical utility of this assay has been assessed in the clinical setting by sampling serum, BAL fluid, cerebrospinal fluid (CSF), and pleural fluid; however, the currently approved test is performed on serum. Additionally, while FDA-approved for use in the diagnosis of IA in HSCT recipients and in patients with leukemia; its usefulness in solid-organ transplant and pediatric populations needs to be established. In most patients, circulating antigen can be detected at a mean of 8 days before diagnosis by other means. The test has a sensitivity ranging from 30% to 100% and a specificity of approximately 85%; however, the sensitivity of the assay is decreased in patients receiving mold-active drugs on the day of sampling.[95] False positives can occur, particularly in patients receiving cyclophosphamide, piperacillin–tazobactam and amoxicillin–clavulanate, those with bifidobacteria infections, and in neonates.[96,97] and there are differences in the cutoff values for a positive result in the United States versus Europe. False negatives can occur during the concomitant use of antifungals, presumably because the level of galactomannan is related to the fungal burden.[95] In addition, it is important to note that the utility of galactomannan testing in the setting of prophylaxis has not been defined.[94]

1,3-β-d-glucan is a component of fungal cell walls that can be detected colorimetrically in clinical samples, including blood and bronchoalveolar lavage specimens, using a chromogenic variant of the limulus amoebocyte lysate assay. However, the current FDA-approved test (Fungitell; Associates of Cape Cod) is performed only on serum. The 1,3-β-d-glucan test can be used to detect most fungi, including *Fusarium*, *Trichosporon*, *Saccharomyces*, and *Acremonium*, which are less common but very important fungal pathogens, with a sensitivity of 55% to 100% and a specificity of 52% to 100%. However, the test does not detect the zygomycetes or cryptococci, and it can produce false positives in patients undergoing hemodialysis with cellulose membranes, and in other cases for unclear reasons.[95] Although a positive test result for the presence of (1,3)-β-d-glucan [BG] does not identify the infecting fungus, the practical application of this test includes its use as a screening assay (presumptive marker) for invasive fungal infection to allow the earlier initiation of antifungal therapy. Other tests are necessary for the confirmation and identification of the fungal pathogen.

TREATMENT

Invasive Aspergillosis

Therapy for IA is far from optimal at this time in part because of the difficulties in establishing a diagnosis and in part because of a lack of truly effective antifungal agents. Administration of amphotericin B appears to decrease mortality from more than 90% to approximately 45%. These data, however, are difficult to interpret because many patients were diagnosed postmortem, or amphotericin B therapy was not administered until the patient had very advanced disease. Mortality from pulmonary aspergillosis in bone marrow transplant recipients exceeds 94% regardless of therapy.[87] Although early diagnosis and administration of antifungal therapy can result in higher response rates, correction of underlying immune deficits (in particular, return of neutrophil counts) is of paramount importance in eradication of infection.[87]

Until the diagnosis of aspergillosis can be determined more rapidly and definitively, empirical therapy must be instituted when invasive disease is suspected. In patients at highest risk for invasive disease (acute leukemia and bone marrow transplant recipients), the most important predisposing factors include prolonged severe neutropenia (less than 100 cell/µL [less than 0.1×10^9/L] for more than 1 week), graft rejection, chronic administration of corticosteroids, and tissue damage from preexisting infection.[87]

Non-HIV-Infected Patient

Prophylaxis

As noted above in the discussion of prophylaxis for *Candida* infections in immunocompromised hosts, prophylaxis with azoles or echinocandins can reduce the incidence of aspergillosis in select high-risk populations.

Specific Therapy

Even though older azole antifungal agents (miconazole and ketoconazole) possess poor in vitro activity against *Aspergillus* species, newer triazoles demonstrate improved activity both in vitro and in animal models of infection. Antifungal agents with in vitro activity against *Aspergillus* species include amphotericin B, the echinocandins, and the azoles itraconazole, voriconazole, posaconazole, and isavuconazole. Historically, high dosages (1-1.5 mg/kg/day) of d-AmB were utilized for the treatment of suspected or proven invasive aspergillosis. Lipid formulations of amphotericin B are overall less nephrotoxic and at least as effective as amphotericin B, and that they can be effective when amphotericin Bis not.[98] They are indicated when preexisting or arising nephrotoxicity or concomitant nephrotoxic agents preclude high-dose amphotericin B therapy or when treatment with amphotericin Bappears to fail. Use of the highest approved dosages of the lipid formulations for treatment of suspected or documented infections is strongly advocated. However, randomized data from clinical trials are limited for most agents. Thus, while open-label trials support the potential of posaconazole and the echinocandins for treatment of invasive aspergillosis in immunocompromised patients, current guidelines from the US and other countries, consider voriconazole as the agent of choice for the primary treatment of aspergillus.

Voriconazole has emerged as the drug of choice of most clinicians for primary therapy of most patients with IA, based on a pivotal study in which a randomized comparison of voriconazole and d-AmB followed by other licensed antifungal agents for primary therapy for invasive aspergillosis demonstrated superior antifungal efficacy and improved survival at week 12 in the voriconazole arm.[99]

Isavuconazole was recently approved for the primary treatment of aspergillosis, based upon the results of a double blind, randomized, multi-national trial in subjects with proven or probable invasive fungal disease caused by *Aspergillus* spp. or other filamentous fungi. Isavuconazole was well tolerated, with fewer drug-related adverse effects than voriconazole.[100,101]

In patients who are unable to tolerate voriconazole, amphotericin B can be used. Because *Aspergillus* is only moderately susceptible to amphotericin B, full doses (1-1.5 mg/kg/day) are generally recommended, with response measured by defervescence and radiographic clearing. To treat microfoci, therapy should be continued after resolution of clinical and radiographic abnormalities until cultures (if they can be obtained) are negative, and reversible underlying predispositions have abated.

Clinical response rather than any arbitrary total dose should guide duration of therapy. The optimal dosage or duration of treatment of invasive disease is unknown and dependent on the extent of disease, the response to therapy, and the patient's underlying disease(s) and immune status. Response to therapy is largely related to the extent of aspergillosis at the time of diagnosis, and host factors, such as resolution of neutropenia and the return of neutrophil function, lessening immunosuppression, and the return of graft function from a bone marrow or organ transplant.

Lipid formulations of amphotericin B can be indicated in patients with impaired renal function, and in those patients who develop nephrotoxicity while receiving d-AmB. The lipid-based formulations may be preferred as initial therapy in patients with marginal renal function or in patients receiving other nephrotoxic drugs. Although these preparations appear less toxic than standard preparations, only limited data regarding their relative efficacy for IA are available at this time, as the studies with the lipid preparations have been open-label or with historical conventional amphotericin B controls.[70,74]

Although caspofungin (and other echinocandins) have in vitro activity against *Aspergillus* species, echinocandins are unable to completely kill or inhibit *Aspergillus* species. Caspofungin is approved by the FDA for use as salvage therapy in patients who are refractory to or intolerant of other therapies such as conventional amphotericin B, lipid formulations of amphotericin B, and/or itraconazole.[18,75] However, for primary therapy of aspergillosis, response rates are lower with caspofungin than those obtained with voriconazole and amphotericin B.[102]

The role of azoles in the management of azole-resistant aspergillosis remains unclear. In patients infected with azole-resistant strains of *Aspergillus*, limited data suggests that combination therapy with liposomal amphotericin B or a combination of voriconazole or posaconazole with an echinocandin may be effective.

Clinical Controversy... The Role of Combination Antifungal Therapy for the Treatment of Invasive Aspergillosis

The outcome of invasive aspergillosis (IA) continues to be associated with significant attributable mortality, especially in patients with hematological malignancies and in HSCT recipients. Based on extensive experience in the management of bacterial, and more recently, retroviral infections, the use of combination agents for synergistic or additive effects is now common practice, particularly for the treatment of IA. However, while the advantages of combination therapy include the possibility of more rapid, synergistic killing, disadvantages include the possibility of antagonism, as well as increased cost and the increased risk of drug interactions and adverse effects.

A 'proof of principle' study demonstrated that combination antifungal therapy could provide superior outcomes versus single agent therapy in the treatment of candidemia. High-dose fluconazole, alone or in combination with amphotericin B, in non-immunocompromised patients with candidemia demonstrated no antagonism and a trend toward improved success and more rapid clearance of *Candida* from the bloodstream. However, renal toxicity (from amphotericin B) was higher in the combination therapy arm.[103] Whether these adverse effects would be similar, if lipid formulations were used instead of the deoxycholate formulation of amphotericin B, is not known.

In a recent large study, combination therapy with voriconazole plus anidulafungin, versus voriconazole alone in the subgroup of patients with invasive aspergillosis demonstrated only a trend toward increased 6 week survival.[104] Thus, there are as yet no firm recommendations regarding the use of such combinations in humans.[104,105]

Secondary Prophylaxis

The use of prophylactic antifungal therapy to prevent primary infection or reactivation of aspergillosis during subsequent courses of chemotherapy is controversial.[12] Studies assessing the utility of IV administration of amphotericin B in low doses (0.1 mg/kg per day) as prophylactic therapy or with higher dosages (0.5-0.6 mg/kg per day) as empirical therapy for IFIs in patients with granulocytopenia have not included sufficient numbers of patients to enable detection of differences in the number of *Aspergillus* infections.

In granulocytopenic patients who recover from an episode of IA, the risk of relapse of aspergillosis during subsequent courses of chemotherapy is greater than 50%. Secondary prophylaxis of aspergillosis with empirical administration of high-dose amphotericin B decreases the risk of relapse. Amphotericin B 1 mg/kg per day is started 24 to 48 hours prior to the start of chemotherapy and continued throughout the period of granulocytopenia.

TREATMENT OPTIONS FOR EMERGING PATHOGENS

The increased frequency of fungal pathogens that were once rare is gaining attention from the medical community. Mucormycosis, previously known zygomycosis, is a term describing infections caused by fungi belonging to the order Mucorales. Permissive environmental conditions, selective antifungal pressure, and increased numbers of immunosuppressed patients have led to increased numbers of infections caused by the

Mucorales, which include *Rhizomucor* spp., *Absidia* spp. (now *Lichtheimia* spp.), *Rhizopus* spp., *Mucor* spp., and *Cunninghamella* spp. Prompt initiation of antifungal therapy is crucial, as treatment delays are associated with increased mortality.[106]

Of currently available systemic antifungals, only amphotericin B (including the lipid formulations) and posaconazole exhibit good in vitro activity against the Mucorales. Isavuconazole displays variable in vitro activity against the Mucorales, with wide MIC ranges. Prompt initiation of antifungal therapy is crucial, as treatment delays are associated with increased mortality.[106]

Mucor Infections

European guidelines recommend surgical debridement, in addition to therapy with a liposomal or lipid-complex formulation of amphotericin B at a dosage of greater than equal to 5 mg/kg/day. Isavuconazole was approved for the primary treatment of invasive mold infections, and as salvage therapy of patients who were intolerant of or failing prior antifungal therapy.[100,101] The approval was based upon the results of an open-label, noncomparative trial of patients with IFIs caused by rare molds, including members of the order Mucorales and patients with invasive aspergillosis and renal impairment.[101,107]

Fusarium* and *Scedosporium

Unfortunately, the early presentation of *Fusarium* and *Scedosporium* infections often mimics that of aspergillosis. On histopathology, *Scedosporium* species resembles *Aspergillus* species with dichotomously branching, septate hyphae and has a tendency for invasion of vascular structures.[106] These pathogens often demonstrate intrinsic resistance to amphotericin B and are associated with high mortality rates. Interpretive CBPs for antifungal MICs and *Scedosporium* spp. are not available, and the optimal choice and duration of therapy is unknown.[108] Voriconazole is FDA approved for the treatment of serious fungal infections caused by *S. apiospermum* and *Fusarium* species, including *Fusarium solani*, in patients intolerant of or refractory to other therapy.[58]

ANTIFUNGAL THERAPY

Pharmacists must have working knowledge of mechanism of action, spectrum of activity, dosing, and adverse effects of azole antifungals in order to provide appropriate recommendations for therapy. Dosing adjustments are needed for many antifungal agents in the setting of renal or hepatic dysfunction. A summary of the most common adverse effects of systemic antifungal agents are summarized in **Fig. 121-3** and described in the text below.[58]

Source: J.T. DiPiro, R.L. Talbert, G.C. Yee, G.R. Matzke, B.G. Wells, L.M. Posey: Pharmacotherapy: A Pathophysiologic Approach, 10th Edition, www.accesspharmacy.com

The antifungal armamentarium for the treatment of IFIs includes: (a) inhibitors of the fungal cell membrane such as polyenes (eg, amphotericin B) and azole antifungals, (b) inhibitors of DNA (5-flucytosine), and (c) inhibitors of cell wall biosynthesis (echinocandins).[58]

Antifungal therapy generally includes one or more antifungal agents, depending on the severity of infection and the patients' immune status. Rarely are the agents used in combination. Often therapy is initiated with an IV agent such as amphotericin B, and therapy is changed to an oral (azole) regimen as the patient's clinical status improves and oral therapy is tolerated.

Amphotericin B

Amphotericin B remains the therapy of choice for many systemic fungal infections despite a lack of controlled clinical trials documenting the optimal dosage, duration of therapy, or relative efficacy of this agent in comparison with newer azole antifungal agents. During pregnancy, amphotericin B remains the treatment of choice for most fungal infections because azole antifungals are teratogenic.[84,109] The side effects of amphotericin B generally are categorized as acute (infusion-related) or long term. Amphotericin B commonly causes renal functional impairment, including decreased glomerular filtration rate, hypokalemia, hypomagnesemia, metabolic acidosis due to distal (or type 1) renal tubular acidosis (RTA), and polyuria due to nephrogenic diabetes insipidus. The nephrotoxicity associated with amphotericin B is usually reversible with discontinuation of therapy. However, recurrent renal dysfunction can occur if treatment is reinstituted. The risk of amphotericin B nephrotoxicity is increased by higher daily doses and concurrent therapy with other nephrotoxins, such as an aminoglycoside or cyclosporine. The incidence and severity of nephrotoxicity can be minimized by administering amphotericin B in lipid-based formulations; liposomal amphotericin B may be less nephrotoxic than the ABLC.[58,110]

Lipid Formulations of Amphotericin B

The use of d-AmB frequently is associated with the development of induced nephrotoxicity. In an attempt to decrease the incidence of nephrotoxicity, three lipid formulations of amphotericin B have been developed and approved for use in humans: ABLC (Abelcet; Enzon Pharmaceuticals), ABCD (Amphotec; Intermune Pharmaceuticals), and liposomal amphotericin B (AmBisome; Gilead Pharmaceuticals). In these preparations, amphotericin B is incorporated into the phospholipid bilayer membrane rather than in the enclosed aqueous phase.

The various lipid formulations of amphotericin B exhibit markedly different pharmacokinetics; however, whether these differences result in different outcomes in the treatment of specific types of infections (eg, CNS infections) is unclear. Although larger doses of these preparations are required to achieve similar pharmacologic effects as the deoxycholate form of amphotericin B, the toxicity appears to be much lower. Although the FDA-approved dosages of these agents are 5 mg/kg per day (ABLC), 3 to 6 mg/kg per day (ABCD), and 3 to 5 mg/kg per day (liposomal amphotericin B), the agents appear generally equipotent. The optimal dose of these compounds for serious *Candida* infections is unknown; however, dosages of 3 to 5 mg/kg per day appear reasonable.[7]

Lipid formulations of amphotericin B are indicated for patients intolerant of, refractory to, or at high risk of being intolerant to conventional antifungal therapy.[7,110] Intolerance generally is defined as initial renal insufficiency (creatinine greater than 2.5 mg/dL [greater than 221 µmol/L] or creatinine clearance less than 25 mL/min [less than 0.42 mL/s]), a significant increase in creatinine (to 2.5 mg/dL [221 µmol/L] for adults or 1.5 mg/dL [133 µmol/L] for children), or severe acute administration-related toxicity, whereas refractory infections are defined as therapeutic failure of more than 500 mg amphotericin B.

Clinical Controversy...

Owing to the higher cost and paucity of randomized trials showing the efficacy of lipid-associated formulations of amphotericin B against proven invasive candidiasis, many clinicians limit their first-line use for the treatment of these infections to individuals who are intolerant to, at high risk of intolerance to, or refractory to amphotericin B deoxycholate. However, the data demonstrating up to a 6.6-fold increase in mortality in patients with amphotericin B-induced nephrotoxicity have convinced other clinicians that high-risk patients (eg, residence in an ICU care or intermediate care unit at the time of initiation of amphotericin B therapy) warrant first-line therapy with these agents.[7,110]

Flucytosine

Flucytosine (also known as 5-flucytosine) is a fluorinated pyrimidine analog that is highly water-soluble. Patients with creatinine clearances of less than 40 mL/min (0.67 mL/s) should receive careful dosage adjustments. Peak serum concentrations (2 hours after an oral dose) should be monitored in all patients (particularly those with a creatinine clearance of less than 10 mL/min [0.17 mL/s]) to maintain peak serum concentrations of more than 100 mg/L (775 µmol/L).[41]

Flucytosine generally is associated with few side effects in patients with normal renal, GI, and hematologic function, although rash, GI discomfort, diarrhea (5%-10%), and reversible elevations in hepatic enzymes are observed occasionally. In patients with renal dysfunction or concomitant amphotericin B therapy, leukopenia, thrombocytopenia, and (rarely) enterocolitis can occur. Although studies have suggested that little or no conversion of flucytosine to fluorouracil occurs in vitro, serum concentrations of greater than 1,000 ng/mL (1 mg/L; ~7.7 µmol/L) (therapeutic for the treatment of malignancies) have been documented in some patients. Investigators have theorized that flucytosine may be secreted into the GI tract, deaminated by intestinal bacteria, and reabsorbed as 5-fluorouracil.[41]

Flucytosine is used in combination with amphotericin B or fluconazole in the treatment of cryptococcosis or (less commonly) candidiasis. The rapid development of resistance to flucytosine, however, precludes its use as single-agent therapy. Mechanisms for drug resistance can include loss of deaminase and decreased permeability to the drug.[41]

Echinocandins

The echinocandins (caspofungin, micafungin, and anidulafungin) are a new class of antifungal agents that act as concentration-dependent, noncompetitive inhibitors of BG synthase, an essential component of the cell wall of susceptible filamentous fungi that is absent in mammalian

cells.[75,111]

All echinocandins display linear pharmacokinetics following administration of IV dosages, and are degraded primarily by the liver (also in the adrenals and spleen) by hydrolysis and *N*-acetylation. Following initial distribution, echinocandins are taken up by red blood cells (micafungin) and the liver (caspofungin and micafungin) where they undergo slow degradation to mainly inactive metabolites, although two uncommon metabolites of micafungin possess antifungal activity. Degradation products are excreted slowly over many days, primarily through the bile. Among the echinocandins, anidulafungin is unique in being eliminated almost exclusively by slow chemical degradation rather than undergoing hepatic metabolism.[75]

Echinocandins are available only as parenteral formulations, are not dialyzable, and do not require dosage adjustment in patients with renal insufficiency. They have minimal CSF penetration, largely because of their high protein binding and large molecular weights, although the clinical relevance of these findings can be disputed, given that several other antifungal agents (amphotericin B and itraconazole) are effective for the treatment of fungal meningitis despite low CSF concentrations.

Adverse effects of echinocandins include histamine release resulting in rash, facial swelling, and itchiness. Limited experience suggests that caspofungin and micafungin are safe to use in pediatric patients; the safety and effectiveness of anidulafungin in pediatric patients has not been established. At the time of FDA approval, there were concerns regarding the safety of caspofungin when combined with cyclosporine. However, three retrospective analyses of the use of caspofungin and cyclosporine in patients do not support a risk of clinically relevant hepatotoxicity.[75,111]

Azole Antifungal Agents

Adverse effects of azoles include GI disturbances (primarily nausea, vomiting, epigastric pain, and diarrhea), which appear to be more common in patients receiving ketoconazole and the solution formulation of itraconazole. Although cyclodextrin is not absorbed following oral administration, use of the IV formulations of itraconazole and voriconazole is limited to 2 weeks because of concerns for potential nephrotoxicity secondary to accumulation of the cyclodextrin vehicle, although recent studies suggest that this is of less concern than previously thought.[112] Fluconazole is well tolerated; intestinal complaints are the most frequently reported, followed by headaches and rash.[113] Unlike ketoconazole, fluconazole does not inhibit testicular or adrenal steroidogenesis in healthy volunteers or hospitalized patients. Reversible alopecia occurs not infrequently and usually appears after several months of treatment with higher doses of fluconazole.[114] Azoles are potentially teratogenic and should be avoided in pregnant women.[58,109]

Azole antifungals have been implicated in idiosyncratic drug induced liver injury with the incidence and pattern of injury varying between specific agents.[114,115,116] The exact mechanism of toxicity has not been elucidated and there is varying level of evidence with regards to the effect of dose on the development of the toxicity. It is recommended that baseline liver function tests (LFTs) be obtained for patients being started on therapy with these agents and periodically monitored. In general, hepatotoxicity can occur at any time after initiation of the antifungal with most cases occurring in the first month of therapy. The liver injury is usually reversible with discontinuation of the offending agent. Several reports support that substitution of the offending azole antifungal with a different azole antifungal can occur without impacting resolution of the toxicity.

Itraconazole

Itraconazole is triazole antifungal with a broad spectrum of antifungal activity. Despite its marked structural similarity to ketoconazole, itraconazole differs in several important respects. Itraconazole appears to have greater specificity against fungal versus mammalian CYP, resulting in greater potency and a decrease in CYP-mediated side effects. In addition, itraconazole possesses excellent in vitro activity against *Aspergillus* and *Sporothrix* species.[58,114]

Like ketoconazole, the capsule formulation of itraconazole depends on the availability of low gastric pH for dissolution and absorption. Administration with food appears to enhance significantly the bioavailability of itraconazole capsules, whereas it decreases the bioavailability of the oral solution. Because itraconazole exhibits pH-dependent dissolution and absorption, absorption of the capsule formulation is impaired in patients receiving antacids or H_2-receptor antagonists and in patients with achlorhydria.[112] Plasma concentrations of itraconazole following a single oral dose (capsules) in HIV-infected patients are approximately 50% lower than concentrations observed in healthy volunteers. The capsule formulation of itraconazole exhibits unpredictable oral bioavailability, particularly in subjects with hypochlorhydria and in patients with enteropathy caused by mucositis or graft versus host disease GVHD of the gut. An oral suspension formulation of itraconazole is available; that uses cyclodextrin as a solubilizing vehicle to increase the solubility of the drug. The oral bioavailability of the solution is unaffected by alterations in gastric pH or in patients with enteropathy.[58,112,114]

Fluconazole

Fluconazole is a triazole antifungal agent with markedly different pharmacologic features than other marketed azole antifungals. The small molecular weight, low protein binding, and increased water solubility of fluconazole result in rapid, essentially complete absorption of drug following oral administration. Because fluconazole is excreted primarily (greater than 80%) as unchanged drug in the urine, dosage adjustments are necessary in patients with renal dysfunction.[58]

Voriconazole

The hepatic biotransformation of voriconazole is fairly complex and involves CYP2C19, CYP3A4, and CYP2C9, with most metabolism mediated through CYP2C19. Two of the CYPs involved in voriconazole metabolism (CYP2C19 and CYP2C9) exhibit genetic polymorphism; variability in the CYP2C19 genotype accounts for approximately 30% of the overall between subject variability in voriconazole pharmacokinetics. About 3% to 5% of white and African human populations are poor metabolizers, while 15% to 20% of Asian populations are poor metabolizers. Drug levels can be as much as fourfold greater in poor metabolizers than in individuals who are homozygous extensive metabolizers. Coadministration of voriconazole with drugs that are potent CYP450 enzyme inducers can significantly reduce voriconazole levels. Voriconazole drug interactions are dose-dependent, as they exhibit unpredictable nonlinear pharmacokinetics; thus, drug interactions are more difficult to predict and manage.[117]

The most common side effect of voriconazole is a reversible disturbance of vision (photopsia), which occurs in approximately 30% of patients but rarely leads to discontinuation of the drug. Symptoms tend to occur during the first week of therapy and decrease or disappear despite continued therapy.

Patients experience altered color discrimination, blurred vision, the appearance of bright spots and wavy lines, and photophobia. Patients should be cautioned that driving can be hazardous because of the risk of visual disturbances. The visual effects are associated with changes in electroretinogram tracings, which revert to normal when treatment with the drug is stopped; no permanent damage to the retina has been demonstrated.[58,118,119,120]

Clinical Controversy…

Controversy has arisen about whether single-drug therapy or combination therapy (eg, voriconazole plus an echinocandin or voriconazole plus a lipid formulation of amphotericin B) is optimum therapy. At present, the highest interest concerns combination therapy in the treatment of aspergillosis, given the continued high mortality of these infections.[83] However, in vitro and animal data have produced conflicting results. Several retrospective studies have suggested an improvement in mortality with combination therapy with two or three antifungal agents; however, prospective, controlled human studies are lacking. Thus, there are as yet no firm recommendations regarding the use of such combinations in humans.[12]

Posaconazole

Posaconazole has a broad spectrum of antifungal activity, including *Aspergillus* and *Candida* species and zygomycetes. In vitro studies demonstrate that posaconazole is an inhibitor but not a substrate of hepatic (but not total) CYP3A4, and both a substrate and an inhibitor of P-glycoprotein (Pgp), suggesting that it may exhibit a drug interaction profile similar to other azoles. In addition, posaconazole undergoes glucuronidation by uridine diphosphate (UDP)-glucuronosyltransferase enzymes.[117]

Posaconazole was initially developed as an oral suspension for the prevention of IFIs in immunocompromised patients, including hematologic malignancy patients with prolonged neutropenia from chemotherapy as well as HSCT patients with GVHD.[121] However, to ensure adequate absorption, the suspension formulation had to be administered 2 to 3 times daily, with a high fat meal or a nutritional supplement. Most patients with GVHD, and many with chemotherapy-associated nausea or vomiting, mucositis or diarrhea, were unable to comply with the requirement for a fatty meal, resulting in decreased plasma concentrations of posaconazole and an increased risk of breakthrough fungal infection.[121,122,123,124] More recently, the development of IV and delayed-release tablet formulations of posaconazole have circumvented these absorption issues. In addition, the tablet formulation allows once daily oral administration of posaconazole following administration of a twice daily loading dose on the first day of therapy.[125]

Isavuconazole

Isavuconazole, is available both orally and IV, has a broad spectrum of activity against a number of clinically important yeasts and molds, including *Candida* spp., *Aspergillus* spp., *C. neoformans*, *Trichosporon* spp., and variable activity against the Mucorales. The most commonly reported adverse events, which are mild and limited in nature, include nausea, diarrhea and elevated liver function tests. Its drug interaction potential appears similar to other azole antifungals, but less than those observed with voriconazole. The potential advantage of this agent over other currently available broad-spectrum azole antifungals is as a clinically useful alternative to voriconazole for the treatment of invasive aspergillosis, due to its lack of genetically determined variability in plasma levels, and more favorable and predictable drug interaction profile. Preliminary studies suggest that it may also prove useful for the treatment of invasive mold infections; however, these indications await the results of clinical trials.[100,101]

Drug Interactions with Antifungal Agents

Drug interactions with azole antifungals generally can be placed into three broad categories: (a) decreases in azole bioavailability because of chelation or secondary to increases in gastric pH, (b) interactions with other CYP-metabolized drugs, and (c) interactions caused by inhibition of Pgp. Drug interactions in the latter two categories can result in increases or decreases in the azole antifungal, in the interacting drug, or in both drugs.[117]

The interaction of azole antifungal agents with other CYP-metabolized drugs is well recognized. The azoles appear to be metabolized almost entirely via the CYP3A4 subfamily. As expected, they interact with other drugs metabolized partly or wholly through this enzyme pathway. In addition, fluconazole and voriconazole use the CYP2C19 pathway. Numerous clinically significant interactions have been documented with azole

antifungals and a variety of other drugs. In most cases, the azole interferes with the metabolism of the other CYP-metabolized drug.[117]

Relative to ketoconazole and itraconazole, fluconazole appears to be intermediate in its ability to inhibit human cytochromes P450. The magnitude of fluconazole-induced inhibition of cyclosporine metabolism appears, however, to depend on the dosage of fluconazole.[117]

Predictably, drugs such as rifampin, rifabutin, isoniazid, phenytoin, and carbamazepine, which are known to induce the activity of cytochromes P450, result in increased metabolism of the azole antifungals and can result in therapeutic failures. Increased dosages of azole antifungals can be required in patients receiving these combinations of drugs.[117]

Itraconazole is an inhibitor of intestinal Pgp. Significant increases in digoxin (a Pgp substrate) have been observed in patients receiving both agents concurrently. Interactions with other substrates of Pgp would be expected to occur.[117]

Echinocandins are not inducers of CYP enzymes, nor do they interact with Pgp, and are considered poor substrates of CYP3A4. Nevertheless, drug interactions are noted with caspofungin and cyclosporine and tacrolimus; the mechanism for these interactions is not yet known. Rifampin both inhibits (acutely) and induces (after chronic administration) caspofungin metabolism, and a dosage increase is recommended in patients receiving other enzyme inducers, such as efavirenz, nevirapine, phenytoin, dexamethasone, and carbamazepine. Although micafungin does not significantly affect the clearance (or area under the plasma-concentration vs time curve [AUC]) of tacrolimus, it increases the AUCs of sirolimus and nifedipine and decreases the clearance of cyclosporine.[75,126]

Therapeutic Drug Monitoring (TDM) of Antifungal Agents

The available, good-quality, prospectively obtained data in the prophylactic or therapeutic setting are insufficient to justify the routine use of therapeutic drug monitoring. In addition, logistics, cost, and incorporation of therapeutic drug monitoring have yet to be worked out in modern prophylactic algorithms. However, under certain circumstances, serum or plasma concentration monitoring is warranted. Given the tremendous interpatient and intrapatient variability in voriconazole metabolism, TDM is warranted in most patients, Also, given the poor oral bioavailability of itraconazole capsules, and posaconazole solution, monitoring is recommended, particularly in patients with GVHD of the gut, mucositis, or diarrhea, or poor oral intake or those receiving concomitant therapy with proton-pump inhibitors.[127,128,129,130,131] Although the use of posaconazole tablets may result in a decreased need for TDM, recent data suggest that patients with a higher weight and those experiencing diarrhea are more likely to have lower levels.[65] Additional settings include patients susceptible to flucytosine toxicity, to document adequate oral absorption of poorly bioavailable azoles in cases of suspected treatment failure or concern about compliance or absorption, solubility and finally, when drug interactions that might reduce or accelerate the metabolism of azoles is suspected.[127,132] Recommendations regarding plasma concentration monitoring of antifungals are summarized in **Table 121-11**.

TABLE 121-11 Plasma Concentration Monitoring of Antifungal Agents[127-132]

	Serum Concentration Monitoring Necessary?	Target Concentration Range	Timing of Sample
Echinocandins	No	NA	NA
Amphotericin B (including lipids)	No	NA	NA
Fluconazole	No	NA	NA
Itraconazole	Yes, to ensure absorption and efficacy	*Efficacy:* Prophylaxis: >0.5 mcg/mL (mg/L; >0.7 µmol/L) Treatment: >1 mcg/mL (mg/L; >1.4 µmol/L) *Toxicity:* <5 mcg/mL (mg/L; <7 µmol/L)	Trough 7 days after initiation of therapy
Voriconazole	Probably yes—in all patients treated for IFI, altered liver function, potential drug–drug interactions, lack of response *Low* concentrations are associated with poor outcome; *high* concentrations are associated with adverse effects Variable metabolism due to nonlinear PK and genetic variability in CYP2C19 → unpredictable dose–exposure	*Efficacy:* Prophylaxis: trough >0.5-2 mcg/mL (mg/L; >1.4-5.7 µmol/L) Treatment: trough >1-2 mcg/mL (mg/L; >2.9-5.7 µmol/L) Concentrations >2.05 mcg/mL (mg/L; >5.7 µmol/L) are associated with improved outcome; 2-5.5 mcg/mL (mg/L; 5.7-15.7 µmol/L) is probably the best target *Toxicity:* concentrations >5.5 mcg/mL	Trough after 5-7 days therapy if no loading dose administered; 48 hours after administration of loading dose in critically ill patient (time to steady state is unpredictable due to nonlinear metabolism)

	Serum Concentration Monitoring Necessary?	Target Concentration Range	Timing of Sample
	relationship	(mg/L; >15.7 µmol/L) are associated with ↑ risk of visual and hepatic adverse events	
Posaconazole	Maybe Outcomes (but not adverse events) correlate with higher plasma concentrations in prophylaxis and possibly treatment	*Efficacy:* Prophylaxis: >0.7 mcg/mL (mg/L; >1 µmol/L) Treatment: Not well studied; concentrations >1.25 mcg/mL (mg/L;1.78 µmol/L) needed ? *Toxicity:* Correlation with toxicity poorly defined	Random level at SS (>7 days therapy). The long $t_{1/2}$ ensures little fluctuation in peaks and troughs at SS
Flucytosine	Yes—High concentrations are associated with toxicity	*Toxicity:* "Peak" <80-100 mcg/mL (mg/L; <620-775 µmol/L) *Efficacy:* Trough >30 mcg/mL (mg/L; >232 µmol/L)	2 hours postdose "peak", 3-5 days after initiation of therapy

NA, not applicable.

Chapter 122: Infections in Immunocompromised Patients

Scott W. Mueller; Douglas N. Fish

INTRODUCTION

KEY CONCEPTS

- 1 An *immunocompromised host* is a patient with defects in host defenses that predispose to infection. Risk factors include neutropenia, immune system defects (from disease or immunosuppressive drug therapy), compromise of natural host defenses, environmental contamination, and changes in normal flora of the host.

- 2 Immunocompromised patients are at high risk for a variety of bacterial, fungal, viral, and protozoal infections. Bacterial infections caused by gram-positive cocci (staphylococci and streptococci) occur most frequently, followed by gram-negative bacterial infections caused by Enterobacteriaceae and *Pseudomonas aeruginosa*. Fungal infections caused by *Candida* and *Aspergillus*, as well as certain viral infections (herpes simplex virus [HSV], cytomegalovirus [CMV]), are also important causes of morbidity and mortality.

- 3 Risk of infection in neutropenic patients is associated with both the severity and duration of neutropenia. Patients with severe neutropenia (absolute neutrophil count less than 500 cells/mm^3 [less than 0.5 × 10^9/L]) for greater than 7 to 10 days are considered to be at high risk of infection.

- 4 Fever (single oral temperature of greater than or equal to 38.3°C [greater than or equal to 101°F], or a temperature of greater than or equal to 38°C [greater than or equal to 100.4°F] for greater than or equal to 1 hour) is the most important clinical finding in neutropenic patients and is usually the stimulus for further diagnostic workup and initiation of antimicrobial treatment. Infection should be considered as the cause of fever until proven otherwise. Usual signs and symptoms of infection may be altered or absent in neutropenic patients. Appropriate empiric broad-spectrum antimicrobial therapy must be rapidly instituted to prevent excessive morbidity and mortality.

- 5 Empiric antimicrobial regimens for neutropenic infections should take into account patients' individual risk factors, as well as institutional infection and susceptibility patterns. The significant morbidity and mortality associated with gram-negative infections require that initial empiric regimens for treatment of febrile neutropenia have good activity against *P. aeruginosa* and Enterobacteriaceae. Parenteral regimens most commonly recommended for initial inpatient treatment include monotherapy with an antipseudomonal β-lactam, or a combination regimen consisting of an antipseudomonal β-lactam, plus an aminoglycoside. Low-risk patients may be successfully treated with oral antibiotics (ciprofloxacin plus amoxicillin-clavulanate), with the treatment setting determined by the patient's clinical status.

- 6 Neutropenic patients who remain febrile after 3 to 5 days of initial antimicrobial therapy should be reevaluated to determine whether treatment modifications are necessary. Common regimen modifications include addition of vancomycin (if not already administered) and antifungal therapy (amphotericin B, an echinocandin, or fluconazole). Therapy should be directed at causative organisms, if identified, but broad-spectrum regimens should be maintained during neutropenia.

- 7 The optimal duration of therapy for febrile neutropenia is controversial. The decision to discontinue antimicrobials is based on resolution of neutropenia, defervescence, culture results, and clinical stability of the patient.

- 8 Prophylactic antimicrobials are administered to cancer patients expected to experience prolonged neutropenia, as well as to hematopoietic stem cell and solid-organ transplant recipients. Prophylactic regimens may include antibacterial, antifungal, antiviral, or antiprotozoal agents, or a combination of these, selected according to risk of infection with specific pathogens. Optimal prophylactic regimens should take into account individual patient risk for infection and institutional infection and susceptibility patterns.

- 9 Patients undergoing hematopoietic stem cell transplantation are at an extremely high risk of infection because of prolonged neutropenia following intensive chemotherapy with or without irradiation, while solid-organ transplant recipients are at high risk because of prolonged administration of immunosuppressive drugs. Fungal (*Aspergillus*) and viral (CMV) infections are particularly troublesome in these populations, and prophylactic regimens directed against these pathogens are commonly used. When documented, these infections must be treated aggressively in order to optimize patient outcomes. Nevertheless, mortality rates are often high despite appropriate and aggressive antimicrobial therapy.

- 10 Immunocompromised patients must be continuously assessed for evidence of infection and response to antimicrobial therapy. Because a large number of antimicrobials may potentially be used, the occurrence of drug-related adverse effects must also be carefully assessed. Efforts should be directed at designing cost-effective treatment strategies that promote optimal patient outcomes.

An immunocompromised host is a patient with intrinsic or acquired defects in host immune defenses

that predispose to infection. Advances in modern medicine have created more immunocompromised hosts than ever before. Historically, many of these patients died of their underlying diseases. Dramatic improvements in survival have been achieved by more aggressive therapy of underlying diseases and improved supportive care. However, because such aggressive therapy often renders patients profoundly immunosuppressed for long periods, opportunistic infections remain important causes of morbidity and mortality. This chapter focuses on risk factors for infection, common pathogens and infection sites, and prevention and management of suspected or documented infections in cancer patients (including hematopoietic stem cell transplantation [HSCT] patients) and solid-organ transplant (SOT) recipients. Chapter e103 discusses infectious complications associated with human immunodeficiency virus (HIV) infection.

RISK FACTORS FOR INFECTION/EPIDEMIOLOGY

Many factors influence the degree of immunosuppression and also influence the epidemiology of the associated infections.

Neutropenia

1 2 3 Neutropenia is defined as an abnormally reduced number of neutrophils circulating in peripheral blood. Although exact definitions of neutropenia can vary, an absolute neutrophil count (ANC) of less than 1,000 cells/mm^3 (1.0 × 10^9/L) indicates a reduction sufficient to predispose patients to infection.[1] ANC is the sum of the absolute numbers of both mature neutrophils (polymorphonuclear cells [PMNs], also called *polys* or *segs*) and immature neutrophils (*bands*). The absolute number of PMNs and bands is determined by dividing the total percentage of these cells (obtained from the white blood cell [WBC] differential) by 100 and then multiplying the quotient obtained by the total number of WBCs.

The degree or severity of neutropenia, rate of neutrophil decline, and duration of neutropenia are important risk factors for infection.[1,2,3,4] All neutropenic patients are considered to be at risk for infection, but those with ANC less than 500 cells/mm^3 (0.5 × 10^9/L) are at greater risk than those with ANCs of 500 to 1,000 cells/mm^3 (0.5 × 10^9 to 1.0 × 10^9/L). Most treatment guidelines use ANC less than 500 cells/mm^3 (0.5 × 10^9/L) as the critical value in making therapeutic decisions regarding the management of suspected or documented infections.[1,2,3,4] Risk of infection and death are greatest among patients with less than 100 neutrophils/mm^3 (0.1 × 10^9/L) ("profound neutropenia").[1,2,3,5] In patients with chemotherapy-induced neutropenia, the risk of infection is also increased according to both the rapidity of ANC decline and duration of neutropenia. Patients with severe neutropenia of more than 7 to 10 days' duration are considered to be at especially high risk for serious infections.[1,2,3,6] The duration of chemotherapy-induced neutropenia varies considerably among subsets of cancer patients according to the specific chemotherapeutic agents used and the intensity of treatment. Patients undergoing HSCT may have no detectable granulocytes in peripheral blood for up to 3 to 4 weeks and are at particular risk for severe infections with a variety of pathogens.[5]

Bacteria and fungi commonly cause infections in neutropenic patients. Gram-positive cocci

(*Staphylococcus aureus*, *Staphylococcus epidermidis*, and other coagulase-negative staphylococci, streptococci, and enterococci) have emerged as the most common cause of acute bacterial infections among neutropenic patients. Gram-negative bacilli (*Escherichia coli*, *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*) traditionally were the most common causes of bacterial infection and remain frequent pathogens.[4,6,7,8,9] Although now not as common as gram-positive bacteria, the incidence of gram-negative infections may again be increasing and account for nearly half of bacterial infections.[2,6,7,8,9] Gram-negative infections are associated with significant morbidity and mortality, in large part due to increasing antibiotic resistance.[7,8,9] Patients who are neutropenic for extended periods and who receive broad-spectrum antibiotics are at high risk for fungal infections, usually due to *Candida* or *Aspergillus* spp.[1,2,3,6,10,11] Viral infections, although not as common as bacterial and fungal infections, also may cause severe infection in neutropenic patients.[1,2,5,6] Successful treatment of infections in neutropenic patients depends on resolution of neutropenia.[1,2]

Although not readily quantifiable, abnormalities may exist in granulocyte function as well as in cell numbers. Defects in phagocyte function may be caused by underlying disease (eg, leukemia) or its treatment (eg, corticosteroids, antineoplastic agents including monoclonal antibodies, and radiation).[2,6]

Immune System Defects

In addition to neutropenia, defects in T-lymphocyte and macrophage function (cell-mediated immunity), B-cell function (humoral immunity), or both predispose patients to infection. Cellular immune dysfunction is the result of underlying disease or immunosuppressive drug therapy; these defects result in a reduced ability of the host to defend against intracellular pathogens. Patients with malignancies and transplant patients receiving a wide variety of immunosuppressive drugs, such as cyclosporine, tacrolimus, sirolimus, mycophenolate, corticosteroids, azathioprine, and antineoplastic agents, are at risk for a variety of bacterial, fungal, viral, and protozoal infections (**Table 122-1**). Although some of these pathogens are associated with asymptomatic or mild disease in normal hosts, they may cause disseminated, life-threatening infections in immunocompromised hosts.

TABLE 122-1 Risk Factors and Common Pathogens in Immunocompromised Patients

Risk Factor	Patient Conditions	Common Pathogens
Neutropenia	Acute leukemia Chemotherapy	Bacteria: *Staphylococcus aureus*, *Staphylococcus epidermidis*, *Escherichia coli*, *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*, streptococci, enterococci Fungi: *Candida*, *Aspergillus*, Mucorales (*Mucor*) Viruses: Herpes simplex
Impaired cell-mediated	Lymphoma Immunosuppressive therapy	Bacteria: *Listeria*, *Nocardia*, *Legionella*, Mycobacteria

Risk Factor	Patient Conditions	Common Pathogens
immunity	(steroids, cyclosporine, chemotherapy)	Fungi: *Cryptococcus neoformans*, *Candida*, *Aspergillus*, *Histoplasma capsulatum* Viruses: Cytomegalovirus, varicella-zoster, herpes simplex Protozo: *Pneumocystis jiroveci*
Impaired humoral immunity	Multiple myeloma Chronic lymphocytic leukemia Splenectomy Immunosuppressive therapy (steroids, chemotherapy)	Bacteria: *S. pneumoniae*, *H. influenzae*, *N. meningitidis*
Loss of protective skin barriers	Venipuncture, bone marrow aspiration, urinary catheterization, vascular access devices, radiation, biopsies	Bacteria: *S. aureus*, *S. epidermidis*, *Bacillus* spp., *Corynebacterium jeikeium* Fungi: *Candida*
Mucous membranes	Respiratory support equipment, endoscopy, chemotherapy, radiation	Bacteria: *S. aureus*, *S. epidermidis*, streptococci, Enterobacteriaceae, *P. aeruginosa*, *Bacteroides* spp. Fungi: *Candida* Viruses: Herpes simplex
Surgery	Solid-organ transplantation	Bacteria: *S. aureus*, *S. epidermidis*, Enterobacteriaceae, *P. aeruginosa*, *Bacteroides* spp. Fungi: *Candida* Viruses: Herpes simplex
Alteration of normal microbial flora	Antimicrobial therapy Chemotherapy Hospital environment	Bacteria: Enterobacteriaceae, *P. aeruginosa*, *Legionella*, *S. aureus*, *S. epidermidis* Fungi: *Candida*, *Aspergillus* Fungi: *Candida*
Blood products, donor organs	Bone marrow transplantation Solid-organ transplantation	Viruses: Cytomegalovirus, Epstein–Barr virus, hepatitis B, hepatitis C Protozo: *Toxoplasma gondii*

Underlying disease also frequently causes defects in humoral immune function. Patients with multiple myeloma and chronic lymphocytic leukemia have progressive hypogammaglobulinemia that results in defective humoral immunity. Splenectomy performed as a part of the staging process for Hodgkin's disease places patients at risk for infectious complications. Disease states with humoral immune dysfunction predispose the patient to serious, life-threatening infection with encapsulated organisms such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis*.

Destruction of Protective Barriers

Loss of protective barriers is a major factor predisposing immunocompromised patients to infection. Damage to skin and mucous membranes by surgery, venipuncture, IV and urinary catheters, radiation, and chemotherapy disrupts natural host defense systems, leaving patients at high risk for infection. Chemotherapy-induced mucositis may erode mucous membranes of the oropharynx and GI tract and establish a portal for subsequent infection by bacteria, HSV, and *Candida*.[1,2,5] Medical and surgical procedures, such as transplant surgery, indwelling IV catheter placement, bone marrow aspiration, biopsies, and endoscopy, further damage the integument and predispose patients to infection. Infections resulting from disruption of protective barriers usually are a result of skin flora, such as *S. aureus*, *S. epidermidis*, and various streptococci.[1,2,6]

Environmental Contamination/Alteration of Microbial Flora

Infections in immunocompromised patients are caused by organisms either colonizing the host or acquired from the environment. Microorganisms may be transferred easily from patient to patient on the hands of hospital personnel unless strict infection control guidelines are followed. Contaminated equipment, such as nebulizers or ventilators, and contaminated water supplies have been responsible for outbreaks of *P. aeruginosa* and *Legionella pneumophila* infections, respectively. Foods, such as fruits and green leafy vegetables, which often are colonized with gram-negative bacteria and fungi, are sources of microbial contamination in immunocompromised hosts.[1,5]

Most infections in cancer patients are caused by organisms colonizing body sites, such as the skin, oropharynx, and GI tract and are therefore caused by the patient's own endogenous flora.[1,2,5,6] The GI tract is a common site from which infections in immunocompromised hosts originate. Periodontitis, pharyngitis, esophagitis, colitis, perirectal cellulitis, and bacteremias are caused predominantly by normal flora of the gut; bloodstream infections are thought to arise from microbial translocation across injured GI mucosa.[1,5,6] Normal flora may be significantly disrupted and altered; oropharyngeal flora rapidly change to primarily gram-negative bacilli in hospitalized patients. Many cancer patients may already be colonized with gram-negative bacilli on admission as a result of frequent prior hospitalizations and clinic visits. In hospitalized cancer patients, however, many infections are caused by colonizing organisms acquired after admission.[1]

Although hospitalization and severity of illness are important risk factors for colonization by gram-negative bacilli, administration of broad-spectrum antimicrobial agents has the greatest impact on flora of immunocompromised hosts. Use of these agents disrupts GI tract flora and predisposes patients to infection with more virulent pathogens. Antineoplastic drugs (eg, cyclophosphamide,

doxorubicin, and fluorouracil) and acid-suppressive therapy (eg, H_2-receptor antagonists, proton-pump inhibitors, and antacids) also may result in changes in GI flora and possibly predispose patients to infection.[1,2]

Numerous factors, such as underlying disease, immunosuppressive drug therapy, and antimicrobial administration, determine the immunocompromised host's risk of developing infection. Several risk factors are present concomitantly in many patients (see Table 122-1).

ETIOLOGY OF INFECTIONS IN NEUTROPENIC CANCER PATIENTS

2 Infection remains a significant cause of morbidity and mortality in neutropenic cancer patients. More than 50% of febrile neutropenic patients have an established or occult infection.[1,2] Patients with profound neutropenia are at greatest risk for systemic infection, with at least 20% of these individuals developing bacteremia.[1,2] Areas of impaired or damaged host defenses, such as the oropharynx, lungs, skin, sinuses, and GI tract, are common sites of infection. These local infections may progress to cause systemic infection and bacteremia.[2] Febrile episodes in neutropenic cancer patients can be attributed to microbiologically documented infection in approximately 30% to 40% of cases, about half of which are due to bacteremia. Further, infections can be documented clinically (but not microbiologically) in another 30% to 40% of patients, with the remaining 20% to 40% of patients manifesting infection only by fever.[2,4,6]

Table 122-1 lists organisms commonly infecting immunocompromised patients. Approximately 45% to 70% of bacteremic episodes in cancer patients are the result of gram-positive organisms compared with less than 30% of episodes documented during the 1970s and 1980s.[1,4,6,7,8] This shift is attributed to the frequent use of indwelling central and peripheral IV catheters, frequent use of broad-spectrum antibiotics with excellent gram-negative activity but relatively poor gram-positive coverage, higher rates of mucositis caused by aggressive cancer treatments, and prophylaxis with trimethoprim–sulfamethoxazole or quinolones.[1,4,6,7,8,12] Staphylococci (especially *S. epidermidis*) account for most infections, but *Bacillus* spp. and *Corynebacterium jeikeium* are also important pathogens.[1,2,6] Rates of infection due to methicillin-resistant *S. aureus* (MRSA) have increased in the hospital and community setting.[2,5,13] Viridans streptococci, which may be resistant to β-lactams, also have emerged as important pathogens, particularly in patients with chemotherapy-induced mucositis of the oropharynx.[2,4,5,12] Enterococci, including vancomycin-resistant strains, also may be problematic in many institutions.[2,5,12] Bacteremia caused by vancomycin-resistant enterococci (VRE) in neutropenic patients is associated with a mortality rate up to 30%.[4,14]

Gram-positive infections do not always cause immediately life-threatening infections and are associated with somewhat lower mortality rates (approximately 5%-10%) compared with gram-negative infections.[1,2,7] However, increasing rates of antibiotic resistance have made treatment of gram-positive infections in immunocompromised patients more challenging.[2,6,7] MRSA infections are associated with increased morbidity, mortality, and hospital costs compared with susceptible

organisms.[15,16] Methicillin resistance among coagulase-negative staphylococci, which may cause 40% to 80% of infections in certain populations, is common (70%-90% of isolates).[1,2,5,6,7] Organisms that are resistant to vancomycin are increasing in importance.[1,2,4,7,14] Thus, prevention and timely diagnosis and treatment of gram-positive infections are clearly of great importance in the management of neutropenic cancer patients.

Gram-negative infections remain important causes of morbidity and mortality (approximately 20%-30%) in immunocompromised cancer patients.[7] However, the relative frequency of infection owing to specific pathogens has been shifting among gram-negative infections. *E. coli* and *Klebsiella* remain the most common isolates at many centers.[2,6] Strains of Enterobacteriaceae producing plasmid-mediated extended-spectrum β-lactamases that hydrolyze extended-spectrum cephalosporins, and carbapenemases that hydrolyze carbapenems have emerged and are cause for concern.[1,2,6,7,12] The global spread of carbapenem-resistant Enterobacteriaceae (CRE) is especially concerning. The frequency of infections resulting from other gram-negative organisms, such as *Enterobacter*, *Serratia*, and *Citrobacter*, has been increasing.[1,2] Infections with these particular organisms may be difficult to treat because of the ease of β-lactamase induction and the more frequent development of resistance to multiple antibiotics.[1,2,6,12]

P. aeruginosa has long been an important pathogen in cancer patients. *P. aeruginosa* infection rates are decreasing in patients with solid tumors but not in patients with hematologic malignancies.[4,6,7] Infections caused by *P. aeruginosa* are associated with significant morbidity and mortality in neutropenic patients, with mortality rates of 31% to 75% reported.[1,3,7] The frequency of infection caused by difficult-to-treat organisms such as *Stenotrophomonas maltophilia* appear to be increasing at many centers, probably because of selective pressures of broad-spectrum antimicrobial use.[6,8] As with gram-positive organisms, antibiotic resistance among gram-negative organisms has continued to increase at alarming rates and has made appropriate antibiotic selection for treatment of febrile neutropenia more difficult.[1,13] Although the GI tract is a common site of bacterial infection, severe infections caused by anaerobic organisms are relatively infrequent. Anaerobes are found most frequently in mixed infections, such as perirectal cellulitis and mucositis-associated oropharyngeal infections.[2,6]

In addition to bacterial infections, neutropenic cancer patients are at risk for invasive fungal infections. Patients with extended periods of profound neutropenia who have been receiving broad-spectrum antibiotics, corticosteroids, or both are at the highest risk for invasive fungal infection. Up to one third of febrile neutropenic patients who do not respond to 1 week of broad-spectrum antibiotic therapy will have a systemic fungal infection.[1,2,8] Large autopsy studies have documented a change over time in invasive fungal infections. Whereas from 1989 to 2003 over 30% of autopsies of patients with hematologic malignancies found deep fungal infection (75% of which were undiagnosed prior to death), this number decreased to 19% from 2004 to 2008 (49% of which were undiagnosed prior to death). These improvements may be due to improved awareness, diagnostic techniques and treatments. One single center estimated the average prevalence of invasive fungal infections was 30% in those autopsied over the 20 year period. Causative pathogens were usually either *Aspergillus* spp., *Candida* spp., or Mucorales fungi (such as *Mucor* spp.).[17]

Candida albicans is a common fungal pathogen in neutropenic cancer patients, especially those with solid tumors.[1,2,4,11,17,18] However, non-*albicans* species of *Candida* including *Candida glabrata*, *Candida tropicalis*, *C. parapsilosis*, and *C. krusei* are being isolated with increasing frequency and are more common than *C. albicans* infections in some studies.[11,18] Increased infections caused by pathogens such as *Trichosporon* spp., *Fusarium* spp., and *Curvularia* spp. have also been reported.[10,11,17] The shift toward more frequent infection with non-*albicans Candida* is important because of significantly decreased rates of susceptibility among many of these strains.[19] Because *Candida* spp. are normal flora, alteration of body host defenses is an important risk factor for the development of these infections. Oral thrush is the most common clinical manifestation of fungal infection. Mucous membranes damaged from chemotherapy and radiation serve as areas of *Candida* surface colonization and subsequent entry into the bloodstream; disease then may disseminate throughout the body. Organs such as the liver, spleen, kidney, and lungs are commonly involved in disseminated disease.[1,2,17] Hepatosplenic candidiasis is a particularly important infection in patients with hematologic malignancies.[6,17,24] Diagnosis of *Candida* infections is difficult and often requires invasive tissue sampling.[6] In patients with invasive candidiasis, overall attributable mortality is as high as 35% to 50%.[4,11,18]

Invasive infections caused by *Aspergillus* spp. are a serious complication of neutropenia. Mortality rates have historically approached 80% in patients with prolonged neutropenia and/or patients undergoing allogeneic HSCT; however, mortality is now reported as low as 35%.[4,10] These infections are particularly prevalent and more common in patients with hematologic malignancies and in patients undergoing HSCT.[4,10,11,17,20] Infections resulting from *Aspergillus* species (including *A. fumigatus*, *A. terreus*, *A. flavus*, and *A. niger*) usually are acquired via inhalation of airborne spores. After colonizing the lungs, *Aspergillus* invades the lung parenchyma and pulmonary vessels, resulting in hemorrhage, pulmonary infarcts, and a high mortality rate. Invasive pulmonary disease is the dominant manifestation of infection in patients with neutropenia. However, *Aspergillus* also may cause other infections, including sinusitis, cutaneous infection, and disseminated disease involving multiple organs, including the CNS.[17,20] Prolonged neutropenia is the primary risk factor for invasive pulmonary aspergillosis in patients with acute leukemia; use of corticosteroids also may predispose patients to disease.[20] Invasive aspergillosis should be suspected in neutropenic cancer patients colonized with *Aspergillus* (in sputum and/or nasal cultures) who remain persistently febrile despite at least 1 week of broad-spectrum antibiotic therapy.[1,2,20] Increased infections caused by other yeasts (such as *Trichosporon*) and molds (such as Mucorales, *Fusarium*, and *Curvularia*) have also been reported.[10,11,17]

Chemotherapy-induced mucous membrane damage may predispose neutropenic cancer patients to reactivation of HSV, manifesting as gingivostomatitis or recurrent genital infections. Untreated oropharyngeal HSV infections may spread to involve the esophagus and often coexist with *Candida* infections. Clinical disease resulting from HSV occurs most often in patients with serologic evidence (eg, serum antibodies to HSV) of prior infection. Both HSV-seropositive HSCT patients and HSV-seropositive leukemics receiving intensive chemotherapy are at high risk for recurrent HSV disease during periods of immunosuppression.[2,4,5]

Pneumocystis jiroveci and *Toxoplasma gondii* are the most common parasitic pathogens found in immunocompromised cancer patients. Patients with hematologic malignancies and those receiving high-dose corticosteroids as part of chemotherapy regimens are at the greatest risk of infection.[2,4,5] Routine use of trimethoprim–sulfamethoxazole prophylaxis has reduced substantially the incidence of these infections.[1,2,5]

Because the majority of infecting organisms in cancer patients are from the host's own flora, some centers have used routine surveillance cultures in an attempt to prospectively identify causes of fever and suspected infection. In a typical surveillance culture program, cultures of the nose, mouth, axillae, and perirectal area are performed twice weekly, and culture results are correlated with the clinical status of the patient. Because these cultures are costly and have low diagnostic yield, the utility of surveillance culture programs is believed to be limited.[1,2] However, surveillance cultures are useful as research tools and in patients with prolonged profound neutropenia and in institutions that have high rates of antimicrobial resistance or have problems with virulent pathogens such as *P. aeruginosa* or *Aspergillus* spp. Surveillance cultures should be limited to the anterior nares for detecting colonization with MRSA, *Aspergillus*, and penicillin-resistant pneumococci and to the rectum for detecting VRE, *P. aeruginosa*, and multiple-antibiotic-resistant gram-negative rods (such as CRE).[1,2]

Knowledge of infection rates and local susceptibility patterns is essential for guiding optimal management of febrile neutropenia. These parameters must be monitored closely because the spectrum of infectious complications is related to multiple factors, including cancer chemotherapy regimens and antimicrobial therapy used for treatment and prophylaxis.

CLINICAL PRESENTATION

4 The most important clinical finding in the neutropenic cancer patient is fever. Because of the potential for significant morbidity and mortality associated with infection in these patients, fever should be considered to be the result of infection until proved otherwise.[1,2,3,6] At the appearance of fever, the patient should be evaluated carefully for other signs and symptoms of infection.

TREATMENT

Management of patients with febrile neutropenia, including both treatment and prophylaxis of infectious complications, can be extremely challenging. Although published guidelines are available, the most optimal clinical management of these patients remains unclear in many aspects.

Febrile Episodes in Neutropenic Cancer Patients

DESIRED OUTCOMES 121-1

4 5 The goals of therapy in neutropenic cancer patients with fever are the following: (a) protect the neutropenic patient from early death caused by undiagnosed infection; (b) prevent breakthrough bacterial, fungal, viral, and protozoal infections during periods of neutropenia; (c) effectively treat

established infections; (d) reduce morbidity and allow for administration of optimal antineoplastic therapy; (e) avoid unnecessary use of antimicrobials that contribute to increased resistance; and (f) minimize toxicities and cost of antimicrobial therapy while increasing patient quality of life. Empirical broad-spectrum antibiotic therapy is effective at reducing early mortality.[7]

Approach to Treatment

General guidelines for management of febrile episodes and documented infections in neutropenic patients are shown in **Figs. 122-1** and **122-2**.[1] Although many controversies remain regarding optimal management of these patients, updated evidence-based guidelines from the Infectious Diseases Society of America (IDSA) for the management of febrile neutropenia were published in 2010.[1] Similarly, the National Comprehensive Cancer Network (NCCN) published updated clinical practice guidelines for the prevention and treatment of cancer-related infections in 2015.[2] Selected specific recommendations are discussed in the following sections of this chapter, and their associated evidence-based rankings are summarized in **Table 122-2**.

FIGURE 122-1

Initial management of febrile episodes in neutropenic patients. (ANC, absolute neutrophil count; HSCT, hematopoietic stem cell transplantation; MASCC, Multinational Association for Supportive Care in Cancer; PO, oral.)

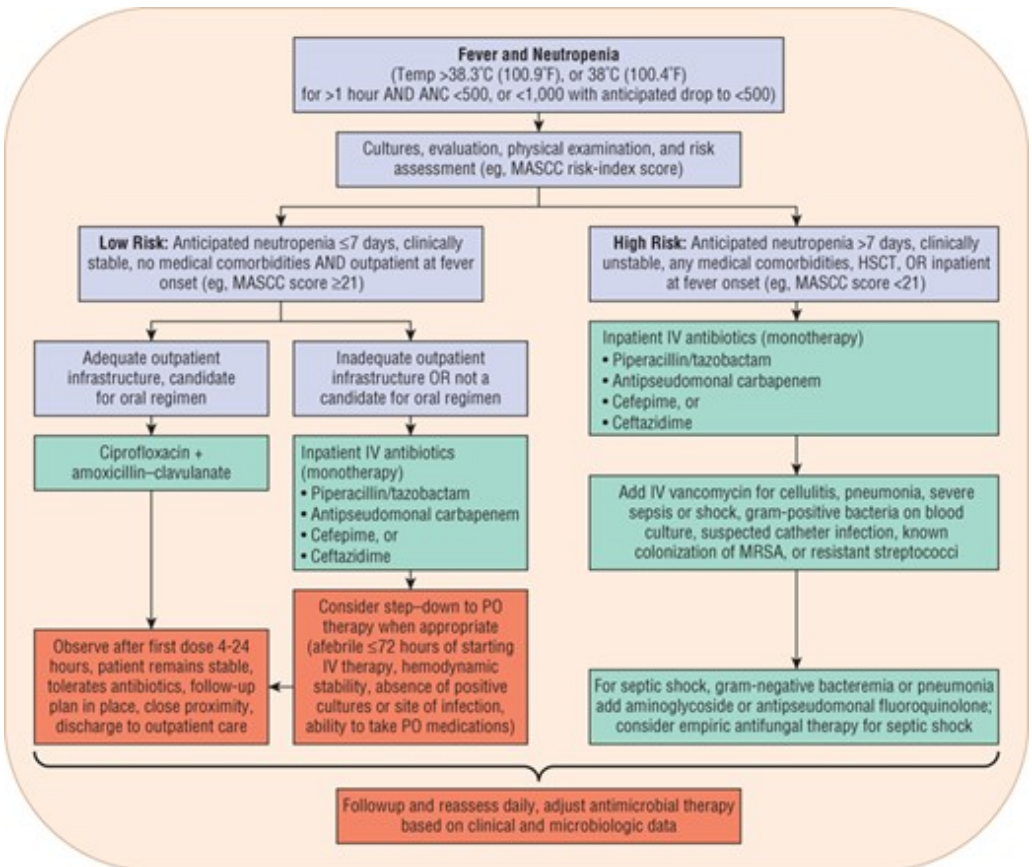

FIGURE 122-2

Subsequent management of febrile episodes in neutropenic patients who have already received empirical antimicrobial therapy for 2-4 days. (ANC, absolute neutrophil count; MDR, multidrug-resistant; PO, oral.)

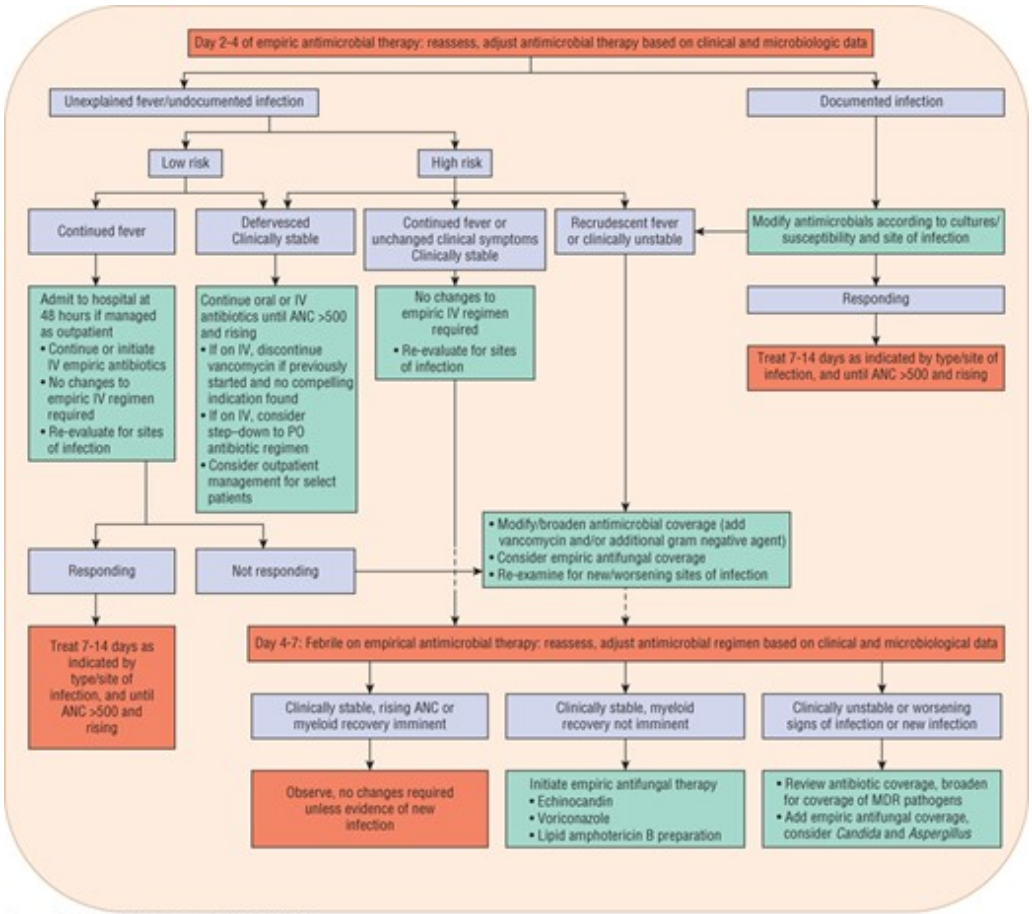

TABLE 122-2 Summary of Evidence-Based Recommendations for Management of Febrile Episodes in Neutropenic Patients

Recommendations	Recommendation Grades[a]
Oral antibiotics are feasible for treatment of carefully selected patients at low risk for complications	A-1
Monotherapy with appropriate antibiotics is as effective as combination regimens for initial empirical treatment of febrile neutropenic episodes	A-1
Patients at high risk for serious life-threatening infections must be initially treated with IV antibiotics. Patients at low risk can be treated with either IV or oral drugs (see text for risk stratification criteria)	A-2
Patients who become afebrile within 2-4 days of beginning initial empirical antibiotic therapy and in whom specific organisms have been identified should be treated for ≥7 days (until cultures are negative and patient has	B-2

Recommendations	Recommendation Grades[a]
clinically recovered). Low-risk patients in whom no organism is identified can be switched to oral antibiotics if desired, whereas patients originally classified as high risk should continue on IV antibiotics	
Management of Patients with Persistent Fever During First 2-4 Days of Treatment	
In patients initially receiving monotherapy or a two-drug regimen *not* including vancomycin, addition of vancomycin can be considered if any criteria for use of vancomycin are present (see the text for specific criteria)	B-3
In patients *already* receiving vancomycin as part of the initial empirical regimen, withdrawal of vancomycin should be considered after 2 days in the absence of a documented pathogen requiring continued therapy	A-2
Other initial antibiotics can be continued if the disease has not progressed, or switched to oral therapy if the patient was classified as low risk even in the presence of continued fever	A-1
Management of Patients with Fever Persisting for More Than 2-4 Days After Initial Treatment	
Reassess patient after 2 days of treatment. If still febrile by day 4, then: (a) continue the same antibiotics if clinically stable; (b) change antibiotics if any evidence of disease progression or antibiotic toxicities; or (c) add an antifungal drug if the duration of neutropenia is expected to be more than 5-7 additional days	Option a: A-1 Option b: A-3 Option c: A-3
Continuation of Antibiotics in Afebrile Patients with no Identified Infection	
Antibiotic therapy can be discontinued after 3 days of treatment if patient is afebrile for ≥48 hours and absolute neutrophil count (ANC) is ≥500 cells/mm^3 (≥0.5 × 10^9/L) for two consecutive days	A-2
If patient remains neutropenic, continue IV or oral antibiotics	A-2
Antibiotics should be continued in patients with profound neutropenia (ANC <100 cells/mm^3 [<0.1 × 10^9/L]), mucous membrane lesions of mouth or GI tract, unstable vital signs, or other identified risk factors	A-2
Antibiotics can be stopped after 2 weeks in patients with prolonged neutropenia of unclear continued duration, no identified site of infection, and who can be closely observed	C-3
Alternatively, antibiotics can be discontinued after 4 days if no infection is documented and the patient shows no response to therapy	C-3
Management of Fungal Infections	
Suspected candidiasis:	
Lipid-associated amphotericin B (LAMB) or caspofungin[b]	A-1
Voriconazole	B-1
Fluconazole or itraconazole	B-1
Candidemia:	

Recommendations	Recommendation Grades[a]
An echinocandin[b] or LAMB	A-2
Fluconazole or voriconazole	B-3
Granulocyte Transfusions	
There are no specific indications for routine use of granulocyte transfusions	C-2
Colony-Stimulating Factors	
Colony-stimulating factors are not indicated for routine treatment of neutropenia in either febrile or afebrile patients	B-2
Prophylactic use of colony-stimulating factors should be considered for patients in whom the anticipated risk of fever and neutropenia is ≥20%	A-2
Antimicrobial Prophylaxis in Neutropenic Patients	
Fluoroquinolone prophylaxis should be considered for high-risk patients with profound neutropenia (ANC <100 cells/mm^3 [<0.1 × 10^9/L]) expected to last 7-10 days	B-1
Antibacterial prophylaxis is not required in routinely recommended in low-risk patients who are expected to be neutropenic <7 days	A-3
Prophylaxis with trimethoprim–sulfamethoxazole should be administered to all patients at risk for *Pneumocystis jiroveci* pneumonia, regardless of whether they are neutropenic	A-1
Prophylaxis with fluconazole, posaconazole, voriconazole, or caspofungin[b] is recommended in high-risk patients, starting with induction chemotherapy and continued for duration of neutropenia; itraconazole is an effective alternative agent	A-1 for all agents except voriconazole and caspofungin[b] (both B-2)
In HSCT, prophylaxis with fluconazole, micafungin[b], posaconazole, itraconazole, voriconazole, or LAMB is recommended during the period of risk of neutropenia	A-1 for fluconazole and micafungin[b], all others B-2
In HSCT patients with graft-versus-host disease, or neutropenic patients with hematologic malignancies, prophylaxis with posaconazole is recommended for prevention of invasive fungal infections	A-1
HSV-seropositive patients undergoing HSCT or leukemia induction therapy should receive acyclovir prophylaxis during neutropenia, and for at least 30 days after HSCT	A-1 for prophylaxis, A-2 for duration
In HSCT, prophylaxis with acyclovir should be administered during neutropenia and for at least 1 year afterward to prevent VZV infection or reactivation	A-2

[a]Strength of recommendations: A, B, C = good, moderate, and poor evidence to support recommendation for use, respectively; D = moderate evidence to support a recommendation against

use.

[b]Expert opinion indicates all echinocandins are likely interchangeable and equally effective.

Quality of evidence: 1 = evidence from ≥1 properly randomized, controlled trial; 2 = evidence from ≥1 well-designed clinical trial without randomization, from cohort or case–control analytic studies, from multiple time series, or from dramatic results from uncontrolled experiments; 3 = evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert committees.

Data from references 1, 2, 5, 18, and 20.

CLINICAL PRESENTATION Febrile Neutropenia General

- Due to high risk for serious infections, frequent (at least daily) careful clinical assessments must be performed to search for possible evidence of infection[1,2,3,4,5,6]
- Physical assessment should include examination of all common sites of infection, including mouth/pharynx, nose and sinuses, respiratory tract, GI tract, urinary tract, skin, soft tissues, perineum, and intravascular catheter insertion sites

Symptoms

- Usual signs and symptoms of infection may be absent or altered in neutropenic patients owing to low numbers of leukocytes and an inability to mount an inflammatory response (eg, no infiltrate on chest x-ray film, urinary tract infection without pyuria)
- Pain may be present at the infection site(s)

Signs

- Fever in this setting is defined as a single oral temperature ≥38.3°C (≥101°F) in the absence of other causes or temperature ≥38°C (≥100.4°F) for 1 hour or more. Other causes of fever unrelated to infection in this patient population include reactions to blood products, chemotherapeutic agents (and other drugs, including biologics), cell lysis, and underlying malignancy
- Usual signs of infection may be absent or altered; patients with bacteremia commonly exhibit no signs of infection other than fever

Laboratory Tests

- Neutropenia (ANC ≤1,000 cells/mm^3 [≤1.0×10^9/L])
- Blood cultures (two or more sets, including vascular access devices) for bacteria and fungi; cultures of other suspected infection sites (infection can be documented microbiologically in only about 30% of cases, about half of which are due to bacteremia)

- Other cultures should be obtained as indicated clinically according to the presence of signs or symptoms
- Recent surveillance cultures (nasal, rectal) should be reviewed, if available
- Complete blood count and blood chemistries should be obtained frequently to monitor neutropenia, plan supportive care, guide drug dosing, and assess patient's overall status

Other Diagnostic Tests

- Chest x-ray film
- Aspiration, biopsy of skin lesions
- Other diagnostic tests as indicated clinically on the basis of physical examination and other assessments

Fever in the neutropenic cancer patient is considered to be caused by infection until proved otherwise. High-dose broad-spectrum bactericidal, usually parenteral, empirical antibiotic therapy should be initiated at the onset of fever or at the first signs or symptoms of infection. Withholding antibiotic therapy until an organism is isolated results in unacceptably high mortality rates. Undiagnosed infection in immunocompromised patients can rapidly disseminate and result in death if left untreated or if treated improperly. Failure to initiate appropriate antibiotic therapy for *P. aeruginosa* bacteremia at the onset of fever in neutropenic cancer patients resulted in mortality rates of 15% and 70% within 12 and 48 hours, respectively.[1,2] Empirical antibiotic therapy is 70% to 90% effective at reducing early morbidity and mortality.[1,2,7] Therapy must be appropriate and initiated promptly. Antimicrobial therapy must also be initiated promptly in afebrile cancer patients with clinical signs and symptoms of infection.

When designing optimal empirical antibiotic regimens, clinicians must consider infection patterns and antimicrobial susceptibility trends in their respective institutions. Patient factors such as risk for infection, drug allergies, concomitant nephrotoxins, and previous antimicrobial exposure (including prophylaxis) must be considered.[1,2,4] Assessment of the patient's risk of infection will help determine the appropriate route and setting for antibiotic administration (Fig. 122-1). Neutropenic patients with fever can be divided into low- and high-risk groups for complications of severe infection. Risk stratification drives both type and setting of antimicrobial therapy. The Multinational Association for Supportive Care in Cancer (MASCC) risk-index score is recommended by many clinical guidelines to assess a patient's risk of complications.[1,2] Most experts agree that, in general, low-risk patients have an anticipated duration of neutropenia less than or equal to 7 days, are clinically stable, and have no or few comorbidities and no bacterial focus or systemic signs of infection other than fever. In contrast, high-risk patients are those with an anticipated duration of neutropenia greater than 7 days or profound neutropenia, are clinically unstable or have comorbid medical problems (eg, focal or systemic signs of infection, GI symptoms, nausea, vomiting, diarrhea, hypoxemia, and chronic lung disease), or have a high-risk cancer (eg, acute leukemia) and/or have undergone high intensity chemotherapy. High-risk patients (MASCC less than 21) should be hospitalized for parenteral antibiotics whereas low-risk patients may be candidates for oral or outpatient antibiotics. Even with

such classifications, careful selection of low-risk patients for oral outpatient management is important (discussed in "Oral Antibiotic Therapy for Management of Febrile Neutropenia" section below).[1,2,21]

The optimal antibiotic regimen for empirical therapy in febrile neutropenic cancer patients remains controversial, but it is clear that no single regimen can be recommended for all patients. Because of their frequency and relative pathogenicity, *P. aeruginosa* and other gram-negative bacilli and staphylococci remain the primary targets of empirical antimicrobial therapy.[1,2] Although *P. aeruginosa* may be documented in fewer than 5% of bloodstream infections in the population of hospitalized patients, adequate antipseudomonal antibiotic coverage still must be included in empirical regimens because of the significant morbidity and mortality associated with this pathogen.[1,4,13] All empirical regimens must be carefully monitored and appropriately revised on the basis of documented infections, susceptibilities of bacterial isolates, development of more defined clinical signs and symptoms of infection, or a combination of these factors.

Although there are some differences among them, consensus guidelines generally recognize three different types of empirical parenteral antibiotic regimens: (a) monotherapy with an antipseudomonal β-lactam such as a cephalosporin (cefepime or ceftazidime), a carbapenem (imipenem–cilastatin or meropenem), or piperacillin–tazobactam; (b) two-drug combination therapy with an antipseudomonal β-lactam plus either an aminoglycoside or an antipseudomonal fluoroquinolone (ciprofloxacin or levofloxacin); and (c) monotherapy or two-drug combination therapy as above, plus the addition of vancomycin (Fig. 122-1).[1,2] Each of these regimens has advantages and disadvantages, which are summarized in **Table 122-3**. There is no overwhelming evidence that any one of these regimens is superior to the others. The overall response to empirical antibiotic regimens in febrile neutropenic cancer patients is approximately 70% to 90% regardless of whether a pathogen is isolated or which antimicrobial regimen is used.[1,2,4,7] Additionally, other alternative regimens may also appropriate based on specific patient characteristics or susceptibilities of suspected pathogens.

TABLE 122-3 Comparative Advantages and Disadvantages of Various Antibiotic Regimens for Empiric Therapy of Febrile Neutropenic Cancer Patients

Regimen	Potential Advantages	Potential Disadvantages
β-Lactam monotherapy (ceftazidime, cefepime, piperacillin–tazobactam, imipenem–cilastatin, or meropenem)	Efficacy comparable to combination regimens; decreased drug toxicities; ease of administration; possibly less expensive	Possibly less efficacy in profound neutropenia or prolonged neutropenia; limited gram-positive activity; no potential for additive/synergistic effects; increased selection of resistant organisms; increased colonization and superinfection rates
Antipseudomonal β-lactam plus aminoglycoside (eg, gentamicin or tobramycin + cefepime, ceftazidime, or piperacillin–tazobactam)	Traditional regimen, broad-spectrum coverage; optimal therapy of *Pseudomonas aeruginosa*; rapidly bactericidal; synergistic activity; decreased	Limited gram-positive activity; potential for nephrotoxicity; need for therapeutic monitoring of aminoglycoside concentrations

Regimen	Potential Advantages	Potential Disadvantages
	bacterial resistance; reduction of superinfections	
Antipseudomonal β-lactam plus fluoroquinolone (ciprofloxacin or higher-dose levofloxacin + ceftazidime, cefepime, or piperacillin–tazobactam)	Efficacy similar to other regimens when used in combination therapy; no cross-resistance with β-lactams; possibility for oral administration; may be useful in patients with renal impairment in whom aminoglycosides are undesirable	Marginal gram-positive activity; fluoroquinolones not recommended as monotherapy; resistance may develop rapidly
Empirical regimens containing vancomycin (added to antipseudomonal β-lactam ± aminoglycoside or fluoroquinolone)	Early effective therapy of gram-positive infections	No demonstrated benefit of vancomycin empirical therapy versus addition of vancomycin if needed later; increased risk of selection for vancomycin-resistant enterococci; risk of toxicities; excessive cost; need for therapeutic monitoring of vancomycin concentrations
Oral antibiotic regimens (eg, ciprofloxacin or levofloxacin + amoxicillin–clavulanate or clindamycin)	Efficacy comparable with parenteral therapy in low-risk patients; less expensive; reduced exposure of patients to nosocomial pathogens	Least studied treatment approach; less potent than parenteral antibiotics; requires compliant patient with 24-hour access to medical care should clinical instability develop

Data from references 1,2,3, 7, 22, and 26.

β-Lactam Monotherapy

Monotherapy with an antipseudomonal β-lactam is recommended by IDSA 2010 and NCCN 2015 guidelines as initial parenteral therapy for management of febrile neutropenia without suspected or proven resistant organisms or complications (eg, pneumonia, hypotension, vascular access infection, etc.).[1,2] Several β-lactam antibiotics in current use have been evaluated as monotherapy for management of febrile episodes in neutropenic cancer patients, including antipseudomonal cephalosporins (ceftazidime and cefepime), piperacillin–tazobactam, and antipseudomonal carbapenems (imipenem–cilastatin and meropenem).[1,2] Three different meta-analyses assessing as many as 46 clinical trials involving more than 7,600 patients found no significant differences overall between monotherapy and combination therapy (β-lactam/aminoglycoside) in rates of survival, treatment response, and bacterial/fungal superinfections.[2] One study also found a higher rate of adverse effects in aminoglycoside-containing combination regimens.[22] In addition, one analysis found that cefepime monotherapy was associated with a significantly higher risk of mortality compared with the other β-lactams evaluated.[1,2,23] A follow-up analysis conducted by the FDA using additional studies and patient-level data failed to confirm an increased risk of mortality with

cefepime, concluding that it is as efficacious as other β-lactams.[1,23,24] Significantly lower response rates for ceftazidime (but not cefepime) monotherapy have been reported in another review of the clinical literature.[1,2] However, until the results of these studies can be validated, ceftazidime is still among the monotherapy regimens routinely recommended as appropriate initial therapy of febrile neutropenic patients, although with a lower strength of evidence in 2015 NCCN guidelines.[1,2,23,24] Institutional susceptibility patterns and patient characteristics should drive drug selection.

Doripenem, ceftazidime-avibactam, and ceftolozane-tazobactam have appropriate overall spectrum of antibacterial activity with good activity against *P. aeruginosa* and other gram-negative organisms as well as many gram-positive pathogens. Neither the 2015 NCCN nor the 2010 IDSA consensus guidelines specifically recommend these agents as appropriate for monotherapy due to a lack of supportive clinical evidence at the time the guidelines were written.[1,2] They are, however, considered by some clinicians to be reasonable treatment options depending on patient- and institution-specific factors related to risk of infection with MDR pathogens.

Use of monotherapy has several potential advantages and disadvantages (see Table 122-3). Perhaps the most common concerns are those regarding the selection of resistant strains of organisms, such as *P. aeruginosa*, *Enterobacter* spp., and *Serratia* spp., through extended-spectrum β-lactamases and type 1 β-lactamases, especially with ceftazidime.[1,2,7,12] Activity against gram-positive organisms such as coagulase-negative staphylococci, MRSA, enterococci (including VRE), penicillin-resistant *S. pneumoniae*, and some strains of viridans streptococci is poor with some single β-lactams, but cefepime and antipseudomonal carbapenems have good activity against viridans streptococci and pneumococci.[1,2] Although ceftazidime has been studied widely and used for treatment of febrile neutropenia, newer agents may be more effective owing to ceftazidime's susceptibility to β-lactamase induction and lower activity against gram-positive organisms.[1,2,7,12,23] Ertapenem, a carbapenem, and tigecycline, a glycylcycline antibiotic, have excellent activity against many gram-negative organisms but should not be used in the empirical treatment of febrile neutropenia due to their weaker activity against *P. aeruginosa*. For the same reason ceftaroline, a cephalosporin active against MRSA, is not an acceptable option for empiric monotherapy in most patients.

As with all empirical antibiotic regimens, patients receiving monotherapy should be monitored closely for treatment failure, secondary infections, and development of resistance. Use of monotherapy may not be appropriate in institutions with high rates of gram-positive infections or infections caused by relatively resistant gram-negative pathogens such as *P. aeruginosa* and *Enterobacter*. The carbapenems are less susceptible to inducible β-lactamases and often may be used effectively in these institutions. Overall, similar efficacy has been observed with monotherapy with antipseudomonal β-lactams compared to aminoglycoside combination therapy for treatment of *P. aeruginosa* infections.[1,2,22]

Aminoglycoside Plus Antipseudomonal β-Lactam

Regimens consisting of an aminoglycoside plus an antipseudomonal β-lactam traditionally have been the most commonly used for empirical treatment of febrile neutropenia, although many such regimens may lack adequate gram-positive activity (see Table 122-3).[1,2] This relative lack of activity

remains a concern because of the increasing frequency of gram-positive infections. The choice of aminoglycoside and β-lactam for inclusion in empirical regimens should be based on institutional epidemiology and antimicrobial susceptibility patterns. Similar efficacy is observed with an antipseudomonal β-lactam in combination with an aminoglycoside.[1,2,22]

Combinations of broad-spectrum β-lactams and aminoglycosides may provide synergistic activity against bacteria commonly infecting neutropenic patients. The exact role of synergy in the outcome of febrile neutropenic patients treated with empirical antibiotic therapy is somewhat controversial, particularly in light of the efficacy of single-drug regimens and nephrotoxicity associated with aminoglycosides.[22] Nevertheless, combinations of antibiotics appear to be beneficial in patients with persistent profound neutropenia.

Aminoglycoside toxicity may be a concern in patients receiving these regimens who are already receiving other nephrotoxic drugs, such as cisplatin and cyclosporine. Administration of aminoglycosides in large single daily doses (once-daily dosing) may be as effective, less costly, and no more toxic than conventional dosing methods. Although once-daily aminoglycoside dosing regimens appear to be safe and effective in these patients, standard dosing regimens are recommended for infections where data are not sufficient to recommend once-daily dosing (eg, endocarditis).[1,2]

Fluoroquinolones as a Component of Empirical Regimens

Because the fluoroquinolone antibiotics have broad-spectrum activity (particularly against gram-negative pathogens), rapid bactericidal activity, and favorable pharmacokinetic and toxicity profiles, these agents have been investigated as empirical therapy for febrile neutropenic patients. Ciprofloxacin is the preferred agent for use in this clinical setting because of its relatively better activity against *P. aeruginosa* and more extensive evidence-based support for its use.[1,2] Response rates to quinolone-containing combination regimens are comparable to those obtained with the other regimens described previously.[1,2,4] Ciprofloxacin is not recommended for monotherapy, however, because of its relatively poor activity against gram-positive pathogens, particularly streptococci, and variable response rates in clinical studies.[1,2] Fluoroquinolones should also not be used as empirical therapy in patients who have received quinolones as infection prophylaxis because of the risk of drug resistance.[1,2] Rates of fluoroquinolone resistance are increasing, and streptococcal treatment failures are a concern.[12,13] Although fluoroquinolones are not generally considered first-line empirical therapy, they may be useful as one component of combination regimens in patients with allergies or other contraindications to first-line agents.[1,2]

Empirical Regimens Containing Vancomycin

The inclusion of vancomycin in initial empirical therapy of febrile neutropenic cancer patients is not currently recommended by IDSA 2010 or NCCN 2015 guidelines unless the patient has specific risk factors; however, this remains an ongoing debate. This controversy continues because of the increasing incidence of gram-positive infections in this population, particularly MRSA. One approach

is to include vancomycin in the initial empirical antibiotic regimen, thereby providing early effective treatment of possible gram-positive infections. Inclusion of vancomycin in initial empirical regimens may be more appropriate today because of higher rates of MRSA infections as well as aggressive chemotherapy regimens causing significant mucosal damage that increases the risk for streptococcal infections. Decreased mortality from penicillin-resistant viridans streptococcal infections has been observed when vancomycin was included in initial therapy.[1,5,25] A second approach is to withhold vancomycin from initial empirical regimens, later adding the drug if gram-positive organisms are isolated from cultures or if there is clinical deterioration. Support for both these approaches can be found in the medical literature.[1,2,25,26] Prospective studies and multiple meta-analyses have failed to document increased response rates or decreased mortality with the routine addition of vancomycin to initial empirical regimens, provided that vancomycin can be added later as needed.[1,2,25,26] In addition to increased costs of therapy, vancomycin was also associated with increased adverse effects, including nephrotoxicity.[2] Finally, concerns remain regarding selection of resistant gram-positive bacteria such as VRE with excessive vancomycin use.[1,2]

Vancomycin is currently recommended for inclusion in initial empirical regimens only in patients at high risk for gram-positive infection, particularly due to MRSA and coagulase-negative staphylococci (including patients with evidence of infection of central venous catheters and other indwelling lines), high risk for viridans streptococcal infection due to severe mucositis, or pneumonitis or soft tissue infection in hospitals with high rates of MRSA infections.[1,2,7,25] Rates of β-lactam resistance among viridans streptococci range up to 25%.[1,2] Empirical vancomycin use may be justified in institutions using empirical or prophylactic antibiotic regimens without good activity against streptococci (eg, ciprofloxacin) and in patients known to be colonized with MRSA or β-lactam–resistant pneumococci. In patients with preliminary culture results indicating gram-positive infection, empirical vancomycin is appropriate while the susceptibility results are pending. Lastly, empirical use of vancomycin may be recommended in patients with hypotension or other evidence of cardiovascular impairment or sepsis without an identified pathogen.[1,2] If empirical vancomycin therapy is initiated and no evidence of gram-positive infection is found after 48 to 72 hours, the drug should be discontinued.[1,2] Continuing vancomycin when not warranted results in higher costs, more toxicities, and greater risk of development of VRE.[1,2]

Other antimicrobial agents, such as quinupristin–dalfopristin, linezolid, daptomycin, telavancin, and ceftaroline, should be reserved for documented infections caused by multiresistant gram-positive pathogens that are not susceptible to, or are unresponsive to, vancomycin. The role of these drugs in the routine treatment of fever in neutropenic patients is undetermined, and linezolid is associated with risk of myelosuppression.[1,2]

Oral Antibiotic Therapy for Management of Febrile Neutropenia

An individual patient's risk for complications of severe infection determines appropriate antibiotic therapy and the proper setting for administration (see Table 122-3).[1,4,5] Risk stratification is based on several parameters (eg, MASCC score as mentioned above) as well as response to empirical antimicrobial therapy if IV therapy is initially given.[1] Because of the excellent spectrum of activity and

favorable pharmacokinetics of currently available oral antibiotics, particularly the fluoroquinolones, oral antibiotics have an important role in the management of selected patients. In patients at low risk for severe or complicated bacterial infection, empirical therapy with broad-spectrum oral antibiotic agents achieves similar patient outcomes as parenteral antibiotics, with response rates of 77% to 95%.[1,2,4,21] This has made possible the treatment of febrile neutropenia in low-risk patients in the outpatient setting. Patients judged to be low risk with reliable follow-up may be appropriate candidates for oral antibiotic therapy administered on an outpatient basis.[1,2,4,21] Ciprofloxacin in combination with amoxicillin–clavulanate (or clindamycin for penicillin-allergic patients) for enhanced gram-positive coverage has been most commonly studied for outpatient therapy in low-risk patients and is recommended by IDSA and NCCN guidelines.[1,2] In general, monotherapy with ciprofloxacin should be avoided due to relatively poor gram-positive activity. Levofloxacin has been used as monotherapy for outpatient treatment of low-risk patients, due to enhanced gram-positive activity; however, this regimen has not been well studied and is not formally recommended by IDSA or NCCN guidelines. If used, only the higher-dose levofloxacin 750 mg regimen should be administered in order to provide adequate activity against organisms such as *P. aeruginosa*.[1,2] Moxifloxacin has been endorsed as an option by NCCN guidelines, however, the lack of *P. aeruginosa* activity warrants special consideration.[2] Careful patient selection obviously is required for such management strategies. Important criteria include patient and provider comfort, a history of medication compliance, good caregiver support, a follow-up plan, and close proximity, prompt access and transportation to appropriate medical care around the clock in the event of failure to respond to outpatient antibiotic therapy. If a patient qualifies for oral therapy based on social and clinical status, the first dose of oral regimen should be given and the patient observed for 4 to 24 hours to ensure tolerance and the patient remains clinically stable. Benefits of oral therapy on an outpatient basis include increased convenience and quality of life for patients and caregivers and reduced exposure to multidrug-resistant institutional pathogens.[1,2] Outpatient therapy of low-risk patients now is common practice in most institutions.

In patients at low risk for severe bacterial infection who were initiated on IV antibiotics, oral antibiotics may play a role in step-down therapy. Carefully selected neutropenic patients may be safely switched from broad-spectrum parenteral therapy to oral antibiotic regimens (eg, ciprofloxacin plus amoxicillin–clavulanate) with response rates comparable to patients remaining on IV therapy.[1,21] Patient selection criteria generally include defervescence within 72 hours of initiation of parenteral therapy, hemodynamic stability, absence of positive cultures or a discernible site of infection, and ability to take oral medications. Many of these patients are able to complete their course of therapy at home.[1,2,21] Changing parenteral antimicrobials to oral regimens in carefully selected patients is now relatively common practice and allows for less expensive hospitalizations and earlier patient discharges.

Antimicrobial Therapy After Initiation of Empirical Therapy

6 After initiation of empirical antimicrobial therapy (**Table 122-4**), judicious assessment of febrile neutropenic cancer patients is mandatory to evaluate response, clinical status, laboratory data, and potential need for therapy adjustments. After 2 to 4 days of empirical antimicrobial therapy, the

clinical status and culture results of febrile neutropenic patients should be reevaluated to determine whether therapeutic modifications are necessary (Fig. 122-2). Modifications of antimicrobial therapy should be based on clinical and laboratory data; antibiotic therapy should be optimized based on culture results. However, during periods of neutropenia, patients generally should continue to receive broad-spectrum therapy because of risk of secondary infections or breakthrough bacteremias when antimicrobial coverage is too narrow.[1,2] The treatment duration for a documented infection should be appropriate for the particular organism and site, and should continue for at least the duration of neutropenia (until ANC greater than or equal to 500 cells/mm^3 [greater than or equal to 0.5×10^9/L]) or longer if clinically necessary.

TABLE 122-4 Drug Dosing Table[a]

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Other
Antibacterial Agents					
Amoxicillin–clavulanate	Augmentin®	875 mg orally two times daily	875 mg orally two times daily		In combination with ciprofloxacin for outpatient treatment
Ceftazidime	Fortaz®	2 g IV every 8 hours	1-2 g IV every 8 hours		
Ceftazidime-avibactam	Avycaz®	2.5 g IV every 8 hours	2.5 g IV every 8 hours		Not studied in febrile neutropenia, but spectrum is appropriate if high rates of MDR gram-negative bacteria (esp. CRE)
Cefepime	Maxipime®	2 g IV every 12 hours	1-2 g IV every 12 hours		
Ceftaroline	Teflaro®	600 mg IV every 12 hours	600 mg IV every 12 hours		Activity against methicillin-resistant *S. aureus*
Ceftolozane-tazobactam	Zerbaxa®	1.5 g IV every 8 hours	1.5 g IV every 8 hours		Not studied in febrile neutropenia, but spectrum is appropriate if high rates of

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Other
					MDR gram-negative bacteria
Piperacillin–tazobactam	Zosyn®	4.5 g IV every 6 hours	3.375-4.5 g IV every 6 hours		
Imipenem–cilastatin	Primaxin®	500 mg IV every 6 hours	250-500 mg IV every 6 hours		
Meropenem	Merrem®	1 g IV every 8 hours	1 g IV every 8 hours		
Doripenem	Doribax®	500 mg IV every 8 hours	500 mg IV every 8 hours		
Tobramycin	Nebcin®	Traditional: 2 mg/kg loading dose, followed by 1.5 mg/kg IV every 8 hours. Alternative: 5-7 mg/kg IV once daily	Traditional dosing: Guided by measured serum concentrations		
Gentamicin	Garamycin®	Traditional: 2 mg/kg loading dose, followed by 1.5 mg/kg IV every 8 hours. Alternative: 5-7 mg/kg IV once daily	Traditional dosing: Guided by measured serum concentrations		
Amikacin	Amikin®	Traditional: 7.5 mg/kg IV every 12 hours. Alternative: 15-20 mg/kg IV once daily	Traditional dosing: Guided by measured serum concentrations		

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Other
Ciprofloxacin	Cipro®	400 mg IV every 8 hours	400 mg IV every 8-12 hours	Outpatient treatment: 750 mg PO every 12 hours	May be given orally in low-risk patients in combination with amoxicillin-clavulanate
Levofloxacin	Levaquin®	750 mg IV once daily	500-750 mg IV once daily	Outpatient treatment: 750 mg PO once daily	May be given orally in low-risk patients
Moxifloxacin	Avelox®	400 mg IV/PO once daily	400 mg IV/PO once daily	Outpatient treatment: 400 mg PO once daily	For select outpatient use, lacks *P. aeruginosa* activity
Vancomycin	Vancocin®	30–40 mg/kg/day IV in two divided doses	Dosing guided by serum concentrations to achieve trough of 15-20 mg/L		For methicillin-resistant *S. aureus* infection
Nafcillin	Nafcil®	2 g IV every 6 hours	1-2 g IV every 4-6 hours		For methicillin-susceptible *S. aureus* infection
Daptomycin	Cubicin®	Skin/soft tissue infections: 4 mg/kg IV once daily; bacteremia: 6 mg/kg IV once daily	Skin/soft tissue infections: 4 mg/kg IV once daily; bacteremia: 6 mg/kg IV once daily		For infection (esp. bacteremia) due to methicillin-resistant *S. aureus*, vancomycin-resistant enterococci
Linezolid	Zyvox®	600 mg IV or orally every 12 hours	600 mg IV or orally every 12 hours		For infection due to vancomycin-resistant enterococci
Ampicillin	Omnipen®, Polycillin®, Principen®	2 g IV every 4 hours	1-2 g IV every 4-6 hours		In combination with gentamicin for *Listeria*

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Other
					infection
Erythromycin	E-mycin®, Erythrocin®	1 g IV every 6 hours	1-2 g IV every 4-6 hours		For *Legionella* infection
Antifungal Agents					
Clotrimazole	Mycelex Troche®	10 mg orally five times daily	10 mg orally five times daily		Administered as oral troche; dissolve in mouth
Nystatin	Nystatin Oral®	100,000 units orally every 6 hours	100,000 units orally every 4-6 hours		Administered as suspension; swish and swallow
Fluconazole	Diflucan®	800 mg IV or orally once, then 400 mg IV or orally once daily	100-800 mg IV or orally once daily	Prophylaxis of *Candida* infection: 400 mg IV or orally once daily	
Itraconazole	Sporanox®	200 mg orally twice daily	200-400 mg/day orally divided twice daily	Prophylaxis of *Candida* infection: 200 mg orally twice daily	Therapeutic drug monitoring recommended
Voriconazole	Vfend®	6 mg/kg IV every 12 hours for two doses, then 4 mg/kg IV every 12 hours	4 mg/kg IV or 200 mg orally every 12 hours	Prophylaxis in high-risk patients: 200 mg orally twice daily	Therapeutic drug monitoring recommended
Posaconazole	Noxafil®	Suspension: 800 mg orally per day in two to four divided doses Oral DR or IV: 300 mg every 12 hours × 2 doses, then 300 mg daily	Suspension: 400 mg orally two times daily Oral DR or IV: 300 mg every 12 hours × 2 doses then 300 mg daily	Prophylaxis in high-risk patients: 200 mg orally three times daily	DR formulation has improved bioavailability, administered with food. Suspension: administer with full meal or enteral nutritional supplements Therapeutic drug monitoring recommended

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Other
Isavuconazonium	Cresemba®	372 mg IV/PO every 8 hours × 6 doses, then 372 mg daily	372 mg IV/PO every 8 hours × 6 doses, then 372 mg daily		Limited clinical experience
Lipid-associated amphotericin B (LAMB)	AmBisome®, Abelcet®	3-5 mg/kg IV once daily	3-5 mg/kg IV once daily	Prophylaxis in high-risk patients: 1 mg/kg IV once daily	
5-Flucytosine	Ancobon®	25 mg/kg/day orally four times daily	25 mg/kg/day orally four times daily		In combination with LAMB for cryptococcal meningitis. Therapeutic drug monitoring recommended
Caspofungin	Cancidas®	70 mg IV once, then 50 mg IV once daily	50 mg IV once daily		
Micafungin	Mycamine®	100 mg IV once daily	100 mg IV once daily	Prophylaxis in high-risk patients: 50 mg IV once daily	
Anidulafungin	Eraxis®	200 mg IV once, then 100 mg IV once daily	100 mg IV once daily		
Antiviral Agents					
Acyclovir	Zovirax®	5 mg/kg IV every 8 hours, or 800 mg orally five times daily	5-10 mg/kg IV every 8 hours, or 800 mg orally two to five times daily	Prophylaxis of HSV or VZV: 800-1,600 mg orally twice daily; CMV prophylaxis in allogeneic HSCT: 800 mg	

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Other
				orally four times daily; HSV or VZV encephalitis: 10mg/kg IV every 8 hours	
Valacyclovir	Valtrex®	1 g orally three times daily	1 g orally three times daily	Prophylaxis of HSV or VZV: 500 mg orally two or three times daily; CMV prophylaxis in allogeneic HSCT: 2 g orally four times daily	
Ganciclovir	Cytovene®	CMV treatment or preemptive therapy: 5 mg/kg IV daily for 2 weeks	CMV treatment or preemptive therapy: After first 2 weeks, 5-6 mg/kg IV daily 5 days/wk	CMV prophylaxis: 5-6 mg/kg IV daily 5 days/wk	
Valganciclovir	Valcyte®	CMV preemptive therapy: 900 mg orally twice daily for 2 weeks	CMV preemptive therapy: After first 2 weeks, 900 mg orally daily	CMV prophylaxis: 900 mg orally daily	
Foscarnet	Foscavir®	CMV treatment: 90 mg/kg IV every 12 hours for 2 weeks; CMV preemptive therapy: 60 mg/kg IV every 12	CMV treatment: after first 2 weeks, 120 mg/kg IV daily; CMV preemptive therapy: after first 2 weeks, 90 mg/kg IV daily 5 days/wk	CMV prophylaxis: 60 mg/kg IV two or three times daily for 7 days, then 90-120 mg/kg IV daily	

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Other
		hours for 2 weeks			
CMV hyperimmune globulin	Cytogam®	400 mg/kg IV every other day for three to five doses	400 mg/kg IV every other day for three to five doses		Consider as adjunct to ganciclovir or foscarnet for treatment of CMV pneumonia; IVIG considered equally effective
Antiprotozoal/Antiparasitic Agents					
Trimethoprim–sulfamethoxazole	Bactrim®, Cotrimoxazole®	15-20 mg/kg/day IV divided every 6 hours[b]	15-20 mg/kg/day IV divided every 6 hours[b]	Prophylaxis of *P. jiroveci*: 160 mg/800 mg orally daily or three times per week	
Atovaquone	Mepron®	750 mg orally every 12 hours	750 mg orally every 12 hours		
Pentamidine	Pentam®	4 mg/kg IV once daily	4 mg/kg IV once daily		
Clindamycin	Cleocin®	450-600 mg orally every 6 hours	450-600 mg orally every 6 hours		In combination with primaquine for *P. jiroveci*, or with pyrimethamine for toxoplasmosis
Primaquine	Aralen® Primaquine®	15 mg orally once daily	15 mg orally once daily		In combination with clindamycin for *P. jiroveci*
Dapsone	Dapsone®	100 mg orally once daily	100 mg orally once daily		In combination with trimethoprim for *P. jiroveci*
Trimethoprim	Triprim®	15-20 mg/kg/day orally divided every 6 hours	15-20 mg/kg/day orally divided every 6 hours		In combination with dapsone for *P. jiroveci*

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Other
Pyrimethamine	Daraprim®	50 mg orally once daily[c]	50-100 mg orally once daily[c]		In combination with sulfadiazine for toxoplasmosis
Sulfadiazine	Sulfadiazine®	1 g orally every 6 hours	1 g orally every 4-6 hours		In combination with pyrimethamine for toxoplasmosis
Thiabendazole	Mintezol®	25 mg/kg orally every 12 hours	25 mg/kg orally every 12 hours (maximum 3 g/day)		For *Strongyloides* and other intestinal worm infections

CMV, cytomegalovirus; CRE, carbapenem-resistant Enterobacteriaceae; DR, delayed-release; HSV, herpes simplex virus; MDR, multidrug-resistant; VZV, varicella zoster virus.

[a]Dosing guidelines in patients with normal renal and hepatic function.

[b]Based on the trimethoprim component of the combination.

[c]Folinic acid (5-10 mg/day) often recommended in conjunction with pyrimethamine-containing regimens for prevention of bone marrow toxicity.

In patients who become afebrile after 2 to 4 days of therapy with no infection identified, it is generally optimal to continue antibiotic therapy until neutropenia has resolved (ANC greater than or equal to 500 cells/mm^3 [greater than or equal to 0.5 × 10^9/L]). Some clinicians switch therapy to an oral regimen (eg, ciprofloxacin plus amoxicillin–clavulanate) after 2 days of IV therapy in low-risk patients who become afebrile and have no evidence of infection. In high-risk patients, parenteral antibiotic regimens should be continued until resolution of neutropenia.[1,2] However, in afebrile patients with prolonged neutropenia but no signs or symptoms of infection, consideration can be given to discontinuing antibiotic therapy or switching to fluoroquinolone prophylaxis (discussed in "Prophylaxis of Infections in Neutropenic Cancer Patients" below), provided that patients can be observed carefully and have ready access to medical care.

The optimal management of patients who remain febrile in the absence of microbiologic or clinical documentation of infection remains highly controversial. Persistently febrile patients should be evaluated carefully, but modifications generally are not made to initial antimicrobial regimens within the first 2 to 4 days of therapy unless there is evidence of clinical deterioration (see Fig. 122-1).[1,2,4] It is important to note that the persistence of fever does not necessarily mean failure of a given antimicrobial regimen; up to 25% of neutropenic patients have fever due to noninfectious causes.[6] This is particularly true if patients are otherwise clinically stable. Fever after 2 or more days of antibiotic therapy can be due to a number of causes, including nonbacterial infection, resistant

bacterial infection or infection slow to respond to therapy, emergence of a secondary infection, inadequate drug concentrations, drug fever, fever at an avascular site (eg, catheter infection or abscess), or noninfectious causes such as tumor or administration of blood products.[1,2,4] Patients with documented infection who are receiving appropriate antimicrobial therapy (based on in vitro susceptibility tests) often remain febrile until resolution of neutropenia occurs. Therefore, the same antibiotic regimen can be continued in patients who remain febrile despite 2 to 4 days of antibiotic therapy but are otherwise clinically stable, especially if neutropenia is expected to resolve within 1 week. However, antibiotic regimens may require modification in patients experiencing toxicities (**Table 122-5**) as well as in patients with evidence of progressive disease, clinical instability, or documentation of an organism not covered by the initial regimen.[1,2,4] If not already part of the regimen, vancomycin should be considered as warranted by clinical and laboratory findings. However, if vancomycin was included in the initial empirical regimen and the patient is still febrile after 2 to 3 days of therapy without isolating a gram-positive pathogen, discontinuation of vancomycin should be considered to reduce the risk of toxicities or resistance.[1,2]

TABLE 122-5 Drug Monitoring of Selected Antimicrobials for Febrile Neutropenia, HSCT, and SOT

Drug	Adverse Reaction	Monitoring Parameters	Comments
Antibaterial Agents			
Aminoglycosides (Tobramycin, Gentamicin, Amikacin)	Nephrotoxicity	Serum creatinine, urine output, serum concentrations	Extended-interval ("once daily") dosing potentially associated with less renal toxicity, similar efficacy to traditional dosing. Goal trough concentration <1 mcg/mL (mg/L; or <2 µmol/L) during extended-interval dosing
Imipenem–cilastatin	CNS toxicities, seizures	Serum creatinine, mental status, CNS function	Increased incidence with higher dose, failure to adjust dose/interval for reduced renal function. Increased risk compared to meropenem or doripenem
Linezolid	Myelosuppression, thrombocytopenia, optic/peripheral neuropathy, serotonin syndrome	CBC, vision changes, serum lactate, heart rate, blood pressure, temperature, myoclonus	Myelosuppression and neuropathy more common with prolonged use. Short course unlikely to affect marrow recovery in HSCT. Weak MAO inhibitor, serotonin syndrome possible with other serotonergic drugs such as SSRIs and SNRIs
Nafcillin	Interstitial nephritis	Serum creatinine, urine output	Reversible, requires switch to alternative β-lactam
Vancomycin	Nephrotoxicity, infusion reactions	Serum creatinine, urine output,	Dose adjustment required for renal dysfunction. Pretreatment and slow

Drug	Adverse Reaction	Monitoring Parameters	Comments
		blood pressure, heart rate, serum concentrations	infusion may decrease incidence of infusion reaction. Goal trough concentration 15-20 mcg/mL (mg/L; 10-14 µmol/L) for serious infections
Antifungal Agents			
Amphotericin B (lipid-associated)	Nephrotoxicity, hepatotoxicity, electrolyte disturbances, infusion reactions	Serum creatinine, electrolytes, LFTs, blood pressure, heart rate	Liposomal preparations associated with less renal toxicity, similar efficacy to standard preparation. Electrolyte disturbances occur before creatinine alterations. Pretreatment and slow infusion may decrease incidence of infusion reaction
5-Flucytosine	Myelosuppression, GI toxicities	CBC, GI symptoms, serum creatinine, 5-flucytosine serum concentrations	Dose adjustment required for renal dysfunction. Goal serum concentrations are peak <100 mcg/mL (<775 µmol/L) and trough 20-40 mcg/mL (155-310 µmol/L)
Posaconazole	Hepatotoxicity, rash; interactions with CYP450 3A4	LFTs, skin, posaconazole serum concentrations	Poor absorption with suspension, goals of >1 mcg/mL (>1.4 µmol/L) for treatment and >0.7 mcg/mL (>1 µmol/L) for prophylaxis. Parenteral formulation contains SBECD, not recommended for patients with CrCL<50 mL/min (<0.83 mL/s). Multiple interactions with drugs metabolized by CYP 3A4, including immunosuppressants; close monitoring needed.
Voriconazole	Mental status changes, headache, hallucinations, visual disturbances, hepatotoxicity, QTc prolongation; interactions with CYP450 2C9, 2C19, and 3A4	Mental status, visual function, LFTs, ECG, voriconazole serum concentrations	Mental status/visual changes associated with elevated troughs >5.5 mcg/mL (>16 µmol/L); goal trough 1-5.5 mcg/mL (3-16 µmol/L) for treatment and prophylaxis, target trough of >2 mcg/ml (>6 µmol/L) in disease with poor prognosis. Parenteral formulation contains SBECD, not recommended for patients with CrCL<50 mL/min (<0.83 mL/s). Multiple interactions

Drug	Adverse Reaction	Monitoring Parameters	Comments
			with drugs metabolized by CYP enzymes, including immunosuppressants; close monitoring needed
Antiviral Agents			
Foscarnet	Nephrotoxicity, hypocalcemia	Serum creatinine, electrolytes	IV hydration prior to administration. Dose adjustment required for renal dysfunction
Ganciclovir, valganciclovir	Myelosuppression, thrombocytopenia	CBC, serum creatinine	Dose adjustment required for renal dysfunction
Antiprotozoal/Antiparasitic Agents			
Dapsone	Hemolytic anemia, hypersensitivity (fever, jaundice, eosinophilia), peripheral neuropathy	CBC, bilirubin, LFTs, muscle strength, G6PD testing before use	Higher incidence of hemolytic anemia in G6PD-deficient patients
Pentamidine (IV)	Nephrotoxicity, leukopenia, hypotension, QTc prolongation, pancreatitis, hypo/hyperglycemia	Serum creatinine, serum blood glucose, blood urea nitrogen, CBC, blood pressure, heart rate; ECG	Adequate hydration recommended
Primaquine	Hemolytic anemia	CBC, bilirubin, G6PD testing before use	Avoid use in G6PD-deficient patients (hemolytic anemia)
Pyrimethamine	Bone marrow suppression	CBC	Folinic acid 5-10 mg/day often used for prevention of bone marrow toxicity
Trimethoprim–sulfamethoxazole	Myelosuppression, hyperkalemia, rash	Serum creatinine, electrolytes, CBC, skin	Dose adjustment required for renal dysfunction

CBC, complete blood count; ECG, electrocardiogram; G6PD, glucose-6-phosphate dehydrogenase; HSCT; hematopoietic stem cell transplantation; LFT, liver function test; MAO, monoamine oxidase; PFT, pulmonary function test; QTc, corrected Q-T interval; SBECD, sulfobutylether-β-cyclodextrin; SOT, solid-organ transplantation; SSNRI, selective serotonin–norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor.

Therapeutic drug monitoring recommendations from reference 33.

Initiation of Antifungal Therapy

Neutropenic patients who remain febrile despite more than 4 to 7 days of broad-spectrum antibiotic therapy are candidates for antifungal therapy. A high percentage of febrile patients who die during prolonged neutropenia have evidence of invasive fungal infection on autopsy, even though many had no evidence of fungal disease before death.[17] Persistence of fever or development of a new fever during broad-spectrum antibiotic therapy may indicate the presence of a fungal infection, most commonly due to *Candida* or *Aspergillus* spp.[10,11,17] Blood cultures are positive in fewer than 50% of neutropenic patients with invasive fungal infections.[10,17] Sensitivity and specificity of fungal galactomannan assay may vary and should only be used when *Aspergillus* is suspected. Rapid, sensitive diagnostic tests for fungi such as serum *β*–d-glucan or fungal DNA assay are not yet in common usage, and waiting for isolation of fungal organisms is associated with high morbidity and mortality. The empirical addition of antifungal therapy is thus justified in this clinical setting.[1,2] Therefore, empirical antifungal therapy should be initiated after 4 to 7 days of broad-spectrum antibiotic therapy in persistently febrile patients if the duration of neutropenia is expected to be greater than 1 week. Administered doses must be adequate to treat undiagnosed fungal infection and prevent fungal superinfection in high-risk febrile neutropenic patients.[1,2,18]

Evidence-based recommendations from published guidelines for management of suspected or documented fungal infections in neutropenic patients are summarized in Table 122-2.[18,20] Empirical coverage for both *Candida* spp. and *Aspergillus* should be considered because these organisms are responsible for more than 90% of fungal infections in neutropenic cancer patients.[5,10,11,17] *Aspergillus* is particularly common in patients with hematologic malignancies and in patients with hematologic malignancies undergoing HSCT; therefore, amphotericin B traditionally has been preferred for these patients.[1,2,27] In the setting of febrile neutropenia, lipid-associated amphotericin B (LAMB) products are similar in efficacy to conventional amphotericin B while causing fewer toxicities. LAMB products are thus almost exclusively recommended over conventional amphotericin B despite the significantly higher cost without clear improvement in efficacy.[1,2,18,20,27] Although the use of higher doses of LAMB has been advocated in an effort to improve efficacy, lower doses (3 mg/kg) of liposomal amphotericin B may be as efficacious as higher doses (10 mg/kg) with lower cost and fewer toxicities.[2]

The azole compounds are also used in the management of febrile neutropenia.[1,2,18,20] Despite the increased cost and toxicities of LAMB, concerns regarding the emergence of *Candida* strains with decreased azole susceptibility and unclear efficacy advantages relative to other agents have prevented these agents from replacing amphotericin B as the gold standard in persistently febrile neutropenic patients.[20,27] Fluconazole has good efficacy against *C. albicans* but lacks activity against molds such as *Aspergillus*. The use of fluconazole as an alternative to amphotericin B for empirical antifungal therapy is thus perhaps most appropriate in hospitals in which infections due to *Aspergillus* or non-*albicans* strains of *Candida* are not common.[1,2,27] If fluconazole is used as antifungal prophylaxis in cancer patients, it should not be included in empirical antifungal regimens. Voriconazole is effective in the treatment of documented invasive fungal infections and is recommended as a reliable option for febrile neutropenia. Despite failing to meet noninferiority

criteria when compared against LAMB for empiric therapy in febrile neutropenic patients, voriconazole is a preferred agent for invasive aspergillosis (especially pulmonary) due to improved survival and less toxicity when compared to amphotericin B.[1,2,20,27,28,29,30,31] Itraconazole has similar efficacy as amphotericin B, with fewer toxicities. However, current lack of a parenteral dosage form, sometimes erratic oral absorption, numerous potential drug–drug interactions, and availability of many other antifungal options limit the use of itraconazole for empiric therapy.[29,30] Posaconazole has extended activity against some Mucorales and rare molds in addition to *Candida* and *Aspergillus*, but is only approved for prophylaxis of fungal infections in neutropenic patients. The improved bioavailability of the delayed-release tablets and availability of a parenteral dosage form make posaconazole an attractive option, however, clinical data remain limited.[2] Isavuconazonium, the prodrug of isavuconazole, is approved for the treatment of invasive aspergillosis and mucormycosis with overall activity generally comparable to voriconazole and posaconazole. Although not addressed by recent clinical guidelines, isavuconazonium showed mortality and treatment success similar to voriconazole in a largely neutropenic patient population with hematologic malignancies and suspected invasive fungal infections including a subgroup of proven or probable aspergillosis.[32] Therapeutic drug monitoring has been recommended for some azole antifungals given potential for interpatient variability, therapeutic failure associated with subtherapeutic concentrations, and toxicities associated with supratherapeutic concentrations (Table 122-5).[2,33]

The echinocandin antifungals (caspofungin, micafungin, and anidulafungin) are attractive agents for treatment of febrile neutropenia because of their broad spectrum of antifungal activity and favorable adverse effect profiles. Caspofungin is as effective as, and also generally better tolerated than, liposomal amphotericin B for empirical treatment of neutropenic patients with persistent fever.[1,2,30] Therefore, caspofungin is considered an appropriate alternative to LAMB and voriconazole.[1,2,18,20,27,30] Micafungin and anidulafungin have not been as well studied specifically in this capacity; however, most experts consider them likely as effective.[1,2,18,20]

Clinical Controversy…

The optimal choice of antifungal agents for treatment of invasive fungal infections in immunocompromised patients (neutropenic patients as well as those undergoing HSCT and SOT) is currently not well defined. Newer agents such as posaconazole and isavuconazonium (isazuconazole) have excellent, broad-spectrum *in vitro* activity against many yeasts and fungi. These agents are also available in both oral and intravenous dosage forms with good bioavailability of the oral products, and their adverse effect and toxicity profiles are favorable compared to other available agents. However, their labeled indications are relatively narrow and clinical data in the treatment of invasive disease caused by *Aspergillus*, *Mucor*, and other difficult pathogens are still relatively limited compared to agents such as voriconazole and LAMB which have been much more extensively used over longer periods of time. Although attractive for more routine clinical use, the optimal role of newer agents remains to be defined.

Initiation of Antiviral Therapy

Febrile neutropenic patients with vesicular or ulcerative skin or mucosal lesions should be evaluated

carefully for infection due to HSV or varicella-zoster virus (VZV). Mucosal lesions from viral infections provide a portal of entry for bacteria and fungi during periods of immunosuppression. If viral infection is presumed or documented, neutropenic patients should receive aggressive antiviral therapy to aid healing of primary lesions and prevent disseminated disease. Acyclovir traditionally has been used in this population. However, the newer antivirals valacyclovir and famciclovir have better oral absorption and more convenient dosing schedules. Routine use of antiviral agents in the management of patients without mucosal lesions or other evidence of viral infection generally is not recommended.[1,2] Treatment recommendations for viral infections are given in **Table 122-6**.

TABLE 122-6 Infectious Complications During Neutropenia, and After Hematopoietic Stem Cell and Solid-Organ Transplantation: Syndromes of Disease and Treatment Guidelines

Pathogen	Syndromes of Disease	Recommended Treatment
Bacterial		
Gram-negative aerobic bacilli (Enterobacteriaceae, *Pseudomonas aeruginosa*, *Haemophilus influenzae*)	Blood, urinary tract, pulmonary, abdomen	*Empiric:* Ceftazidime + aminoglycoside,[a,b] cefepime + aminoglycoside[a,b]; piperacillin–tazobactam; imipenem–cilastatin ± aminoglycoside[a,b] *Definitive:* According to culture and sensitivity results
Gram-positive cocci (*Staphylococcus aureus*, *Staphylococcus epidermidis*, *Streptococcus pneumoniae*, *Enterococcus faecalis*)	Skin, blood, urinary tract, pulmonary, abdomen	*Empiric:* Nafcillin; vancomycin *Definitive:* According to culture and sensitivity results
Legionella spp.	Pulmonary	Erythromycin; ciprofloxacin; levofloxacin
Listeria monocytogenes	CNS	Ampicillin with gentamicin[a]; trimethoprim–sulfamethoxazole
Nocardia spp.	Skin, pulmonary, CNS	Sulfadiazine; trimethoprim–sulfamethoxazole
Fungal		
Candida spp.[c]	Blood, urinary tract, mucous membranes, skin, disseminated disease	Clotrimazole; nystatin; fluconazole; itraconazole; amphotericin B ± 5-flucytosine; lipid-associated amphotericin B (LAMB); caspofungin; micafungin; anidulafungin
Aspergillus spp.[d]	Skin, pulmonary, CNS	Voriconazole; LAMB; caspofungin; micafungin; posaconazole; itraconazole
Cryptococcus neoformans	Skin, pulmonary, CNS	LAMB + 5-flucytosine; fluconazole

Pathogen	Syndromes of Disease	Recommended Treatment
Mucorales (*Mucor*)	Rhinocerebral disease	LAMB; posaconazole
Viral		
Herpes simplex virus	Skin, CNS, mucous membranes, pulmonary	Acyclovir; foscarnet
Human herpesvirus-6	CNS, hepatic, bone marrow	Ganciclovir; foscarnet
Cytomegalovirus	Pulmonary, blood, urinary tract, GI tract	Ganciclovir; foscarnet; immunoglobulin
Varicella-zoster virus	Skin, disseminated disease	Acyclovir; foscarnet
Epstein–Barr virus	Lymphoproliferative disease	Rituximab
Papovaviruses (BK, JC)	Skin, CNS	No effective treatment
Protozoal/Parasitic		
Pneumocystis jiroveci	Pulmonary	Trimethoprim–sulfamethoxazole; atovaquone; pentamidine; dapsone + trimethoprim; clindamycin + primaquine
Toxoplasma gondii	CNS	Pyrimethamine + sulfadiazine; pyrimethamine + clindamycin
Strongyloides stercoralis	Pulmonary, CNS	Thiabendazole

[a]Choice of specific agent determined according to institutional susceptibilities to individual drugs.

[b]For penicillin-allergic adults, use aztreonam or ciprofloxacin + an aminoglycoside.

[c]Refer to the Clinical Practice Guidelines of the Infectious Diseases Society of America (*reference 18*) for selection and dosing of antifungal agents for specific infections.

[d]Refer to the Clinical Practice Guidelines by the Infectious Diseases Society of America (*reference 20*) for selection and dosing of antifungal agents for specific infections.

Duration of Antimicrobial Therapy

7 The optimal duration of antimicrobial therapy in the neutropenic cancer patient remains controversial. Decisions regarding discontinuation of empirical antimicrobial therapy often are more difficult and complex than those regarding initiation of therapy (see Fig. 122-1). One point on which experts agree, however, is that the most important determinant of the total duration of antibiotic therapy is the patient's ANC.[1,2] If ANC is greater than or equal to 500 cells/mm^3 (greater than or equal to 0.5 × 10^9/L) for two consecutive days, if the patient is afebrile and clinically stable for 48 hours or more, and if no pathogen has been isolated, then antibiotics can be discontinued. Some

clinicians advocate that patients with ANC less than 500 cells/mm^3 (0.5×10^9/L) be maintained on antibiotic therapy until resolution of neutropenia, even if they are afebrile. However, prolonged antibiotic use has been associated with superinfections resulting from resistant bacteria and fungi and increases the risk of antibiotic-related toxicities.[1,2] If low-risk patients are stable clinically with negative cultures but the ANC still is less than 500 cells/mm^3 (0.5×10^9/L) antibiotics may be discontinued after a total of 5 to 7 afebrile days. However, patients with profound neutropenia (ANC greater than 100 cells/mm^3 [greater than 0.1×10^9/L]), mucosal lesions, or unstable vital signs or other risk factors should continue to receive antibiotics until ANC has increased greater than or equal to 500 cells/mm^3 (greater than or equal to 0.5×10^9/L) and the patient is stable clinically.[1,2]

Patients who are persistently neutropenic and febrile, but who are stable clinically with no active site of infection, often can be successfully discontinued from antimicrobials after at least 2 weeks of therapy. However, these patients must be monitored carefully because reinstitution of antibiotics may be necessary.[1,2] An alternative approach is to place these patients on antimicrobial prophylaxis (discussed in "Prophylaxis of Infections in Neutropenic Cancer Patients" below). Patients with documented infections should receive antimicrobial therapy until the infecting organism is eradicated and signs and symptoms of infection have resolved (at least 10-14 days of therapy).

Consensus guidelines provide useful information regarding the management of febrile episodes in cancer patients with neutropenia.[1,2] However, therapy (including initial empirical regimens, modifications, and duration of treatment) must be individualized based on individual patient parameters and response to therapy.

Colony-Stimulating Factors

Because resolution of neutropenia is arguably the most important determinant of patient outcome from both febrile episodes and documented infections, numerous studies have evaluated hematopoietic colony-stimulating factors (CSFs) (sargramostim [granulocyte-macrophage colony-stimulating factor] and filgrastim [granulocyte colony-stimulating factor]) as adjunct therapy to antimicrobial treatment of febrile neutropenic cancer patients. A meta-analysis found that use of CSFs is associated with reduced total duration and severity of chemotherapy-related neutropenia, reduced duration of antibiotic use, fewer hospitalizations, and decreased hospital length of stay.[34] However, this meta-analysis failed to demonstrate a benefit of CSFs in relation to important outcomes such as decreased overall mortality or infection-related mortality.[34] Evidence-based guidelines from the IDSA, American Society of Clinical Oncology (ASCO), and the NCCN recommend that CSFs should not be routinely initiated in patients with uncomplicated fever and neutropenia.[1,2,35,36] However, CSFs should be considered in patients who are at high risk for infection-associated complications, or who have factors that are predictive of poor clinical outcomes.[2,35,36] These factors are summarized in **Table 122-7**. Patients with prolonged neutropenia and documented severe infections who are not responding to appropriate antimicrobial therapy may also benefit from treatment with CSFs.[35,36] Clinical judgment must be exercised in determining which patients may benefit from judicious use of these expensive agents.

TABLE 122-7 Recommendations for Use of Colony-Stimulating Factors in the Management of Neutropenic Cancer Patients and Those Undergoing Hematopoietic Stem Cell Transplantation

A Primary prophylaxis of febrile neutropenia

1. Colony-stimulating factors (CSFs) (filgrastim, pegfilgrastim, or sargramostim) may be considered in patients who have a high risk of febrile neutropenia (>20% incidence) based on myelotoxicity of the planned chemotherapy regimen

2. When risk of febrile neutropenia is 10%-20%, CSFs may be considered in the presence of certain patient and clinical factors predisposing to increased complications from prolonged neutropenia, including: patient age >65 years; poor performance status; extensive prior treatment including large radiation ports; administration of combined chemoradiotherapy; cytopenias due to bone marrow involvement by tumor; poor nutritional status; presence of open wounds or active infections; previous surgery; poor renal function; liver dysfunction, particularly when evidenced by increased bilirubin; and lack of antibiotic prophylaxis

B Secondary prophylaxis of febrile neutropenia

1. CSFs (filgrastim, pegfilgrastim, or sargramostim) recommended for patients who experienced neutropenic complications from prior cycles of chemotherapy, and in which a reduced dose may compromise disease-free or overall survival or treatment outcome

C Therapeutic use in febrile neutropenia

1. CSFs should not be routinely used for patients with neutropenia who are afebrile

2. CSFs (filgrastim or sargramostim only) may be considered in patients with febrile neutropenia who are at high risk for infection-associated complications, or who have prognostic factors that are predictive of poor clinical outcomes, including: profound neutropenia (absolute neutrophil count <100 cells/mm^3 [<0.1 × 10^9/L]); expected prolonged period of neutropenia (>10 days); patient age >65 years; uncontrolled primary disease; sepsis syndrome, or severe infection manifest by hypotension and multiorgan dysfunction; pneumonia; invasive fungal infection; other clinically documented infection; hospitalized at the time of the development of fever; or severe complications during previous episode of febrile neutropenia

D Reduction in duration of neutropenia in HSCT

1. CSFs are recommended to mobilize peripheral-blood progenitor cells (PBPC) prior to chemotherapy and to reduce the duration of neutropenia after autologous PBPC transplantation

Data from references 2, 35, and 36.

Direct transfusion of neutrophils has also been studied for treatment of febrile neutropenia or documented infections.[3,37] Routine use of neutrophil transfusions is not generally supported by data

demonstrating improved clinical outcomes. However, use may be considered in patients with profound prolonged neutropenia with severe documented infections and in whom causative organisms have not been eradicated with appropriate antimicrobial therapy in combination with CSFs.[2] At present, the use of neutrophil transfusions is not recommended for routine management of febrile neutropenic patients.[2]

Prophylaxis of Infections in Neutropenic Cancer Patients

8 Owing to the potential morbidity and mortality of infections in neutropenic cancer patients, environmental modifications and prophylactic antimicrobial regimens have been implemented to prevent these complications. The overall goal of antimicrobial prophylaxis in cancer patients is to decrease the number and severity of systemic infections during prolonged periods of neutropenia. As with febrile neutropenia, patient risk factors for development of infection and complications should be assessed prior to initiation of prophylaxis (**Table 122-8**).

TABLE 122-8 Risk-Based Prophylactic Strategies for Patients with Neutropenia

Risk Group	Patient Characteristics	Prophylactic Strategies
High risk	*Neutropenia:* Severe (absolute neutrophil count <100/mm^3 [<0.1 × 10^9/L]) and/or prolonged (≥10 days) *Malignancy/treatment:* Hematologic malignancy (acute leukemia), allogeneic HSCT, GVHD with high dose steroids, or use of alemtuzumab	Consider bacterial prophylaxis with fluoroquinolone for duration of neutropenia. Give fungal prophylaxis with product and duration based on patient-specific factors. Consider viral prophylaxis with product and duration based on patient-specific factors
Moderate risk	*Neutropenia:* Moderate duration (7-10 days) *Malignancy/treatment:* Autologous HSCT, multiple myeloma, lymphoma, chronic lymphocytic leukemia, purine analog therapy	Consider bacterial prophylaxis with fluoroquinolone for duration of neutropenia. Consider fungal prophylaxis with product and duration based on patient-specific factors. Give/consider viral prophylaxis with product and duration based on patient-specific factors
Low risk	*Neutropenia:* Short duration (≤7 days) *Malignancy/treatment:* Solid tumor treated with conventional chemotherapy	Antibacterial and antifungal prophylaxis not indicated. Viral prophylaxis considered during neutropenia if patient has prior HSV episode

GVHD, graft versus host disease; HSCT, hematopoietic stem cell transplant; HSV, herpes simplex virus.

Data from references 1, 2, 5, 21, 38, and 39.

General Measures

Because approximately 50% of pathogens infecting neutropenic cancer patients are acquired in the hospital, reducing acquisition of infectious organisms from the environment is a basic component in controlling nosocomial infections.[1,2,5] Neutropenic patients should be placed in reverse isolation (isolation to protect patients from contracting infections after exposure to others) with standard barrier precautions, and strict adherence to infection control guidelines by hospital personnel.[1,2,5] Plants and fresh or dried flowers are usually prohibited as part of standard neutropenic precautions in order to minimize risk of exposure to pathogenic bacteria. Proper meticulous handwashing by hospital personnel is a simple yet very effective infection control measure. Most neutropenic patients do not require specific room ventilation; however, HSCT recipients should be placed in a private positive-pressure room with greater than 12 air exchanges per hour and HEPA filtration.[1,2,5]

Bacterial Infections

Combinations of oral nonabsorbable antibiotics, such as gentamicin, nystatin, vancomycin, polymyxin B, and colistin, have been widely studied as a means of reducing colonization of the GI tract with virulent pathogens. Although selective intestinal decontamination with oral nonabsorbable antibiotics successfully reduces infections, these regimens are not routinely recommended for prophylaxis because of problems that include unpalatability, cost, frequent adverse effects (eg, nausea, vomiting, and diarrhea), and development of resistance.[1,2,3,4,5]

Prophylaxis with orally administered, systemically available antibiotics such as trimethoprim–sulfamethoxazole and fluoroquinolones is effective at reducing gram-negative infections.[1,2] Although trimethoprim–sulfamethoxazole is effective as prophylaxis against *P. jiroveci*, its lack of activity against *P. aeruginosa* is worrisome when used as prophylaxis against bacterial infection, particularly in institutions where pseudomonal infections are frequent.[1] Other concerns with trimethoprim–sulfamethoxazole prophylaxis include selection of resistant organisms, predisposition to development of oral fungal infections, and delay in bone marrow recovery resulting in prolonged neutropenic episodes.[1,2,5]

Fluoroquinolones are more effective than placebo in preventing all-cause mortality, infection-related mortality, febrile episodes and gram-negative infections in neutropenic cancer patients.[1,2,5,38] However, there are several potential limitations to their use. In particular, ciprofloxacin may lack adequate gram-positive activity and may not be the preferred fluoroquinolone for this reason. Although fluoroquinolone prophylaxis has been associated with the development of resistant gram-negative organisms, these findings have not been consistent in various studies.[1,2,8,38] Also the risk of colonization or infection with strains resistant to the prophylactic agent is lower with fluoroquinolones than with trimethoprim–sulfamethoxazole.[38] However, patients experiencing breakthrough infection during fluoroquinolone prophylaxis should not be subsequently placed on a fluoroquinolone-containing empirical antibiotic regimen.[1,2]

Clinical Controversy…

A primary concern with the use of fluoroquinolones for prophylaxis of infections in neutropenic cancer patients is the development of antimicrobial resistance and subsequent infection with

fluoroquinolone-resistant bacteria. A meta-analysis which included 56 clinical trials found that fluoroquinolone prophylaxis was associated with an increase in colonization with quinolone-resistant bacteria but that this increase was not statistically significant compared with placebo (Relative Risk [RR] 1.68; 95% Confidence Interval [CI], 0.71-4.00). This same study also found no difference in the incidence of infections caused by quinolone-resistant bacteria (RR 1.04; 95% CI, 0.73-1.50).[2] Although this and other studies have not documented increased fluoroquinolone resistance in association with prophylaxis, other potentially unfavorable outcomes such as increased risk of *Clostridium difficile* infection should also be considered in weighing the potential benefits of fluoroquinolone prophylaxis.[1,2,8,38]

Although the benefits of prophylaxis with fluoroquinolones outweigh the potential risks in neutropenic patients with intermediate to high risk for infection (Table 122-8), antibacterial prophylaxis in general remains somewhat controversial due to continued concerns regarding the potential for development of resistant bacteria, high cost, and lack of impact on patient survival.[1,2,8] Therefore, antibacterial prophylaxis is not recommended routinely for all neutropenic patients. Prophylaxis with ciprofloxacin or levofloxacin generally is indicated for intermediate- to high-risk patients expected to be profoundly neutropenic for more than 1 week, such as HSCT patients.[1,2,5] High dose levofloxacin may be preferred by some clinicians due to enhanced gram-positive activity, but many other clinicians consider them similar in efficacy. If fluoroquinolone prophylaxis is used, strategic monitoring of gram-negative resistance to the drugs should be employed. Neutrophil recovery eliminates the need for continued prophylaxis, and recovery may be facilitated by use of CSFs.[35] CSFs have also been formally recommended by ASCO and NCCN for primary prevention of febrile neutropenia in high-risk patients (see Table 122-7).[1,2]

Fungal Infections

Because neutropenic patients are at risk for mucocutaneous and invasive fungal infections that are difficult to diagnose and treat in this population, antifungal prophylaxis can be considered in intermediate- to high-risk patients at institutions where fungal infections in cancer patients occur frequently.[1,2] The goal of antifungal prophylaxis is to prevent development of invasive fungal infections during periods of risk, thereby reducing morbidity and mortality. A meta-analysis of antifungal prophylaxis in 38 trials involving more than 7,000 cancer patients reported a decrease in the use of parenteral antifungal therapy, superficial and invasive systemic fungal infections, and fungal infection-related mortality rate.[39] Antifungal prophylaxis in these studies resulted in decreased mortality in patients with prolonged neutropenia and HSCT.

Although the choice of antifungal prophylaxis agents remains controversial, fluconazole prophylaxis has been particularly well studied and reduces the incidence of both superficial and systemic fungal infections; it also significantly decreases mortality from fungal infections in patients with leukemia and HSCT recipients.[2,39] However, use of fluconazole prophylaxis has contributed to the emergence of infections caused by *C. krusei* and *C. glabrata*, pathogens that frequently are resistant to fluconazole and other azole-type antifungal agents.[2,19] When compared to prophylaxis with mold-active agents, patients on fluconazole have higher rate of aspergillosis and invasive fungal-

related mortality but lower rate of adverse events leading to discontinuation.[40] Therefore, antifungal prophylaxis with oral fluconazole, itraconazole, voriconazole, posaconazole, an echinocandin, or LAMB is recommended for prophylaxis in select patients starting at the time of induction chemotherapy.[2] The choice of a specific agent should be determined by the types of fungal isolates at individual institutions and the chemotherapeutic regimen.[1,2,18] Patients in whom prophylaxis should be considered include those at intermediate to high infection risk as shown in Table 122-8. After initiation, antifungal prophylaxis should be continued until resolution of neutropenia or the need for institution of antifungal therapy for suspected/documented infection.[2,18]

Itraconazole, low to moderate doses of amphotericin B, intranasal and aerosolized amphotericin B, LAMB products, voriconazole, posaconazole and the echinocandins have all been investigated for *Aspergillus* prophylaxis in neutropenic patients.[2,5,20,40] Posaconazole was more effective than either fluconazole or itraconazole in the prevention of *Aspergillus* and other invasive fungal infections in patients with hematologic malignancies and prolonged neutropenia.[2,20]

Other Infections

Use of trimethoprim–sulfamethoxazole in cancer patients at risk for *P. jiroveci* pneumonia has substantially reduced the incidence of this protozoal infection.[1,2] Antiviral prophylaxis with acyclovir, valacyclovir, or famciclovir is used in most centers to reduce the risk of HSV reactivation in patients with acute leukemia undergoing intensive chemotherapy. Varicella vaccine provides good protection (90%) in leukemic children and may be useful in seronegative adults, although the vaccine has been less well studied in this population.

When considering use of antimicrobial (antibacterial, antifungal, antiprotozoal, and antiviral) prophylaxis in neutropenic patients with cancer, the risks and benefits of prophylaxis must be weighed against issues with development of resistance, toxicities, and other concerns.

Evaluation of Therapeutic Outcomes

10 Close monitoring of febrile neutropenic patients, including both clinical and laboratory parameters, is essential for early detection and treatment of infectious complications. Three general therapeutic outcomes have been defined in the setting of febrile neutropenia: (a) success (survival during the febrile episode until resolution of neutropenia by judicious selection of empirical antimicrobial therapy), (b) success with modification (same as [a] but with additions/modifications to empirical therapy), and (c) failure (death during febrile neutropenia).[13] Because many of the drugs that can be used in this setting (eg, aminoglycosides and amphotericin B) have significant toxicity potential, careful attention must be paid to prevention and management of drug-related adverse effects. Evaluations of the parameters given in the Clinical Presentation are appropriate to help monitor and guide therapy. In addition, the NCCN guidelines for febrile neutropenia provide comprehensive recommendations on clinical/laboratory monitoring parameters, including schedules.[2] The reader is referred to individual chapters within this book for more detailed discussions of monitoring parameters related to specific types of infections (eg, pneumonia and

urinary tract infections).

INFECTIONS IN PATIENTS UNDERGOING HSCT

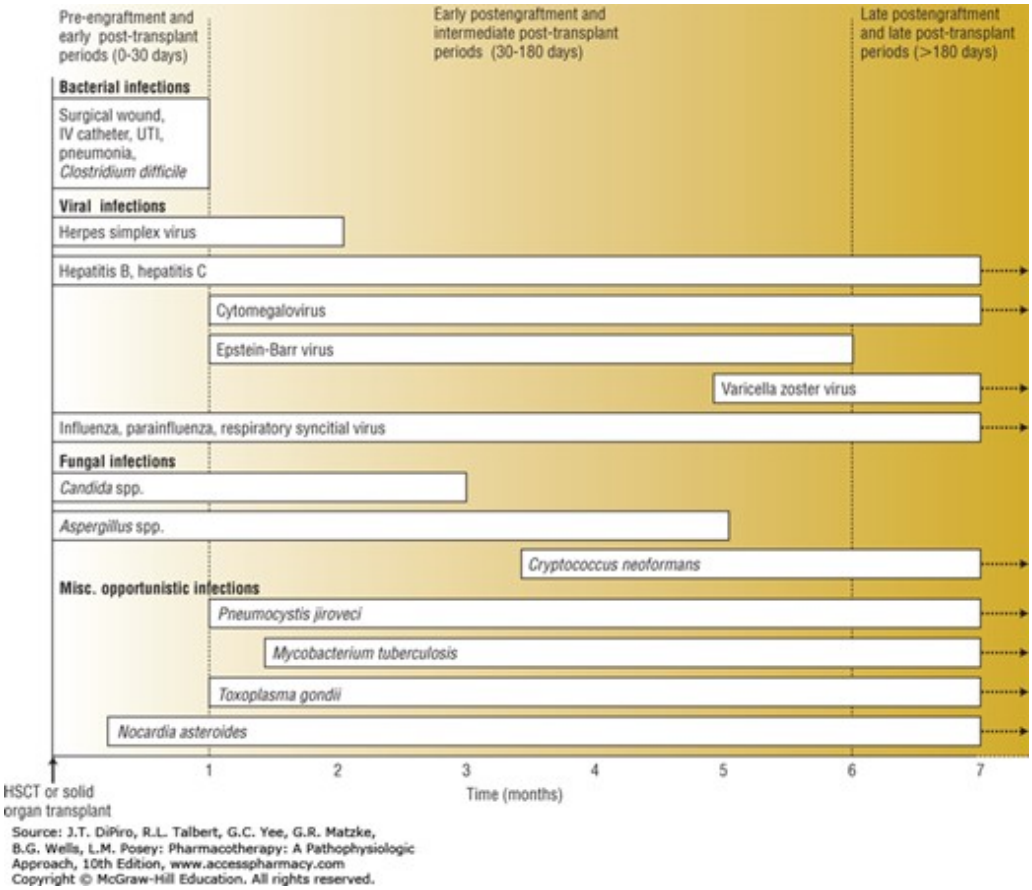
1 Infection remains a major barrier to successful HSCT.[1,2,5,41] Recipients of HSCT are at enhanced risk for infection because of prolonged periods of neutropenia. In addition, patients receiving allogeneic or matched unrelated donor transplants receive prolonged immunosuppressive drug therapy for prevention and treatment of graft-versus-host disease (GVHD). Intensive pretransplant conditioning regimens (high-dose chemotherapy and total-body irradiation), as well as GVHD itself, often disrupt protective barriers, such as mucous membranes, skin, and the GI tract, placing patients at further risk of infection. Although infectious complications are still associated with considerable morbidity and mortality, studies have documented significant reduction in mortality after HSCT in association with reductions in disease caused by bacterial, fungal, and viral infections.[41]

Etiology and Clinical Presentation of Infections

2 10 The timing with which specific types of infections typically occur following HSCT is shown in **Fig. 122-3**, but the relative incidence and importance of specific pathogens vary greatly according to the specific type of HSCT performed. Patients receiving allogeneic transplants are at greatest risk for infection after HSCT and are predisposed to earlier and more severe infections with opportunistic pathogens such as *Aspergillus*. The presence of GVHD also has an impact on the incidence and timing of various infections, including invasive fungal infections.

FIGURE 122-3

Timetable for the occurrence of infections in hematopoietic stem cell transplantation (HSCT) and solid-organ transplant patients. (UTI, urinary tract infection.)



After administration of intensive conditioning regimens to eliminate malignant cells and prevent rejection of donor cells, patients may remain profoundly neutropenic for 3 to 4 weeks. During this preengraftment period, patients are at risk for the same types of infectious complications that occur in other granulocytopenic cancer patients (eg, bacterial and fungal infections) and should be managed accordingly (see Table 122-1). Table 122-6 lists regimens for treatment of specific infections.

HSCT recipients remain at high risk for infection after bone marrow engraftment has occurred.[2,5,41] Significant defects in neutrophil function and cell-mediated and humoral immunity, persisting for several months after transplantation, predispose patients to infectious complications. Acute and chronic GVHD also result in prolonged periods of immunosuppression and increased infection rates.

Patients undergoing HSCT are at significant risk for serious bacterial infections.[2,5,41,42] The risk of bacterial infection is particularly increased in patients undergoing allogeneic transplantation and those with GVHD. Gram-negative bacteremia occur in approximately 20% of patients, and mortality rates may reach 25%.[42]

Fungal infections, especially those caused by *Candida* and *Aspergillus* spp., are serious and often result in fatal complications. Fungi remain a serious cause of infection, particularly in allogeneic HSCT recipients, for up to 1 to 2 years following transplantation and may occur in as many as 20% of patients.[5,41,43] Significant mortality is associated with invasive aspergillosis and mucormycosis infections.[5,10,41,42,43]

HSCT recipients are also at risk for serious viral infections, particularly HSV and cytomegalovirus

(CMV). HSV infections may include gingivostomatitis, esophagitis, genital lesions, and, rarely, pneumonia during the first month after transplant.[2,5,6,44,45] Clinical disease is more common in patients with serologic evidence of prior exposure and latent HSV infection pretransplant. Therefore, reactivation of latent disease during periods of immunosuppression is the most common etiology of HSV infection. Without prophylaxis, as many as 80% of HSV-seropositive patients experience mucocutaneous disease after intensive chemotherapy compared with less than 25% of seronegative patients.[2,6,44,45] HSV infections often coexist with *Candida* infection and mucositis secondary to chemotherapy, radiation, or both.[2,44,45] Painful swallowing associated with these conditions often makes it difficult for patients to take oral medications and maintain adequate nutritional intake. Because of the considerable morbidity associated with HSV reactivation after transplantation, the HSV serologic status of patients should be determined prior to transplant.

HSCT recipients are at high risk for CMV infections during the early postengraftment period. Infections range in severity from asymptomatic infection with viral shedding (urine, throat, and lungs), to life-threatening disseminated disease and interstitial pneumonia.[2,44,45]

As with HSV, patients seropositive for CMV before transplantation are at high risk for reactivation of infection during periods of immunosuppression; up to 70% of seropositive patients develop reactivation after transplantation compared with only 3% of seronegative patients.[2,41,44,45] Other risk factors for CMV infection in HSCT patients include advanced age, human lymphocyte antigen mismatch, total-body irradiation, multiagent conditioning regimens, and presence of GVHD.[2,5,44,45] Patients without evidence of latent CMV infection (CMV-seronegative) before transplantation may develop primary CMV infection after receiving bone marrow or blood products from CMV-seropositive donors. Although the typical onset of both primary and recurrent CMV infection is 1 to 2 months after transplantation, late-onset infections may occur more than 100 days after transplantation.[2,5,41,44,45] Patients receiving allogeneic transplants are at highest risk for CMV reactivation, with progression to clinical disease in approximately 10% to 30% of patients.[44,45]

The most serious clinical manifestation of CMV disease and a leading cause of infectious death in HSCT recipients is interstitial pneumonia, which is associated with an 85% mortality rate if left untreated.[44,45] This clinical syndrome manifests as fever, dyspnea, hypoxia, nonproductive cough, and diffuse pulmonary infiltrates. As many as 40% of allogeneic HSCT patients will develop interstitial pneumonia; a significant proportion are viral in etiology.[44,45] Interstitial pneumonia also may result from other infectious (*P. jiroveci*, VZV) and noninfectious causes (pulmonary damage by radiation and chemotherapy).[2,44,45]

During the late postengraftment period (beginning approximately 180 days after transplantation), infections remain a major problem in patients suffering from chronic GVHD. Infections common during the late postengraftment period include those caused by encapsulated bacteria, such as *S. pneumoniae* and *H. influenza*, fungi, and viruses, including CMV and VZV.[2,5] Patients not undergoing allogeneic transplantation or suffering from chronic GVHD generally have few infections in this period.

Up to 50% of all patients surviving up to 10 months after transplantation develop an infection caused

by VZV.[44,45] Infection with VZV is most common in allogeneic HSCT recipients with acute or chronic GVHD.[44,45] Both primary (varicella) or recurrent disease (herpes zoster) usually present as skin lesions, most of which remain contained to local areas; however, 30% to 45% of these infections may disseminate to other cutaneous areas or body organs, causing mortality as high as 50%.[44,45]

TREATMENT

Desired Outcomes

The goals of therapy in managing HSCT recipients from the neutropenic period through the late postengraftment period are: (a) protect the patient from early death caused by undiagnosed infection; (b) employ effective prophylactic therapy to prevent common bacterial, fungal, viral, and protozoal/parasitic infections; (c) effectively and aggressively treat established infections; (d) avoid unnecessary use of antimicrobials that contribute to increased resistance; and (e) minimize toxicities and cost while increasing patient quality of life.

Prophylaxis and Management of Infections in Recipients of HSCT

8 9 The overall goal of prophylaxis and treatment of infection in HSCT patients is prevention of infectious morbidity and mortality. Specific goals of antimicrobial drug use in HSCT patients include (a) prevention of bacterial, fungal, viral, and protozoal infections during preengraftment and postengraftment periods and (b) effective treatment of established infections. These goals must be achieved at the lowest possible toxicity and cost. Prophylactic therapy should be aimed specifically at pathogens known to cause a high incidence of infection within the HSCT population, the specific institution, or both. In addition, prophylactic therapy should be limited to regimens proved to be effective through well-designed clinical trials.

Appropriate immunizations should be a primary consideration in the prevention of infections in HSCT recipients. Immunizations against common bacterial and viral pathogens are timed to avoid periods of severe immunosuppression following HSCT when the protective response to vaccination potentially would be decreased.[2,5] Recommendations for immunization of HSCT patients include three doses each of diphtheria–pertussis–tetanus (or diphtheria–tetanus), inactivated polio, conjugated *H. influenzae* type b, conjugated 13-valent pneumococcal, and two doses each of hepatitis A and B, and one dose of meningococcal conjugate vaccines 6 to 12 months post-transplant. One dose of the 23-valent pneumococcal vaccine should follow after 12 months. The influenza vaccine should be resumed at least 4 to 6 months after transplantation, and continued annually for life. Family members, close contacts, and healthcare providers of HSCT patients also should be vaccinated annually against influenza. Finally, the measles–mumps–rubella vaccine should be administered no sooner than 24 months after HSCT if the patient is considered to be immunocompetent. The varicella vaccine may be considered on a case by case basis owing to the live-attenuated nature of the product and the risk of VZV infection, but if administered should occur no sooner than 24 months after transplant. The injectable inactivated influenza vaccine is preferred both before and after HSCT due to severe underlying illnesses pretransplant and contraindication of the live-attenuated intranasal product posttransplant.[1,2,5]

Bacterial Infections

Prophylaxis of infections in HSCT patients is similar in many ways to that used in other neutropenic patients. Oral antibacterial prophylaxis is used commonly; considerations are the same as those discussed previously in the "Prophylaxis of Infections in Neutropenic Cancer Patients" section. Although rates of bacteremia and other bacterial infections are decreased after HSCT, overall mortality rates have not been consistently reduced.[1,2,5,44] Therefore, routine use of prophylactic antibiotics in HSCT is still controversial but should be considered in patients at moderate to high risk of infection (Table 122-8). Fluoroquinolones are the most frequently used agents, with levofloxacin preferred over ciprofloxacin due to enhanced gram-positive activity.[1,2,5,44] These regimens usually are started either within 72 hours of beginning the chemotherapy conditioning regimens or on the day of hematopoietic stem cell infusion and continued throughout the neutropenic period. Patients who become febrile while receiving prophylaxis should be managed according to general guidelines for febrile neutropenic patients.

Antibiotic prophylaxis against bacterial infection is also recommended in the late postengraftment period (greater than 100 days after transplantation) in certain high-risk patients, specifically allogeneic transplant recipients with chronic GVHD.[2,6] Antibiotics should be targeted against encapsulated bacteria, particularly *S. pneumonia*, and should be selected based on local susceptibility patterns for these organisms; penicillin is preferred in areas with low rates of penicillin-resistant pneumococci.[2] Patients receiving trimethoprim–sulfamethoxazole for prophylaxis of other opportunistic infections may be protected adequately and do not necessarily require an additional antibiotic.[2,5] Prophylaxis should be continued as long as the chronic GVHD is being actively treated.

VIRAL INFECTIONS

Prophylaxis of recurrent HSV infection is recommended for all HSV-seropositive patients undergoing HSCT.[1,2,5,44,45] Approximately 0% to 10% of HSV-seropositive patients receiving acyclovir experienced viral shedding, clinical symptoms of viral reactivation, or both compared with 60% to 80% of patients receiving placebo.[5,44,45] IV acyclovir therapy eventually is necessary in many patients because of the development of severe mucositis from conditioning regimens. However, oral acyclovir, valacyclovir, or famciclovir is effective and considerably less expensive in patients who can take oral medications. Valacyclovir has replaced acyclovir as first-line therapy in many institutions.[2,5,44] The antiviral agent usually is started at the time of the conditioning regimen and continued until bone marrow engraftment or resolution of mucositis (approximately 30 days after HSCT), although longer durations of prophylaxis may be considered in allogeneic HSCT recipients with GVHD or frequent HSV reactivations before transplantation.[2,5,44,45] In addition to preventing recurrence of HSV disease, acyclovir prophylaxis may reduce the incidence of CMV reactivation.[2,5] Patients receiving ganciclovir or foscarnet for prophylaxis or treatment of CMV infection do not need additional antiviral therapy for prevention of HSV or VZV.[2] Patients developing active HSV or VZV infection should be treated with high-dose acyclovir.[2,44,45]

Oral acyclovir or valacyclovir given for up to 12 months after transplantation also significantly

reduces reactivation of VZV infections and prevents the occurrence of severe VZV disease.[1,2] Patients receiving either allogeneic or autologous HSCT may therefore be considered for long-term (up to 1 year after transplantation) prophylaxis against VZV.[2] Patients who received HSCT within the previous 24 months, or those more than 24 months after HSCT who have chronic GVHD or are undergoing immunosuppressive therapy, should receive varicella-zoster immunoglobulin 625 units intramuscularly within 48 to 96 hours after close contact with persons with chickenpox or shingles for prevention of VZV-related disease.[5]

Acyclovir-resistant HSV has been reported occasionally in HSCT patients receiving acyclovir prophylaxis. Foscarnet is a drug of choice for treatment of documented infection with acyclovir-resistant HSV and should be reserved for this use.[2,5,44,45]

Prevention of CMV disease is a well-accepted indication for prophylaxis in HSCT patients because of the high associated infectious morbidity and mortality. If possible, CMV-seronegative patients should receive donor cells and supportive blood products from seronegative donors only; however, CMV-seropositive patients are not at significant additional risk by receiving blood or donor cells from seropositive donors.[44,45] Although acyclovir has relatively poor in vitro activity against CMV, a decrease in CMV infection and an improvement in overall survival were reported in HSV- and CMV-seropositive allogeneic HSCT recipients receiving IV acyclovir.[2,5,45]

Ganciclovir has been well studied for prophylaxis because of its superior activity against CMV compared with acyclovir.[2,5] Oral valganciclovir has also been well studied in the setting of HSCT.[2,5] Valganciclovir has excellent pharmacokinetics and produces serum levels of ganciclovir which are at least similar to those achieved after IV administration. Valganciclovir is routinely used in many centers based on the favorable pharmacokinetic properties and convenience of oral dosing in certain patients.[2,5] Although administration of prophylactic ganciclovir to CMV-seropositive patients may significantly decrease the occurrence of CMV disease, there is no clear survival benefit, and ganciclovir-related bone marrow suppression frequently was problematic. Therefore, ganciclovir prophylaxis is somewhat controversial and is not universally recommended for routine use, and a preemptive approach is reasonable.[2,5,44] It may, however, be considered for allogeneic HSCT recipients for the first 100 days after transplantation.[2,5,44]

Perhaps a more appropriate role for ganciclovir and valganciclovir is preemptive therapy, in which ganciclovir is administered at first isolation of CMV from the blood or bronchoalveolar lavage fluid. Detection of CMV can be accomplished by use of either a monoclonal antibody-based test for viral antigens or by detection of viral DNA through polymerase chain reaction (PCR)-based tests. Preemptive therapy significantly reduced the occurrence of CMV disease (including CMV pneumonia) and improved survival significantly up to 180 days after transplantation.[2,44] Because CMV viremia and bronchoalveolar lavage cultures are highly predictive of subsequent CMV disease, preemptive ganciclovir or valganciclovir therapy should be considered for autologous HSCT recipients within the first 100 days after transplantation or in allogeneic HSCT recipients at any time after transplantation.[2,5,44] The doses of ganciclovir or valganciclovir for preemptive therapy are the same as those used for prophylaxis. Foscarnet can also be used for either prophylaxis or preemptive

therapy of CMV disease in patients intolerant of ganciclovir.

CSFs are beneficial in this setting (Table 122-6), providing benefits similar to those noted in neutropenic patients with acquired immunodeficiency syndrome receiving ganciclovir therapy for CMV retinitis. Prophylaxis of CMV disease with either IV immunoglobulin (IVIG) or cytomegalovirus hyperimmune globulin (CMVIG) produced variable and inconclusive results, and their use is not currently recommended.[46,47]

Ganciclovir or valganciclovir are the drugs of choice for treatment of active CMV infection in HSCT patients (see Table 122-5). Foscarnet also may be of benefit for treatment or prevention of infections in HSCT patients and may be used as an alternative to ganciclovir/valganciclovir because of its relative lack of bone marrow toxicity. Foscarnet-related nephrotoxicity may be problematic, however, especially in the post-transplant period when patients may be receiving other nephrotoxic agents. Cidofovir has not been well studied in HSCT patients and is also associated with nephrotoxicity, but this agent may also be considered for preemptive therapy or treatment of active disease.[2]

Numerous single-agent treatments such as interferon and ganciclovir have been used unsuccessfully as treatment for CMV pneumonitis. However, the combination of high-dose IVIG and ganciclovir may decrease the mortality of the syndrome from 85% to 30% to 50%.[44,46,48] Ganciclovir plus hyperimmune CMVIG also is considered effective for treatment of CMV disease, although this regimen has not been studied as extensively in the HSCT population in a controlled fashion. However, CMVIG was not more effective than IVIG, therefore ganciclovir plus IVIG is considered as the treatment regimen of choice for severe or life-threatening CMV disease based on benefit-versus-risk considerations more than definitive clinical data.[2] The potential for ganciclovir-associated bone marrow suppression prior to marrow engraftment and in patients who are just recovering from granulocytopenia remains a concern, especially in patients with unstable renal function.

Fungal Infections

Prophylaxis with antifungal agents is efficacious and generally recommended for prevention of mucocutaneous and disseminated fungal infections in high-risk HSCT patients (Tables 122-2 and 122-8).[2,5,18,40,49,50,51] Patients specifically recommended for prophylaxis include all allogeneic recipients and autologous transplant recipients who are expected to have prolonged neutropenia, have received intensive conditioning regimens associated with extensive mucositis, or have recently received fludarabine.[2,5,18,49,50] Fluconazole is the most commonly used agent; it is started on the day of transplantation and continued until resolution of neutropenia or, in allogeneic HSCT, for at least 75 days after transplantation.[2,5,18,44,50] The variable activity of fluconazole against non-*albicans* species of *Candida* may be problematic in this population, as is lack of activity against *Aspergillus*.[2,19,50] Prophylaxis with fluconazole (as well as itraconazole), although effectively reducing colonization and infection with yeasts, has not consistently been demonstrated to reduce overall mortality or invasive infections such as aspergillosis in HSCT recipients.[2,40,49,50,51] Micafungin was more efficacious than fluconazole in the prevention of early-onset *Candida* infections in patients with neutropenia prior to engraftment, and also showed a trend to fewer episodes of invasive aspergillosis.[2] Posaconazole was

also more effective than fluconazole in the late prevention of invasive *Aspergillus* and other fungal infections in HSCT patients with GVHD. In a meta-analysis, prophylaxis with agents active against *Aspergillus* were also associated with a 33% reduction in mortality related to invasive fungal infections compared to fluconazole.[40] Fluconazole, itraconazole, voriconazole, posaconazole, echinocandins, and LAMB products are all recommended for prophylaxis of fungal infections in HSCT. Posaconazole is the preferred agent in high-risk HSCT patients with GVHD (Table 122-2).[2,20,49,50,51]

Protozoal Infections

Pulmonary infection with *P. jiroveci* is a relatively infrequent complication of HSCT. However, mortality rates in this population are approximately 60% and are especially high in patients with GVHD.[2,5] Prophylactic trimethoprim–sulfamethoxazole is recommended for a period of 3 to 6 months after autologous HSCT, and for at least 6 months and while receiving immunosuppressive therapy after allogeneic HSCT. Toxoplasmosis is not a common infection in HSCT patients but is associated with mortality rates of approximately 70%.[52] Toxoplasmosis should also be prevented by trimethoprim–sulfamethoxazole prophylaxis.[2,5]

Use of Colony-Stimulating Factors

Filgrastim, pegfilgrastim, and sargramostim have been studied in HSCT patients in an effort to speed bone marrow recovery, reduce the period of neutropenia, and decrease infectious complications. CSFs appear effective as well as safe following autologous transplantation, although increased rates of GVHD and mortality have been reported with use of CSFs following allogeneic transplantation.[35] The use of CSFs is now routinely recommended to mobilize blood progenitor cells and reduce the period of neutropenia in autologous transplants (Table 122-6).[2,35,36]

Evaluation of Therapeutic Outcomes

10 Close monitoring of HSCT patients, including clinical and laboratory data, is essential for early detection and treatment of infectious complications. In addition, because many of the drugs commonly used in this setting (eg, ganciclovir, amphotericin B, and trimethoprim–sulfamethoxazole) have significant toxicity potential in HSCT patients, careful attention must be paid to prevention and management of drug-related adverse effects. Monitoring parameters related to specific types of infections (eg, pneumonia and urinary tract infections) should be applied as appropriate. The reader is referred to other chapters within this book for more specific information.

INFECTIONS IN SOLID-ORGAN TRANSPLANT RECIPIENTS

Solid-organ transplantation (SOT) has become an established mode of treatment for end-stage diseases of the heart, lungs, kidney, liver, pancreas, and small bowel. Patient and allograft survival rates have greatly improved due to improvements in immunosuppressive drug therapy, candidate selection, and transplant surgery techniques as well as more experience in the management of complications (including infection) in these patients. Despite advances in diagnostic techniques and

antimicrobial therapy, infectious complications remain important causes of morbidity and mortality after SOT.

Risk Factors

1 Many risk factors for infection are present in SOT patients (see Table 122-1). The most important risk factor in this population is immunosuppressive drug therapy for prevention and treatment of allograft rejection. Risk of infection depends on specific immunosuppressive drug regimens as well as the intensity (numbers and doses of drugs) and duration of immunosuppression. Most opportunistic infections in transplant patients occur during the first 6 months after transplantation, when the intensity and total cumulative doses of immunosuppressive therapy are very high.[53,54]

Immunosuppressive drugs, often in escalated doses, are used to treat episodes of graft rejection and include immunoglobulins directed against T cells (eg, antithymocyte globulin), murine monoclonal antibodies (muromonab), antibodies against interleukin 2 receptors (daclizumab and basiliximab), T-cell–depleting antibodies (alemtuzumab), and high-dose corticosteroids. Rejection episodes often occur during the period 2 to 4 months post-transplant when the overall cumulative dose or net state of immunosuppression is highest.[53,55] Therefore, patients already at risk for infection are placed at even higher risk if additional immunosuppressive therapy is needed to treat one or more episodes of graft rejection. Immunosuppressive drug therapy must be evaluated carefully when infections occur because, in many cases, immunosuppression may have to be reduced to allow patients to survive the infectious episode, at the expense of increased risk of graft rejection. Risk of increased infectious complications from immunosuppressive therapy used to treat rejection episodes is determined, at least in part, by the specific therapy used.[53,54,55]

Etiology

2 As with cancer patients, microorganisms infecting SOT patients are present before transplantation or are acquired from exogenous sources. All transplant recipients are at risk for mucocutaneous candidiasis from species colonizing body sites. Invasive fungal infection is less common following kidney and pancreas transplantation (5%-15%) but may occur in 30% to 60% of heart, lung, liver, and small bowel transplant recipients. Rates are highest following lung, liver, and small bowel transplantation and are associated with mortality rates up to 60% to 80%.[53,56,57,58,59,60] Approximately 50% to 90% of all systemic fungal infections in transplant recipients are caused by *Candida* spp.[53,56,57] Abdominal surgery, especially the more complex procedures required for liver and small bowel transplantation, predispose patients to serious fungal disease, most likely as a consequence of entering an area already colonized with *Candida* spp.[56] Lung and heart transplant recipients are particularly at risk for invasive aspergillosis; these infections may occur in up to 15% of patients and in lung transplant recipients may be more common than infections caused by *Candida* spp.[56,57,58,59] Liver and lung transplant recipients are at high risk for serious gram-negative bacterial infections as a result of the technically difficult surgical procedures.[53] Although opportunistic viral, fungal, and protozoal infections may occur commonly, bacterial infections remain the most frequent infectious complications after transplantation in all allograft recipients.

Organisms present as latent tissue infections may reactivate and cause clinical disease with administration of immunosuppressive drug therapy. Disease resulting from infection reactivation has been noted with viruses (HSV, human herpesvirus-6, CMV, VZV, Epstein–Barr virus [EBV]), protozoa (*T. gondii*, *P. jiroveci*), and mycobacteria (*Mycobacterium tuberculosis*).[61,62] Serologic or immunologic tests are performed prior to transplantation to assess the risk for reactivation infection and identify other subclinical infections (eg, hepatitis B virus [HBV], hepatitis C virus [HCV], *Legionella*). Many patients with reactivated infection have no clinical symptoms; often the only evidence of active infection is a rise in antibody titer from the pretransplant baseline, positive culture, or histologic evidence. Reactivation of latent infection may result in severe life-threatening disease in immunosuppressed hosts.[62]

Exogenous sources of infection in transplant patients include environmental contamination and transmission of microorganisms via transplanted organs and blood products. Environmental sources of infection are similar to those noted in other immunocompromised hosts, such as cancer patients. Airborne pathogens, especially fungi such as *Aspergillus* and *Cryptococcus neoformans*, may cause infections in transplant patients; this is thought to be a direct cause of increased *Aspergillus* infections among lung transplant patients.[53,56] Transplant patients are at high risk for nosocomial infections (MRSA, *P. aeruginosa*, *Acinetobacter*). Optimal prevention and management of nosocomial infections in transplant patients require knowledge of the current epidemiology of infections and susceptibility patterns in the institution.

Infections transmitted via donor organs or blood products are major causes of morbidity and mortality in transplant patients and may include HSV, *T. gondii*, HBV, and HCV. The most important infections transmitted from the donor, however, are caused by CMV. These infections may cause serious disease, and predispose patients to other opportunistic infections, and contribute to acute and chronic allograft dysfunction or rejection, post-transplant lymphoproliferative disorders (particularly associated with EBV), and cardiac complications and atherosclerosis in heart transplant recipients.[53,63] In contrast to reactivation disease, transplant patients contracting primary CMV disease are at increased risk for serious life-threatening infections.[53,64,65,66] The most important source of primary CMV infection in transplant patients is the donor organ. Efforts are made to avoid transplanting organs from CMV-seropositive donors into CMV-seronegative recipients because of the potentially severe consequences. With the relative scarcity of suitable organs and the rapidity with which transplant decisions often must be made, however, this is not always possible. The consequences of transplanting an organ from a CMV-seropositive donor into an already CMV-seropositive recipient are less clear. CMV reinfection (as well as reactivation) syndromes may occur in these patients.[53,54,66] In addition to transmission from donor organs, primary CMV disease may be transmitted from seropositive blood products, although this is a much less common mode of transmission.

Organs from donors seropositive for *T. gondii* or HSV generally are not withheld from seronegative patients. Organs from known HIV-infected donors, however, are not used for transplantation. Asymptomatic HIV-seropositive individuals with $CD4^+$ lymphocyte count greater than 100 cells/mm^3 (0.1×10^9/L) and no active opportunistic infection or malignancy may be considered for SOT (as well as HSCT) without prohibitively high risk for acceleration of HIV disease.[66] The impact of protease

inhibitors and highly active antiretroviral therapy on long-term outcome of HIV-infected patients following transplantation is not precisely known but is believed to have improved the overall feasibility of transplanting these individuals.[66]

Timing of Infections After Transplantation

As with HSCT, the overall time course for infections can be divided into three general periods after transplantation (see Fig. 122-3). Although risk of infection with specific pathogens varies with the type of transplant, the time course of infections is similar in all transplant recipients. During the early post-transplant period (within the first month after transplantation), patients are at risk for infections already present and brought forward from the pretransplant period (eg, HBV); postoperative infections, such as surgical wound and catheter infections; infection resulting from colonized donor organs (pneumonia following lung transplant); and reactivation of HSV.[53,54,62] In the intermediate post-transplant period (2-6 months after transplant), risk is highest for viral infections, including CMV, EBV, HBV, and HCV. The combination of these "immunomodulating" viruses plus sustained immunosuppressive therapy leads to a high risk for opportunistic infections with pathogens such as *P. jiroveci*, *Aspergillus*, and *Nocardia asteroides*.[53,54,56,62] In the late post-transplant period (greater than 6 months after transplant), patients are at risk for persistent infections (particularly viral) from earlier post-transplant periods, reactivation of VZV and *C. neoformans*, and routine infections affecting the general population.[53] In addition, patients who required additional immunosuppression therapy for acute or chronic rejection are at continued high risk for opportunistic infections (*Aspergillus* and *P. jiroveci*).[53,54,56] Although Fig. 122-3 illustrates infection patterns common to all solid-organ transplants, the relative incidence and importance of a particular pathogen vary according to the type of transplant.

Types of Infections and Clinical Presentation

10 Transplant patients are at risk for infections occurring at a variety of sites, including skin, surgical wound, urinary tract, lungs, blood, abdomen, and CNS. However, most infections occur at or near the site of the transplanted organ. For example, heart transplant and heart and lung transplant recipients most often are infected within the lungs or thoracic cavity. Urinary tract infections remain an important cause of morbidity in renal transplant patients, especially in the early post-transplant period. Administration of prophylactic antibiotics (eg, trimethoprim–sulfamethoxazole) to these patients has reduced the incidence and severity of urinary tract infections.[53,54] Serious bacterial and fungal infections originating from the abdomen and GI tract are most common after liver transplantation and are related to variables such as length of surgery and surgical procedures performed. Risk of bacteremia, usually originating from the gut, is highest in liver transplant patients. Renal transplant recipients are at the lowest risk for infections and infectious deaths, whereas patients receiving heart, lung, and liver transplants are at the highest risk for infection-related morbidity and mortality.[53,54,56]

In contrast to febrile neutropenic patients, the threshold for initiating empirical antimicrobial therapy is higher in febrile transplant patients. Appropriate therapy for the large numbers of pathogens that

may cause infections in transplant patients varies greatly from organism to organism (Table 122-5). Therefore, careful attempts at definitive diagnosis of suspected infections must be made. If comprehensive workup reveals no source of infection, careful observation of the febrile transplant patient (rather than empirical therapy) is common practice. Surveillance cultures may be useful during the first 3 months for detecting CMV and HSV infections.[53,56,64,65,67,68] Management and monitoring of documented infections are similar to that in other types of patients.

TREATMENT

Desired Outcomes

The goals of therapy in managing SOT recipients are similar to those in HSCT and include: (a) protect the patient from early death caused by undiagnosed infection, from the surgical procedure through the late postengraftment period; (b) prevent common bacterial, fungal, viral, and protozoal/parasitic infections; (c) effectively and aggressively treat established infections; (d) avoid unnecessary use of antimicrobials; and (e) minimize toxicities and cost while increasing patient quality of life and avoiding harm to the engrafted organ(s).

CLINICAL PRESENTATION Infections in Solid-Organ Transplant Patients General

- Because transplant patients are at high risk for serious infections, frequent (at least daily), careful clinical assessments must be performed to search for evidence of infection
- Clinical presentation of infection is variable and depends on the type and site of infection, type of transplant, time after transplantation, immune status of the host, and dose and duration of immunosuppressive therapy
- Primary viral disease usually is more symptomatic and severe than disease caused by reactivation
- Physical assessment should include examination of all common sites of infection, including mouth/pharynx, nose and sinuses, respiratory tract, GI tract, urinary tract, skin, soft tissues, perineum, and intravascular catheter insertion sites

Symptoms

- Usual signs and symptoms of infection may be absent or altered in patients receiving intensive immunosuppressive regimens owing to an inability to mount a typical inflammatory response (eg, no infiltrate on chest x-ray film, urinary tract infection without pyuria)
- Pain may be present at infection site(s)

Signs

- Fever is the single most important clinical sign indicating the presence of infection. Other causes of fever unrelated to infection in this patient population include reactions to blood products, drugs, embolic events, and ischemic injury

- Usual signs of infection may be absent or altered
- Signs of allograft dysfunction may be related to infection. Distinguishing fever caused by allograft rejection from that caused by infection often is difficult and frequently requires allograft biopsy

Laboratory Tests

- Blood cultures (at least two sets, including vascular access devices) for bacteria and fungi; cultures of other suspected or potential infection sites (urine, lungs, surgical wounds, and soft tissue infections)
- Other cultures should be obtained as clinically indicated according to the presence of signs or symptoms
- Complete blood count and chemistries should be obtained frequently to monitor allograft function, plan supportive care, guide drug dosing, and assess patient's overall status
- Surveillance cultures for CMV and HSV may be useful during first 3 months after transplantation for early detection of infection

Other Diagnostic Tests Chest x-ray film

- Aspiration, biopsy of skin lesions
- Other diagnostic tests as indicated clinically on the basis of physical examination and other assessments

Prevention of Infection in Solid-Organ Transplantation

8 The goals of antimicrobial drug use in solid-organ transplant recipients are (a) prevention of infectious complications in the immediate postoperative period, (b) prevention of late infectious complications associated with prolonged periods of immunosuppression, and (c) effective treatment of established infections in order to prevent graft dysfunction and rejection and decrease patient morbidity and mortality. All of these goals must be achieved at the lowest possible toxicity and cost.

Prevention of infection in the transplant patient can be accomplished in a number of ways. First, risk of environmental contamination should be minimized.[69] Patients should be protected from institutional infectious outbreaks. Transplant patients should receive the pneumococcal vaccine once and the influenza vaccine yearly; however, their immunologic responses to these vaccines may be suboptimal due to immunosuppressive therapy.[53] Timing of reinstitution of regular vaccinations in relation to transplantation is less clear, but is probably similar to that previously discussed for HSCT recipients.[70]

Because the most important source of primary CMV infection is an infected donor organ, CMV-seronegative patients should not receive organs or blood products from seropositive donors if

possible. A number of pharmacologic strategies have been studied in an attempt to prevent CMV infection. Prophylaxis with IV ganciclovir or oral valganciclovir is effective in reducing the incidence of both primary and reactivated CMV infection in SOT.[48,53,54,63,64,65,66] Ganciclovir prophylaxis also may significantly reduce reactivation of CMV infection in seropositive patients receiving antithymocyte globulin or muromonab for treatment of acute rejection.[54,65,66] High-dose oral acyclovir effectively reduces the incidence of CMV infection and disease following renal transplantation. However, acyclovir is less efficacious in high-risk renal transplant patients (donor positive, recipient negative for CMV serum antibodies) and other nonrenal transplant types.[53,54,63,64,65,66,71] Preemptive ganciclovir or valganciclovir (initiated after actual isolation of CMV from blood, urine, bronchoalveolar lavage fluid, or other site) is more effective than acyclovir in preventing CMV disease in liver transplant recipients. Preemptive ganciclovir effectively prevents CMV disease in other types of solid-organ transplants as well.[64,65,68] Ganciclovir-related bone marrow suppression is not as problematic in solid-organ transplant recipients as in HSCT patients; most studies report that the drug is reasonably well tolerated.[48,53,64,65,68,71]

Whether prophylaxis or preemptive therapy is the best approach to preventing CMV disease in SOT is controversial.[48,53,60,64,65,66,68,72,73,74] Prophylaxis is effective and easy to administer without the need for careful discrimination among suitable patients. However, universal prophylaxis results in unnecessary exposure of low-risk individuals to adverse effects of drugs, and there are concerns that prolonged exposure may increase the risk of viral resistance to drugs.[64,65,71,72,73] Preemptive therapy is effective and results in exposure of fewer patients to drugs. Prophylactic therapy is recommended primarily in patients at highest risk of disease (ie, seronegative patients receiving organs from seropositive donors), whereas other lower-risk patients are often recommended to receive only preemptive therapy.[53,64,65,68,71,72,73,74] However, the risk of CMV infection and disease in lung transplant recipients is so high and is associated with such severe consequences (ie, chronic graft dysfunction, decreased survival) that prophylaxis is routinely recommended for all lung transplant recipients.[62,68,72,73,74] The duration of prophylactic therapy in SOT recipients is typically 100 days (typically using valganciclovir), although the duration may be extended to 6 months in high-risk kidney transplant recipients and to 12 months in high-risk lung and heart transplant patients.[62,68,72,73,74,75]

Clinical Controversy…

Sirolimus and everolimus are classified as mTOR (mammalian target of rapamycin) inhibitors and are often used, either alone or in combination with calcineurin inhibitors (CNI), in immunosuppressive regimens in SOT recipients. Experimental and clinical data suggest that mTOR inhibitors exert a marked anti-CMV effect through reduction in viral replication and/or potent immunomodulating properties.[76] In a meta-analysis, patients receiving immunosuppressant regimens containing mTOR inhibitors (with or without CNI) displayed a nearly three-fold reduced incidence of CMV infections compared to patients receiving CNI alone; it has even been suggested that routine prophylaxis of CMV infection may be eliminated in patients receiving mTOR inhibitors.[76] The potential for mTOR inhibitors to reduce the need for CMV prophylaxis in favor of preemptive treatment of CMV infection is the subject of extreme clinical interest, but will remain controversial until prospective clinical trials

can be conducted.

Although use of prophylactic acyclovir in HSV-seropositive patients undergoing HSCT is well accepted, prophylaxis in solid-organ transplant recipients remains controversial. Reactivation disease caused by HSV occurs in approximately 25% of HSV-seropositive patients who are not receiving prophylaxis.[53] Oral or genital mucocutaneous disease is the most common presentation, but HSV pneumonitis also is seen occasionally and is associated with a mortality rate of approximately 75%.[53] Acyclovir is therefore used at some centers because of the high incidence of clinical HSV infection after transplantation. Acyclovir for prophylaxis of HSV infection may be considered in patients following a preemptive strategy for management of CMV infection, but would not be necessary in patients receiving ganciclovir or valganciclovir for CMV prophylaxis.

Prophylactic antimicrobial agents are also of benefit to SOT patients in certain other clinical situations. Antibiotic prophylaxis, with agents such as cefazolin started perioperatively and continued for less than 24 hours, is considered to reduce wound infection rates effectively following renal transplantation.[53,54,68] Although the benefits of perioperative prophylaxis have not been well demonstrated in other types of transplantation procedures, surgical prophylaxis usually is considered mandatory for liver, heart, lung, or small bowel transplant patients because of the high risk of perioperative bacterial infections.[53,68] Pulmonary infections are particularly common in lung and heart-lung transplant recipients. They often are caused by bacteria colonizing the airways of the diseased organs prior to transplantation. Therefore, perioperative antibiotics for lung and heart and lung procedures often are selected based on pretransplant sputum cultures and/or known colonizations.[53,68] In addition, posttransplant antibiotic prophylaxis is effective in decreasing the number of bacterial infections in renal transplant patients. Prophylactic trimethoprim–sulfamethoxazole traditionally has been used because it is inexpensive and well tolerated; other antibiotics, such as the fluoroquinolones, also have been evaluated.[53] Administration of oral low-dose trimethoprim–sulfamethoxazole (one double-strength tablet, either daily or 3 times/week) for 6 to 12 months for prevention of *P. jiroveci* infection following heart and lung transplantation is common, although the efficacy and optimal duration are somewhat controversial.[53,74] Selective bowel decontamination with nonabsorbable antibiotics in combination with a low-bacterial diet (no fresh fruits and vegetables) effectively reduces oropharyngeal and GI colonization with gram-negative aerobes and *Candida* in liver transplant patients. However, selective bowel contamination is less efficacious when administered for a period of less than 1 week prior to transplantation.[68,77] Because liver transplantation usually is performed without advance notice as organs become emergently available, the practice of selective bowel decontamination remains controversial and is not recommended routinely.[53,68]

Because immunosuppressed transplant recipients are at risk for mucocutaneous fungal infections, prophylactic oral or topical antifungal agents may be indicated in these patients. Liver, pancreas, and small bowel transplant recipients are clearly at high risk for invasive fungal infections and should receive prophylaxis with fluconazole.[18,53,56,73] Antifungal prophylaxis has also been suggested for lung and heart–lung transplant recipients due to the high incidence of invasive fungal infections in these patients (up to 25% of patients, with mortality rates up to 82%).[78] Prophylaxis with inhaled

LAMB, itraconazole, voriconazole, and echinocandins have all been reported; however, data from well-designed trials supporting either the general recommendation for prophylaxis or choice of specific agent are largely lacking and center-to-center variability is great.[18,56,60,73] Oral voriconazole or inhaled LAMB for a period of 3 to 6 months post-transplant are most often recommended for prophylaxis of invasive fungal infection in lung and heart lung transplant recipients.[78] Concentrations of immunosuppressant drugs should be monitored closely in transplant patients receiving azole-type antifungal agents (fluconazole, itraconazole, and voriconazole).

Transplant patients, especially heart and heart and lung recipients, without serologic evidence of prior exposure to *T. gondii* who receive organs from seropositive donors are at high risk for toxoplasmosis.[53,60,68] Many of these patients will be receiving trimethoprim–sulfamethoxazole for prophylaxis of *P. jiroveci* infection; this agent will also provide effective prophylaxis against *T. gondii* as well as *N. asteroides*. Although prophylaxis is not given routinely at all centers, this therapy for a period of up to 12 months may be justified in high-risk patients because of the delays in diagnosis and serious infections associated with toxoplasmosis.[53,60,68,75]

PERSONALIZED PHARMACOTHERAPY

Desired treatment outcomes in febrile neutropenia and in HSCT and SOT recipients are achieved through close monitoring and frequent patient assessment, including judicious evaluation of antimicrobial therapies based on suspected or documented infections. Treatment of known infections must be individualized based on documented pathogens and antimicrobial susceptibilities; effective treatment may require durations of therapy well beyond recovery of ANC in febrile neutropenic patients. High intensity of immunosuppression regimens in HSCT and SOT, as well as the presence of GVHD in HSCT, also dictate aggressive antimicrobial use with potentially long durations of therapy. However, such aggressive antimicrobial use must be balanced against unnecessary administration of drugs, which may lead to increased antimicrobial resistance, adverse effects, and cost. Proper evaluation of an individual patient's risk of complications during febrile neutropenia or after transplantation allows for determination of proper prophylaxis regimens, selection of appropriate antimicrobials for treatment of infection, and selection of appropriate treatment settings (eg, inpatient versus outpatient), all of which may allow for the most cost-effective therapy and contribute to an increased quality of life for the patient.

Chapter 123: Antimicrobial Prophylaxis in Surgery

FIGURE 123-1

Salmaan Kanji

INTRODUCTION

KEY CONCEPTS

- 1 Prophylactic antibiotic therapy differs from presumptive and therapeutic antibiotic therapy in that the latter two involve treatment regimens for presumed or documented infections, whereas the goal of prophylactic therapy is to prevent infections in high-risk patients or procedures.
- 2 The risk of a surgical site infection (SSI) is determined from both the type of surgery and the patient-specific risk factors; however, most commonly used classification systems account for only procedure-related risk factors.
- 3 The timing of antimicrobial prophylaxis is of paramount importance. Antibiotics should be administered within 1 hour before surgery to ensure adequate drug levels at the surgical site prior to the initial incision.
- 4 Antimicrobial agents with short half-lives (eg, cefazolin) may require intraoperative redosing during procedures last more than 3 hours or 2.5 half-lives of the antimicrobial used.
- 5 The type of surgery, intrinsic patient risk factors, most commonly identified pathogenic organisms, institutional antimicrobial resistance patterns, and cost must be considered when choosing an antimicrobial agent for prophylaxis.
- 6 Single-dose prophylaxis is appropriate for many types of surgery. First-generation cephalosporins (eg, cefazolin) are the mainstay for prophylaxis in most surgical procedures

because of their spectrum of activity, safety, and cost.

- 7 Vancomycin as a prophylactic agent should be limited to patients with a documented history of life-threatening β-lactam hypersensitivity or those in whom the incidence of infections with organisms resistant to cefazolin (eg, methicillin-resistant *Staphylococcus aureus*) is documented or high enough to justify use.

According to the National Center for Health Statistics and the National Hospital Discharge Survey, nearly 57 million outpatient and 51 million in patient surgical procedures are performed annually in the United States.[1,2] Infection is the most common complication of surgery.[3] Surgical site infections (SSIs) occur in ~3% to 6% of patients and prolong hospitalization by an average of 7 days at a direct annual cost of $5 billion to $10 billion.[4,5] SSIs are the third (14%-16%) most frequent cause of nosocomial infections among hospitalized patients and the primary (40%) cause of nosocomial infection in surgical patients.[4] Prophylactic administration of antibiotics decreases the risk of infection after many surgical procedures and represents an important component of care for this population.

Antibiotics administered prior to the contamination of previously sterile tissues or fluids are called prophylactic antibiotics. The goal of prophylaxis is to prevent an infection from developing. Although eradication of distal (preexisting, unrelated to surgery) infections lowers the risk for subsequent postoperative infections, it does not per se constitute a prophylactic regimen. In fact, surgical prophylaxis should be prescribed concurrently under these circumstances because of important antimicrobial spectrum- and timing-related concerns. Both SSIs and hospital-acquired infections not directly related to the surgical site (eg, urinary tract infections and pneumonia) are termed *nosocomial*. Prevention of hospital-acquired infections is a major goal of antibiotic prophylaxis.

1 Presumptive antibiotic therapy is administered when an infection is suspected but not yet proven. Clinical scenarios where presumptive therapy is used commonly include acute cholecystitis, open compound fractures, and acute appendicitis of less than 24 hours' duration. In these situations, if signs of perforation, contamination or infection are absent during surgery, then routine prophylactic treatment rather than presumptive therapy is warranted. An operative finding of a gangrenous gallbladder or a perforated appendix, however, is suggestive of an established infectious process, and a therapeutic antibiotic regimen is required.[4]

According to the Centers for Disease Control and Prevention's (CDC) National Nosocomial Infections Surveillance System (NNIS),[4] SSIs can be categorized as either incisional (eg, cellulitis of the incision site) or organ/space (eg, meningitis; **Fig. 123-1**). Incisional SSIs are subcategorized into superficial (involving only the skin or subcutaneous tissue) and deep (fascial and muscle layers) infections. Organ/space SSIs can involve any anatomic area other than the incision site. For example, a patient who develops bacterial peritonitis after bowel surgery has an organ/space SSI. By definition, SSIs must occur within 30 days of surgery. If a prosthetic implant is involved, a deep incisional or organ/space SSI can be reported up to 1 year from the date of surgery. Although microbiologic testing of surgical drainage material or sites may help to guide care, the specificity of a negative culture is poor and generally does not rule out an SSI.[4]

RISK FACTORS FOR SURGICAL SITE INFECTIONS

2 SSI incidence depends on both procedure- and patient-related factors. The risk for SSIs has been stratified by surgical procedure in a classification system developed by the National Research Council (NRC; **Table 123-1**).[6] The NRC classification system proposes that the risk of an SSI depends on the microbiology of the surgical site, the presence of a preexisting infection, the likelihood of contaminating previously sterile tissue during surgery, and the events during and after surgery.[6,7] A patient's NRC procedure classification is the primary determinant of whether antibiotic prophylaxis is warranted. However, because a patient's NRC wound classification is influenced by surgical findings (eg, gangrenous gallbladder) and perioperative events (eg, major technique breaks), categorization generally occurs intraoperatively.[8]

TABLE 123-1 National Research Council Wound Classification, Risk of Surgical Site Infection, and Indication for Antibiotics

	SSI Rate (%)			
Classification	**Preoperative Antibiotics**	**No Preoperative**	**Criteria**	**Antibiotics**

				Antibiotics
Clean	5.1	0.8	No acute inflammation or transection of GI, oropharyngeal, genitourinary, biliary, or respiratory tracts; elective case, no technique break	Not indicated unless high-risk procedure[a]
Clean–contaminated	10.1	1.3	Controlled opening of aforementioned tracts with minimal spillage/minor technique break; clean procedures performed emergently or with major technique breaks	Prophylactic antibiotics indicated
Contaminated	21.9	10.2	Acute, nonpurulent inflammation present; major spillage/technique break during clean–contaminated procedure	Prophylactic antibiotics indicated
Dirty	N/A	N/A	Obvious preexisting infection present (abscess, pus, or necrotic tissue present)	Therapeutic antibiotics required

N/A, not applicable; SSI, surgical site infection.

[a]High-risk procedures include implantation of prosthetic materials and other procedures where surgical site infection is associated with high morbidity (see the text).

Data from references 5 and 11.

Inherent Patient Risk

The NRC classification system does not account for the influence of underlying patient risk factors for SSI development, instead categorizing the risks for SSIs simply based on a specific surgical procedure. Disease states and conditions known to increase SSI risk are listed in **Table 123-2**. Preexisting distal infections increase SSI rates and should be resolved prior to surgery whenever possible. Diabetic patients have an increased risk for SSIs, especially those with uncontrolled perioperative blood sugars. Preoperative smoking is an independent risk factor for SSI because of the deleterious effects of nicotine on wound healing. Preoperative immunosuppression, including corticosteroid use, may increase infection risk. Patients coinfected with human immunodeficiency virus (HIV) and hepatitis C are at approximately double the risk of SSI as the general population.[9] Malnutrition is a well-described risk factor for postoperative complications, including SSI, impaired wound and colonic anastomosis healing, and prolonged hospital stay. Although enteral feeding during the perioperative period can reduce bacterial translocation by maintaining the integrity of the intestinal mucosa, nutritional supplementation does not decrease the incidence of infection.[10]

TABLE 123-2 Patient and Operation Characteristics That May Influence the Risk of Surgical Site

Infection

Patient	Operation
Age	Duration of surgical scrub
Nutritional status	Preoperative skin preparation
Diabetes	Preoperative shaving
Smoking	Duration of operation
Obesity	Antimicrobial prophylaxis
Coexisting infections at distal body sites	Operating room ventilation
Colonization with resistant microorganisms	Sterilization of instruments
Altered immune response	Implantation of prosthetic materials
Length of preoperative stay	Surgical drains
	Surgical technique

Colonization of the nares with *S. aureus* is a well-described SSI risk factor.[4] A large multicenter study involving more than 38,000 patients undergoing more than 42,000 cardiac and orthopedic procedures showed that pre-operative screening for carriers of *S. aureus* followed by intranasal mupirocin administration and chlorhexidine bathing for five days before surgery significantly reduced *S. aureus* SSI from 0.36% to 0.2%.[11] Although the absolute risk difference is small, this represents a 44% relative risk reduction. The potential impact on patient outcomes and health resource utilization is large given the number of surgeries performed annually. However, the logistics and cost of pre-screening and treatment of colonized patients represents a challenge. Other factors shown to increase the risk of SSI are age, length of preoperative hospital stay, and obesity.[4]

Identifying SSI Risk

Two large epidemiologic studies have objectively quantified SSI risk based on specific patient- and procedure-related factors. The Study on the Efficacy of Nosocomial Infection Control (SENIC) analyzed more than 100,000 surgery cases to identify and validate risk factors for SSI.[12] Abdominal operations, operations lasting longer than 2 hours, contaminated or "dirty" procedures (as per NRC classification), and more than three underlying medical diagnoses each was associated with an increased incidence of SSI. When NRC classification was stratified by number of SENIC risk factors present, SSI incidence varied by as much as a factor of 15 within the same NRC operative category (**Table 123-3**).[13]

TABLE 123-3 Surgical Site Infection Incidence (%) Stratified by NRC Wound Classification and SENIC Risk Factors[a]

Number of SENIC Risk Factors	Clean	Clean–Contaminated	Contaminated	Dirty

Number of SENIC Risk Factors	Clean	Clean–Contaminated	Contaminated	Dirty
0	1.1	0.6	N/A	N/A
1	3.9	2.8	4.5	6.7
2	8.4	8.4	8.3	10.9
3	15.8	17.7	11.0	18.8
4	N/A	N/A	23.9	27.4

In a subsequent analysis of more than 84,000 surgical cases, the NNIS attempted to simplify and refine the SENIC system by quantifying intrinsic patient risk using the American Society of Anesthesiologists' (ASA) preoperative assessment score (**Table 123-4**).[14,15] An ASA score greater than or equal to 3 was a strong predictor for the development of an SSI. Other factors associated with increased SSI incidence are contaminated or "dirty" operations (NRC criteria) and surgical procedures lasting longer than average. As in the SENIC study, the SSI rate was linked to the number of risk factors present and varied considerably within NRC class. The NNIS basic SSI risk index is composed of the following criteria: ASA score = 3, 4, or 5; wound class; and duration of surgery. Overall, for 34 of the 44 NNIS procedure categories, SSI rates increased proportionally with the number of risk factors present.[16] The SSI rate was generally lower when the procedure was done laparoscopically.

TABLE 123-4 American Society of Anesthesiologists' Physical Status Classification

Class	Description
1	Normal healthy patient
2	Mild systemic disease
3	Severe systemic disease that is not incapacitating
4	Incapacitating systemic disease that is a constant threat to life
5	Not expected to survive 24 hours with or without operation

Data from reference 15.

Although evidence-based recommendations for antimicrobial prophylaxis during surgery are best established using the results of randomized clinical trials, many studies have small sample sizes and do not stratify patients according to overall SSI risk. Future studies, particularly those involving clean

procedures, should be stratified by SSI risk so that the subset of high-risk patients who might benefit the most from prophylaxis is clearly established.

BACTERIOLOGY

The most important consideration when choosing antibiotic prophylaxis is the bacteriology of the surgical site. Organisms involved in an SSI are acquired by one of two ways: endogenously (from the patient's own normal flora) or exogenously (from contamination during the surgical procedure). Based on the type and anatomic location of the procedure and the NRC classification (see Table 123-1), resident flora can be predicted and appropriate antibiotic choices made. According to NNIS data, *S. aureus,* coagulase-negative staphylococci, enterococci, *Escherichia coli*, and *Pseudomonas aeruginosa* are the pathogens most commonly isolated (**Table 123-5**).[14] With the widespread use of broad-spectrum antibiotics, however, *Candida* species and methicillin-resistant *Staphylococcus aureus* (MRSA) are becoming more prevalent.[14]

TABLE 123-5 Major Pathogens in Surgical Wound Infections

Pathogen	Percent of Infections[a]
Staphylococcus aureus	20
Coagulase-negative staphylococci	14
Enterococci	12
Escherichia coli	8
Pseudomonas aeruginosa	8
Enterobacter species	7
Proteus mirabilis	3
Klebsiella pneumoniae	3
Other *Streptococcus* species	3
Candida albicans	3
Group D streptococci	2
Other gram-positive aerobes	2
Bacteroides fragilis	2

[a]Data reported by the National Nosocomial Infections Surveillance System from January 1992 through June 2004.

Data from reference 5.

Factors affecting the ability of an organism to induce an SSI depend on organism count, organism virulence, and host immunocompetency. Organisms in the commensal flora generally are not pathogenic. These organisms often serve the host as a form of protection against invasive organisms that otherwise would colonize the surgical site. Opportunistic organisms usually are kept in check by normal flora and rarely are problematic unless they are present in large numbers. The loss of normal flora through the use of broad-spectrum antibiotics can destabilize homeostasis, allowing pathogenic

bacteria to proliferate and infection to occur.[5]

Normal flora translocated to a normally sterile tissue site or fluid during a surgical procedure can become pathogenic. For example, *S. aureus* or *Staphylococcus epidermidis* may be translocated from the surface of the skin to deeper tissues or *E. coli* from the colon to the peritoneal cavity, bloodstream, or urinary tract. Studies in animals and healthy volunteers have shown bacterial virulence to be an important determinant in the development of secondary infections.[17,18] Whereas more than one million *S. aureus* per square centimeter or gram of tissue are required to produce infection in animals, less than 100,000 *Streptococcus pyogenes* per square centimeter or gram of tissue are required at the same site.[18,19]

Impaired host defense reduces the number of bacteria required to establish an infection. A breach of normal host defenses through surgical intervention (eg, insertion of a prosthetic device) may enable organisms to cause infection. In addition, the loss of specific immune factors, such as complement activation, tissue-derived inhibitors (eg, proinflammatory cytokines), cell-mediated response (eg, T-cell function), and granulocytic or phagocytic function (eg, neutrophils or macrophages) can greatly increase the risk for SSI development.[20] Vascular occlusive states related to the surgical procedure or those occurring from hypovolemic shock can greatly affect blood flow to the surgical site, thus diminishing host defense mechanisms against microbial invasion. Traumatized tissue, hematomas, and the presence of foreign material also lead to more infections. When a foreign body is introduced during a surgical procedure, fewer than 100 bacterial colony-forming units are required to cause an SSI.[21] Studies examining *S. aureus*-contaminated wound infections on the skin of healthy volunteers demonstrate a 10,000-fold reduction in the number of organisms required to establish a wound infection if sutures are not present.[17]

ANTIMICROBIAL RESISTANCE

Colonization of the host with antibiotic-resistant hospital flora prior to or during surgery may lead to an SSI that is unresponsive to routine antibiotic therapy. The most common cause of nosocomially acquired multiresistant organisms is transmission from hospital personnel.[22] Patients treated with broad-spectrum antibiotic therapy are at increased risk for colonization with hospital flora.

With cephalosporins established as first-line agents for prophylaxis, organisms resistant to cephalosporins represent the majority of pathogens causing SSIs. MRSA and coagulase-negative staphylococci have emerged as the most common pathogens in patients who develop SSIs despite prophylaxis with cephalosporins particularly in cardiothoracic, vascular, orthopedic, and neurologic surgery. Methicillin resistance not only limits the treatment/-prophylaxis options available, but it also is associated with increased mortality, longer hospital lengths of stay, and increased costs.[23,24] Although the use of vancomycin for prophylaxis may be appropriate for some operations performed in hospitals with a high rate of infection due to MRSA, there is little guidance on what constitutes a "high rate" of MRSA infection and whether providing prophylaxis with vancomycin alone will result in fewer SSIs.[25] A more effective strategy would be to screen elective surgical candidates for MRSA colonization preoperatively. MRSA colonization is predictive of MRSA SSI and thus effective

prophylaxis with vancomycin is then reserved for carriers only. Some single center studies evaluating the decolonization of MRSA carriers preoperatively (ie, with intranasal mupirocin, chlorhexidine showers) yield mixed results and may not be cost-effective.[26,27]

Although cefazolin remains a mainstay in cardiovascular SSI prophylaxis, its failure has been reported in cases involving methicillin-sensitive *Staphylococcus aureus* (MSSA). In a comparison trial between cefamandole and cefazolin, significantly more failures were attributed to cefazolin, even though the primary pathogen was MSSA.[28] However, a similar trial comparing cefazolin and cefuroxime did not show any difference in SSI incidence between the two regimens.[28] The β-lactamase expressed by some MSSA may be capable of hydrolyzing cefazolin more readily than cefuroxime or cefamandole. Although this trend is disturbing, the overall incidence of cefazolin failure remains low, and cefazolin remains the drug of choice for SSI prophylaxis in cardiovascular surgery.[28]

The increase in frequency of fungal infections in surgical patients has drawn concern. In hospitalized patients, the incidence of nosocomial *Candida* infections nearly doubled from 1992 to 2004.[14,29] Overzealous use of broad-spectrum antibiotics is the most likely cause for this increase. A study of patients undergoing cardiovascular surgery identified female sex, length of stay in the ICU, and duration of central venous catheterization as risk factors for postoperative *Candida* infections.[30] Although presurgical *Candida* colonization is associated with a higher risk of fungal SSIs, routine preoperative use of prophylactic antifungal agents is not being advocated at this time.[29,31]

SCHEDULING ANTIBIOTIC ADMINISTRATION

3 4 The following principles must be considered when providing antimicrobial surgical prophylaxis: (a) the agents should be delivered to the surgical site prior to the initial incision, and (b) bactericidal antibiotic concentrations should be maintained at the surgical site throughout the surgical procedure. Although animal and human models have demonstrated the efficacy of a single dose of an antibiotic administered just prior to bacterial contamination, long operations often require intraoperative doses of antibiotics to maintain adequate concentrations at the surgical site for the duration of surgery.[32] Antibiotic administration should be completed within 60 minutes prior to the initial incision, preferably at the time of anesthetic induction. Since the administration duration varies between antimicrobials, this needs to be considered when determining when to start the infusion. Administration of antibiotics too early may result in concentrations below the MIC toward the end of the operation, and administration too late leaves the patient unprotected at the time of initial incision. In a study examining the timing of antibiotic administration to 2,847 patients receiving prophylaxis, Classen et al.[32] evaluated patients who received prophylaxis early (2-24 hours before surgery), preoperative prophylaxis (0-2 hours prior to surgery), perioperative prophylaxis (up to 3 hours after first incision), and postoperative prophylaxis (greater than 3 hours after the first incision). The risk of infection was lowest (0.6%) for patients who received preoperative prophylaxis, moderate (1.4%) for those who received perioperative antibiotics, and greatest for those who received postoperative antibiotics (3.3%) or preoperative antibiotics too early (3.8%). The risk for an SSI increases dramatically with each hour from the time of initial incision to the time when antibiotics are eventually administered. For these reasons, prophylactic antibiotics should not be prescribed to be

given “on call to the operating room (OR),” which can occur two or more hours prior to the initial incision, nor should concurrent therapeutic antibiotics be relied on to provide adequate protection. In both situations, the chance for improperly timed doses is high. Although the landmark study by Classen et al.[32] confirmed that antimicrobial prophylaxis should be administered within 2 hours prior to the initial incision, administration immediately prior to the incision may not allow enough time for the drug to distribute throughout the tissues involved in the surgery.

In a large prospective observational study of 3,836 visceral, trauma, and vascular surgeries where antimicrobial prophylaxis with cefuroxime and metronidazole was employed, the incidence of SSIs was analyzed according to the timing of antimicrobial administration. When antimicrobial prophylaxis was administered within 30 minutes or between 1 and 2 hours before the initial incision, the risk of SSI was greater when compared to antimicrobial prophylaxis administered 30 to 59 minutes prior to the initial incision. The authors conclude that the optimal window for antimicrobial (cefuroxime and metronidazole) is between 30 and 59 minutes prior to the initial incision.[33] This effect may be a function of the pharmacodynamics and pharmacokinetics of the antimicrobial chosen for the prophylactic regimen. A larger study of 4,472 patients undergoing cardiac, orthopedic, and gynecologic surgery with a variety of antimicrobial prophylactic regimens also evaluated the temporal relationship between SSI occurrence and the timing of antibiotics. After excluding patients who received drugs with prolonged infusion times (ie, fluoroquinolones and vancomycin), there was a nonsignificant trend toward fewer SSIs in patients who received their prophylactic regimen within the 30 minutes prior to incision as compared with those who received the regimen 31 to 60 minutes prior to incision (odds ratio, OR: 1.74; 95% confidence interval: 0.98-3.04).[34]

Despite the importance of appropriately timed prophylactic antibiotic therapy, many patients receive antibiotics outside of the optimal time window in relation to surgery. Potential barriers include antibiotics ordered after the patient has arrived in the OR, delayed antibiotic preparation or delivery, and use of antibiotics that require long infusion times. One retrospective study assessed the timing of prophylactic antibiotics in more than 32,000 patients and found that 91.9% of patients received an antibiotic dose within 60 minutes of the initial surgical incision.[35]

Although most studies comparing single versus multiple doses of prophylactic antibiotics have failed to show a benefit of multidose regimens, the duration of operations in these studies may not be as long as that frequently observed in clinical practice. Proponents of administering a second antibiotic dose during lengthy operations suggest that the risk for SSI is just as great at the end of surgery (during wound closing) as it is during the initial incision. One study of patients undergoing cleancontaminated operations suggests that procedures longer than 3 hours require a second intraoperative dose of cefazolin or substitution of cefazolin with a longer-acting antimicrobial agent.[5] A second study of patients undergoing elective colorectal surgery suggests that low serum antimicrobial concentrations at the time of surgical closure is the strongest predictor of postoperative SSI.[36] Studies of patients undergoing cardiac surgery also have demonstrated a higher infection rate among patients with undetectable antibiotic serum concentrations at the conclusion of the procedure.[37] Ideally antibiotic prophylaxis should be repeated when surgeries last longer than two half-lives of chosen antibiotic (ie, four hours for cefazolin) or if intraoperative blood loss exceeds 1.5 L.[38]

One strategy to ensure appropriate redosing of prophylactic antibiotics during long operations is use of a visual or auditory reminder system. One hospital reported its experience with such a system, finding that an automated reminder improved compliance and reduced SSIs. However, even with the reminder system, intraoperative redosing was done in only 68% of eligible patients.[39] Another strategy currently being evaluated is the role of continuous infusions of cefazolin, which one pilot study has found to be a feasible way to ensure adequate serum concentrations of antibiotic during prolonged surgeries.[40] Further trials are required before such an intervention can be recommended.

ANTIMICROBIAL CHOICE

5 The choice of prophylactic antibiotic depends on the type of surgical procedure, the most frequent pathogens seen with this procedure, safety and efficacy profiles of the antimicrobial agent, current literature evidence supporting its use, and cost. Although most SSIs involve the patient's normal flora, antimicrobial selection also must take into account the susceptibility patterns of nosocomial pathogens within each institution. Typically, gram-positive coverage should be included in the choice of surgical prophylaxis because organisms such as *S. aureus* and *S. epidermidis* are encountered commonly as skin flora. The decision to broaden antibiotic prophylaxis to agents with gram-negative and anaerobic spectra of activity depends on both the surgical site (eg, upper respiratory, GI, or genitourinary tract) and whether the operation will transect a hollow viscous or mucous membrane that may contain resident flora.[4]

Although antimicrobial prophylaxis can be administered through a variety of routes (eg, oral, topical, or intramuscular), the parenteral route is favored because of the reliability by which adequate tissue concentrations may be acheived.[41] Cephalosporins are the most commonly prescribed agents for surgical prophylaxis because of their broad antimicrobial spectrum, favorable pharmacokinetic profile, low incidence of adverse side effects, and low cost. First-generation cephalosporins, such as cefazolin, are the preferred choice for surgical prophylaxis, particularly for clean surgical procedures.[4,5,8] In cases where broader gram-negative and anaerobic coverage is desired, antianaerobic cephalosporins, such as cefoxitin and cefotetan, are appropriate choices. Although third-generation cephalosporins (eg, ceftriaxone) have been advocated for prophylaxis because of their increased gram-negative coverage and prolonged half-lives, their inferior gram-positive and anaerobic activity and high cost have discouraged the widespread use of these agents.[4,5,8]

Allergic reactions are the most common side effects associated with cephalosporin use. Reactions can range from minor skin manifestations at the site of infusion to rash, pruritus, and rarely anaphylaxis (less than 0.02%). The structural similarity between penicillins and cephalosporins (each contains a β-lactam ring) has led to considerable confusion about the cross-allergenicity between these two classes of drugs. Twenty percent of the general population is labeled "penicillin allergic," yet of these patients, only 10% to 20% have positive results of a penicillin skin test.[42] The rate of cross-reactivity with cephalosporins is ~2%, but as only 20% of all "penicillin-allergic" patients truly are penicillin allergic, the true incidence of cross-reactivity likely is less than 1%. Routine penicillin skin testing is not cost-effective.[42] The administration of cephalosporins is both safe and cost-effective for many patients who are labeled "penicillin allergic," and they can be used by patients who have not

experienced an immediate or type I penicillin allergy.

Vancomycin can be considered for prophylactic therapy in surgical procedures involving implantation of a prosthetic device in which the rate of MRSA is high.[24,43] If the risk of MRSA is low, and a β-lactam hypersensitivity exists, clindamycin can be used for many procedures instead of cefazolin to limit vancomycin use. Infusion-related side effects, such as thrombophlebitis and hypotension, particularly with vancomycin, usually can be controlled by adequate dilution and slower administration rates.[44]

Pseudomembranous colitis secondary to cephalosporins is uncommon and generally easily treated with a short course of oral metronidazole. Although infrequent, bleeding abnormalities related to cephalosporin use have been reported.[45] The primary hematologic effect appears to be inhibition of vitamin K-dependent clotting factors that results in prolongation of the prothrombin time. The mechanism for this effect, most commonly seen with cefotetan, is related to the methylthiotetrazole side chain of the *β*-lactam molecule. Patients at greatest risk for this hypoprothrombinemic effect have received a prolonged course of these agents and have underlying risk factors for vitamin K deficiency, such as malnutrition.[46]

Because inappropriate prophylactic antibiotic use not only can induce antibiotic resistance but also can negatively affect an institution's antibiotic budget, initiatives to curtail inappropriate antibiotic use have become the focus of many drug use evaluation efforts. Potential sources of inappropriate antibiotic prophylaxis include the use of broad-spectrum antimicrobials when a narrow-spectrum agent is warranted, extending prophylaxis for durations beyond that recommended in published guidelines, and using expensive antibiotics when equivalent, less expensive agents are available. The most effective tools for ensuring appropriate prophylactic antibiotic prescribing are knowledge of the institutional postoperative infection rate for each type of surgical procedure and familiarity with the bacterial epidemiology patterns for each surgical population. Individualized institutional guidelines that take into account the best literature evidence, institution-based antibiotic susceptibility data, and surgeon preference are important tools for rationalizing antibiotic prophylaxis use.[47]

RECOMMENDATIONS FOR SPECIFIC TYPES OF SURGERY

Guidelines for surgical prophylaxis usually are structured according to the tissues affected during an operation. Although many different surgical procedures may be performed at any one anatomic site, this method of categorization still is optimal because the factors related to the success of a prophylactic regimen, such as the endogenous flora that are expected and the pharmacokinetics, pharmacodynamics, and spectrum of selected antimicrobials, generally are constant for a particular surgical site (see the discussion above). The choice of antimicrobial prophylaxis is always best evaluated using the results of properly conducted clinical trials. In the absence of studies specific to the procedure in question, extrapolation from data on regimens for different procedures in the same anatomic site in question usually can be made. Subsequent modifications to each prophylactic regimen should be based on intraoperative findings or events.

6 A comprehensive review of the surgical prophylaxis literature is beyond the scope of this chapter,

but important factors are reviewed here for each type/site of surgery. Specific recommendations are summarized in **Table 123-6**. The reader is referred to published guidelines and review articles.[3,4,5,8,41,48,49]

TABLE 123-6 Most Likely Pathogens and Specific Recommendations for Surgical Prophylaxis

Type of Operation	Likely Pathogens	Recommended Prophylaxis Regimen[a]	Comments	Grade of Recommendation[b]
GI Surgery				
Gastroduodenal	Enteric gram-negative bacilli, gram-positive cocci, oral anaerobes	Cefazolin 1 g × 1	High-risk patients only (obstruction, hemorrhage, malignancy, acid suppression therapy, morbid obesity)	IA
Cholecystectomy	Enteric gram-negative bacilli, anaerobes	Cefazolin 1 g × 1 for high-risk patients Laparoscopic: none	High-risk patients only (open biliary tract procedures, acute cholecystitis, common duct stones, previous biliary surgery, jaundice, age >60 years, obesity, diabetes mellitus)	IA
Transjugular intrahepatic portosystemic shunt (TIPS)	Enteric gram-negative bacilli, anaerobes	Ceftriaxone 1 g × 1	Longer-acting cephalosporins preferred	IA
Appendectomy	Enteric gram-negative bacilli, anaerobes	Cefoxitin or cefotetan 1 g × 1 or cefazolin 1 g plus metronidazole 1 g × 1	Second intraoperative dose of cefoxitin may be required if procedure lasts longer than 3 hours	IA

Type of Operation	Likely Pathogens	Recommended Prophylaxis Regimen[a]	Comments	Grade of Recommendation[b]
Colorectal	Enteric gram-negative bacilli, anaerobes	Orally: neomycin 1 g + erythromycin base 1 g at 1, 2, and 11 PM 1 day preoperatively plus mechanical bowel preparation IV: cefoxitin or cefotetan 1 g × 1	Role of mechanical bowel preparation is controversial. It is widely used despite evidence suggesting it may have no effect on SSI or other clinical outcomes	IA
GI endoscopy	Variable, depending on procedure, but typically enteric gram-negative bacilli, gram-positive cocci, oral anaerobes	Orally: amoxicillin 2 g × 1 IV: ampicillin 2 g × 1 or cefazolin 1 g × 1	Recommended only for high-risk patients undergoing high-risk procedures (see the text)	IA
Urologic Surgery				
Prostate resection, shock-wave lithotripsy, ureteroscopy	*Escherichia coli*	Ciprofloxacin 500 mg orally or Trimethoprim–sulfamethoxazole 1 DS tablet	All patients with positive preoperative urine cultures should receive a course of antibiotic treatment	IA–IB
Removal of external urinary catheters, cystography, urodynamic studies, simple cystourethroscopy	*E. coli*	Ciprofloxacin 500 mg orally or Trimethoprim–sulfamethoxazole 1 DS tablet	Should be considered only in patients with risk factors (see the text)	IB
Gynecological Surgery				
Cesarean section	Enteric gram-negative bacilli, anaerobes, group B streptococci,	Cefazolin 2 g × 1	Most guidelines recommend administration	IA

Type of Operation	Likely Pathogens	Recommended Prophylaxis Regimen[a]	Comments	Grade of Recommendation[b]
	enterococci		before incision. Administration after cord clamping may be as effective based on conflicting studies.	
Hysterectomy	Enteric gram-negative bacilli, anaerobes, group B streptococci, enterococci	Vaginal: cefazolin 1 g × 1 Abdominal: cefotetan 1 g × 1 or cefazolin 1 g × 1	Metronidazole 1 g IV × 1 is recommended alternative for penicillin allergy	IA
Head and Neck Surgery				
Maxillofacial surgery	*Staphylococcus aureus*, streptococci oral anaerobes	Cefazolin 2 g or clindamycin 600 mg	Repeat intraoperative dose for operations longer than 4 hours	IA
Head and neck cancer resection	*S. aureus*, streptococci oral anaerobes	Clindamycin 600 mg at induction and every 8 hours × 2 more doses	Add gentamicin for clean–contaminated procedures	IA
Cardiothoracic Surgery				
Cardiac surgery	*S. aureus*, *S. epidermidis*, *Corynebacterium*	Cefazolin 1 g every 8 hours × 48 hours Intranasal mupirocin twice daily for 5 days preoperatively for patients colonized with *S. aureus*	Patients >80 kg (>176 lb) should receive 2 g of cefazolin instead; in areas with high prevalence of *S. aureus* resistance, vancomycin should be considered	IA
Thoracic surgery	*S. aureus*, *S. epidermidis*,	Cefuroxime 750 mg IV every 8	First-generation cephalosporins	IA

Type of Operation	Likely Pathogens	Recommended Prophylaxis Regimen[a]	Comments	Grade of Recommendation[b]
	Corynebacterium, enteric gram-negative bacilli	hours × 48 hours	are deemed inadequate, and shorter durations of prophylaxis have not been adequately studied	
Vascular Surgery				
Abdominal aorta and lower extremity vascular surgery	*S. aureus*, *S. epidermidis,* enteric gram-negative bacilli	Cefazolin 1 g at induction and every 8 hours × 2 more doses	Although complications from infections may be infrequent, graft infections are associated with significant morbidity	IB
Orthopedic Surgery				
Joint replacement	*S. aureus*, *S. epidermidis*	Cefazolin 1 g × 1 preoperatively, then every 8 hours × 2 more doses Intranasal mupirocin twice daily for 5 days preoperatively for patients colonized with *S. aureus*	Vancomycin reserved for penicillin-allergic patients or where institutional prevalence of methicillin-resistant *S. aureus* warrants use	IA
Hip fracture repair	*S. aureus*, *S. epidermidis*	Cefazolin 1 g × 1 preoperatively, then every 8 hours for 48 hours	Compound fractures are treated as if infection is presumed	IA
Open/compound fractures	*S. aureus*, *S. epidermidis,* gram-negativebacilli, polymicrobial	Cefazolin 1 g × 1 preoperatively, then every 8 hours for a course of presumed infection	Gram-negative coverage (ie, gentamicin) often indicated for severe open	IA

Type of Operation	Likely Pathogens	Recommended Prophylaxis Regimen[a]	Comments	Grade of Recommendation[b]
			fractures	
Neurosurgery				
CSF shunt procedures	*S. aureus*, *S. epidermidis*	Cefazolin 1 g every 8 h ours × 3 doses or ceftriaxone 2 g × 1	No agents have been shown to be better than cefazolin in randomized comparative trials	IA
Spinal surgery	*S. aureus*, *S. epidermidis*	Cefazolin 1 g × 1	Limited number of clinical trials comparing different treatment regimens	IB
CSF shunt procedures	*S. aureus*, *S. epidermidis*	Cefazolin 1 g every 8 h ours × 3 doses or ceftriaxone 2 g × 1	No agents have been shown to be better than cefazolin in randomized comparative trials	IA
Craniotomy	*S. aureus*, *S. epidermidis*	Cefazolin 1 g × 1 or cefotaxime 1 g × 1	Vancomycin 1 g IV × 1 can be substituted for patients with penicillin allergy	IA

CSF, cerebrospinal fluid; DS, double strength.

[a]One-time doses are optimally infused at induction of anesthesia except as noted. Repeat doses may be required for long procedures. See the text for references.

[b]Strength of recommendations:

Category IA: Strongly recommended and supported by well-designed experimental, clinical, or epidemiologic studies.

Category IB: Strongly recommended and supported by some experimental, clinical, or epidemiologic studies and strong theoretical rationale.

Category II: Suggested and supported by suggestive clinical or epidemiologic studies or theoretical rationale.

Gastrointestinal Surgery

GI surgery can be categorized according to surgical site and infectious risk. Gastroduodenal surgery and hepatobiliary surgery generally are considered to be clean or clean–contaminated surgeries, with SSI rates generally less than 5%. Colorectal surgery, including appendectomies, is considered contaminated because of the large quantities and polymicrobial nature of bacterial flora within the colon. SSI rates for these types of surgeries generally range from 15% to 30%. Emergent abdominal surgery involving bowel perforation or peritonitis is considered a dirty surgical procedure, associated with a greater than 30% risk of SSI, and should be treated with therapeutic rather than prophylactic antibiotics.[4]

Gastroduodenal Surgery

Insignificant numbers of bacteria usually are found in the stomach and duodenum because of their acidity. The rate of SSIs in gastroduodenal surgery generally is low, so procedures in this region can be classified as clean. The risk for an SSI in this population increases with any condition that can lead to bacterial overgrowth, such as obstruction, hemorrhage, or malignancy, or increasing the pH of gastroduodenal secretions with concomitant acid suppression therapy. Antimicrobial prophylaxis is of clinical benefit only in this high-risk population. In most cases, a single dose of IV cefazolin will provide adequate prophylaxis.[50] For patients with a β-lactam allergy, oral ciprofloxacin is as efficacious as parenteral cefuroxime as prophylactic therapy for gastroduodenal surgery.[50] Antimicrobial prophylaxis is indicated in esophageal surgery only in the presence of obstruction. Postoperative therapeutic antibiotics may be indicated if perforation is detected during surgery, depending on whether an established infection is present.

Use of antibiotic prophylaxis for percutaneous endoscopic gastrostomy placement is also warranted. Postoperative peristomal infection can occur in up to 30% of patients and a systematic review of 12 trials involving 1,271 patients found a significant reduction in peristomal infections with antimicrobial prophylaxis (OR 0.36, 95% CI 0.26-0.50).[51] A single dose of cefazolin given 30 minutes preoperatively is preferred over longer regimens.

There are no well-designed clinical trials of antimicrobial prophylaxis in bariatric surgery. However, given that obesity is a consistently identified risk factor for SSIs, guidelines do promote antimicrobial prophylaxis with cefazolin but at higher doses.[8]

Hepatobiliary Surgery

Although bile normally is sterile, and the SSI rate after biliary surgery is low, antibiotic prophylaxis is of benefit in this population. Bile contamination (bactobilia) can increase the frequency of SSIs and is present in many patients (eg, those with acute cholecystitis or biliary obstruction and those of advanced age).[48] In general, however, the correlation between bactobilia in surgical specimens and

the subsequent pathogens implicated in an SSI is poor. The most frequently encountered organisms are *E. coli*, *Klebsiella* species, and enterococci. *Pseudomonas* is an uncommon finding in the absence of cholangitis. Most of the SSI literature on biliary tract surgery pertains to cholecystectomy while more recent trials pertain to laparoscopic procedures which have eclipsed the traditional open cholecystectomy because of a reduction in recovery time and hospital stay. The evidence in open cholecystectomy strongly supports the use of antimicrobial prophylaxis while the evidence for laparoscopic procedures is less impressive.[8] Trials comparing first-, second-, and third-generation cephalosporins have not demonstrated benefit over single-dose cefazolin prophylaxis even in high-risk patients (eg, age greater than 60 years, previous biliary surgery, acute cholecystitis, jaundice, obesity, diabetes, and common bile duct stones).[52] Ciprofloxacin and levofloxacin are effective alternatives for β-lactam-allergic patients undergoing open cholecystectomy.[53,54] In fact, orally levofloxacin appears to provide similar intraoperative gallbladder tissue concentrations.[54] For patients undergoing elective laparoscopic cholecystectomy, antibiotic prophylaxis is not of benefit and is not recommended.[55,56] Detection of an active infection during surgery (eg, gangrenous gallbladder and suppurative cholangitis) is an indication for a course of postoperative therapeutic antibiotics. The risk for SSIs in cirrhotic patients undergoing transjugular intrahepatic portosystemic shunt surgery may be reduced with a single prophylactic dose of ceftriaxone,[57] but not with single doses of shorter-acting cephalosporins.[58]

Appendectomy

Acute appendicitis can be broadly categorized as complicated (evidence of perforation, gangrene, peritonitis or abscess formation) or uncomplicated. Complicated appendicitis should be treated as an active intra-abdominal infection. While appendectomy for uncomplicated appendicitis is more common it has been associated with SSI rates of 9% to 30% in the absence of antimicrobial prophylaxis. Randomized controlled trials do suggest that pre-operative antimicrobials are effective at reducing this risk and should be administered in all cases.[59] Numerous antibiotic regimens, all with activity against gram-positive and gram-negative aerobes and anaerobic pathogens, are effective in reducing SSI incidence.[48] A cephalosporin with antianaerobic activity, such as cefoxitin or cefotetan, is recommended as first-line therapy; however, a comparative trial of cefoxitin and cefotetan suggests that cefotetan may be superior, possibly because of its longer duration of action.[60] Alternatively, cefazolin in combination with metronidazole is also effective. In patients with β-lactam allergy, metronidazole in combination with gentamicin is an effective regimen. Broad-spectrum antibiotics covering nosocomial pathogens (eg, *Pseudomonas*) do not further reduce SSI risk and instead may increase the cost of therapy and promote bacterial resistance.[61] Although single-dose therapy with cefotetan is adequate, prophylaxis with cefoxitin may require intraoperative redosing if the procedure extends beyond 3 hours.

Colorectal Surgery

In the absence of adequate prophylactic therapy, the risk for SSI after colorectal surgery is high because of the significant bacterial counts in fecal material present in the colon (frequently greater

than 10^9 per gram). Anaerobes and gram-negative aerobes predominate, but gram-positive aerobes also may play an important role. Reducing this bacterial load with a thorough bowel preparation regimen (4 L of polyethylene glycol solution or 90 mL of sodium phosphate solution administered orally the day before surgery) is controversial; however, 99% of surgeons in a survey routinely use mechanical preparation.[62] Risk factors for SSIs include age over 60 years, hypoalbuminemia, poor preoperative bowel preparation, corticosteroid therapy, malignancy, and operations lasting longer than 3.5 hours.[8]

Antimicrobial prophylaxis reduced mortality from 11.2% to 4.5% in a pooled analysis of trials comparing antimicrobial prophylaxis with no prophylaxis for colon surgery.[63] Effective antibiotic prophylaxis consisting of an oral and IV regimen reduces even further the risk for an SSI. A Cochrane review comparing oral, IV and combination regimens found that while each one was more effective at reducing SSI than placebo, combination therapy (oral and IV) was superior to oral regimens alone (OR 0.52 [0.35, 0.76]) and IV regimens alone (OR 0.55 [0.43, 0.71]).[64]

Several oral regimens designed to reduce bacterial counts in the colon have been studied.[48] The combination of 1 g neomycin and 1 g erythromycin base given orally 19, 18, and 9 hours preoperatively is the regimen most commonly used in the United States.[65] Neomycin is poorly absorbed, but provides intraluminal concentrations that are high enough to effectively kill most gram-negative aerobes. Oral erythromycin is only partially absorbed but still produces concentrations in the colon that are sufficient to suppress common anaerobes. If surgery is postponed, the antibiotics must be readministered to maintain efficacy. Optimally, the bowel preparation regimen (if used) should be completed prior to starting the oral antibiotic regimen. This is of particular concern because most procedures now are performed electively on a “same-day surgery” basis. In this case, the bowel preparation regimen is self-administered by the patient at home on the day prior to hospital admission, and compliance cannot be monitored carefully.

Single dose cephalosporins are the most used and studied preoperative IV antimicrobial. Cefoxitin or cefotetan is used most commonly, but other second- and some third-generation cephalosporins also are effective.[66] The role of metronidazole in combination with cephalosporin therapy is unclear. Only retrospective evidence suggests that the addition of metronidazole to a cephalosporin or extended-spectrum penicillin provides additional benefit.[67] Until this finding is confirmed in prospective studies, metronidazole should be reserved for combination therapy with cephalosporins with poor anaerobic coverage (eg, cefazolin). At this time, the evidence recommending the addition of metronidazole to cephalosporins with anaerobic activity (eg, cefotaxime, cefoxitin, and ceftriaxone) is insufficient.[68] For β-lactam-allergic patients, perioperative doses of gentamicin and metronidazole have been used. Combination therapy (ie, oral and IV therapy) is controversial. Postoperative antibiotics generally are unnecessary in the absence of any untoward events or findings during surgery. IV antibiotics are required for colostomy reversal and rectal resection because enterally administered antibiotics will not reach the distal segment that is to be reanastomosed or resected.[69]

Clinical Controversy…

A randomized trial of 380 patients undergoing elective colorectal surgery suggests that SSIs are not

reduced by preoperative mechanical bowel preparation.[70] This finding was confirmed in two meta-analyses showing that mechanical bowel preparation does not reduce the risk of anastomotic leakage or other complications, including postoperative infection.[71,72] Despite this new evidence, mechanical bowel preparations continue to be a standard of practice prior to elective bowel surgery.

Gastrointestinal Endoscopy

Despite the large number of endoscopic procedures performed each year, the rate of postprocedural infection is relatively low. The highest bacteremia rates have been reported in patients undergoing esophageal dilation for stricture or sclerotherapy for management of esophageal varices. Although postprocedural bacteremia can occur in as many as 22% of patients, the bacteremia usually is transient (less than 30 minutes) and rarely results in clinically significant infection. Therefore, antimicrobial prophylaxis is routinely recommended only for high-risk patients (eg, patients with prosthetic heart valves, a history of endocarditis, systemic-pulmonary shunt, synthetic vascular graft less than 1 year old, complex cyanotic congenital heart disease, obstructed bile duct, or liver cirrhosis, as well as immunocompromised patients) undergoing high-risk procedures (eg, stricture dilation, variceal sclerotherapy, and endoscopic retrograde cholangiopancreatography, ERCP).[73] Single-dose preprocedural regimens similar to those for endocarditis prophylaxis are most common (amoxicillin for patients who can tolerate oral premedication or either IV ampicillin or cefazolin). A meta-analysis of antimicrobial prophylaxis for endoscopic placement of percutaneous feeding tubes also suggests that a single preoperative dose of antibiotics reduces the risk of postoperative infection compared with no antibiotic (6.4% vs 24%).[74] Consensus guidelines have adopted this recommendation and suggest a single dose of cefazolin within 30 minutes prior to the procedure.[73]

Urologic Surgery

Preoperative bacteriuria is the most important risk factor for development of an SSI after urologic surgery. All patients should have a preoperative urinalysis and should receive therapeutic antibiotics if bacteriuria is detected. Patients undergoing clean urologic procedures with sterile urine preoperatively are at low risk for developing an SSI and antimicrobial prophylaxis is not recommended.[8] Antibiotic prophylaxis is recommended for all patients undergoing transurethral resection of the prostate or bladders tumors, shock-wave lithotripsy, percutaneous renal surgery, or ureteroscopy.[75] The exact incidence of SSIs in this population is obscured by the frequent use of postoperative urinary catheters and the subsequent risk of bacteriuria. *E. coli* is the most frequently encountered organism. Routine use of broad-spectrum antibiotics, such as third-generation cephalosporins and fluoroquinolones, does not decrease SSI rates more than cefazolin, but the ability to administer fluoroquinolones orally rather than IV makes antimicrobial prophylaxis with ciprofloxacin easier and less expensive.[76] First- or second-generation cephalosporins are considered the antimicrobial agents of choice for patients undergoing open or laparoscopic procedures involving entry into the urinary tract and any urologic surgical procedures involving the intestine, rectum, vagina, or implanted prosthesis.[75] The evidence supporting antimicrobial prophylaxis for the removal of external urinary catheters, cystography, urodynamic studies, simple cystourethroscopy, and open or laparoscopic urologic procedures that do not involve entry into the urinary tract is not

as evident. Only patients considered to have risk factors (patients of advanced age; those with anatomic anomalies, poor nutritional history, externalized catheters, colonized endogenous/exogenous material, or distant coexistent infection; smokers; immunocompromised patients; and those who are hospitalized for a prolonged stay) should receive antimicrobial prophylaxis.[75]

Obstetric and Gynecologic Surgeries

Cesarean Section

Cesarean section is the most frequently performed surgical procedure in the United States.[8] Prophylactic antibiotics are given to prevent endometritis, the most commonly occurring SSI. In the past, antibiotics were recommended for only high-risk patients, including those with premature membrane rupture or those not receiving prenatal care. Several large trials, as well as a meta-analysis of 81 trials, have shown benefit in administering prophylactic antibiotics to all women undergoing emergent or elective cesarean section regardless of their underlying risk factors.[77] Cefazolin remains the drug of choice despite the wide spectrum of potential pathogens, and a single 2 g dose appears to be superior to single or multiple 1 g doses.[78] Providing a broader spectrum of coverage with cefoxitin (for anaerobes) or piperacillin (for *Pseudomonas* or enterococci) does not further reduce postoperative infection rates. For patients with a β-lactam allergy, preoperative metronidazole is an acceptable alternative.[77]

Clinical Controversy...

During a cesarean section, unlike other surgical procedures, the most appropriate timing of antibiotic administration is controversial. Traditionally, antimicrobials were administered after the initial incision and when the umbilical cord was clamped in an attempt to minimize infant drug exposure, which theoretically could mask the signs of infection and induce antimicrobial resistance. Published guidelines recommend administering prophylactic antibiotics pre-incision but recent trials and meta-analyses show conflicting results.[78,79,80]

Hysterectomy

The most important factor affecting the incidence of SSI after hysterectomy is the type of procedure performed. Vaginal hysterectomies are associated with a high rate of postoperative infection when performed without the benefit of prophylactic antibiotics because of the polymicrobial flora normally present at the operative site.[81] As with cesarean sections, cefazolin is the drug of choice for vaginal hysterectomies despite the wide spectrum of possible pathogens.[81] The American College of Obstetricians and Gynecologists (ACOG) recommends a single dose of either cefazolin or cefoxitin.[82] For patients with a β-lactam allergy, a single preoperative dose of either metronidazole or doxycycline also is effective.[82]

Prophylactic antibiotics are recommended for abdominal hysterectomy despite the lack of bacterial contamination from the vaginal flora. Both cefazolin and antianaerobic cephalosporins (eg, cefoxitin

and cefotetan) have been studied extensively. Single-dose cefotetan is superior to single-dose cefazolin,[83] and the investigators suggest that cefotetan should be the drug of choice for abdominal hysterectomies. However, other investigators suggest that either agent is appropriate, provided 24 hours of antimicrobial coverage is not exceeded.[8] The ACOG guidelines suggest that first-, second-, or third-generation cephalosporins can be used for prophylaxis.[82] Metronidazole plus an aminoglycoside or fluoroquinolone is also effective and can be used if patients are allergic to β-lactam antibiotics. Antibiotic prophylaxis may not be required in laparoscopic gynecologic surgery or tubal microsurgery.[84] As with other surgical procedures, perioperative events and findings may require the use of therapeutic antibiotics after surgery.

Head and Neck Surgery

The use of prophylactic antibiotics during head and neck surgery depends on the procedure type. Clean procedures (per NRC definition), such as thyroidectomy, lymph node excision and simple tooth extraction, are associated with a low incidence of SSI. Antimicrobial prophylaxis is not recommended for these procedures. Head and neck surgeries involving an incision through a mucosal layer are associated with a higher risk for SSI but antimicrobial prophylaxis is not always associated with a reduction in SSI (ie, adenoidectomy, tonsillectomy and septoplasty).[8] The normal flora of the mouth is polymicrobial; both anaerobes and gram-positive aerobes predominate. Although typical doses of cefazolin usually are ineffective for anaerobic infections, a 2 g dose produces concentrations high enough to inhibit these organisms. A pharmacokinetic study suggested that a single dose of clindamycin is adequate for prophylaxis in maxillofacial surgery unless the procedure lasts longer than 4 hours, when a second dose should be administered intraoperatively.[85] The greatest evidence for antimicrobial prophylaxis is in head and neck cancer resection surgeries. For most head and neck cancer resection surgeries, including free-flap reconstruction, 24 hours of clindamycin is appropriate, and no additional benefit of extending therapy beyond 24 hours is seen. A combination of clindamycin and gentamicin to cover aerobic, anaerobic, and gram-negative bacteria in clean-contaminated oncologic surgery is recommended.[86] Topical therapy with clindamycin, amoxicillin–clavulanate, and ticarcillin–clavulanate has been described in small trials, but the exact role of topical antibiotics is not defined.[87] Antimicrobial prophylaxis is not indicated for endoscopic sinus surgery without nasal packing.[41]

Cardiothoracic Surgery

Although cardiac surgery generally is considered a clean procedure, antibiotic prophylaxis lowers SSI incidence.[48] The substantial morbidity related to an SSI in this population, coupled with the routine implementation of prosthetic devices, further justifies the routine use of prophylaxis.[88] Patients who develop SSIs after coronary artery bypass graft surgery have a mortality rate of 22% at 1 year compared with 0.6% for those who do not develop an SSI.[89] Risk factors for developing an SSI after cardiac surgery include obesity, renal insufficiency, connective tissue disease, reexploration for bleeding, and poorly timed administration of antibiotics.[88] Skin flora pathogens predominate; gram-negative organisms are rare.

Cefazolin has been studied extensively and is considered the drug of choice. Although several studies and a meta-analysis advocate the use of second-generation cephalosporins (eg, cefuroxime) rather than cefazolin, various methodologic flaws in these studies have limited the extrapolation of these results to practice. Cefazolin was as effective as cefuroxime in a large randomized trial of 702 patients undergoing open heart surgery and thus remains the standard of care.[90] Both patient weight and timing of cefazolin administration relative to surgery must be considered when developing a dosing strategy. Patients weighing greater than 80 kg (greater than 176 lb) should receive 2 g cefazolin rather than 1 g. Doses should be administered no earlier than 60 minutes before the first incision and no later than the beginning of induction.[86] Extending therapy beyond 48 hours does not further reduce SSI rates. Single-dose cefazolin therapy may be sufficient but is not recommended by the Society of Thoracic Surgeons at this time pending further study.[91]

7 Routine vancomycin administration may be justified in hospitals having a high incidence of MRSA or when sternal wounds are to be explored surgically for possible mediastinitis. However, a large comparative trial enrolling almost 900 patients in a single center with a high prevalence of MRSA infections found that both cefazolin and vancomycin had similar efficacy in preventing SSI in patients undergoing cardiac surgery that required sternotomy.[92] Mediastinitis constitutes a failure of a prior prophylactic regimen. Continued postoperative vancomycin should be guided by culture and sensitivity data.[42] Subsequent antibiotic therapy is guided by intraoperative findings.

Since *S. aureus* is routinely identified as the most common pathogen in SSIs after cardiac surgery, several studies have investigated alternative methods for preoperative eradication including nasal mupirocin administration (ie, twice daily for 5 days pre-operatively) and chlorhexidine body wash (ie, daily pre-operatively for up to 5 days). A bundled approach (ie, more than one intervention implemented together) in addition to pre-operative antimicrobials appears to further reduce the risk of postoperative SSI in both cardiac and orthopedic surgeries.[11,93]

Pulmonary resection is associated with significant SSI risk, and prophylactic antibiotics have an established role in preventing postoperative infectious morbidity. Pleuropulmonary infections are much more common than wound infections, and pathogenic organisms likely migrate from the oral cavity or pharynx.[94] First-generation cephalosporins are inadequate; 48 hours of cefuroxime is preferred. A regimen of ampicillin–sulbactam is superior to first-generation cephalosporins, but further studies are required before this agent can be recommended as first-line prophylactic therapy.[95]

Vascular Surgery

Vascular surgery, like cardiac surgery, generally is considered clean by NRC criteria. Although vascular graft infections occur infrequently (3%-5%), the associated morbidity and mortality are extensive because treatment often requires surgical graft removal along with therapeutic antibiotic therapy.[96] Prophylactic antibiotics are of benefit, particularly for procedures involving the abdominal aorta, lower extremities or the implantation of prosthetic devices. Cefazolin is regarded as the drug of choice.[97] Twenty-four hours of prophylaxis with cefazolin is adequate; longer courses may lead to

bacterial resistance.[98] For patients with β-lactam allergy, 24 hours of oral ciprofloxacin was effective.[96]

Orthopedic Surgery

Most orthopedic surgery is clean by definition; thus, prophylactic antibiotics generally are indicated only when prosthetic materials (eg, pins, plates, and artificial joints) are implanted.[21] A late-occurring infectious complication in this surgical population can result in substantial morbidity and may lead to prosthesis failure and subsequent removal. Staphylococci species are the most frequently encountered pathogens; gram-negative aerobes are infrequent. The use of cefazolin is supported by substantial evidence in the literature and therefore is the prophylactic agent of choice. Vancomycin, although effective, is not recommended for routine use unless a patient has a documented history of a serious allergy to β-lactams, or the propensity for MRSA infections at a particular institution necessitates its use. The current recommended duration of prophylaxis for joint replacement and hip fracture surgery is 24 hours.[8] Antibiotic-impregnated cement and beads have been used to lower SSI rates, but conclusive data regarding their efficacy are lacking.[21]

Duration of prophylaxis for the surgical repair of long bone fractures depends on the nature of the fracture. Multiple doses of prophylactic antibiotics offer no advantage over a single preoperative dose for repair of closed bone fractures and is more cost effective.[99,100] Patients suffering open (compound) fractures are particularly susceptible to infection because bacterial contamination almost always has occurred already. Under these circumstances, the use of antibiotics is presumptive. In this setting, cefazolin often is combined with an aminoglycoside, but controlled trials are lacking.[101] A clinical trial comparing clindamycin and cloxacillin suggests that clindamycin is superior and may be appropriate as monotherapy for Gustilo type I and II open fractures but not for type III fractures, for which added gram-negative activity is recommended.[102] Duration of antibiotic therapy is highly variable and depends on surgical findings during debridement, results of intraoperative cultures, and clinical status. A prospective trial comparing short (less than 24 hours) and long (greater than 24 hours) courses of antimicrobial prophylaxis for severe trauma suggests that longer courses of antibiotics do not offer additional benefit and may be associated with the development of resistant infections.[103] However, established joint infections and osteomyelitis require an extended course of therapeutic antibiotics.

As in cardiac surgery, there is evidence to support the use of preoperative intranasal mupirocin and chlorhexidine body wash for patients colonized with *S. aureus*. For elective procedures patients would be instructed to administer these at home in the days prior to the surgery. This bundled approach appears to further reduce the risk of postoperative SSI in addition to preoperative antimicrobials.[11,93]

Neurosurgery

The rates of SSI after clean neurosurgical operations (ie, craniotomy, spinal procedures) are low, however, the morbidity and mortality of central nervous system SSI, should they occur, are high. Pre-operative antibiotics are effective at reducing SSI rates and are recommended even in clean

procedures.[104,105] While many antimicrobials have been studied, a single dose of cefazolin is what is recommended.[8]

Procedures involving cerebrospinal fluid (CSF) shunt placement should be considered separately because this procedure involves placement of a foreign body and is associated with higher infection rates. A study of 780 patients undergoing neurosurgical procedures that included shunt surgery reported that single doses of cefotaxime and trimethoprim–sulfamethoxazole were equally effective in preventing SSIs.[106] Most studies of procedures involving a shunt have been small in size and do not consistently show lower infection rates with antibiotic prophylaxis, although the results of a systematic review and meta-analysis suggest that a significant improvement in the incidence of shunt infection with 24 hours of systemic antibiotics (ie, cefazolin) and the use of antibiotic-impregnated catheters independently.[107]

SSIs associated with spinal surgery are rare but devastating when they occur. The use of antimicrobial prophylaxis in this setting is warranted and recommended by a meta-analysis.[108] Large randomized, controlled trials are lacking, but cefazolin is the antibiotic recommended most commonly. Cephalosporin penetration into the vertebral disk has been questioned. Some small studies suggest that the addition of gentamicin, which has better penetration, might be warranted; however, there is a paucity of clinical trials comparing these two regimens.[109]

NONPHARMACOLOGIC INTERVENTIONS

Strategies other than antimicrobial and aseptic technique for reducing postoperative infections have been investigated in different types of surgeries. The most commonly cited and practiced interventions include intraoperative maintenance of normothermia, provision of supplemental oxygen in the perioperative period, and aggressive perioperative glucose control.

Clinical Controversy…

Although interventions to maintain normothermia intraoperatively, provide supplemental oxygen in the perioperative period, and aggressively control perioperative glucose show a significant reduction in SSI, they cannot be generalized to all types of surgeries. However, given the simplicity and low cost of these interventions, many clinicians consider applying these measures outside of the studied population(s). At this time, pending further research, these interventions can be recommended for routine use only in the type of patient or surgery for which they were studied.

Core body temperature can fall by 1 to 1.5°C intraoperatively in patients under general anesthesia. Intraoperative hypothermia has been associated with impaired immune function, decreased blood flow to the surgical site, decreased tissue oxygen tension, and an increased risk of SSI. Efforts to maintain intraoperative normothermia should be exercised and may include the use of warming blankets and IV fluid warmers to maintain core body temperature between 36 and 38°C. One prospective trial of 200 patients undergoing colorectal surgery found that maintenance of normothermia reduced postoperative infection rates along with other morbidity parameters, including length of stay.[110]

Clinical Controversy…

Several studies have investigated the role of specialized enteral formulas fortified with a variety of immunomodulating micronutrients thought to enhance the immune response and gut function after trauma or surgery. Although many clinicians are exploring the role of supplements such as glutamine, arginine, omega fatty acids, and nucleotides, no study to date has shown a significant reduction in postoperative infection rates using these formulations.

Low oxygen tension in the tissues that make up the surgical site increases the risk of bacterial colonization and subsequent SSI by decreasing the efficiency of neutrophil activity. Administration of high concentrations of oxygen (80% via ventilator or 12 L/min via a nonrebreather mask) reduced postoperative infection rates significantly in a multicenter randomized trial of 500 patients undergoing colorectal surgery.[111]

Diabetes and poor glucose control are well-known risk factors for SSI. The increased risk of infection is thought to be due to both macrovascular (vasculopathy and venoocclusive disease) and microvascular (subtle immunologic deficiencies, including neutrophil dysfunction and reduced complement and antibody activity) complications. Aggressive control of perioperative blood glucose level decreases the incidence of SSI in diabetics undergoing cardiac surgery and is being evaluated in other types of surgery and in nondiabetic patients.[112] Perioperative blood glucose levels should be checked in all patients and conventional glucose targets (blood glucose less than 10 mmol/L [180 mg/dL]) should be encouraged. Hypoglycemia is similarly associated with poor outcomes and thus blood glucose levels less than 4.1 mmol/L (74 mg/dL) should be avoided.[8]

PERSONALIZED PHARMACOTHERAPY

Prophylactic antibiotics are only effective when therapeutic concentrations in the surgical field are maintained for the entire duration of the surgery. While consideration of drug half-life in the context of the duration of surgery has been discussed earlier in this chapter, other patient-related factors may influence the effectiveness of antibiotic prophylaxis and warrant consideration when choosing a prophylactic regimen (**Table 123-7**).

TABLE 123-7 Strategies for Implementing an Institutional Program to Ensure Appropriate Use of Antimicrobial Prophylaxis in Surgery

1. **Educate**

   Develop an educational program that enforces the importance and rationale of timely antimicrobial prophylaxis

   Make this educational program available to all healthcare practitioners involved in the patient's care

2. **Standardize the ordering process**

Establish a protocol (eg, a preprinted order sheet) that standardizes antibiotic choice according to current published evidence, formulary availability, institutional resistance patterns, and cost

3. **Standardize the delivery and administration process**

   Use system that ensures antibiotics are prepared and delivered to the holding area in a timely fashion

   Standardize the administration time to <1 hour preoperatively

   Designate responsibility and accountability for antibiotic administration

   Provide visible reminders to prescribe/administer prophylactic antibiotics (eg, checklists)

   Develop a system to remind surgeons/nurses to readminister antibiotics intraoperatively during long procedures

4. **Provide feedback**

   Follow up with regular reports of compliance and infection rates

Obese patients require larger doses of prophylactic antibiotics to maintain therapeutic drug levels when compared to nonobese patients. Patients with a body mass index greater than 40 are more likely to have subtherapeutic concentrations at the end of surgery with cefazolin 1 g preoperatively (and intraoperative for surgeries greater than 3 hours) and thus should receive 2 g doses.[113,114] Underlying disease states that may affect antibiotic metabolism and/or elimination should be considered when developing a prophylactic regimen. For example, patients with thermal burn and spinal cord injuries eliminate certain classes of antibiotics, primarily the aminoglycosides and β-lactams, at unusually high rates compared with controls and will need more frequent intraoperative dosing. Conversely, individuals with renal failure may need less frequent dosing of renally cleared antibiotics. For example, while intraoperative dosing for cefazolin should be every 3 to 4 hours in patients with normal renal function, this interval should be extended to 8 hours for patients with creatinine clearances of less than 50 mL/min (0.83 mL/s). Individuals who are aggressively fluid resuscitated pre- or intraoperatively or those undergoing cardiac bypass may have altered antibiotic disposition related to increased volume of distribution and reduced total body clearance and may need larger doses (ie, 2 g cefazolin).

EVALUATION OF THERAPEUTIC OUTCOMES

When evaluating the outcome of surgical antibiotic prophylaxis, it is important to differentiate any potential SSI from other postoperative infection or complication. Although fever and leukocytosis are common in the immediate postoperative period, they typically resolve with prompt ambulation, timely removal of invasive devices, prevention and/or resolution of atelectasis through optimal respiratory care, and effective analgesia. It is important to remember that the emergence of distal infections, such as pneumonia, does not constitute a failure of surgical prophylaxis. Prophylaxis

should be as short as possible because prolonged prophylactic regimens may contribute to the selection of resistant organisms and may make any infection more difficult to treat.

Surgical site appearance is the most important determinant of the presence of an infection. Drainage of pus from the incision accompanied by redness, warmth, and pain or tenderness is highly suggestive of an SSI. By definition, any surgical site that requires incision and drainage by the surgeon is considered infected regardless of appearance. Failure to heal and wound dehiscence also are seen with SSIs, although the surgical technique and nutritional status may be important contributing factors.

The presentation of signs and symptoms consistent with an SSI in relation to previous surgery is an important consideration when evaluating therapeutic outcomes after surgical prophylaxis. Many SSIs will not be evident during acute hospitalization. In fact, SSIs may not become evident until up to 30 days later or, in the case of prosthesis implantation, up to 1 year later. Thus, the true incidence of SSI can be determined only by completing comprehensive postdischarge surveillance. All studies investigating the efficacy of surgical prophylaxis must include adequate postdischarge follow-up to be able to thoroughly assess the success of any prophylactic regimen.

Chapter e124: Travel Health

FIGURE e124-1

Douglas Slain; Scott Kincaid

INTRODUCTION

Key Concepts

- 1 Travelers should consult practitioners with travel health expertise when going to tropical or developing countries.
- 2 For the pretravel consultation recommendations, travelers should be given written material to reinforce and supplement verbal instructions.
- 3 The pretravel screening appointment should include a discussion of items that should be contained in a travel medical kit.
- 4 Pregnant travelers should consult obstetric and travel medicine experts prior to traveling to developing countries.
- 5 Immunocompromised patients may need longer periods of pretravel preparatory time to allow for adequate immunization, given their sometimes blunted antibody responses to vaccines.
- 6 Travelers to sub-Saharan Africa, Southern Asia, Central and South America, and the Caribbean experience higher rates of infection than those traveling to other parts of the world.
- 7 Although prophylactic antibiotic use may reduce the risk of traveler's diarrhea, such use is generally not recommended, primarily because of the risk of developing drug resistance or *Clostridium difficile* infection.
- 8 Prevention strategies are essential for limiting vector-borne infections during travel.

- 9 The mainstay of therapy in all altitude-related illnesses is descent to a lower altitude (typically at least a 300-meter reduction in altitude).
- 10 Patients who have previously been diagnosed with depression should continue their prescribed medications and minimize alcohol consumption while traveling.

Global (international) travel has increased dramatically over the past 20 years. A sizable proportion of this increased travel can be explained by individuals traveling from developed countries to developing countries.[1] Reasons for travel to developing countries are variable, but include work-related travel, leisure travel, medical tourism, adventure travel, medical mission or outreach, and study abroad programs.

Travel to distant lands has always been associated with risks to mental and physical health. Twenty-two percent to 64% of travelers experience health problems while traveling.[2] Travel to developing and/or tropical countries can be associated with even higher risks to traveler health than travel to developed or temperate countries. Many health problems arising during travel are self-limiting or not bothersome enough for travelers to seek medical care. However, approximately10% of travelers seek help from physicians either during or soon after traveling.[3] In addition to infectious and noninfectious health problems, global travelers face potential dangers from vehicle and pedestrian traffic accidents, drowning, animal attacks, and assaults. This chapter focuses on health risks and diseases that affect global travelers, with primary emphasis on travel from developed countries to developing or tropical countries. Some travel-related information is included in other chapters, and readers will be referred accordingly.

PRETRAVEL PREPARATION

Travelers should review information about their destinations and itinerary and consider potential self-care options for health issues that may arise during travel. Pretravel preparation often involves the assistance of healthcare providers, which is typically more important for patients with chronic health conditions and those traveling internationally, especially to the developing world. Travelers from North American and Europe heading to developing countries seek pretravel health advice 35% to 50% of the time.[4] Of these, only about 10% to 20% of travelers consult travel medicine experts or travel clinics. Informed primary care providers without extensive travel health expertise can provide adequate advice to travelers en route to low-risk destinations, but 1 travelers should consult practitioners with travel health expertise when going to tropical or developing countries.[4]

Travel clinics and travel health experts are often underutilized.[4] Global travelers may not seek specialty travel advice because health insurance may not cover expenses associated with pretravel care.[5] In addition, immigrants living in developed countries, going back to their home countries to visit friends and relatives (VFR) often believe they are immune to local diseases and do not feel the need to seek advice.[6] Unfortunately, VFR travelers often display some of the highest rates of travel health problems.[4,6] U.S. residents traveling on global VFR trips make up about 33% of all travelers.[7] Other global travelers may not seek travel expert advice for travel to resorts in nearby countries. For

example, Caribbean travel was associated with a higher proportion of travelers who did not seek pretravel advice among ill-returning travelers than travelers to other regions.[8] Even travelers staying at all-inclusive Caribbean resorts are subject to travel health issues.

Practitioners seeking to become travel medicine experts can gain expertise and credentials in travel health through many different pathways. The majority of travel medicine specialists are primary care and infectious diseases physicians, but other types of physicians, pharmacists, nurse practitioners, nurses, and physician assistants can also become travel health specialists. Many U.S. specialists complete certification programs offered by either the International Society of Travel Medicine (ISTM) or the American Society of Tropical Medicine and Hygiene (ASTMH).[4] In addition, some travel experts have specific expertise in the diagnosis and treatment of illnesses acquired in the tropics (tropical medicine). Travel health consultants with extensive travel experience can be helpful to travelers, especially if they have travelled to the same region as the traveler.

The Pretravel Consultation

Global travelers should make pretravel consultation appointments several weeks to months before traveling to allow time for adequate immunizations.[1] The pretravel consultation should be performed in a structured and standardized manner (**Table e124-1**).[1,3,4,9] There should be an assessment of the traveler's health and pertinent medical history, including a thorough medical history, including travel history, medications, vaccinations, and allergies. Next there should be an assessment of the traveler's risk, including discussion about the destinations, itinerary, accommodations, and planned activities. The consultant should have access to up-to-date travel health references on the travel destination. The consultant should provide preventative advice. Principal discussion points (depending on destination) may include vaccine-preventable illness, avoidance of insects, malaria prophylaxis (if applicable), prevention and self-treatment of traveler's diarrhea (including food and drink safety), responsible personal behavior (ie, discussions about alcohol and substance use), sexually transmitted infections (STIs), general safety, travel medical insurance, and access to medical care during travel.[4] Pretravel screening also provides an excellent opportunity to assess travelers' routine immunization status. For individuals in the United States, a review of the Centers for Disease Control and Prevention (CDC) Advisory Committee on Immunization Practices (ACIP) recommendations will help to identify routine vaccinations that should be offered to travelers for their general health based on age, vaccination history, comorbidities, and planned travel.[10] Travelers should receive any recommended vaccines in time to provide protection prior to travel. Refer to Chapter 125 for discussion of routine vaccinations. Finally, the consultant should provide post-travel advice. This typically involves reminders about continuing malaria prophylaxis (if appropriate), and a discussion about self-assessment of any abnormal symptoms. During the pretravel consultation, travelers should be given written material to reinforce and supplement verbal instructions. Written material can also include citations for online or printed resources.[4]

TABLE e124-1 Template of a Structured Pretravel Consultation

Stage	Elements

Stage	Elements
Risk assessment	• Assess current state of health • Complete a thorough medical history (including medication and allergy history) • Review travel itinerary (including countries visited, routes of transportation, season, and accommodations) • Discuss planned and possible activities in which the traveler might participate
Preventive advice	• Recommend routine vaccinations if not up-to-date • Recommend destination-specific travel-related vaccinations • Discuss prevention of vector-borne illness including need for malaria prophylaxis (if applicable) • Provide food and drink safety tips and traveler's diarrhea counseling • Review non-infectious travel conditions (motion sickness, jet lag, altitude sickness, and travel associated venous thromboembolism) • Discuss travel medical kits
Immunizations and prescriptions	• Provide any needed recommended vaccinations • Prescribe/dispense antimalarial prophylaxis medications, motion sickness medication, and empiric medications for traveler's diarrhea
General safety and health advice	• Discuss travel health resources • Discuss personal safety and sexual health • Discuss alcohol and drug use • Comment on travel insurance and medical evacuation coverage • Provide post-travel advice • Provide written material to the traveler to reinforce and supplement verbal instructions discussed during appointment

Data from references 1,3,4,9.

Travel Medical Kits

Assembling a medical kit is an essential part of preparing for any international travel.[11,12,13] Such a kit can contain medications and health-related supplies for a single traveler, a family, or a group of travelers. The kit can vary from a few non-prescription medications to several large containers of medications and health-related supplies for a group. Some common kit items are non-prescription medications, sunscreen, chronic prescription medications, antimalarial agents, anti-infectives for traveler's diarrhea, motion sickness medications, first aid kit items, sanitizing hand gel or wipes, insect repellant, potable water tablets, topical antibacterial ointments, rehydrating salts, and surgical masks. **Table e124-2** contains a list of items that travelers could consider taking in their medical kits.

TABLE e124-2 Potential Items for Personal Travel Medicine Kits*

Type of Medical Kit	Items
Basic items	Personal prescription medications as permitted by the host country
	Non-prescription analgesics
	Non-prescription antidiarrheals
	Antihistamines
	Decongestants
	Laxative
	Antacid
	Sunscreen
	Lip balm
	Insect repellant
	Alcohol-based hand gel
	Motion sickness medications
	Antimalarial prophylaxis (if needed)
	Antibiotics for empiric treatment of traveler's diarrhea
	Antiseptic wipes
	Water purification tablets (if needed)

Type of Medical Kit	Items
Comprehensive personal items *Consider for high risk travelers like backpackers on longer independent trips to developing countries*	Basic first aid-items (bandages, antibiotic ointment, tweezers) Topical corticosteroid cream Antibiotic cream Tissues Digital thermometer Melatonin (for jet lag) Medical exam gloves First aid dressings Medical tape Healing plasters Wound closures Blister plasters Support bandage Artificial tears Eye wash Antibiotic eye and ear drops Topical antifungal medication Antiemetic Medications for altitude sickness Temporary dental fillings Empiric malaria treatment
Additional items for special circumstances	Epinephrine auto-injector Antiretroviral agents for postexposure prophylaxis (if providing direct care to HIV-infected patients) Doxycycline for leptospirosis prophylaxis (consult a travel medicine specialist for need)

Type of Medical Kit	Items
	Condoms

*Table has been developed for travel to developing countries.

Data from references 11,12,13.

3 The pretravel screening appointment should include a discussion of items that should be contained in a travel medical kit based on a thorough risk-assessment that considers traveler health history, destinations, duration, and type of activities. Travelers also need to anticipate available medical resources while travelling. Unfortunately, counterfeit or poor quality medications can be found in the shops and hospitals of some countries.[1] Therefore, travelers should bring important medications from home. Limited access to hospitals, doctors, and pharmacies may require the traveler to carry many items in their medical kits. Small groups can order commercially prepared medical/first aid kits from travel specialty supply companies and web-based mass marketers (eg, Amazon.com) that can serve some the general needs of the group while individual members assemble personal kits for individualized needs.[13] In general, most medications in kits should be suitable for self-administration. Preparation of medical kits for larger travel groups can be much more extensive and may need to be maintained by a healthcare provider.[12]

Travelers may have their medications examined by security or customs officials when entering certain countries.[14] To facilitate travel with medications (non-prescription or prescription) it is best to avoid having opened containers with loose tablets and capsules when possible. As a general rule, individually packaged and labeled medications ("units of use") or sealed commercial bottles will raise less scrutiny and may better protect medications. In addition, waterproof packaging may be needed for certain travel destinations or wilderness travel. Traveling with controlled substances or psychotropic medications can create additional difficulties.[15] Travelers with controlled or psychotropic medications should check the International Narcotics Control Board (INCB) website (www.incb.org) or official governmental sites before traveling with such substances.[13,14] Countries may not permit the entry of some substances by travelers, or there may be criteria for entering with certain medications.

Travelers with Special Concerns

Older Adults and Travelers with Chronic Conditions

Older travelers with chronic conditions or those who lack strength and agility should be evaluated by their physician for fitness to travel. Some destinations and activities require more strength and stamina than others. Accidental traumas are a leading cause of death among older travelers, in part because of slow reactions, poor coordination, and auditory or visual impairment.[16] The most common natural causes of death among older travelers are cardiac-related. The stress of travel, poor oral intake, dehydration, physical exertion, and medication non-adherence may contribute to these deaths.[16]

Travelers of any age with chronic health issues must self-monitor their conditions and take medications appropriately. More patients with chronic conditions are traveling now due largely to advances in medicine.[17] A study from Israel estimated that 18% of travelers to developing countries had chronic illness.[18] Travelers with chronic conditions should check with their physicians as they plan to make global travel plans.

Pregnant Travelers

The incidence of pregnant women traveling to developing countries is considerably higher among VFR travelers than non-VFR travelers.[6,19] Pregnant travelers should consult obstetric and travel medicine experts prior to traveling to developing countries.[1] Pregnancy presents added challenges for travelers heading to developing countries. For example, live vaccines are contraindicated during pregnancy. The concern with live vaccines is that they can transmit vaccine strain illness to the fetus.[20] Some live vaccines may need to be used if the benefit is believed to outweigh the risk to the fetus. With regard to antimalarials, chloroquine has been the antimalarial agent of choice in pregnancy.[19] Mefloquine, which has not been extensively studied in pregnancy is believed to be safe and has been supported as a first-line agent.[1,21,22] Antimalarial decisions can be difficult if traveling to chloroquine and mefloquine-resistant regions, because the safety of alternatives is less certain. Atovaquone-proguanil has not been well-studied in pregnancy, and currently carries an FDA category C pregnancy rating.[19] Doxycycline is contraindicated because of detrimental effects on bone and teeth development.[19] All women of childbearing age should know their pregnancy status before receiving live vaccines or malaria prophylaxis.

Pregnancy places long-distance travelers at high risk for venous thromboembolism (VTE).[19,23] Unfortunately, VTE prevention data in pregnancy are limited. The American College of Chest Physicians (ACCP) list two recommendations for pregnant patients making long distance travel in the Antithrombotic Therapy and Prevention of Thrombosis guidelines.[24] They are: (1) frequent ambulation, calf muscle exercise, or sitting in an aisle seat if feasible, and (2) use of properly fitted, below-knee graduated compression stockings (GCS) providing 15 to 30 mm Hg (2-4 kPa) of pressure at the ankle during travel. These actions were given a grade of 2C, which is defined as a weak recommendation from low-quality studies. These approaches are not likely to harm, so they are frequently advised.[1]

The first and third trimesters of pregnancy have been the most worrisome for global travelers. Fetal development complications and miscarriages are most common during the first trimester.[19] Preventive vaccines and medications should be used with caution during this time. During the third trimester, women are generally uncomfortable and at risk of preterm labor. Airlines and cruise ships may require documentation for pregnant travelers at or beyond 36 weeks of gestation.[19] Cabin pressurization on commercial airlines is not expected to be a problem for uncomplicated pregnancies, but more complex pregnancies could be affected by corresponding changes in maternal oxygenation.[25] Women who plan to travel during the third trimester should assess available medical facilities at the destination in anticipation of potential complications or early delivery. Health

insurance companies should also be contacted prior to travel to confirm any coverage restrictions.[19]

Clinical Controversy…

Antimalaria prophylaxis options for pregnant travelers going to chloroquine-resistant and mefloquine-resistant regions have not been well-studied. Atovaquone-proguanil and the more toxic sulfadoxine-pyrimethamine may be considered, if travel cannot be avoided during pregnancy. These options have both been given an FDA pregnancy category C rating, based on some teratogenicity studies.

Immunocompromised Travelers

One large observational study of 15,440 travel clinic patients identified that 4.2% of the travelers were immunocompromised patients.[26] Other studies report that up to 45% of HIV-infected patients and up to 36% of solid organ transplant recipients regularly engage in global travel.[27,28] Travelers with compromised immune systems face an increased risk of infection during travel. Many immunocompromised patients are at increased risk of traveler's diarrhea, largely because of impaired mucosal immunity.[29] Additionally, immunocompromised patients who become infected with tuberculosis (TB) are more likely to develop a primary progressive form of disease.[30] Immunocompromised patients should involve travel experts and their specialist physicians in pretravel assessment.[1]

5 Immunocompromised patients may need longer periods of pretravel preparatory time to allow for proper vaccination, given their sometimes blunted antibody responses to vaccines. Additional time to assess serologic titers with possible booster immunization may be required.[29] Live vaccines are contraindicated in many immunocompromised patients, because the vaccine strain may cause an active infection in these patients. For patients with HIV infection who need a vaccines for travel, immune responses are thought to be better and the chance of vaccine infectivity reduced when the CD4+ cell count is 200 cells/mm^3 (0.2 × 10^9/L) or greater.[29,31] Counts of 500 cells/mm^3 (0.5 × 10^9/L) or greater are preferred for immunization, if possible. Live vaccines use has also been associated with organ rejection in solid organ transplant recipients.[29]

Clinical Controversy…

The ACIP advises that yellow fever (YF) vaccine is contraindicated in individuals with symptomatic HIV infection or CD4+ T-lymphocytes less than 200/mm^3 (<0.2 × 10^9/L). Controversy exists on whether or not to vaccinate HIV-infected patients with CD4 cells more than 200/mm^3 (>0.2 × 10^9/L). The risk of developing active infections, including encephalitis may be less with higher CD cell counts, but HIV-infected persons with less immunosuppression still have difficulty in developing YF virus neutralizing antibodies.

TRAVEL-RELATED DISEASES

Infectious Diseases

Infection and global travel have been linked throughout history. Up to 10% of global travelers develop infections during travel.[3] However, many of these infections could be avoided through proper vaccination and risk avoidance. Travelers themselves have served as conduits for spreading various infectious diseases across the globe. For example, travelers from China brought cases of severe acute respiratory syndrome (SARS) to North America in 2003.[32]

6 Travelers to sub-Saharan Africa, Southern Asia, Central and South America, and the Caribbean experience higher rates of infection than those traveling to other parts of the world.[8] The major routes of infection in the developing world include: (1) food or waterborne pathogens spread via fecal-oral transmission, (2) insect vector-borne infections, (3) transcutaneous spread (eg, helminthic), (4) respiratory-spread, and (5) STIs.

Food and Water Borne Infections

Diarrheal Illness. Gastrointestinal ailments are common among travelers.[1] Nausea, gas, changes in stool consistency and frequency can occur in even the most cautious global travelers. These changes can be brought on by changes in diet, stress, and alteration of gastrointestinal flora.[33] Most diarrheal and gastroenteritis episodes are caused by consumption of infectious (fecal) contaminated food or water.[4] The entity called *traveler's diarrhea* is defined as three or more unformed stools per 24 hours plus at least one additional symptom (abdominal cramping, tenesmus, nausea, vomiting, fever, or fecal urgency).[34] Traveler's diarrhea, which can be caused by bacteria, viruses and protozoa, has an estimated incidence of 10% to 40% for 2-week global travels.[34] The highest rates of infection occur in Asia, the Middle East, Africa, Central America, and South America.[1] See Chapter 91 for additional discussion of traveler's diarrhea.

Common bacterial causes of traveler's diarrhea include: enterotoxigenic or enteroaggregative strains of *Escherichia coli*, *Campylobacter*, *Salmonella* (non-typhoidal), and *Shigella*. Common viral causes include: Rotavirus and Norovirus.[1,33,34] The most common protozoal cause of traveler's diarrhea is *Giardia intestinalis*. Less common protozoal causes include: amebiasis (*Entamoeba histolytica*), Cryptosporidiosis, and Cyclosporiasis. With the exception of Cyclosporiasis, protozoal disease onset usually takes longer because of a 1- to 2-week incubation period.[1] Infections caused by these organisms and their treatment are discussed in Chapter 113.

A key feature of the pretravel consultation should include a discussion about safe eating and drinking practices. Risk avoidance is the best way to reduce the occurrence of traveler's diarrhea, but it is difficult to avoid all risks. Even following the old adage "boil it, cook it, peel it, or forget it" may not always protect travelers.[33,34] Use of probiotics and drinking non-ice containing alcoholic beverages when eating potentially infected food may reduce the occurrence of infection, but supportive data have not been consistent.[34,35] Several water purification techniques and products are available. They include heat, filtration, ultraviolet light treatment, halogen treatment, and chlorine dioxide-based treatment.[36] Each method has advantages and disadvantages that can be discussed with travel health

experts. Heat is generally the most consistent method, but it has difficulty in masking bad tastes and odors.

Oral bismuth subsalicylate has been used to prevent traveler's diarrhea. Bismuth subsalicylate is believed to exert some antisecretory and limited antimicrobial activity.[33,37] Use of bismuth subsalicylate was 65% effective in preventing traveler's diarrhea during a 3-week clinical trial in Mexico.[37] Common side effects include darkening of the tongue and stool. The drug is contraindicated in patients who should not take salicylates (ie, hypersensitivity to salicylates, children). Bismuth subsalicylate also interferes with the absorption of doxycycline, which is often used in travel medicine.[4]

7 Although prophylactic antibiotic use can reduce the risk of traveler's diarrhea, such use is generally not recommended, primarily because of the risk of developing drug resistance or *Clostridium difficile* infection.[1] Travelers can bring antibiotics in their medical kit for self-directed initiation for symptomatic disease along with antimotility agents like loperamide.[11,12,13] The recommended adult empiric antibiotic regimen is single-dose or short-course oral fluoroquinolones (eg, ciprofloxacin 500 mg daily for 1-3 days) or azithromycin (500 mg daily for 3 days or 1,000 mg once).[34] Azithromycin may now be preferred in South or Southeastern Asia because of increased presence of fluoroquinolone-resistant *Campylobacter*. Dehydration is a serious side effect of pronounced diarrheal illness. Travelers to remote areas with high rates of traveler's diarrhea should consider packing oral rehydration solution powder.[4]

Good hand hygiene is also important for limiting traveler's diarrhea. Unfortunately, travelers may not always have access to soap and clean running water. This can be a concern for travelers in remote areas without water and "squat potty" restrooms. Alcohol hand sanitizers reduce the occurrence of traveler's diarrhea, and thus should be used when soap and water are not available.[38]

Vaccine-Preventable Food and Water Borne Pathogens. Typhoid fever (caused by *Salmonella enterica* serotype Typhi) is a serious disease spread by contaminated food and water. Clinical presentation may include high fever, weakness, stomach pain, headache, loss of appetite, constipation, and rash. Internal bleeding and death can occur rarely.[1] The U.S. ACIP recommends typhoid vaccine for travelers to certain countries (see http://wwwnc.cdc.gov/travel). Vaccination may be given by either injectable killed Vi capsular polysaccharide vaccine or by oral live-attenuated Ty21a vaccine.[1,39] The injectable vaccine is recommended as a single IM injection for travelers elder than or equal to 2 years of age. A booster is recommended if needed for travel every 2 years.[39] Immunization with the live oral capsule vaccine consists of one capsule taken every other day for four doses. A booster can be taking every 5 years if needed. The live vaccine is for travelers elder than or equal to 6 years of age. The capsules must be refrigerated and taken with cool water. The oral vaccine has been associated with more gastrointestinal side effects and rash. The live vaccine is contraindicated in immunocompromised travelers, and pregnancy is an additional caution.[1,39]

A cholera vaccine is available outside the United States, but given the low risk of infection in travelers, vaccination is no longer routinely recommended.[4] Interestingly, Cholera vaccines may provide some

protection against some strains of enterotoxigenic *E. coli*.[3]

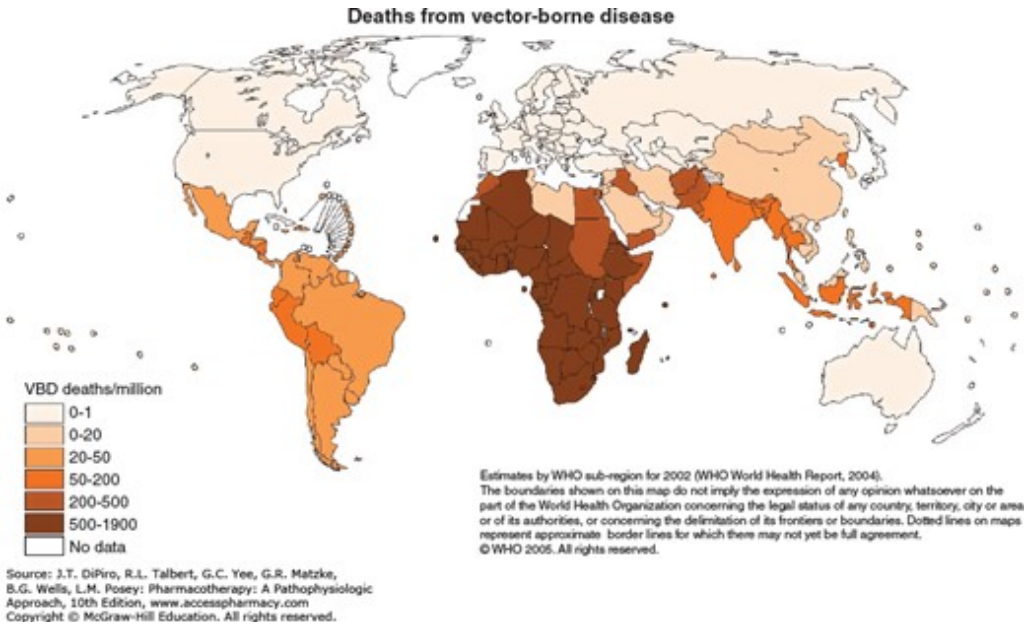
Hepatitis A is a picornavirus shed in the feces of infected persons that can contaminate food and water. Vaccination is now widely available in the United States and other developed nations and has become a standard pediatric vaccine (see Chapter 40).[10]

Vector-Borne Infections

Infections transmitted by arthropods (eg, insects) are common in the developing world. Vector-borne infections can range from asymptomatic to fatal. **Figure e124-1** displays a WHO world map of vector-borne infection deaths. The majority of vector-borne infections are attributed to arboviruses, which is a term that means arthropod-borne virus.[40] Most of these infections do not have reliable treatments.[41] Therefore, 8 prevention strategies are essential for limiting vector-borne infections. Such "risk avoidance" strategies should include avoiding infected habitats, wearing protective clothing, using protective bed netting, and applying insect repellent.[42] If available, use of recommended vaccines and chemoprophylaxis when indicated is also essential. Travelers with flexible travel plans can reduce exposure by traveling during seasons with less insect activity (ie, the dry season). Travelers should also be educated about daily insect activity patterns. While insect bites can occur at any time of day or night, there are times of increased insect activity. For example, mosquitoes that transmit Dengue, YF, and chikungunya bite more frequently between dawn and dusk, whereas mosquitoes that transmit malaria and Japanese encephalitis primarily bite from dusk to dawn.[1] Exposure to mosquitoes and other insects may occur indoors as well as outdoors. Exposure risk is reduced in air conditioned buildings or in areas that do not have direct exposure to the outdoors.[43] Pyrethroid insecticide-treated bed netting provides a greater protective effect than untreated netting.[44]

FIGURE e124-1

World-wide deaths from vector-borne disease for 2002.



Wearing protective clothing that limits access to human skin in areas of high insect activity is highly advisable. This can be a challenge in very hot climates or when participating in outdoor activities. Application of EPA-registered insect repellant such as DEET (N,N-diethyl-3-methylbenzamide) or picaridin to skin can provide protection against vector-borne disease. Unfortunately, compliance with daily application can be suboptimal.[45] For best effect and safety, DEET 20% to 50% concentration should be used.[1] Travelers should be provided with written material about proper application to reduce the risk of repellant toxicity. In addition, it is advisable to purchase repellants in developed countries to ensure product quality. Clothing can also be sprayed with repellants to increase protection.[45] Alternatively, clothing that has been pretreated with repellants and insecticide agents like permethrin can be purchased through specialty travel vendors.

When infected with arboviruses, humans experiencing periods of high viremia can serve as amplification sources of infection if they remain in areas with mosquito activity. These individuals should continue to be protected from mosquitoes to reduce further spread of infection.

Mosquito-Borne Infections. Malaria, which is caused by *plasmodium* protozoa and spread by *Anopheles* mosquitoes, is an important travel-related infection. Travelers to malaria-affected regions should discuss preventative strategies with an expert during pretravel consultation. The selection of prophylactic medications (if any) is based on potential efficacy, safety, and affordability. Antimalarial drugs should always be purchased before traveling overseas. In the developing world antimalarial drugs can be purchased, but they may be counterfeit, subject to resistance, or of substandard quality.[1] Malaria is discussed in more detail in Chapter 115.

Dengue fever is caused by one of four related single-stranded RNA *Flaviviruses*, named Dengue Virus (DENV) 1, 2, 3, or 4.[46] DENVs are endemic in over 100 countries throughout the tropics and subtropics, which includes parts of the Americas, the Caribbean, Africa, South Asia, and Oceania. Areas of recent Dengue fever activity can be seen on the Healthmap.org surveillance website (http://www.healthmap.org/dengue/index.php). Dengue is the most common vector-borne infection affecting travelers in tropical and subtropical countries, with estimates of 50 to 100 million Dengue

cases per year.[47] Dengue cases have surpassed malaria in all regions except for sub-Saharan Africa.[8] Dengue is also more common in urban and suburban environments than malaria because of the type of mosquito vector.[48] DENV transmission is facilitated by the daytime-biting *Aedes aegypti* or *Aedes albopictus* mosquitoes.

Most patients with Dengue fever experience either an asymptomatic (75%) or a self-limiting, febrile illness that can be quite pronounced.[1,49] Classic symptoms include acute onset of high fever, severe headache, retro-orbital pain, fatigue, myalgias, arthralgias, and rash.[49] As its former name "break-bone fever" suggests, bone and joint pain can be quite intense. About 5% of infected individuals go on to develop severe infection with shock, which typically involves plasma leakage (increased vascular permeability) with or without bleeding.[46] Severe infections may include hepatitis, neurologic disorders, myocarditis, blood dyscrasias, shock, or severe bleeding. Overall, about 1% of patients develop hemorrhagic fever.[41]

The clinical course of Dengue in symptomatic cases occurs in three stages: (1) febrile stage, (2) critical stage, and (3) recovery. During the first stage, fever lasts from 2 to 7 days. Patients experience defervescence as they enter the critical phase, which is characterized by some degree of plasma leakage. Most patients improve during this phase, but others progress to more severe disease. As plasma leakage diminishes, the patient enters the recovery phase. After any DENV infection, patients usually have lifelong protection against that specific DENV serotype. Unfortunately, patients subsequently infected with a different serotype may develop an extremely severe secondary infection that is triggered by an immune response in the presence of cross-reactive non-neutralizing antibodies.[46,49,50]

Classic Dengue fever is rarely fatal among travelers, but they may require hospitalization and even medical evacuation to their home countries for care.[49] Mortality rates up to 20% have been estimated in severe infection if left untreated, whereas patients receiving proper supportive care have only a 1% mortality rate.[46] Acetaminophen is preferred over aspirin or other nonsteroidal anti-inflammatory drugs (NSAIDs) for fever reduction because of the increased risk of bleeding with symptomatic disease.[49] There are currently no vaccines, antiviral medication treatments or prophylactic agents for patients with Dengue fever. However, a new quadrivalent vaccine has been developed and is under regulatory review at the time of writing.[51] Risk avoidance remains the best way to avoid Dengue.

Chikungunya virus (CHIKV) is a single-stranded RNA *Togavirus*. CHIKV transmission is facilitated by the daytime-biting *A. aegypti* or *A. albopictus* mosquitoes. CHIKV was initially endemic in rural parts of Africa but spread to Indian Ocean nations and Asia over the past 70 years.[52] Prior to 2013, CHIKV was not active in the western hemisphere.[53] Since that time, the virus has become endemic in Central and South America and the Caribbean. The number of suspected or confirmed cases of CHIKV has now reached 1.74 million in the Americas, with about 80% of CHIKV infections coming from six countries (Dominican Republic, Colombia, El Salvador, Guadeloupe, Honduras, and Martinique).[54] Worldwide estimates of CHIKV activity are difficult to tabulate, but an autochthonous incidence rate of 118.7 cases/100,000 population has been reported for the Americas for 2014.[55]

From 3% to 28% of people infected with CHIKV remain asymptomatic.[1] After an incubation period of about 2 to 4 days, symptomatic patients may abruptly manifest symptoms of high fever, headache, back pain, myalgia, and intense arthralgias.[52] A variety of skin manifestations also accompanies infection in 40% to 50% of infected persons, with maculopapular rash predominating. Given similar symptoms, the same vector and overlapping endemic regions, it can be difficult to distinguish Chikungunya from Dengue. Incapacitating arthralgias (primarily of the hands and feet) are said to occur more with Chikungunya.[53] Dengue patients experience more blood dyscrasias. As with Dengue, there are no vaccines, antiviral medication treatments or prophylactic agents for CHIKV. Risk avoidance is the best way to avoid Chikungunya infection. Supportive care and treatment is similar between Chikungunya and Dengue, except that NSAIDs can be used in the care of CHIKV infected patients because of the lack of thrombocytopenia or hemorrhagic complications in this condition.[52] CHIKV infection are rarely fatal (<1%), although the elderly may have worse prognoses than younger individuals.[53]

Japanese Encephalitis Virus (JEV) is a single-stranded RNA *flavivirus* that is transmitted to humans by the *Culex* species mosquitoes. Pigs serve as a major reservoir for the virus, but wading birds can also serve as reservoirs.[56,57] Endemic regions for JEV include East Asia, western Asia islands between the main continent and the northern tip of Australia, and the Indian subcontinent. The transmission risk is much lower than with Dengue or malaria, with an estimated incidence of less than 1 case per 1 million travelers.[58] Rates are much higher if travelers stay longer in endemic areas or have significant rural exposure (ie, near pigs and rice paddies). In the more temperate regions of northeast Asia, JEV transmission is seasonal; epidemics are more likely to occur between April and October.[57] In the subtropics and tropics, transmission can occur year round but may intensify during the rainy season.

Most humans develop asymptomatic JEV infection; less than 1% of infected patients develop symptoms.[1] The most common manifestations include fever, flu-like symptoms, acute encephalitis, or aseptic meningitis. Humans infected with JEV do not experience very high viremia and are therefore less likely to amplify the spread of infection.[57] JEV has been associated with severe illness and an estimated case-fatality rate of 20% to 30% with neurologic sequelae in about 30% to 50% of severe infection survivors.[58] Fortunately, vaccines are available to prevent infection. The vaccine available in North America and Europe is an inactivated JEV SA14-14-2 strain prepared in Vero cells (trade name: Ixiaro). It is administered in a two-dose series given 28 days apart.[59] The vaccine contains protamine sulfate, which may be associated with hypersensitivity reactions. Very rare but serious reactions including anaphylaxis could occur following vaccination.[4,59,60]

The JEV vaccine is recommended for travelers who plan to spend a month or longer in endemic areas during the JEV transmission season (season varies with latitude).[57,58] This includes long-term travelers or expatriates who will be based in urban areas but are likely to visit endemic rural or agricultural areas during a high-risk period of JEV transmission. The JEV vaccine should be considered for short-term (<1 month) travelers to endemic areas during the JEV transmission season if they plan to travel outside of an urban area and have an increased risk for JEV exposure (eg, spending substantial time outdoors in rural or agricultural areas; participating in extensive outdoor activities; staying in accommodations without air conditioning, screens, or bed nets), and travelers to an area

with an ongoing JEV outbreak or travelers to endemic areas who are uncertain of specific destinations, activities, or duration of travel. JEV vaccine is not recommended for short-term travelers whose visit will be restricted to urban areas or periods outside of a well-defined JEV transmission season. The vaccine is FDA approved for adults and children as young as 2 months of age.[59]

Yellow fever virus is a single-stranded RNA *Flavivirus* that is spread by *Aedes* or *Haemagogus* species of mosquitoes. The World Health Organization (WHO) estimates that 200,000 cases of YF and 30,000 deaths attributable to YF occur annually.[61] The major areas of endemic YF activity are equatorial South America and sub-Saharan Africa (within 15 degree of the equator). YF virus has three transmission cycles: jungle (sylvatic), intermediate (savannah), and urban, each with different proportionate roles for nonhuman and human primates as a source of vector-facilitated transmission.[62]

Yellow fever infections cause asymptomatic or subclinical infections in the majority of infected persons.[1] Symptomatic individuals can experience variable clinical presentations that can range from mild, undifferentiated febrile illness to severe disease with jaundice and hemorrhagic manifestations. Infected patients can experience an abrupt onset of a high fever (up to 104°F [40°C]), chills, severe headache, myalgias, back pain, anorexia, nausea, prostration, vomiting, and dizziness. Some infected patients develop a severe form of illness characterized by jaundice, hemorrhagic symptoms, shock, and multiorgan system failure, after a brief (hours to days) remission period.[1] Case-fatality rates are 20% to 50% in severe cases.[63]

While there are no effective antiviral medications to treat YF, vaccines can prevent infection. At least four live-attenuated vaccines are approved by the WHO.[1] The formulation available in North America is a 17D-204 strain (trade name: YF-Vax).[64] The vaccine is recommended as a single-dose immunization for adults and children at least 9 months of age. Immunity usually develops by the 10th postvaccination day. Reimmunization was recommended every 10 years for those at continuing risk of exposure, but most experts do not recommend a "booster" dose because the vaccine provides immune protection for many decades.[1,61]

Adverse reactions to the YF vaccine include local site reactions, mild headaches, myalgia, and low-grade fevers, which can last for 5 to 10 days.[62] The product labeling carries precautionary warning about three serious adverse reactions. The first is immediate hypersensitivity reactions including anaphylaxis. These reactions have mainly been seen in patients with egg allergies. The vaccine is contraindicated in anyone with a history of acute hypersensitivity reaction to any components of the vaccine (including gelatin) or a history of acute hypersensitivity to eggs or egg products. The second serious reaction is vaccine-associated neurotropic disease (referred to as YEL-AND), previously described as postvaccination encephalitis. YEL-AND also includes acute disseminated encephalomyelitis, Guillain-Barre syndrome, bulbar palsy, and Bell's palsy.[41] Lastly, vaccine-associated viscerotropic disease (YEL-AVD), previously described as multiple organ system failure, is another rare serious adverse event associated with vaccination. The relationship between YF vaccination and these subsequent illnesses is not well understood. The incidence of YEL-AND and YEL-AVD has been estimated at 0.8 cases/100,000 doses administered and 0.4 cases/100,000 doses

administered, respectively.[41] However, the incidence of each appears to increase with advancing age.

Because it is a live vaccine it is contraindicated in immunocompromised patients, including symptomatic HIV-infected patients or those with CD4+ cells less than 200/mm^3 (<0.2 × 10^9/L), patients with malignant neoplasms, patients on immunosuppressant therapy, and children less than 6 months of age. A history of thymic dysfunction is now also regarded as a contraindication due to an apparent association with YEL-AVD.[62] The vaccine should be used with caution in children 6 to 8 months of age, patients 60 years of age and older, asymptomatic HIV-infected patients with CD4+ cells between 200 and 499/mm^3 (0.2 × 10^9 and 0.499 × 10^9/L), pregnancy, and during breastfeeding. An additional precaution is use in patients with latex allergies because the vial stopper is made of latex.[64]

According to International Health Regulations, YF vaccine must only be administered at certified YF vaccination centers.[1,62] Within the United States, state and territorial health departments have the authority to designate nonfederal vaccination centers. Most other countries use governmental-affiliated clinics to provide official YF vaccinations. Under International Health Regulations, any country may require proof of YF vaccination from travelers coming from countries with YF activity, even if travelers stop in a country to connect flights. A few countries (mostly in Africa) require proof of vaccination from all arriving travelers. Travelers must allow a minimum of 10 days from vaccination to country entry. Proof of vaccination must be in the form of a signed and stamped International Certificate of Vaccination or Prophylaxis.[1] The same form can be used as a waiver to document that a patient has a contraindication to receiving YF vaccination. Each country may have its own entry requirements. For example, some countries may require a YF vaccine booster at 10 years. Global travelers should check health-related entry requirements for each country they plan to visit. This information can be obtained from travel medicine consultants, foreign embassies, or governmental websites. An informed traveler is less likely to experience quarantine, refusal of entry, or vaccination in country.[1]

Tick-Borne Infections. Ticks are small blood-sucking acarines that can introduce parasites, bacteria, or viruses into vertebrates.[65] After mosquitoes, ticks are the next most common vector for transmitting human infectious diseases world-wide. In North America and Eurasia, they are actually the most common vectors.[66] Some of the most common tick-borne infections that travelers may encounter outside of the Unitede States are: *Borrelia burgdorferi* (Lyme borreliosis), *Borrelia Spp*. (Tick-borne relapsing fever), *Rickettsia africae* (African tick bite fever), tick-borne encephalitis virus (TBEV; European encephalitis), *Rickettsia conorii* (Mediterranean spotted fever), *Francicella tularensis* (tularemia), and *Babesia Spp*. (babesiosis).[65] While antimicrobial therapies are available to treat most of the bacterial and protozoal pathogens, prevention is the best strategy to protect travelers from unwanted infections and complications.[1,65]

Travelers spending time in outdoor environments with tick activity should wear protective clothing, and apply DEET to unprotected skin.[65] Clothing can also be sprayed with the acaricide permethrin. Daily self-inspection is important to identify ticks early. Proper tweezer removal should be performed if ticks are found to be attached to skin.

There are no effective treatments for TBEV, but vaccines are available outside the United States. These vaccine are often recommended for campers, hikers, or occupational workers who are likely to be exposed to ticks in the TBEV regions of Europe and Asia.[1,65]

Rabies. Rabies, a noninsect vector-borne infection, is an important life-threatening infection, which causes more than 60,000 deaths annually.[67] Certain wild mammals are referred to as high-risk "rabies vector species" such as raccoons, foxes, skunks, bats, and groundhogs. However, humans traveling in the developing world are more likely to contract the infection from domestic-appearing vectors, like dogs.[4,68] In these parts of the world it is not uncommon to see dogs, cats, and monkeys on the streets or in tourist areas. Postexposure bite management is identical with wild and domestic exposures. The affected site should be cleaned immediately with soap and water, and then victims should be assessed for post-exposure prophylaxis.[1] Unfortunately, access to quality rabies vaccine and immune globulin may be a challenge for global travelers, especially in remote areas.[4] In some countries, pharmaceutical quality standards may not be as high as in developed countries. In addition, supplies of available rabies products at local medical facilities may be counterfeit or poorly stored (subject to temperature variations).[1] With such a high mortality risk, exposed individuals, especially in small towns and villages, may require medical evacuation to reliable hospitals with adequate supplies of quality vaccine and immune globulin. Rabies is discussed in more detail in Chapter 125.

Respiratory-Transmitted Infections

Tuberculosis is one of the most common infectious diseases in the developing world. Travelers to developing countries can be easily exposed to infected persons with contagious "active" forms of the disease.[30] The CDC advises travelers to "avoid exposure to TB patients in crowded environments (such as hospitals, prisons, or homeless shelters)."[1] Travelers providing care to such patients should consider the use of personal protective devices, such as N-95 masks. TB infection is discussed in Chapter 112.

Influenza is another important global infection concern. There are concerns about pandemic avian influenza epidemics occurring in the future.[4] Fortunately, human-to-human cases are unlikely. Global travelers should avoid markets and farms where live poultry are sold or raised and avoid contact with dead poultry, chicken blood, or undercooked chicken in avian influenza-affected areas.[1] Influenza is discussed in Chapter 109.

Middle East Respiratory Syndrome Coronavirus (MERS-CoV) is responsible for a severe illness that was first reported in Saudi Arabia in 2012 and has since spread to several other regions, including North America.[69] Common symptoms include severe acute respiratory illness including fever, cough, and shortness of breath. Mortality rates have been estimated at 30% to 40% among patients with laboratory-confirmed infection.[70] All reported cases have been linked to countries in and near the Arabian Peninsula. Currently, there are no antiviral medications to treat MERS-Co-V, nor are there vaccines to prevent MERS-CoV infection at present time. Risk avoidance strategies in endemic areas include good hand hygiene, avoiding contact with sick people, and avoiding contact with camels and

raw or uncooked camel milk or meat.[1,69]

Two vaccine-preventable infections that should be assessed as part of pretravel consultation are measles and meningococcal infections. Most travelers have immunity against measles, but an assessment of vaccine history with consideration of measuring titers should be part of a pretravel consultation. Widespread vaccination against *Neisseria meningitidis* is less likely than measles. Persons traveling to high risk areas like the "meningitis belt" of sub-Saharan Africa should also be assessed for immunity.[1] These vaccine-preventable illnesses are discussed in greater detail in Chapter 125.

Neglected Tropical Diseases

Neglected tropical disease are infectious diseases that are found in some of the poorest tropical regions of the world and have not been considered a priority by funding agencies, pharmaceutical companies, or global policymakers.[71] These diseases rarely cause infection among global travelers from more developed countries unless they spend significant time in high-risk areas. Some of the more common diseases in this category are leishmaniasis, trypanosomiasis (Chagas and African), schistosomiasis, ascariasis, lymphatic filariasis, hookworm infection, and dracunculiasis (Guinea worm). Interested readers can learn more about these in the CDC Yellow book[1] or in Chapter 115.

Sexually-Transmitted Infections

Global travel has long been linked with STIs.[72] Global travelers may alter their behavior patterns as they leave their "normal environment." Travelers may give into hedonistic tendencies, especially if they use alcohol and illicit drugs. Travelers may behave with increased promiscuity when in exotic places, including sexual activity with commercial sex workers.[72,73] Global travelers taking part in risky (unprotected) sexual activity put themselves at risk for infections such as syphilis, gonorrhea, chlamydia, HIV, and hepatitis B (see Chapters 117 and 126).

Miscellaneous Travel Infections

Ebola virus belongs to the family of filoviruses and causes a viral hemorrhagic fever. Ebola can be spread through direct contact with blood or body fluids of an infected person through broken skin or mucous membranes in the eyes, nose, mouth, or other areas.[74] Ebola has long been feared because of its ability to spread with an insidious incubation period of up to 21 days. There have been at least 20 recognized outbreaks of Ebola, all occurred in Africa. Estimated fatality rates have been between 25% and 90%.[75] The largest Ebola outbreak in West Africa in 2014 attracted worldwide attention. Healthcare workers from around the globe went to the region to assist, and many of them contracted the virus and died.[74]

Noninfectious Diseases

Altitude Sickness

Altitude sickness or high altitude illnesses (HAI) result when the partial pressure of oxygen (PO_2) in the inspired air is lower than that to which the patient is accustomed. There are three main syndromes that can develop from high altitude exposure: (1) acute mountain sickness (AMS), (2) high altitude cerebral edema (HACE), and (3) high altitude pulmonary edema (HAPE). These different manifestations depend upon a few factors: the terminal altitude, the rate of ascent, the time spent at maximum altitude and the altitude when sleeping. The reduction in oxygen inspired over short periods leads to physiologic changes that place stress on the body and may lead to severe illness and even death.[76,77,78,79,80] Patients who are exposed to reduced oxygen concentrations gradually are able to compensate. This process is called acclimatization. However, when individuals ascend too rapidly they will experience a characteristic set of symptoms.[81]

An individual who experiences rapid ascent will begin to hyperventilate, become tachycardic and could experience erythropoiesis upregulation to increase available red blood cells to carry oxygen. Characteristic symptoms of AMS includes headache combined with one of the following symptoms: anorexia, nausea or vomiting, fatigue, headache, insomnia, or dizziness.[81] If the appropriate steps are not taken to treat or abate the progression of AMS, the individual could deteriorate further and develop HACE. This deterioration can occur in as little as 12 hours and could subsequently lead to death from vasogenic edema and decreased cerebral perfusion. The signs and symptoms of HACE are ataxia, seizures, slurred speech, neurologic deficits (rare), altered mentation, and decreased consciousness. Decreased consciousness and cerebellar ataxia are the most useful signs in identifying HACE.[81] Although patients may present with pulmonary edema in addition to central nervous system effects, patients may also present only with pulmonary edema. HAPE presents as increased breathlessness upon exertion and progresses to increased breathlessness during rest with weakness and cough. HAPE is due to a noncardiogenic, hydrostatic pulmonary edema.[82] Individuals who ascend to high altitude will experience some degree of hypoxic pulmonary vasoconstriction that leads to pulmonary hypertension and increased capillary pressure in patients who are susceptible to HAPE. HAPE has the potential to be more rapidly fatal than any of the other HAIs.[76,78,79,81,82,83,84,85]

9 The mainstay of therapy in all altitude-related illnesses is descent to a lower altitude (typically at least a 300-meter reduction in altitude). The administration of oxygen is an appropriate adjunct in severe cases and potentially is an option in mild cases. Due to the lack of availability in the field and the repercussions of mismanagement of deteriorating cases, oxygen therapy is not a likely option for treatment until the patient is able to descend to a base station with supplies.

Several medications have shown benefit in treating or preventing HAI and could be used as adjunctive therapy to decent and oxygen therapy.[78,82,83,86] Acetazolamide has been used for many years for the treatment and prevention of AMS and HACE. Acetazolamide is a carbonic anhydrase inhibitor that reduces hydrogen ion secretion in the proximal renal tubules and increases renal excretion of sodium, potassium, bicarbonate, and water leading to metabolic acidosis. This metabolic acidosis leads to a compensatory hyperventilation and increased oxygenation of the blood. This mechanism facilitates the acclimatization process and quickly improves AMS and HACE. Due to its sulfonamide chemical structure, individuals with documented allergies to sulfonamides should avoid acetazolamide.[76,78,84,87]

Clinical Controversy…

Phosphodiesterase-5 (PDE-5) inhibitors do not have proven efficacy as monotherapy for the treatment of HAPE. Several case reports exist that are contradictory regarding efficacy and true benefit as a sole agent. The majority of clinicians utilize PDE-5 inhibitors as prophylaxis but the question remains regarding treatment benefit.

Dexamethasone is a corticosteroid that has been used as an alternative to acetazolamide in the treatment and prevention of AMS, HACE, and even HAPE. Once initiated, dexamethasone should not be discontinued at altitude prior to acclimatization due to the possibility of rebound cerebral and pulmonary edema. The mechanism by which dexamethasone provides benefit in patients with AMS, HACE, and HAPE has not been well established but is thought to act through its anti-inflammatory properties and antagonism of vascular endothelial growth factor.[78,82,83]

Nifedipine is a calcium channel antagonist that has proven efficacy for treatment of HAPE. Nifedipine causes pulmonary arterial vasodilation, which improves alveolar fluid clearance and oxygenation of the blood. Reduced pulmonary artery pressure and pulmonary vascular resistance contribute to the positive effects of nifedipine on HAPE.[80,81,83]

Phosphodiesterase-5 inhibitors (evidence exists for sildenafil and tadalafil) are effective in preventing HAPE, but there is a paucity of studies regarding their use as monotherapy for treatment of HAPE. Although evidence for the treatment of HAI does not currently exist for vardenafil, it is likely that it would have the same beneficial effect as prophylaxis given its mechanism of action. The theoretical concern that these agents have risk for systemic hypotension is present; however, the clinical relevance of this risk in healthy populations without medication interactions is questionable.[76,81,82,88]

Opioid analgesics should be avoided in individuals who will be ascending to high altitude (or even in individuals ascending to a higher relative altitude prior to acclimatization) due to their ability to reduce the hypoxic ventilator response (HVR).[81]

Jet Lag

Jet lag is a syndrome that develops when travelers cross one or more time zones and are unaccustomed to the new time zone. This syndrome can be characterized by fatigue, malaise, and a disorganized sleep-wake cycle that can lead to poor performance and gastrointestinal distress. The syndrome is created by misaligning an individual's normal activity schedule with their circadian rhythm. The main treatment for jet lag is to realign the circadian rhythm with the new schedule.[89] Use of natural methods for adjusting circadian rhythms, such as sunlight exposure, phototherapy, or pretravel sleep schedule modification, are typically inexpensive, easy to administer and provide good outcomes.[89] Adjustment of a sleep schedule prior to travel may be difficult depending upon the individual's normal habits and the destination of their travel. As the number of time zones increases the difficulty of adjustment of sleep schedule also increases. This is also true regarding the severity of jet lag experienced. Other treatment modalities, such as supplemental melatonin, may provide a more flexible treatment method.[89,90,91]

In the majority of double-blind, placebo-controlled trials, melatonin was beneficial for treatment of jet lag.[92] Melatonin is produced endogenously by the pineal gland and is essential in the regulation of circadian rhythms. Positive effects on quality of sleep were seen when patients were given melatonin prior to sleep. The dosing range varies among studies but doses from 0.5 mg to 8 mg appear to have equal efficacy.[93] Melatonin also has some hypnotic effects and can aid in initiation of sleep. Melatonin's status as a dietary supplement lends to it being readily available and the known side effects of melatonin are relatively mild (eg, dizziness, enuresis, headache, and nausea). There is also no definitive evidence of toxicity associated with high dosages of melatonin.[89,94,95,96,97]

Sedative hypnotics, such as benzodiazepines and other medications that agonize the benzodiazepine receptors, are also effective at initiation of sleep and maintenance of sleep, but have inherent drawbacks to their use. Although safe to use in most patients, cognition and alertness can be impaired after benzodiazepine-induced sleep. They are also potentially habit forming and should be reserved for severe cases that are not effectively managed with light therapy and melatonin.[89,90]

Stimulants, such as modafinil or amphetamines, can be used to increase alertness and performance during the adjustment period after travel if the patient's daily life or performance at work is impaired. Side effect profiles, drug-drug interactions, and abuse potential also limit their utility for regular use.[89]

Traveler's Thrombosis

Traveler's thrombosis, also referred to as travel associated venous thromboembolism (TAVTE), can occur in otherwise healthy individuals who are not known to be hypercoagulable. Individuals traveling for multiple hours in confined spaces that limit ambulation are at particular risk for thrombosis. Other risk factors for traveler's thrombosis include personal height less than 63 inches (160 cm) and height over 75 inches (190 cm) in individuals traveling by air.[98] Those who are less than 63 inches (160 cm) will likely be unable to place their feet firmly on the floor during the flight and may experience increased pressure on the popliteal vein. This pressure contributes to development of venous stasis, which is one of Virchow's classic triad of risk factors for VTE. Individuals over 75 inches (190 cm) in height are more likely to be restricted from movement when in a standard seat. This restriction could limit blood flow and also cause venous stasis. Other factors that have been shown to increase the risk of TAVTE are genetic predispositions to clotting (Factor V Leiden), obesity, and oral contraceptive use.[98,99,100,101]

Although increased fluid intake has been purported to be helpful for preventing TAVTE, scientific evidence does not support this theory.[102] However, this should not dissuade passengers from staying well hydrated. While hydration may have no direct beneficial effect on prevention of traveler's thrombosis, the need to urinate may prompt the individual to ambulate to the restroom. Average healthy urine production ranges from 40 to 80 mL/h and the adult bladder capacity ranges from 300 to 400 mL. The urge to void usually occurs when the bladder is one quarter full. This would mean that assuming normal hydration the average healthy traveler would be prompted to urinate every 1 to 2 hours. Ambulation and the use of lower extremity muscles, by isometric exercises performed during long haul travel, is the best known way to prevent VTE and traveler's thrombosis. Compressions

stockings have been shown to reduce asymptomatic clots when appropriately fitted.[103] Compression stockings that have not been custom fitted or appropriately sized do not add any additional protection and in some cases could cause more issues. Pharmacologic prophylaxis is not warranted in most situations and should be avoided due to an increased risk of major bleeding. Patients who have previously been diagnosed with VTE, undergone recent major surgery, or have known malignancy are at high risk of VTE without the added impact of confined travel and therefore should be considered on an individual basis for pharmacologic prophylaxis.[24] The use of aspirin for prevention of traveler's thrombosis is not supported by the literature and should not be recommended for prophylaxis in travelers.[99,100,101,104]

Clinical Controversy…

Chemical prophylaxis for traveler's thrombosis in patients who are at high risk for clotting is currently not recommended by the CHEST guidelines while other guidelines suggest to consider a low-molecular weight heparin when certain risk factors are present. There have been no studies designed to identify risk of clotting when traveling with no chemical prophylaxis in patients with significant risk.

Mental Health

Travel, whether short or long, exposes the traveler to both physical and mental stress. Traveling into regions with disrupted personal routines and unfamiliar environmental and cultural elements can make assimilation difficult. This process of exposure and reaction to a different culture has been referred to as acculturation or "culture shock."[105,106] Controlled psychiatric illnesses and undiscovered predispositions to mental illness may be induced by exposure to these stressful situations. Pretravel screening and education are essential for travelers who are going to be abroad for a substantial amount of time. Patients with a history of mental illness should be counseled on the need for an adequate medication supply and impeccable adherence while abroad.

The most common psychiatric reason for evacuation from an international trip is depression.[107] Patients who have previously been diagnosed with depression should continue their prescribed medications and minimize alcohol consumption while traveling. Nearly all psychiatric illnesses that are experienced while traveling require treatment with medication.[107] Proper preparation for the trip will reduce the difficulties associated with acquiring appropriate medications and medical care. Given the propensity for exacerbations of mental illness while travelling internationally and the possibility of suicide due to untreated or unrecognized depression, it is prudent to purchase travel insurance that includes medical evacuation coverage and coverage for repatriation of remains. The costs associated with medical evacuation can be high, and travel insurance is typically quite affordable in comparison.[105,106,107]

Healthcare Outreach

Global Health Organizations and Non-Governmental Organizations

Global health organizations provide many services to developing and developed countries along with information and education resources. Guidance to travelers regarding issues they may encounter while in country is one of these services. From travel advisories to health emergencies, organizations like the WHO provide timely information and guidance for the prevention of illnesses that could lead to significant morbidity or mortality. Many countries have organizations similar to the WHO that serve the country in which they are based. These organizations also provide guidelines and statistical information regarding travel and disease in their specific impoverished areas.[108]

Non-governmental organizations (NGO) are non-profit, voluntary citizens' groups that organized on a local, national, or international level.[109] They provide substantial quantities of quality medical care to patients throughout developing countries.[109] Due to NGO's contributions to the impoverished population's care, they have established themselves as a major contributor to improving the health of individuals who would normally not have access to quality healthcare. These contributions improve quality and quantity of life in developing countries.[109]

Medications and Supplies for Medical Missions and Outreach

Providing medical services in other countries require supplies similar to those used in the country of origin. There is a varied approach to regulation of medications in different parts of the world. There are concerns with acquisition and use of medications in these countries that must be considered. Many countries do not have a regulatory body that regulates the standards for the purity and the quality of the products that are distributed. Consequently, medications acquired abroad could be impure or contain varied amounts of the active medication.[110] Due to this variability, it is advisable to obtain medications in the origin country or from a company that has a good reputation for standardization and quality. Medication costs also differ among countries, and the cost could be lower or higher depending on site-specific factors. Medications that undergo quality and safety checks are typically more expensive due to the time required to validate the methods and verify product quality. In many parts of the developing world, medication acquisition is as simple as walking into a pharmacy and requesting the medication with or without a prescription.[14]

The transport of medications into a country may require significant documentation regarding origin of the medication, visual inspection of the product, and potential taxation. Legal regulations of medications also vary significantly. Seizure of supplies by customs agents could lead to fines and cancellation of the planned provision of medical care. Researching custom law of the destination country is vital to facilitate entrance and exit of the country. Many organizations have paid employees that deal with this aspect of the trips to ensure there are no issues. However, this may be a role for pharmacists given their product knowledge and versatility.[14]

LIST OF ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

ACCP	American College of Chest Physicians
ACIP	Advisory Committee on Immunization Practices

AMS	acute mountain sickness
ASTMH	American Society of Tropical Medicine and Hygiene
CDC	Centers for Disease Control and Prevention
CHIKV	Chikungunya virus
DEET	N,N-diethyl-3-methylbenzamide
DENV	Dengue virus
GCS	graduated compression stockings
FDA	Food and Drug Administration
HAI	high altitude illnesses
HACE	high altitude cerebral edema
HAPE	high altitude pulmonary edema
HIV	Human Immunodeficiency Virus
HVR	hypoxic ventilator response
INCB	International Narcotics Control Board
ISTM	International Society of Travel Medicine
JEV	Japanese Encephalitis Virus
MERS-CoV	Middle East Respiratory Syndrome Coronavirus
NGO	non-governmental organizations
NSAID	nonsteroidal anti-inflammatory drug
NTD	neglected tropical diseases
PDE-5	phosphodiesterase-5
PO_2	partial pressure of oxygen
SARS	severe acute respiratory syndrome
STIs	sexually transmitted infections
TAVTE	travel associated venous thromboembolism
TB	tuberculosis
TBEV	tick-borne encephalitis virus
VFR	visit friends and relatives
VTE	venous thromboembolism
WHO	World Health Organization
YEL-AND	yellow fever vaccine-associated neurotropic disease
YEL-AVD	yellow fever vaccine-associated viscerotropic disease
YF	yellow fever

Chapter 125: Vaccines and Immunoglobulins

Mary S. Hayney

INTRODUCTION

KEY CONCEPTS

- 1 Live vaccines may confer life-long immunity but cannot be administered to immunosuppressed patients.
- 2 Inactivated and subunit vaccines and toxoids often require multiple doses to protect from infection, and generally booster doses are needed following the primary series.
- 3 Children less than 2 years of age are unable to mount T-cell–independent immune responses that are elicited by polysaccharide vaccines.
- 4 Severely immunocompromised individuals should not receive live vaccines, and their responses to inactivated, polysaccharide, toxoid, and recombinant vaccines may be poor.
- 5 The childhood and adult immunization schedules are updated frequently and published annually. These documents can be used to develop an immunization plan.
- 6 Immunoglobulin (Ig) provides short term, rapid postexposure protection from measles, hepatitis A, varicella, and other infections.
- 7 Ig adverse effects are often secondary to infusion rate. Slowing the IV infusion rate ameliorate chills, nausea, and fever that may develop during administration.
- 8 Rh_o(D) Ig prevents Rh-negative mothers from mounting an immune response against hemolytic disease of the newborn. Hemolytic disease of the newborn results when Rh-negative mothers are sensitized to the Rh(D) antigen on the red blood cells of their fetuses.

Immunization is defined as rendering a person protected from an infectious agent. Immunity to an infectious agent can be acquired by exposure to the disease, by transfer of antibodies from mother to fetus, through administration of immunoglobulin (Ig), and from vaccination. Immunization is the process of introducing an antigen into the body to induce protection against the infectious agent without causing disease. An *antigen* is a substance that induces an immune response. An *antibody* produced by the humoral arm of the immune system usually is the response that is measured as evidence of successful vaccination. However, cellular immune responses, which are more difficult to measure, are also an important aspect of vaccine responses.

This chapter introduces the clinical use of vaccines and immunoglobulins. Agents with a limited use, such as agents for bioterrorism or travel, are beyond the scope of this chapter.

PRODUCTS USED TO IMMUNIZE

Vaccines induce active immunity—that is, immunity generated by a natural immunologic response to an antigen. Vaccines can be live attenuated or inactivated. Inactivated vaccines may consist of whole or a particle of the pathogen that induces a protective immune response. Bacterial vaccines generally are inactivated specific bacterial antigens or conjugates. Live-attenuated vaccines induce an immunologic response more consistent with that occurring with natural infection.[1] Because the organisms in live-attenuated vaccines undergo limited replication in the vaccinated individual after administration, they may confer lifelong immunity with one dose (as does a natural infection).[2] Multiple doses of inactivated vaccines usually are needed to induce long-lasting, effective immunity. Additional doses at varying time intervals (booster doses) often are required to maintain immunity. Booster doses of such vaccines elicit memory responses from the B cells that produce immunoglobulin G (IgG). The immune system already has developed an array of antibodies to the antigen. Upon restimulation with a booster dose, the B cells, which produce the most specific antibodies against the antigen, are activated. Restimulation allows the most active antibodies against the antigen to be selected and maintained in the "immunologic memory." Thus, the booster dose results in a rapid, intense antibody response that is long lasting. Inactivated vaccines can also differ in immunity potential, depending on their composition. For example, polysaccharide vaccines tend to be poorly immunogenic in infants, whereas protein–polysaccharide conjugated vaccines of the same antigen tend to be highly immunogenic (eg, pneumococcal polysaccharide vaccine vs pneumococcal conjugated vaccine).[3] T-cell–independent immune response is made to polysaccharide antigens that stimulate B cells directly.[1] There is no maturation or booster response with a T-cell–independent immune response, and children younger than 2 years cannot make this type of response. Protein–polysaccharide conjugate vaccines stimulate T cells and promote interactions between T cells and B cells when producing the protective immune responses consisting of immunologic memory and high-affinity IgG.

Toxoids are inactivated bacterial toxins that generally are combined with aluminum salts to enhance their antigenicity by prolonging antigen absorption and exposure. These adjuvants also increase local tissue irritation when injected. Toxoids stimulate the production of antibodies against the bacterial toxins rather than the infecting bacterial pathogens.

Immunoglobulins are sterile solutions containing antibody derived from human (Ig) sources. Igs are derived from donor pools of blood plasma and are processed using cold ethanol fractionation in order to inactivate known potential pathogens. These products are indicated for induction of passive immunity (temporary immunity to infection as a result of administration of antibodies not produced by the host; see Other Immunoglobulins below).

In addition to the active component in a vaccine, other active and inert ingredients are often present. Suspending agents, such as water, saline, or complex fluids containing proteins (eg, albumin), are used as the vehicle for the vaccines. Preservatives, stabilizers, and antibiotics may be added to help maintain the integrity of the product. Immunized individuals may respond with allergic reactions not to the agent itself but to the other components of the pharmaceutical preparation. Different manufacturers of the vaccines have different active and inert ingredients or different quantities of these ingredients in their products.

Certain vaccines manufactured by various companies are considered interchangeable. Hepatitis A, hepatitis B, and *Haemophilus influenzae* type b (Hib) conjugate vaccines from different manufacturers used for the primary series of three doses are considered interchangeable. It is preferable to use diphtheria, tetanus toxoids, and

acellular pertussis (DTaP) vaccine from the same manufacturer to complete the entire primary series. However, immunization should not be delayed if the particular type of vaccine administered for the initial doses cannot be ascertained easily.[1]

FACTORS AFFECTING RESPONSE TO IMMUNIZATION

Various factors are known to affect response to vaccines. Viability of the antigen is an important factor (live attenuated vs. inactivated), as discussed previously. Total dose also is important because there seems to exist a threshold dose above which no further increase in antibody titer is seen. The interval between immunization doses, number of doses given, or both may change immune response to an agent. Among hepatitis B vaccine nonresponders, a significant proportion of individuals mount a vaccine response when given additional doses of vaccine.[2] In contrast, additional doses of influenza vaccine are minimally effective in individuals with chronic illness.[3] Generally, intervals longer than those recommended between vaccine doses do not reduce immune response.[1]

The route and site of administration of the immunobiologic are important. This is best illustrated by the hepatitis B vaccine, which elicits a satisfactory antibody response when given in the deltoid muscle but not a consistent response when administered in the gluteal area. Injections should be administered at a site with little likelihood of site damage. Vaccines containing adjuvants should be given into a muscle mass because they can cause irritation when given subcutaneously or intradermally.[1]

Host factors influence vaccine response. Immunocompromise, increasing age, underlying disease, and genetic background have been associated with poor response rates.[1,4,5,6]

VACCINE ADMINISTRATION

Subcutaneous injections should be administered into the thigh of infants and in the upper arm area over the triceps of older children and adults. A $^{5}/_{8}$-inch, 25-gauge needle (0.508 mm × 1.6 cm) should be used, taking care not to administer the dose intradermally or intramuscularly (IM). For IM injection, the anterolateral aspect of the upper thigh (infants and toddlers) or the deltoid muscle of the upper arm (children and adults) should be used. When giving an IM injection to an adult weighing less than 60 kg, a $^{5}/_{8}$-inch or 1-inch needle (1.6 cm or 2.5 cm) can be used. If a $^{5}/_{8}$-inch needle (1.6 cm) is used, the skin over the injection site must be stretched tight, and the needle must enter the skin at a 90° to assure that the needle reaches the muscle. A 1-inch needle (2.5 cm) should be used for adults who weigh 60 to 70 kg. Immunizers can choose either a 1-inch or $1^{1}/_{2}$-inch needle (2.5 cm or 3.8 cm) for women who weigh 70 to 90 kg and for men who weigh 70 to 118 kg. For women weighing more than 90 kg and men who weigh more than 118 kg, a $1^{1}/_{2}$-inch needle (3.8 cm) must be used.[1] The buttock should not be used because of the potential for inadequate immunologic response and the potential risk of injury to the sciatic nerve. When the buttock must be used (as for large doses of Ig), only the upper outer quadrant should be used with the needle inserted anteriorly. An influenza vaccine for intradermal administration over the deltoid is supplied in an injection device that reliably delivers the vaccine to the intradermal space.[3]

The rotavirus vaccines are administered orally. The tube of vaccine should be squeezed inside the infant's mouth toward the inner cheek until the dosing tube is empty. If the infant regurgitates or spits out the vaccine, readministration is not recommended.[8]

dministered intranasally.[3] A specially designed sprayer is inserted just

inside the nostril, and the dose is sprayed by rapidly depressing the plunger of the sprayer. The clip is removed from the plunger so that the second half of the dose can be administered into the other nostril. The vaccinated individual should breathe normally. The dose does not need to be repeated if the individual sneezes during or shortly after administration.

Questions often arise concerning the simultaneous administration of vaccines. In general, inactivated and live-attenuated vaccines can be administered simultaneously at separate sites. If two or more inactivated vaccines cannot be administered simultaneously, they can be administered without regard to spacing between doses. Inactivated and live vaccines can be administered simultaneously or, if they cannot be administered simultaneously, at any interval between doses, except for cholera (killed) and yellow fever (live) vaccines, which should be given at least 3 weeks apart. If live vaccines are not administered simultaneously, their administration should be separated by at least 4 weeks. Live viral vaccines may interfere with purified protein derivative response; thus, tuberculin testing should be postponed for 4 to 6 weeks after administration of live-virus vaccine.[1]

Simultaneous administration of Ig and live-attenuated vaccines may interfere with host antibody response. A dose relationship exists between administration of Ig and inhibition of immune response to a vaccine (**Table 125-1**). Whole blood and other blood products containing antibodies may interfere with the response to the measles, mumps, and rubella (MMR) and varicella vaccines. In any individual, if vaccination with MMR or varicella is followed by emergency Ig administration, the vaccine can be repeated or seroconversion to viral antigens can be confirmed after sufficient time has elapsed (see Table 125-1). Ig does not interfere with the response to oral vaccines, zoster vaccine, or yellow fever vaccine.[1]

Inactivated vaccines and Igs may be administered simultaneously. However, different sites are recommended for killed vaccine and Ig administration.

VACCINE STORAGE

Appropriate storage is critical to maintaining the integrity of vaccines because improperly stored vaccines can fail to protect the individuals to whom they are administered. Refrigerator temperature is defined as between 2°C and 8°C (36°F to 46°F) and freezer temperature as –50°C (–58°F) to –15°C (5°F). Inactivated vaccines are stored refrigerated. Varicella and zoster vaccines must be stored frozen. MMR vaccine can be stored in either the freezer or refrigerator. Live-attenuated influenza vaccine is stored in the refrigerator. Specific storage conditions for individual vaccines can be found in the package insert.

IMMUNIZATION OF SPECIAL POPULATIONS

Groups of individuals may have precautions to vaccines. Many precautions are temporary, and vaccines can be administered

TABLE 125-1 Recommended Intervals Between Administration of Immunoglobulin and Measles- or Varicella-Containing Vaccine[1]

TABLE 125-1 Recommended Intervals Between Administration of Immunoglobulin and Measles- or Varicella-Containing Vaccine[1]

Product/Indication	Dose, Including mg Immunoglobulin G(IgG)/kg Body Weight	Recc Inter M V Co V Adm
RSV monoclonal antibody (Synagis®)[b]	15 mg/kg intramuscularly (IM)	Non
TIG	250 units (10 mg IgG/kg) IM	3 mc
HAIG		
Contact prophylaxis	0.02 mL/kg (3.3 mg IgG/kg) IM	3 mc

Infants

The age of the recipient is an important determining factor in vaccine response. In the first few months of life, passively transferred maternal antibodies acquired during the third trimester of gestation protect an infant. However, the maternal antibodies also inhibit the immune response to live vaccines because the circulating antibodies neutralize the vaccine before the infant has the opportunity to mount an immune response. For this reason, measles, mumps, rubella, and varicella vaccines are not administered until maternal antibodies have waned, generally by infant age 12 months.

Premature infants should be vaccinated at the same chronologic age using the same schedule and precautions for full-term infants. The full recommended doses of vaccines should be used, regardless of age or birth weight. Breastfed infants should be vaccinated according to standard pediatric schedules.

Pregnant Women and Postpartum Immunization

The benefit of most vaccines outweighs the risk for administration to pregnant females. As with most drugs, a lack of information regarding risks to the fetus exists rather than any actual known risk. No adverse birth outcome has ever been attributed to vaccine exposure.[1] For example, no cases of congenital rubella syndrome from inadvertent administration of rubella vaccine to a pregnant woman have ever been reported. Universal influenza immunization is recommended for women who will be or are pregnant during influenza season. Pregnant women should receive Tdap during the late second trimester or third trimester of pregnancy.[4] Although live vaccines generally are avoided because of the theoretical risk of transmission of the vaccine organism to the fetus, inactivated vaccines may be administered to pregnant women when the benefits outweigh the risks.[1] Hepatitis B, hepatitis A, meningococcal, and inactivated polio vaccines should be administered to pregnant females if they are otherwise indicated. Insufficient evidence is available for pneumococcal vaccines, and the human papillomavirus (HPV) series should be deferred during pregnancy.[5]

Administration of live vaccines, such as rubella or varicella, are deferred until pregnancy is completed and are routinely recommended for new mothers who do not have evidence of immunity prior to hospital discharge. These live vaccines can be administered without regard to administration of Rh_0(D) Ig

y, Tdap is recommended

Product/Indication	Dose, Including mg Immunoglobulin G(IgG)/kg Body Weight	Recc Inter M V Co V Adm
International travel	0.06 mL/kg (10 mg IgG/kg) IM	3 mc
HBIG	0.06 mL/kg (10 mg IgG/kg) IM	3 mc
RIG	20 IU/kg (22 mg IgG/kg) IM	4 mc
Measles prophylaxis IG		
Standard (ie, nonimmunocompromised) contact	0.25 mL/kg (40 mg IgG/kg) IM	5 mc
Immunocompromised contact	0.5 mL/kg (80 mg IgG/kg) IM	6 mc
Blood transfusion		
RBCs, washed	10 mL/kg negligible IgG/kg IV	Non
RBCs, adenine-saline added	10 mL/kg (10 mg IgG/kg) IV	3 mc
Packed RBCs (Hct 65%) [0.650][c]	10 mL/kg (60 mg IgG/kg) IV	6 mc
Whole blood (Hct 35%–50%)[0.35–0.50][c]	10 mL/kg (80–100 mg IgG/kg) IV	6 mc
Plasma/platelet products	10 mL/kg (160 mg IgG/kg) IV	7 mc
Cytomegalovirus IV immunoglobulin (IGIV)	150 mg/kg maximum	6 mc
IVIG		
Replacement therapy for immune deficiencies[d]	300-400 mg/kg IV[c]	8 mc
Immune thrombocytopenic purpura	400 mg/kg IV	8 mc
Immune thrombocytopenic purpura	1 g/kg IV	10 m

for all new mothers who have not received a Tdap before because household contacts are frequently implicated as the source of pertussis infection in a young infant.[4]

Immunocompromised Hosts

4 Immununization of individuals with chronic disease, such as immunocompromise, diabetes or connective tissue disease, alcoholism, or those with cancer or HIV disease, must be individualized based on the disease state and its treatment. In general, severely immunocompromised individuals should not receive live vaccines. Administration of other vaccines may be indicated, but responses may be lower than those mounted by healthy individuals, but may still confer protection.[6]

Patients with chronic pulmonary, renal, hepatic, or metabolic disease who are not receiving immunosuppressants can receive both live-attenuated and killed vaccines and toxoids to induce active immunity. These patients often need higher doses of vaccines or more frequent dosing to induce immunity. Generally, immunization should be considered early in the course of the disease in an attempt to induce immunity at a point when the disease is less severe.[2]

Patients with active malignant disease can receive killed vaccines or toxoids but should not be given live vaccines. The MMR vaccine is not contraindicated for close contacts, however. Live-virus vaccines can be administered to persons with leukemia who have not received chemotherapy for at least 3 months. Vaccines should be timed so that they do not coincide with the start of chemotherapy or radiation therapy.[6] Zoster vaccine should be administered at least 2 weeks prior to the start of immunosuppressing therapy.[7] Annual influenza vaccine should be administered 2 weeks prior to chemotherapy or between cycles.[6] If vaccines cannot be given at least2 weeks before the start of these therapies, immunization should be postponed until 3 months after the therapy has been completed. Passive immunization with Ig can be used in place of active immunization regardless of the history of immunization.

Glucocorticoids may cause suppressed responses to vaccines. For the purposes of immunization, the immunosuppressing dose of corticosteroids is prednisone 20 mg or more daily or 2 mg/kg daily, or an equivalent dose of another steroid, for at least 2 weeks. Patients receiving long-term, alternate-day steroid therapy with short-acting agents, administration of maintenance physiologic doses of steroids (eg, 5 to 10

Product/Indication	Dose, Including mg Immunoglobulin G(IgG)/kg Body Weight	Recc Inter M V Co V Adm
Postexposure varicella prophylaxis[e]	400 mg/kg IV	8 mc
Kawasaki's disease	2 g/kg IV	11 m

HAIG, Hepatitis A IG; HBIG, Hepatitis B IG; RBCs, Red blood cells; RIG, Rabies IG; TIG, Tetanus IG.

[1]This table is not intended for determining the correct indications and dosages for using antibody-containing products. Unvaccinated persons might not be fully protected against measles during the entire recommended interval, and additional doses of Ig or measles vaccine might be indicated after measles exposure. Concentrations of measles antibody in an Ig preparation can vary by manufacturer's lot. Rates of antibody clearance after receipt of an Ig preparation also might vary. Recommended intervals are extrapolated from an estimated half-life of 30 days for passively acquired antibody and an observed interference with the immune response to measles vaccine for 5 months after a dose of 80 mg IgG/kg.

[a]Varicella-containing vaccine, as used here, does not include zoster vaccine. Zoster vaccine may be given without regard to antibody-containing blood products.

[b]Contains antibody only to respiratory syncytial virus (RSV).

[c]Assumes a serum IgG concentration of 16 mg/mL (g/L).

[d]Measles and varicella vaccinations are recommended for children with asymptomatic or mildly symptomatic human immunodefi ciency virus (HIV) infection but are contraindicated for persons with severe immunosuppression from HIV or any other immunosuppressive disorder.

mg/day of prednisone) topical, aerosol, intraarticular, bursal, or tendon steroid injections require no special consideration for immunization. If patients have been receiving high-dose corticosteroids or have had a course lasting longer than 2 weeks, then at least 1 month should pass before immunization with live-virus vaccines.[1]

[e]The investigational product VariZIG, similar to licensed VZIG, is a purified human Ig preparation made from plasma containing high levels of anti-varicella antibodies (immunoglobulin class G [IgG]). The interval between VariZIG and varicella vaccine is 5 months.

Patients with HIV infection require special consideration. Responses to live and inactivated vaccines generally are suboptimal and decrease as the disease progresses because HIV produces defects in cell-mediated immunity and humoral immunity. The routinely recommended vaccines should be administered to children. MMR should be administered to anyone older than 12 months of age without evidence of immunity and are not severely immunocompromised (CD4% greater than 15% and CD4 count greater than 200 lymphocytes/mm^3 [greater than equals to 0.2 × 10^9/L] for at least 6 months).[8] Two doses of varicella vaccine separated by 3 months are recommended for those with no evidence of immunosuppression. Adults should receive routinely recommended vaccines. Zoster vaccine may be administered to individuals with HIV infection who do not have clinical manifestations of AIDS and have CD4 counts greater than 200/mm^3 (greater than 0.200 × 10^9/L).[7]

Solid Organ Transplant Patients

Organ transplantation has become routine treatment of end-stage organ disease of many causes. Solid-organ transplant patients remain on immunosuppressive regimens for the rest of their lives. These immunosuppressive regimens result in a higher risk of infection and decrease the protection conferred by immunization.[9]

Whenever possible, transplant patients should be immunized prior to transplantation. Live vaccines generally are not given after transplantation. Posttransplantation diphtheria, tetanus, pneumococcal, and influenza vaccine responses are unpredictable. Decreased immune response has been documented following hepatitis B vaccine.

Hematopoietic Stem Cell Transplant Patients

Reimmunization of patients with hematopoietic stem cell transplantation is necessary because antibody concentrations wane rapidly. Annual influenza immunization may begin as soon as 6 months after successful engraftment. Reimmunization with inactivated vaccines should begin approximately 6 months after hematopoietic stem cell transplantation. Hematopoietic stem cell transplant recipients are at increased risk for fulminant infection with encapsulated bacteria, so 13-valent pneumococcal vaccine (PCV13), the 23-valent pneumococcal polysaccharide vaccine (PPSV23), meningococcal vaccines, and Hib vaccines are recommended. MMR vaccine (MMR) can be administered at 24 months. Varicella vaccine is not routinely recommended but can be considered on a case-by-case basis. Immunization of household contacts and healthcare workers also is necessary.[1,6]

CONTRAINDICATIONS AND PRECAUTIONS

There are few contraindications to the use of vaccines except those outlined earlier. The contraindications include a history of anaphylactic reactions to the vaccine or a component of the vaccine. Unexplained encephalopathy occurring within 7 days of a dose of pertussis vaccine is a contraindication to future doses of pertussis vaccines. Immunosuppression and pregnancy are temporary contraindications to live vaccines. An interval of time must elapse based on the dose of Ig before a live vaccine can be administered (see Table 125-1). Precautions for DTaP administration include hypotonic hyporesponsive episode, fever of 40.5°C (104.9°F) or greater, crying lasting more than 3 hours within 48 hours of a previous dose, and seizures with or without fever

within 3 days after a dose. A personal or family history of seizures is a precaution for receiving the combination MMR–varicella (MMRV) vaccine. Immunizers should use MMR and varicella vaccines separately.[1] Generally, mild-to-moderate local reactions, mild acute illnesses, concurrent antibiotic use, prematurity, family history of adverse events, diarrhea, and lactation or breastfeeding are not contraindications to immunization.

OBTAINING AN IMMUNIZATION HISTORY

An immunization history should be obtained from every patient, regardless of the reason for the healthcare visit. Ideally, any history provided by the patient from memory should be verified by reviewing the patient's personal written immunization record or a database that contains the complete immunization history. State-based or other public health jurisdiction-based immunization information systems, also called immunization registries, have been developed to improve immunization coverage by allowing healthcare providers access to records at any contact with the healthcare system. Registries are aimed primarily at facilitation of childhood immunization records.[10] If an official written record is not available, patient characteristics (eg, military service, travel history, and occupation) may provide clues to the immunization history. Serologic testing for immunity against certain diseases can provide specific information but is used routinely for only a few selected diseases (eg, measles, rubella, hepatitis A and B, and varicella) and selected circumstances (eg, employment in a healthcare facility). If a written record does not exist, one should be generated at the time of initiation of immunization. Patients without a written record should be considered susceptible, and an immunization program started and completed unless a serious adverse reaction occurs. As a general rule, the risks associated with overimmunization are minimal relative to the risks associated with contracting vaccine-preventable diseases.[1]

Every healthcare visit, regardless of its purpose, should be viewed as an opportunity to review a patient's immunization status and to administer needed vaccines. Immunization is perhaps the most cost-effective health intervention available. Each visit should include assessment of individuals' vaccine needs, administration of indicated vaccines, and documentation of immunization histories. The outcome measurement of what percentage of patients in a particular practice site is completely immunized is extremely important because the benefits of optimal vaccine use extend beyond the individual patient to the public as a whole.

NATIONAL VACCINE INJURY COMPENSATION PROGRAM

The National Childhood Vaccine Injury Act of 1986 was passed by the US Congress in response to reports of vaccine side effects and liability concerns of vaccine manufacturers and healthcare providers. With vaccine safety being questioned and manufacturers ceasing the development and marketing of vaccines, the National Vaccine Injury Compensation Program was implemented to offer a no-fault alternative means to compensate individuals for injury following vaccination. The program offers liability protection to manufacturers and an efficient means of recovering damages for individuals potentially injured by vaccines. The types of vaccine-related injuries that are considered for compensation are outlined in the Health Resources and Services Administration's Vaccine Injury Table (http://www.hrsa.gov/vaccinecompensation/vaccinetable.html). Healthcare providers must report all events requiring medical attention within 30 days of vaccination to the Vaccine Adverse Event Reporting System (VAERS), which serves as a central depot for vaccine-related adverse effects. Only a temporal association between the adverse event and vaccine administration is required. No adverse event rates can be determined because only the number of adverse events reported is known; the number of vaccines administered is not known. This database can be used to survey for changes in the frequencies of adverse events, to evaluate risk factors for adverse events, and to find rare adverse events.[11] VAERS report forms can be obtained by calling 1-800-822-7967, or reports can be made online at https://vaers.hhs.gov/esub/index.

USE OF VACCINES

The Advisory Committee on Immunization Practices (ACIP) makes recommendations for use of vaccines for the United States. Other professional organizations, for example, the American Academy of Pediatrics, the American Academy of Family Physicians, or the American College of Obstetrics and Gynecology, publish guidelines. Usually, these guidelines are the same as those issued by the ACIP or the groups try to reconcile their recommendations.

5 The appendices show the recommended schedules for routine immunization of children and adults. The latest vaccine schedules can be found at http://www.cdc.gov/vaccines/schedules/hcp/index.html. All states require children to be fully immunized prior to entering elementary school; however, optimal protection is achieved by immunizing at the recommended ages, which requires special attention to children younger than 2 years. Adults and adolescents also require vaccination and often are unaware of this need. An early adolescent preventive health visit is recommended. This visit is an opportunity to catch up on missed immunizations and to administer meningococcal conjugate, Tdap, and HPV vaccines. All individuals older than 6 months of age should receive an annual seasonal influenza vaccine. Adults should receive routine tetanus–diphtheria (Td) or Tdap boosters and be immune to measles, mumps, rubella, and varicella by either immunization or history of infection. Older adults need zoster vaccine after age 60 years, and pneumococcal vaccines after age 65 years. Certain individuals with conditions or lifestyles that put them at high risk for vaccine-preventable diseases also should be immunized as described in the following text and outlined in the immunization schedules in the appendices.

Clinical Controversy

Some parents and clinicians consider an alternative schedule for the immunization of young children. The advantages of the alternative schedule are that fewer injections and fewer vaccines are administered in any single visit and the child is immunized using more visits. Disadvantages to the use of an alternative immunization schedule are that childhood vaccines are subject to concomitant use studies to investigate immunogenicity and safety when administered at the same time. Second, delaying vaccines leaves the child susceptible to vaccine-preventable diseases until the vaccine is administered. Finally, studies show that an infant is no more stressed by one injection than multiple injections in a single visit as measured by cortisol production.[12]

VACCINES

Diphtheria Toxoid Adsorbed

Diphtheria is an acute illness caused by the toxin released by a *Corynebacterium diphtheriae* infection. The toxin inhibits cellular protein synthesis, and membranes form on mucosal surfaces. Systemic toxemia can result in myocarditis, neuritis, and thrombocytopenia. Membrane formation can cause respiratory obstruction, and significant toxin absorption can lead to severe illness and death.

Diphtheria toxoid adsorbed is a sterile suspension of modified toxins of *C. diphtheriae* that induces immunity against the exotoxin of this organism. Two strengths of diphtheria toxoid are available in the United States: pediatric strength (D) and adult strength (d), which contains less antigen. The widespread use of diphtheria toxoid essentially has eliminated diphtheria from the United States.

Primary immunization with diphtheria toxoid (D) is indicated for children older than 6 weeks. The toxoid is given nd acellular pertussis vaccine (as DTaP or in combination with additional

childhood vaccines that have been licensed to decrease the number of injections required to complete the childhood immunization recommendations) at age 2, 4, and 6 months. Additional doses are given at age 15 to 18 months and again at age 4 to 6 years.[13] Booster doses should be given every 10 years.

For unimmunized adults, a complete three-dose series of diphtheria toxoid should be administered, with the first two doses given at least 4 weeks apart and the third dose given 6 to 12 months after the second. One of the vaccine doses in this series should be Tdap. The combined Td preparation is used for adults because it contains less diphtheria toxoid than the pediatric dose and is associated with fewer reactions to the diphtheria component. All adults should receive booster doses of Td every 10 years.[14] Adverse effects of diphtheria toxoid include mild-to-moderate tenderness, erythema, and induration at the injection site. Systemic reactions occur very rarely.

Haemophilus Influenzae **Type B Vaccines**

Before 1995, Hib was responsible for thousands of cases of serious illnesses (eg, meningitis, epiglottitis, pneumonia, sepsis, and septic arthritis). The incidence of Hib disease has declined more than 99% since the introduction of the conjugate vaccines based on the organism's capsular substance, polyribosylribitol phosphate (PRP).[15]

The Hib vaccines are conjugate products consisting of either a polysaccharide or an oligosaccharide of PRP covalently linked to a protein carrier. The protein carrier is important because it provides for T-lymphocyte–dependent immunologic response, whereas earlier Hib vaccines that consisted of only unconjugated PRP elicited a response that was T-cell independent. T-cell involvement in the response provides for (a) a greater antibody response regardless of the age of the patient receiving the vaccine, (b) immunologic response at an earlier age (including infants), and (c) a booster effect on subsequent exposure to the Hib capsule, whether through revaccination or natural exposure. The protein carrier is not considered a vaccine and should not be substituted for immunization against tetanus, diphtheria, or *Neisseria meningitidis*.

Hib conjugate vaccines are indicated for routine use in all infants and children younger than 5 years. Multiple products in various combinations are available for use in infants and children of different ages. The primary series of Hib vaccination consists of a 0.5-mL IM dose at ages 2, 4, and 6 months. If Hib PRP-OMP (outer membrane protein of *Neisseria meningitides* as the protein conjugate) is being used, the primary series consists of doses given at ages 2 and 4 months. The series should not be initiated in an infant younger than 6 weeks. Although use of one product for the entire primary series is desirable, adequate protection is achieved even when different products are used during the initial series. Following the primary series, a booster dose is recommended at age 12 to 15 months. Any of the Hib conjugate vaccines are suitable for the booster dose regardless of which conjugate was used for the primary series of doses.[15]

Schedules are more complex for infants who do not begin Hib immunization at the recommended age or who have fallen behind in the immunization schedule. For infants 7 to 11 months of age who have not been vaccinated, three doses of Hib vaccine should be given: two doses spaced 4 weeks apart and then a booster dose at age 12 to 15 months (but at least 8 weeks since the second dose). For unvaccinated children ages 12 to 14 months, two doses should be given, with an interval of 2 months between doses. In a child older than 15 months, a single dose of any of the vaccine preparations is indicated.[15]

Vaccines for Hib are recommended for routine use only for children up to age 59 months; beyond this age, the incidence of invasive Hib disease is very low. Patients with certain underlying conditions (eg, HIV infection, IgG_2 subclass deficiency, sickle cell disease, splenectomy, and hematopoietic stem cell transplants and those receiving chemotherapy for malignancies) are at higher than normal risk for Hib infection, and use of at least

one dose of vaccine in these patients should be considered.[13,14,15]

Adverse reactions to the Hib vaccine are uncommon. Erythema and induration at the injection site occur in approximately 5% to 30% of children and resolve within 12 to 24 hours. Fever, diarrhea, and vomiting are reported occasionally.[15]

Hepatitis Vaccines

Information on vaccination for viral hepatitis is given in Chapter 40.

Human Papillomavirus Vaccine

HPV infections are the most common sexually transmitted infections, with the highest prevalence of infection in sexually active young adults. Although more than 120 different HPV types have been identified, at least 40 different types of HPV infect the anogenital tract. These 40 different viruses are grouped into low-risk and high-risk types. Low-risk types can cause genital warts and mild abnormalities on Papanicolaou (Pap) tests. Ninety percent of all cases of genital warts and the majority of respiratory papillomatosis are caused by types 6 and 11. As many as 18 types are considered high risk as they have the ability to penetrate the nucleus of an epithelial cell to transform it to a precancerous cell. They cause abnormal Pap test results and may lead to cancer of the cervix, vulva, vagina, anus, or penis. Types 16 and 18 cause about 70% of all cervical cancers. Another 10% of HPV-related cancers are caused by types 31, 33, 45, 52, and 58. Men who have sex with men (MSM) are at a higher risk for infection with HPV, genital warts, and anal cancer.[16] The incidence of cancers associated with HPV is higher among MSM, and the rate of anal cancer among MSM continues to rise.[16,17] High-risk HPV infections are necessary but not sufficient for the development of cervical cancer and for the majority of other anogenital and oral squamous cell cancers.

A nine valent HPV vaccine against types 6 and 11 and 16, 18, 31, 33, 45, 52, and 58 is licensed for the prevention of HPV. ACIP recommends HPV vaccine for the prevention of HPV-related disease in females aged 9 to 26 years. The nine valent vaccine can be used for males aged 9 to 26 years. This vaccine is administered as a three-dose series using a schedule of 0, 1 to 2, and 6 months.[18] The vaccines are recommended for adolescents aged 11 to 12 years and for all females aged 13 to 26 years. Males should be immunized routinely up to age 21 years. Males who have sex with males and the immunocompromised should be immunized through age 26 years. Males aged 22 to 26 years may receive the series.[18]

The vaccine is well tolerated, with injection-site reactions and systemic reactions (eg, headache and fatigue) occurring as commonly in immunized individuals as in the groups receiving placebo. Although syncope is possible with any immunization, the target population of adolescents and young adults has a higher incidence of syncope, including with administration of the HPV vaccine.[19]

The effective vaccine is an important advance, but the need for a Pap test for cervical cancer screening remains. Surveillance for the duration of protection conferred by the vaccine series is ongoing; the need for future booster doses is not yet known.

Influenza Virus Vaccine

Information on vaccination for influenza is given in Chapter e88.

Measles Vaccine

Measles (rubeola) is a highly contagious viral illness characterized by rash and high fever. Complications of measles infections include severe diarrhea, otitis media, pneumonia, and encephalitis. Measles results in one to two deaths per 1,000 cases, with a much higher death rate in developing countries. With widespread vaccination, measles is on the verge of elimination from the Western Hemisphere.

The measles vaccine is a live-attenuated viral vaccine that produces a subclinical, noncommunicable infection. Approximately 95% of vaccine recipients mount a protective immune response after a single dose, and most individuals are protected for life.[25] Most persons who do not respond to the first dose of measles vaccine will respond after receiving a second dose, and this forms the basis for the two-dose vaccine strategy that was implemented in the United States in 1989.

The measles vaccine is administered subcutaneously as a 0.5-mL dose in the arm (or in the thigh if the patient is younger than 15 months). The vaccine is administered routinely for primary immunization to persons 12 to 15 months of age. Two combinations of measles containing vaccines are available—measles–mumps–rubella (MMR) or measles–mumps–rubella–varicella (MMRV). The measles vaccine is not administered earlier than 12 months (except in certain outbreak circumstances or for travel) because persisting maternal antibody that was acquired transplacentally late in gestation can neutralize the vaccine virus before the vaccinated person can mount an immune response. A second dose of measles-containing vaccine is recommended when children are 4 to 6 years old.[8] The second dose of vaccine results in seroconversion in 95% of individuals who were first-dose nonresponders.

Measles-containing vaccine should not be given to pregnant women or immunosuppressed patients. An exception is HIV-infected patients, who are at very high risk for severe complications if they develop measles. Adults with HIV infection who have no evidence of measles immunity should be immunized as long as they are not severely immunocompromised (CD4 greater than 200 lymphocytes/mm^3 [greater than equals to 0.2 × 10^9/L] for at least 6 months). The second dose should be given 1 month later.[8] Children with HIV who are not severely immunocompromised can be immunized according to the childhood immunization schedule at 12 months and 4 to 6 years of age.[8,13]

Recent administration of Ig interferes with measles vaccine response, so the recommended interval between the Ig andvaccine is determined by the dose of Ig (see Table 125-1).[1] Live vaccines not administered during the same visit must be delayed for at least 30 days following measles or MMR vaccine. Live measles vaccine may suppress a positive tuberculin skin test for up to 6 weeks postadministration.[1]

Measles vaccine is indicated in all persons born after 1956 or in those who lack documentation of wild virus infection by either history or antibody titers. Two doses of a measles-containing vaccine separated by at least one month are required for children, college students, and healthcare workers who were born in 1957 or later.[13,14]

The measles vaccine has an excellent safety record. The most common side effect following vaccination is fever, which occurs in 5% to 15% of vaccinees. Transient generalized rash may occur in approximately 5% of vaccine recipients. These reactions generally appear 5 to 12 days postvaccination and last 2 to 5 days. Other adverse effects, such as headache, cough, sore throat, eye pain, malaise, and transient thrombocytopenia, occur less frequently.[8]

Meningococcal Vaccines

N. meningitidis is a leading cause of meningitis and sepsis in children and young adults in the United States. Five [illegible] almost all infections in humans. The infection is transmitted by

respiratory droplets from infected individuals and asymptomatic carriers. Symptoms include severe headache, sensitivity to light, stiff neck, nausea and vomiting, and high fever. Mortality occurs in 24 to 48 hours following onset of symptoms in 10% to 13% of infected individuals.[33] Immunization is recommended for high-risk populations, such as those exposed to the infection, those in the midst of uncontrolled outbreaks, travelers to areas with epidemic or hyperendemic meningococcal disease, and individuals who have terminal complement component deficiencies or asplenia.

MenACYW Conjugate and Polysaccharide Vaccines

Two meningococcal conjugate vaccines combining the same serotypes are licensed for use in individuals aged 9 months to 55 years old (Menactra®, Sanofi-Pasteur) or 2 to 55 years old (Menveo®, Novartis). A quadrivalent vaccine containing capsular polysaccharides for serotypes A, C, Y, and W-135 (Menimmune®, Sanofi-Pasteur) has been available since the early 1970s.

The meningococcal conjugate vaccine is recommended for adolescents at ages 11 to 12 years with a second dose at age 16 years. Reimmunization at 5-year intervals is recommended for individuals who are at high risk.[34] The polysaccharide vaccine should be reserved for those older than 55 years of age who require immunization.

Injection-site reactions are the most common adverse effects following administration of either the meningococcal conjugate or polysaccharide vaccine.

MenB vaccines

Meningococcal serogroup B (MenB) vaccines use other antigens from the bacterial capsule, specifically factor H binding protein, Neisseria adhesin A, and neisserial neparin binding antigen. Two MenB vaccines have been licensed for the prevention of invasive disease caused by *N. meningitidis* serogroup B for individuals aged 10 to 25 years. The ACIP recommends either of the two MenB vaccines, Trumenba® and Bexsero®, for individuals at high risk for invasive meningococcal disease.[20] Additionally, MenB vaccine use is acceptable for adolescents and young adults. Trumenba® requires two or three dose series administered at 0 and 6 months or 0, 2, and 6 month intervals. Bexsero® requires two doses with at least one month between doses. Both vaccines were licensed based upon antibody response studies.[20] The most common adverse events after MenB vaccines are pain at the injection site, fatigue, headache, myalgia, and chills.

Mumps Vaccine

Mumps is a viral illness that classically causes bilateral parotitis 16 to 18 days after exposure. Fever, headache, malaise, myalgia, and anorexia may precede the parotitis. Serious complications are rare but more common in adults.

The mumps vaccine is a lyophilized live-attenuated vaccine. The vaccine is available in combinations with measles, rubella (as MMR), and varicella (MMRV) vaccines.

The vaccine is administered as a 0.5-mL subcutaneous injection in the upper arm. Dosing recommendations coincide with those for measles vaccine, with the first dose administered at age 12 to 15 months and the second dose prior to the child's entry into elementary school. Two doses of mumps-containing vaccine are recommended for school-aged children, international travelers, students in post-high school educational institutions, and healthcare workers born after 1956.[8] A single dose of vaccine is acceptable documentation of immunity to mumps for other adults considered at lower risk of mumps infection, including adults born after 1956 and those with a reported history of wild virus infection. Mumps vaccine should not be given to

pregnant women or immunosuppressed patients.[1]

Serious adverse reactions to the vaccine are reported rarely. Fever, parotitis, rash, and lymphadenopathy occur rarely. Local reactions, including soreness, burning, and stinging, may occur at the injection site.[8]

Pertussis Vaccine

Pertussis is caused by a bacterial infection with *Bordetella pertussis*. The infection starts with signs and symptoms of an acute respiratory infection, called the catarrhal stage. The coughing spells manifest about a week later. Typically, young children will have the characteristic whoop as they struggle to inhale while coughing. Adolescents and adults are more likely to have prolonged periods of coughing. Pertussis can affect any age group, but young infants are at much higher risk for pneumonia, seizures, brain damage, and death. Their rate of hospitalization is much higher than for other age groups. The individual is contagious during the catarrhal stage and the first two weeks of the cough.[4,21]

Acellular pertussis vaccines contain components of the *B. pertussis* organism. All acellular vaccines contain pertussis toxin, and some contain one or more additional bacterial components (eg, filamentous hemagglutinin, pertactin [a 69-kDa outer membrane protein], and fimbriae types 2 and 3). Acellular pertussis vaccine is recommended for all doses of the pertussis schedule at 2, 4, 6, and 15 to 18 months of age. A fifth dose of pertussis vaccine is given to children 4 to 6 years of age.[13] Pertussis vaccine is administered in combination with diphtheria and tetanus (DTaP). Administration of an acellular pertussis-containing vaccine is also recommended for adolescents once between ages 11 and 18 years. In addition, they should receive a pertussis-containing vaccine with their next dose of Td toxoids.[13,21] Special attention is warranted for the immunization of individuals who have close contact with young infants. Tdap should be administered to women in their late second or third trimester of pregnancy. Tdap should also be administered to all close contacts, including household contacts and out of home care providers.[4]

Local administration site reactions are relatively common. Systemic reactions, such as moderate fever, occur in 3% to 5% of vaccinees. Very rarely, high fever, febrile seizures, persistent crying spells, and hypotonic hyporesponsive episodes occur following vaccination. Encephalopathy without known cause within 7 days of a pertussis vaccine are contraindications to future doses of this vaccine.[1]

Pneumococcal Vaccines

Streptococcus pneumoniae is a common pathogen with a range of manifestations, including asymptomatic upper respiratory tract colonization, sinusitis, acute otitis media, pharyngitis, pneumonia, meningitis, and bacteremia. Rates of invasive infections are highest in children younger than 2 years and in the elderly.[35,36] Invasive pneumococcal infections cause approximately 40,000 deaths annually. Most of the deaths occur in the elderly or in those with underlying medical conditions. Approximately half the deaths could be preventable by vaccine. Two pneumococcal vaccine preparations, PCV13 and 23-valent pneumococcal polysaccharide vaccine (PPV23) are available. The vaccines have different indications and are not interchangeable.

Pneumococcal Polysaccharide Vaccine

Pneumococcal polysaccharide vaccine (Pneumovax 23) is a mixture of highly purified capsular polysaccharides from 23 of the most prevalent or invasive types of *S. pneumoniae* seen in the United States. Serotypes included are 1, 2, 3, 4, 5, 6B, 7F, 8, 9N, 9V, 10A, 11A, 12F, 14, 15B, 17F, 18C, 19A, 19F, 20, 22F, 23F, and 33F. These 23 types represent 85% to 90% of all blood isolates and 85% of pneumococcal isolates from other generally sterile sites

e is administered IM or subcutaneously as a single 0.5-mL dose.

PPSV23 is recommended for the following individuals:[22]

1. Persons 65 years and older (if an individual received vaccine more than 5 years earlier and was younger than 65 years at the time of administration, revaccination should be given).
2. Persons aged 2 to 64 years with a chronic illness (congestive heart failure, cardiomyopathy, chronic pulmonary disease, diabetes, alcoholism, and liver disease).
3. Persons aged 2 to 64 years with functional or anatomic asplenia (when splenectomy is planned, PPSV23 should be given at least 2 weeks before surgery; a single revaccination is recommended at 5 years in subjects older than 10 years and at 3 years in subjects younger than 10 years).
4. Persons aged 19 to 64 years who smoke cigarettes or have asthma.
5. Persons with cochlear implants.

PPSV23 is recommended for immunocompromised persons 2 years and older with (a) HIV infection, (b) leukemia, (c) lymphoma, (d) Hodgkin disease, (e) multiple myeloma, (f) generalized malignancy, (g) chronic renal failure or nephrotic syndrome, (h) patients receiving immunosuppressive therapy including corticosteroids, and (i) organ and bone marrow transplant recipients. A single revaccination should be given if 5 years or more have passed since the first dose in subjects older than 10 years. In subjects 10 years of age and younger, revaccination should be given 3 years after the previous dose.

PPSV23 induces type-specific antibodies (T-cell-independent mechanisms) with a twofold rise within 2 to 3 weeks in 80% of young healthy adults. No correlation of antibody levels and protection has been determined. Antibody levels to these strains remain elevated for at least 5 years. In certain individuals, these levels decline within 10 years. Children may be protected for only 3 to 5 years. Elderly individuals and patients with chronic disease may have lower antibody levels produced with the vaccine. Children younger than 2 years do not respond adequately to the vaccine.

A number of other groups, including immunocompromised patients (eg, leukemia, lymphoma, and multiple myeloma), dialysis patients, and patients with acquired immune deficiency syndrome, have reduced antibody production with the vaccine. Asymptomatic HIV-infected patients respond sufficiently to the vaccine. Patients with Hodgkin disease respond to the vaccine better before splenectomy, chemotherapy, or radiation therapy.

PPSV23 vaccine efficacy has been debated in the literature. Study results generally point to a reduction in invasive pneumococcal disease in the general population and in the elderly. In immunosuppressed populations, the reduction in invasive disease is estimated at 50% to 80% with immunization.[37] Adults hospitalized with community-acquired pneumonia are significantly less likely to die if they have been immunized. In addition, immunized patients were less likely to have respiratory failure and had hospitalization stays that were shorter by 2 days.[38]

PPSV23 safety is well documented. Local reactions occur frequently within the first 48 hours and generally are mild. Local erythema and induration (30%), local discomfort (40%), and local swelling (3%) are the side effects observed most commonly. Revaccination has been associated with self-limited injection-site reactions more commonly than after the first dose. Severe systemic reactions occur rarely and consist of weakness, myalgia, headache, photophobia, chills, and fever.

Pneumococcal Conjugate Vaccine

s even more frequently in children younger than 2 years than in those

older than 65 years. The infection ranges goes from nasopharyngeal carriage to bacteremia and meningitis. Because of the lack of immune responsiveness in children younger than 2 years when exposed to polysaccharide vaccines, a conjugate vaccine was developed to protect young children from certain strains of *S. pneumoniae*. However, the 13-valent vaccine is also licensed for individuals aged 50 years and older. The 13 valent vaccine (Prevnar-13) contains the conjugated capsular polysaccharides of serotypes 1, 3, 4, 5, 6A, 6B, 7F, 9V, 14, 18C, 19A, 19F, and 23F. In clinical use, the vaccine is associated with a dramatic decline in invasive disease not only in immunized young children but also in individuals in all age groups.[23]

Immunization of Children

PCV13 is administered as a 0.5-mL IM injection at 2, 4, and 6 months of age and between 12 and 15 months of age. A single dose of PCV13 should be administered to children aged 6 to 18 years with sickle cell disease or splenic dysfunction, HIV infection, immunocompromising conditions, cochlear implant, or cerebral spinal fluid leak should be immunized. PPSV23 can be used in conjunction with PCV13. PPSV23 should be administered after age 2 years and at least 2 months after the last dose of PCV13.[24,25]

Immunization of Adults

The PCV13 offers some additional protection over PPSV23 alone in adult high-risk populations protection is at least as good as PPSV23. PCV13 is safe in these populations. Based on this information, the ACIP recommended PCV13 for adults with immunocompromising conditions and for those 65 years of age and older.[26,27] (**Table 125-2**). PCV13 should be administered prior to PPSV23 in adults who have not been immunized previously. PCV13 should be administered with at least a year interval in those adults for whom it has been recommended and have already received one or more doses of PPSV23.

TABLE 125-2 ACIP Recommendations for Use of PCV13 and PPSV23[40]

Vaccine naïve adults

- PCV13 first with PPSV23 administered at least 8 weeks later
- Second dose of PPSV23 at 5-year interval and PPSV23 at age 65 years and at least 5 years after last dose

PPSV23-immunized adults

- PCV13 at least 1 year after last dose of PPSV23
- Second dose of PPSV23 at 5 year interval and PPSV23 at age 65 years and at least 5 years after last dose

Indications for PCV13 for adults 19 years and older

- Functional or anatomic asplenia
- Immunocompromising conditions
    - Congenital or acquired immunodeficiencies
    - HIV infection
    - Chronic renal failure or nephrotic syndrome
    - Leukemias, lymphomas, Hodgkin's lymphoma

    - Generalized malignancy
    - Diseases requiring treatment with immunosuppressive drugs, including long-term systemic corticosteroids or radiation therapy
    - Solid organ transplantation
    - Multiple myeloma
- Cerebral spinal fluid leaks or cochlear implants

PCV13, 13-valent pneumococcal conjugate vaccine. PPSV23, 23-valent pneumococcal polysaccharide vaccine.

Poliovirus Vaccines

Poliomyelitis is a contagious viral infection that usually causes asymptomatic infection; however, in its serious form it causes acute flaccid paralysis. Poliovirus is spread via the fecal–oral route. The virus replicates in the upper respiratory tract, GI tract, and local lymphatics. The vast majority of polio infections are subclinical and asymptomatic. Polio has been eliminated from the United States since 1979, and the last case in Western Hemisphere was reported in 1991. Global eradication efforts are entering the final stages, and the eradication of polio should be accomplished in the next few years.

An inactivated trivalent vaccine developed by Jonas Salk was licensed for use in 1955. In 1987, an enhanced-potency inactivated polio vaccine (IPV) was introduced and has replaced the original inactivated vaccine. A live-attenuated oral polio vaccine (OPV) was developed by Albert Sabin in 1962. OPV was the primary immunizing agent for poliovirus infection. Widespread OPV use is responsible for the elimination of wild-type polio in most of the world. However, with no poliovirus circulation in the United States for years, IPV is the recommended vaccine for the primary series and booster dose for children.[28] OPV will continue to be used in areas of the world that have circulating poliovirus. The CDC maintains a stockpile of OPV to be used only in case of an outbreak.

The IPV series is administered routinely to children at ages 2, 4, and 6 to 18 months, and 4 to 6 years.[13] Primary poliomyelitis immunization is recommended for all children up to age 18 years. Primary immunization of adults over age 18 years is not recommended routinely because a high level of immunity already exists in this age group, and the risk of exposure in developed countries is exceedingly small. However, unimmunized adults who are at increased risk for exposure because of travel, residence, or occupation should receive IPV series. Incompletely immunized adults or children should complete the series of IPV regardless of the interval since initiation of primary immunization. Adults do not need a booster dose routinely unless they are at increased risk of exposure (travel), in which case a single dose of IPV can be given.[29]

No serious side effects are attributable to IPV. Pregnant women should be given IPV only if there is a clear need, such as women who will be traveling or living in an area with endemic or epidemic poliovirus.

Rabies Vaccine and Immunoglobulin

Rabies is a virtually universally fatal infection in humans. Although all mammals are susceptible to rabies, carnivorous mammals are reservoirs of the virus and responsible for persistence of the virus in nature. In the United States, most human cases of rabies are from exposure to rabid bats, but raccoons, foxes, skunks, and coyotes are also associated with possible exposure. Worldwide, canines are the primary vectors. Transmission of

rabies can occur via percutaneous, permucosal, or airborne exposure to the rabies virus. Circumstances favoring such transmission include animal bites and attacks and contamination of scratches, cuts, abrasions, and mucous membranes with saliva or other infectious material (brain tissue). Unprovoked attacks and daytime attacks by nocturnal animals are considered highly suspect. A few cases of person-to-person transmission have been reported.

Symptoms of rabies are nonspecific during the prodomal stage—fever, headache, malaise, irritability, nausea, and vomiting. The acute neurologic phase is characterized by hyperexcitability, hyperactivity, hallucinations, salivation, a fear of water, and air. A minority of patients present with limp paralysis. Patients die within 5 days of presentation with these neurologic symptoms.

Human diploid cell vaccine, and purified chick embryo cell rabies vaccine are killed vaccines used for preexposure and postexposure rabies virus prophylaxis. Preexposure indications for rabies vaccine include persons whose vocation or avocation place them at high risk for rabies exposure, such as veterinarians, animal handlers, laboratory workers in rabies research or diagnostic laboratories, cavers, wildlife officers where animal rabies is common, and anyone who handles bats. Travelers who will be in a country or area of a country where there is a constant threat of rabies, whose stay is likely to extend beyond 1 month, and who may not have readily available medical services (eg, Peace Corps workers and missionaries) should be considered for preexposure prophylaxis. Rabies immunization of immunocompromised individuals should be postponed until the immunosuppression has resolved, or activities should be modified to minimize the potential exposure to rabies. If the vaccine is used in immunocompromised persons, antibody titers should be checked postimmunization. Pregnancy is not a contraindication if the risk of rabies is great. Both vaccine preparations can be administered for preexposure prophylaxis as a three-dose series of 1 mL IM on days 0 and 7 and once between days 21 and 28.[30] Individuals with ongoing risk of exposure—either continuous risk (eg, research laboratory staff or those involved in rabies biologics production) or individuals with frequent exposures (eg, those involved with rabies diagnosis, spelunkers, veterinarians, animal control workers, and wildlife workers in rabies-enzootic areas)—should undergo serologic testing every 6 months and 2 years, respectively, to monitor rabies antibody concentrations. A booster dose is recommended if the complete virus neutralization is less than 1:5 serum dilution by the rapid fluorescent focus inhibition test.

Preexposure prophylaxis does not eliminate the need for postexposure therapy. Persons previously immunized with rabies vaccine or those who previously received postexposure prophylaxis should receive two 1-mL IM doses of rabies vaccine on postexposure days 0 and 3.[31] Rabies Ig should not be given to this group.

Postexposure prophylaxis should be given after percutaneous or permucosal exposure to saliva or other infectious material from a high-risk source. Each case must be considered individually. Consideration needs to be given to the geographic area, species of animal, circumstances of the incident, and type of exposure. Local or state health departments should be contacted for assistance. Thorough cleansing of the wound with soap and water followed by irrigation with a virucidal agent such as povidone–iodine solution is an extremely important part of the management of rabies-prone wounds. Individuals who have not been immunized previously should receive the recommended regimen of rabies Ig (see Rabies Immunoglobulin below) and four doses of rabies vaccine 1 mL IM on days 0, 3, 7, and 14 after exposure. However, a fifth dose in a series should be considered if the exposed individual is immunocompromised. Vaccine response for these immunocompromised individuals should be checked.[31] Rabies vaccine must be administered in the deltoid muscle in adults and in the anterolateral thigh in children. The gluteal region should not be used.[1,31]

Adverse reactions to rabies biologicals are less common and less serious with the currently available vaccines compared with previously used preparations. Local or mild systemic symptoms can typically be managed with anti-inflammatory medications or antihistamines. Systemic allergic reactions ranging from hives to anaphylaxis

occur in a very small number of subjects. Given the lack of alternative therapy and the fact that rabies infection is almost always fatal, persons exposed to rabies who do have adverse reactions should continue the vaccine series in a setting with medical support services.[30]

Human rabies Ig is used in conjunction with rabies vaccine as part of postexposure rabies management for previously unvaccinated individuals. The product is derived from plasma obtained from donors who have been hyperimmunized with rabies vaccine and have high titers of circulating antibody.

In persons who previously have not been immunized against rabies, rabies Ig is given simultaneously with rabies vaccine to provide optimal coverage in the interval before immune response to the vaccine occurs. The efficacy of this regimen has been clearly demonstrated as it provides virtually complete protection from rabies when administered with the vaccine series promptly following exposure.[31] Rabies Ig does not interfere with vaccine-induced antibody formation. Its use is not recommended beyond 8 days after initiation of the vaccine series nor in persons previously immunized to rabies.

Human rabies Ig is administered in a dose of 20 international units/kg (0.133 mL/kg). If anatomically feasible, the entire dose should be infiltrated around the wound(s). Any remaining volume should be administered IM at a site distant from the rabies vaccination site. This product should never be administered by the IV route. Because other antibodies in the rabies Ig may interfere with the response to live-virus vaccines (MMR and varicella), it is recommended that these immunizations be delayed for 3 months.[1]

Side effects are rare but may include local soreness at the wound or IM injection site and mild temperature elevations. Caution is advised when administering the product to persons with known systemic allergies to Ig or thimerosal. Pregnancy is not a contraindication to its use.

Rubella Vaccine

Rubella (German measles) is characterized by an erythematous rash, lymphadenopathy, arthralgia, and low-grade fever. The most important consequence of rubella infection occurs during pregnancy, particularly during the first trimester. Congenital rubella syndrome is associated with auditory, ophthalmic, cardiac, and neurologic defects. Rubella infection during pregnancy can also result in miscarriage or stillbirth. The primary goal of rubella immunization is to prevent congenital rubella syndrome. Rubella is no longer endemic in the United States, but high immunization rates are necessary to prevent rubella outbreaks from imported cases.[8]

Rubella vaccine contains lyophilized live-attenuated rubella virus grown in human diploid cell culture. The vaccine is available in combinations with measles and mumps (as MMR), or varicella (MMRV) vaccines.

Rubella vaccine induces antibodies that are protective against wild-virus infection. The duration of immunity has not been established. A second dose is recommended, however, at the same time measles vaccine is administered (as a second dose of MMR). The vaccine is indicated for children older than 1 year of age. Individuals born before 1957 are assumed to be immune to rubella except for females who could become pregnant. Therefore, all females of childbearing potential should have documentation of receiving at least one dose of a rubella-containing vaccine or laboratory evidence of immunity.[8] The vaccine should not be given to immunosuppressed individuals, although MMR vaccine should be administered to individuals with HIV infection without evidence of immunity (see Measles).[8] The vaccine should not be given to individuals who have experienced anaphylactic reactions to neomycin.

Adverse effects of the rubella virus vaccine tend to increase with the age of the recipient. Mild symptoms are similar to wild-virus infection and include lymphadenopathy, rash, urticaria, fever, malaise, sore throat, [redacted] of the extremities. These symptoms occur 7 to 12 days after vaccination

and last 1 to 5 days. Joint symptoms occur more often in susceptible postpubertal females. Arthralgia occurs in 25% of vaccinees, and 10% have arthritis-like symptoms. These symptoms usually begin 1 to 3 weeks after vaccination, persist for 1 day to 3 weeks, and rarely recur.[8] The vaccine may cause suppression of tuberculin skin tests for up to 6 weeks after vaccination.

The rubella vaccine has never been associated with congenital rubella syndrome, but its use during pregnancy is contraindicated. However, routine pregnancy testing prior to vaccination is not recommended. Females should be counseled not to become pregnant for 4 weeks following vaccination.[8] Termination of pregnancy is not indicated in women who are accidentally given the vaccine or who become pregnant during the month after vaccination.

Tetanus Toxoid Adsorbed and Tetanus Immunoglobulin

Tetanus is a severe acute illness caused by the exotoxin of *Clostridium tetani*. Tetanus is the only vaccine-preventable disease that is not contagious as it is acquired from the environment. Tetanus toxin interferes with neurotransmitters that promote muscle relaxation, leading to continuous muscle spasms that are characteristic of tetanus. Death can be due to the tetanus toxin itself or secondary to a complication such as aspiration pneumonia, dysregulation of the autonomic nervous system, or pulmonary embolism.

Tetanus toxoid adsorbed (adsorbed onto aluminum hydroxide, phosphate, or potassium sulfate to increase antigenicity) is a sterile suspension of the toxoid derived from *C. tetani*. A series of three 0.5-mL doses of tetanus toxoid elicits protection in virtually all individuals. Primary vaccination provides protection for at least 10 years.[21] Additional doses of tetanus toxoid (combined with diphtheria toxoid, ie, Td) are recommended as part of wound management if a patient has not received a dose of tetanus toxoid within the preceding 5 years. For minor or clean wounds, no dose is given. **Table 125-3** summarizes these recommendations. Tetanus Ig should be given to individuals who have received fewer than three doses of tetanus toxoid and have more serious wounds. It can be administered with tetanus toxoid, provided that separate syringes and separate injection sites are used.

TABLE 125-3 Tetanus Prophylaxis[20]

Vaccination History	Clean, Minor		All Other	
	Td[a]	TIG	Td[a]	TIG
Unknown or fewer than three doses	Yes	No	Yes	Yes
Three or more doses	No[a,b]	No	No[a,c]	No

[a]A single dose of Tdap should be used for the next dose of tetanus-diphtheria toxoid for individuals aged >10 years.

[b]Yes, if more than 10 years since last dose.

[c]Yes, if more than 5 years since last dose.

In children, primary immunization against tetanus usually is offered in conjunction with diphtheria and pertussis vaccination (using DTaP or a combination vaccine that includes other antigens used to decrease the number of injections to complete the childhood immunization schedule). A 0.5-mL dose is recommended at age 2, 4, 6, and 15 to 18 months.[13] In children 7 years and older and in adults who have not been immunized previously, a series of three 0.5-mL doses of a tetanus toxoid-containing vaccine is administered IM initially. The first two doses are given 1 to 2 months apart, and the third dose is recommended at 6 to 12 months after the second dose. Boosters are recommended every 10 years, and unless there is contraindication to diphtheria toxoid, Td

should be used. Tetanus toxoid can be given simultaneously with other killed and live vaccines, and, if indicated, it can be given to immunosuppressed patients.[21]

Adverse reactions to tetanus toxoid include mild-to-moderate local reactions at the injection site, such as warmth, erythema, and induration. Occasionally, a nodule at the injection site develops and remains for a few weeks. This type of reaction is indicative of high preexisting antibody concentrations, and additional doses of toxoid should not be given any sooner than 10 years. Local reactions do not limit the use of the toxoid for further dosing.[21]

Tetanus Ig is a sterile, concentrated, nonpyrogenic solution of Igs prepared from hyperimmunized humans. It is used to provide passive immunity to tetanus after the occurrence of traumatic wounds in nonimmunized or suboptimally immunized persons (see Table 125-3).[32] A dose of 250 to 500 units IM should be administered. When administered with tetanus toxoid, separate sites for administration should be used. Tetanus Ig also is used for treatment of tetanus. In this setting, a single dose of 3,000 to 6,000 units IM is administered.

Adverse effects of tetanus Ig include pain, tenderness, erythema, and muscle stiffness at the injection site, which may persist for several hours. Systemic reactions occur rarely. IV administration has been associated with severe adverse reactions and is not recommended.

Varicella and Zoster Vaccines

Varicella is a highly contagious disease caused by varicella-zoster virus. The clinical illness is characterized by the appearance of successive waves of pruritic vesicles that rapidly crust over. Malaise and fever are common and last for 2 to 3 days. The virus remains dormant in the dorsal ganglia and reactivates as herpes zoster, also known as *shingles*. Although the exact stimulus for reactivation is unknown, a decrease in varicella-specific cell-mediated immunity associated with age or immunosuppression appears to be necessary but not sufficient for reactivation.

Varicella Vaccine

Live-attenuated varicella vaccine contains the Oka/Merck strain of varicella virus, which was attenuated by propagation through several different cell culture lines. Varicella vaccine is a lyophilized product that must be kept frozen and protected from light. Once reconstituted, it must be administered subcutaneously within 30 minutes. Each 0.5-mL dose contains a minimum of 1,350 plaque-forming units of virus as well as 12.5 mg of hydrolyzed gelatin and trace amounts of neomycin, fetal bovine serum, and residual components from cell culture.[33]

The varicella vaccine is safe and immunogenic in healthy children and adults. In clinical studies, varicella vaccine has been 70% to more than 95% effective in preventing chickenpox. Vaccinated individuals who develop chickenpox typically experience milder disease, often with low or no fever and fewer skin lesions, many of which do not vesiculate.[33]

The varicella vaccine is recommended for all children at 12 to 18 months of age, with a second dose prior to entering school between ages 4 and 6 years.[13] A second dose is also recommended for individuals older than this age if they have not already had chickenpox. Varicella vaccine can be used for postexposure prophylaxis. The vaccine is effective in the prevention or modification of varicella infection when given within 3 days and possibly 5 days of exposure. Because the varicella vaccine is a live vaccine, it is contraindicated in pregnant women and in immunocompromised individuals. An exception is children with asymptomatic or mildly symptomatic HIV infection, who should receive two doses of varicella vaccine 3 months apart. In addition,

children with humoral immune deficiencies may be immunized. Varicella vaccination is contraindicated in individuals with a history of anaphylactic reaction to any component of the vaccine. Persons who have received blood, plasma, or Ig products in the recent past should not receive varicella vaccine because of concern that passively acquired antibody will interfere with response to the vaccine. The recommended time interval between antibody-containing products and varicella vaccine depends on the dose of Ig (see Table 125-1).[1] Although no adverse events associated with salicylate use after vaccination have been reported, salicylates should be avoided for 6 weeks after vaccination because of the association of salicylate use and Reye syndrome following varicella infection.[33]

The varicella vaccine has an excellent safety record. Pain, local swelling, and erythema at the injection site occur in up to 32% of patients and fever in 10% to 15%. A varicella-like rash occurs in approximately 4% of vaccinees, accompanied by few, if any, systemic symptoms. The rash may be localized at the injection site or generalized. Lesions usually are few in number (2 to 10) and often papular rather than vesicular. Transmission of vaccine virus to susceptible close contacts has occurred but is rare and believed to occur only when the vaccinee develops a rash. Because the risk of vaccine virus transmission is very low and primary infection can be very severe, vaccination of household contacts of immunocompromised patients is recommended to prevent introduction of varicella into the household.[33]

Zoster Vaccine

After the primary infection with varicella-zoster virus manifested as chicken pox, the virus remains latent in the dorsal ganglia. Herpes zoster, more commonly known as *shingles*, occurs upon reactivation of varicella-zoster virus replication. Herpes zoster can occur at any age, but the incidence dramatically increases with increasing age. The rate of disease increases sharply after age 50 years. The disease rate in individuals older than 80 years of age is 15 cases per 1,000 person-years.[34] Patients with HIV, cancer, or other conditions associated with immunosuppression are at increased risk for disease.[35] The development of the disease is associated with declining cellular immunity to varicella-zoster virus.

The clinical presentation of herpes zoster usually is a vesicular eruption limited to one dermatome. The most common complication is postherpetic neuralgia, which is pain that persists after the skin lesions have healed. Postherpetic neuralgia can persist for weeks to years. The risk of postherpetic neuralgia increases dramatically with age. Virtually no risk of developing postherpetic neuralgia with herpes zoster exists prior to age 50 years, but the risk increases to 50% to 75% after ages 60 and 75 years, respectively. The pain can be so severe as to limit activities of daily living and quality of life.[7]

The zoster vaccine contains 19,000 plaque-forming units of Oka/Merck strain live varicella-zoster virus. Although the same strain of vaccine virus is contained in the childhood varicella vaccines, the doses of vaccine virus are dramatically different, and the vaccines are *not* interchangeable. Zoster vaccine reduces the burden of disease by 60%. The burden of disease is a composite measure considering incidence, severity, and duration of herpes zoster. The incidence of zoster is cut in half and the development of postherpetic neuralgia can be decreased by 67%.[36] The duration of protection from the vaccine is about 8 years for prevention of zoster and about 10 years for decrease in burden of disease which includes incidence, severity, and complications of zoster.[37]

The zoster vaccine is licensed for individuals 50 years of age and older. However, the ACIP recommends the zoster vaccine for routine use in individuals aged 60 years and older. This live vaccine should not be used in immunocompromised individuals, including those on high-dose corticosteroids or with HIV (CD4 cell count less than 200/mm^3) [less than 0.200 × 10^9/L] or malignancies.[7] Immunization of some special populations can be done (see **Table 125-4**).

TABLE 125-4 Zoster Vaccine Use in Special Populations[7]

- Immunize patients with a history of shingles
- Screening patients for a history of chickenpox is not necessary. Assume anyone born before 1980 is immune to varicella[47]
- Zoster vaccine may be administered to individuals on inhaled, topical or intraarticular steroids or low dose oral steroids
- Zoster vaccine may be administered to individuals treated with low-dose methotrexate (less than 0.4 mg/kg/wk) or mercaptopurine (less than 1.5 mg/kg/day). These therapies are often used for autoimmune diseases
- The vaccine may be administered to individuals anticipating immunosuppressive therapy. The minimum duration between immunization and initiation of immunosuppressive therapy is 14 days, and some clinicians recommend 1 month
- Stop antiviral therapy at least 24 hours before immunization and restart it at least 14 days after immunization
- Zoster vaccine can be administered without regard to blood product or immunoglobulin administration
- Do not administer zoster vaccine to
    - Individuals with AIDS or clinical manifestations of HIV, such as a $CD4^+$ count less than 200 per mm^3
    - Patients on high doses of steroids (prednisone or its equivalent of 20 mg daily or more for more than 2 weeks)
- Risks and benefits of administering zoster vaccine to individuals on immune modulators, such as tumor necrosis factor agents, must be determined on a case-by-case basis. Immunize prior to initiating therapy if possible

Varicella-Zoster Immunoglobulin

Varicella-zoster Ig is used after exposure to varicella for passive immunization of susceptible immunodeficient patients or other susceptible individuals at particularly high risk for complications of varicella infection. Postexposure prophylaxis with varicella-zoster Ig is indicated for the following susceptible individuals: (a) immunocompromised patients without evidence of immunity, (b) neonates whose mothers develop varicella within 5 days before or 2 days after delivery, (c) hospitalized premature infants (more than 28 weeks of gestation) whose mothers have no evidence of immunity (d) hospitalized preterm infants (less than 28 weeks' gestation or weight less than 1,000 g), and (e) susceptible pregnant women.[38] If varicella is prevented, vaccination should be offered at a later date. Exposure to varicella is defined as direct indoor contact for more than 1 hour with an infectious person. A negative history of clinical disease is not a reliable indicator of varicella susceptibility. Most people with a negative clinical history will have detectable antibody on laboratory testing. Caution is warranted when interpreting a low-positive result in an immunosuppressed patient who has received blood products or Ig because the circulating antibody may be acquired passively.

For maximum effectiveness, varicella-zoster Ig must be given as soon as possible and not more than 10 days

following exposure.[38] Because this agent may only attenuate infection, patients who receive varicella-zoster Ig still may have a period of communicability, and varicella-zoster Ig may prolong the incubation period to 28 days. Antiviral therapy can be initiated if signs and symptoms of varicella infection become apparent.

Administration of varicella-zoster Ig is by the IM route at doses of 125 plaque-forming units per 10 kg of body weight up to 625 units (five vials) for patients weighing more than 40 kg. The dose for newborn infants is 125 units.[38]

OTHER IMMUNOBIOLOGICS

Immunoglobulin

Ig is available as both an intramuscular immunoglobulin (IMIG) and an IV immunoglobulin (IVIG) preparation. The IMIG preparation, or the Cohn fraction II, is prepared from pooled plasma of several thousand donors by cold ethanol fractionation. It typically contains greater than 95% IgG and trace amounts of IgM, IgA, and other plasma proteins. Because Ig is harvested from a large donor pool, it contains a wide spectrum of IgG antibodies to the pathogens prevalent in the area from which the donors were obtained. In the fractionation process, high-molecular-weight IgG aggregates are formed, which can activate complement in the absence of antigen and precipitate anaphylactoid reactions. For this reason, IMIG is unsuitable for IV administration. IMIG typically contains 15% to 18% protein and not less than 90% IgG. A number of IVIG preparations are available commercially in the United States. Generally, these preparations contain greater than 90% IgG monomers and trace to small amounts of IgA. These products are available as lyophilized powders or solutions.

When administered either IV or IM, Ig distributes in approximately 5% of the body weight of the recipient. The plasma half-life of Ig ranges from 18 to 32 days. This range of half-life probably is attributable to the variation in the half-life of IgG subclasses. Peak serum concentrations occur immediately with IVIG but within 2 days with IMIG. After the initial period of equilibration, circulating IgG levels are superimposable between IV and IM equivalent dosages. No dosage adjustment is necessary in patients with renal insufficiency, hepatic insufficiency, or both, dialysis patients, or geriatric patients.

6 Ig is indicated in a wide variety of circumstances to provide passive immunity to individuals. The indications for IMIG differ from those for IVIG. IMIG is indicated for providing passive immunity in patients with hepatitis A infections in those less than 1 year and older than 39 years, hepatitis B exposures (however, hepatitis B Ig is significantly more effective), measles, varicella, and primary immunodeficiency diseases. Although IMIG is indicated for the treatment of primary immunodeficiency, IVIG is better tolerated and is more effective. IMIG is not indicated for prevention of rubella, mumps, or poliomyelitis. **Table 125-5** lists the suggested dosages of IMIG for prevention or attenuation of various infectious diseases.

TABLE 125-5 Indications and Dosage of Intramuscular Immunoglobulin in Infectious Diseases

Primary immunodeficiency states	1.2 mL/kg IM then 0.6 mL/kg every 2-4 weeks
Hepatitis A exposure	0.02 mL/kg IM within 2 weeks if <1 year or >39 years of age
Hepatitis A prophylaxis	0.02 mL/kg IM for exposure <3 months' duration
	0.06 mL/kg IM for exposure up to 5 months' duration
Hepatitis B exposure	0.06 mL/kg (HBIG preferred in known exposures)
Measles exposure	0.25 mL/kg (maximum dose 15 mL) as soon as possible

	0.5 mL/kg (maximum dose 15 mL) as soon as possible for immunocompromised individuals

There are many licensed indications, as well as off-label uses, for IVIG.[39] The therapeutic dose of IVIG is set empirically at 2 g/kg, often given as five daily doses of 400 mg/kg each.[40] Mechanisms of IVIG action for treatment of these conditions have been hypothesized.[41]

1. *Primary Immunodeficiency States.*[42] In primary immunodeficiency states, monthly doses of between 100 and 800 mg/kg are administered; the average dose is 200 to 400 mg/kg. The immunodeficiency states for which IVIG is indicated include both antibody deficiencies and combined immune deficiencies. Significant reactions can occur in patients with low intrinsic levels of IgA given IVIG with greater amounts of IgA. An IVIG product with very low amounts of IgA should be used for these patients.

2. *Immune Thrombocytopenia.*[43] For the treatment of hemorrhage associated with immune thrombocytopenia (ITP), doses of 1 g/kg daily for 2 to 3 days plus high-dose methylprednisolone are indicated. Adults tend to respond less well to IVIG than do children. IVIG is acceptable for treatment of both chronic and acute ITP, and IVIG has been used for ITP associated with pregnancy without adverse effects on the fetus. Corticosteroids remain the drugs of choice for adult ITP. In thrombotic thrombocytopenia purpura, IVIG is reported to be effective in patients who do not respond to plasmapheresis. Other platelet disorders in which IVIG may be useful include neonatal immune thrombocytopenia, perinatal autoimmune thrombocytopenia, drug-induced thrombocytopenia, thrombocytopenia secondary to infection, and transfusion-refractory thrombocytopenia; however, the data supporting these uses are minimal.

3. *Chronic Lymphocytic Leukemia.* IVIG is used as a prophylactic measure in patients with chronic lymphocytic leukemia who have had a serious bacterial infection. Doses of 400 mg/kg every 3 to 4 weeks are used.

4. *Kawasaki Disease.*[44] This disease, which generally occurs in children, carries the hallmark of development of coronary artery abnormalities. Generally, the American Academy of Pediatrics recommends that if the strict criteria for Kawasaki disease are met, an IVIG dose of 400 mg/kg/day for 4 consecutive days be used or, preferably, 2 g/kg as a single dose. The dose should be administered within 10 days of disease onset. Aspirin therapy also should be initiated.

5. *Pediatric HIV infection.*[45] IVIG prevents serious bacterial infections in children with HIV infection. However, in the era of highly active anti-retroviral therapy, its use has waned.

6. *Allogeneic bone marrow transplantation.*[41]

7. *Chronic inflammatory demyelinating polyneuropathy.*[46] This disabling neuropathy often responds to corticosteroids, IVIG, or plasmapheresis.

8. *Multifocal motor neuropathy*[47] IVIG is considered first line therapy.

9. *Kidney transplantation involving a recipient with high antibody concentrations or an ABO-incompatible donor.*[48] Some transplant recipients have antibody concentrations that present an immunological barrier to transplantation. Desensitization can be accomplished using IVIG.

Many other proposed uses of IVIG have been identified. It is important to note that these uses are off-label but may be generally accepted in the medical community for routine treatment.[39,41]

7 Adverse effects of Ig vary with the route of administration. Following IMIG, pain, tenderness, and muscle stiffness persisting for hours or days are common. Repeat courses may cause sensitization with resulting allergic reactions. Chills, fever, nausea, and vomiting often are related to the rate of the infusion.[49] Infusion should be given at a rate of 0.01 to 0.02 mL/kg/min for 30 minutes. If no reactions occur, then the rate can be increased to 0.02 to 0.04 mL/kg/min. If reactions do occur, the infusion should be stopped for 30 minutes and restarted at a lower rate. Although recommendations for infusion rate vary slightly depending on the preparation, the guidelines presented can be followed for the various IV preparations.

Most adverse reactions are mild and transient. Arthralgia, myalgia, fever, pruritus, nausea, vomiting, chest tightness, palpitations, diaphoresis, dizziness, pallor, and respiratory distress have been reported. Rarely, aseptic meningitis has occurred from a few hours to 2 days after high-dose infusion. The syndrome resolves within days without sequelae. Acute renal failure has been reported, primarily in individuals with underlying renal dysfunction, diabetes, sepsis, volume depletion, or other nephrotoxic drugs or in patients older than 65 years. To minimize the risk, ensure adequate hydration prior to infusion and choose an IVIG product that does not contain high sucrose concentrations for individuals at high risk.[49]

Ig products are derived from human blood. Precautions such as donor screening and fractionation procedures and solvent–detergent treatment during the manufacturing process render the IVIG products free of HIV and hepatitis B and C viruses. Although no manufacturing process can guarantee no viral contamination, the potential infection risk from Ig preparations is very small.

Rh_o(D) Immunoglobulin

Second only to the ABO blood group system, Rhesus antigen D [Rh_o(D)] is an important antigen in human blood. The Rh_o(D) locus encodes this antigen, but this locus is absent in approximately 15% of the population. 8 Individuals lacking the Rh_o(D) locus are Rh_o(D) negative and have the potential to mount an antibody response to erythrocytes with the Rh_o(D) present. Rh_o(D) incompatibility during pregnancy can lead to sensitization of the mother. The maternal antibodies developed following normal fetal leakage of erythrocytes to the mother can cause hemolytic disease of the newborn during subsequent pregnancies.

Rh_o(D) Ig is a sterile solution of Igs prepared from human sera with high titers of Rh_o(D) antibody. Rh_o(D) Ig suppresses the antibody response and formation of anti-Rh_o(D) in Rh_o(D)-negative women exposed to Rh_o(D)-positive blood. Administration of Rh_o(D) Ig prevents hemolytic disease of the newborn in subsequent pregnancies with a Rh_o(D)-positive fetus. When administered within 72 hours of delivery of a full-term infant, Rh_o(D) Ig reduces active antibody formation from 1% to about 0.2%.[50] The reduction in antibody formation is lower when Rh_o(D) Ig is given beyond 72 hours postpartum. Smaller doses of Rh_o(D) Ig are used after abortion, miscarriage, amniocentesis, or abdominal trauma. In addition, Rh_o(D) Ig is used in the case of a premenopausal woman who is Rh_o(D) negative and has inadvertently received Rh_o(D)-positive blood or blood products.[50]

The dosage of Rh_o(D) Ig varies with the indication. A standard dose of 300 mcg is given within 72 hours of a term delivery. Occasionally, when the fetus is known to be Rh_o(D) positive, a 300-mcg dose is given at 28 weeks' gestation and within 72 hours after delivery. For postpregnancy termination occurring up to 13 weeks' gestation, one microdose (50 mcg) vial is given within 72 hours. For pregnancy termination after 13 weeks, one standard dose (300 mcg) is given within 72 hours. In other circumstances, such as in abdominal trauma, amniocentesis, or transfusion accidents, the dosage (number of standard dose vials) is based on the estimated packed red blood cell volume of fetal/maternal hemorrhage divided by 15. Rh_o(D) Ig is administered IM only.

When considering use of Rh_o(D) Ig use, the mother's Rh_o(D) antigen status must be known with certainty. Rh_o(D) Ig should not be given to individuals positive for this antigen or to those with anti-Rh_o(D) antibodies. Occasionally, a large fetal bleed of Rh_o(D)-positive blood may make cross-matching of the mother difficult. In these cases, Rh_o(D) Ig should be given only if previous tests have shown that the mother is Rh_o(D) negative with no anti-Rh_o(D) antibody.

Adverse reactions to Rh_o(D) Ig include injection-site tenderness and fever. Rh_o(D) does not interfere with response to rubella vaccine. Rubella-seronegative women should be immunized at hospital discharge even if they received Rh_o(D) Ig postpartum.

VACCINE INFORMATION RESOURCES

The field of vaccinology is developing even more rapidly, with numerous changes in recommendations for vaccine use made each year. Keeping up to date with the current recommendations can be a challenge. The childhood, adolescent, and adult immunization schedules are updated frequently and published annually. Recommendations for the use of influenza vaccine are issued annually. Healthcare providers involved in primary care and immunization delivery must keep themselves abreast of these changes in a systematic way. Reading electronic newsletters and browsing reliable Websites are efficient methods for obtaining information (**Table 125-6**). Although several excellent, reliable, and timely Websites exist, hundreds of sites with misleading and incorrect information also exist. Many of these sites are targeted at parents.

Although the medical community has moved past the controversy, the public still has questions regarding the possible connection between vaccine exposure and autism. The only study to demonstrate a link between vaccines and autism was a series of case reports published in 1998 that has since been withdrawn, and its lead author has been accused of fraud.[51] None of ten studies that have been conducted have found a connection between vaccine exposure and the development of autism.[52] The Vaccine Education Center at the Children's Hospital of Philadelphia has several documents for parents who have questions about vaccine safety. *http://www.chop.edu/centers-programs/vaccine-education-center/vaccine-safety/are-vaccines-safe#.VhHMbyta0rI* The CDC is another source of information for parents. *http://www.cdc.gov/vaccines/vac-gen/safety/*.

PERSONALIZED PHARMACOTHERAPY

Immunization programs are an important part of public health for all people. Therefore, immunization schedules are used across the population with little consideration of individual variability. Recommendations for some vaccines are based on risks, occupation, lifestyle, or age.

However, pharmacogenomics can be used to predict which individuals may be likely to have a vigorous or poor response to a vaccine. Some apparently healthy individuals fail to mount an immune response to a particular vaccine.[53] The consequence of these research findings are not yet ready to be used in clinical care of patients. As the field matures, these polymorphisms may be considered for vaccine design, immunization scheduling or vaccine safety.

Vaccines are the only class of medications to which nearly every patient is exposed. Knowledge of these agents is critical to providing pharmaceutical care. Dramatic progress in public health has been made through the appropriate use of immunization. Additional improvements in quality of life and mortality can be made through continued increases in vaccination coverage with careful attention to this aspect of care by all healthcare providers.

Chapter 126: Human Immunodeficiency Virus Infection

Peter L. Anderson; Thomas N. Kakuda; Courtney V. Fletcher

INTRODUCTION

KEY CONCEPTS

- 1 Infection with human immunodeficiency virus (HIV) occurs through three primary routes: sexual, parenteral, and perinatal. Sexual intercourse, primarily receptive anal and vaginal intercourse, is the most common method for transmission.
- 2 HIV infects cells expressing cluster of differentiation 4 (CD4) receptors, such as T-helper lymphocytes, monocytes, macrophages, dendritic cells, and brain microglia. Infection occurs via an interaction between glycoprotein 160 (gp160) on HIV with CD4 (primary interaction) and chemokine coreceptors (secondary interactions) present on the surfaces of these cells.
- 3 The hallmark of untreated HIV infection is profound CD4 T-lymphocyte depletion and severe immunosuppression that puts patients at significant risk for infectious diseases caused by opportunistic pathogens. Opportunistic infections (OIs) in settings without access to antiretroviral drugs are the chief cause of morbidity and mortality associated with HIV infection.
- 4 The current goal of combination antiretroviral therapy (ART) is to achieve maximal and durable suppression of HIV replication, taken to be a level of HIV-RNA in plasma (viral load) less than the lower limit of quantitation. Another equally important outcome is an increase in CD4 lymphocytes because this closely correlates with the risk for developing OIs.
- 5 General principles for the management of OIs include preventing or reversing immunosuppression with ART, preventing exposure to pathogens, vaccination, prospective immunologic monitoring, primary chemoprophylaxis, treatment of acute episodes, secondary chemoprophylaxis, and discontinuation of such prophylaxes following ART and subsequent immune recovery.
- 6 Clinical use of antiretroviral agents is complicated by drug–drug interactions. Some

interactions are beneficial and used purposely; others may be harmful, leading to dangerously elevated or inadequate drug concentrations. For these reasons, clinicians involved in the pharmacotherapy of HIV infection must exercise constant vigilance and maintain a current knowledge of drug interactions.

- 7 Recommendations for the initial treatment of HIV advocate a minimum of three active antiretroviral agents from at least two drug classes. The typical regimen consists of two nucleoside/nucleotide analogs with either a protease inhibitor (PI; pharmacokinetically enhanced by coadministration with a CYP3A inhibitor) or an integrase strand transfer inhibitor (InSTI).

- 8 Inadequate suppression of viral replication allows HIV to select for antiretroviral-resistant HIV variants, a major factor limiting the ability of antiretroviral drugs to inhibit virus replication. Recommendations for treating drug-resistant HIV include choosing at least two drugs (preferably three) to which the patient's virus is susceptible. Susceptibility can be assessed using either genotypic or phenotypic resistance testing.

- 9 The reduction of viral load with ART lowers the risk of transmission to others. Additionally, prophylaxis with antiretroviral agents in at-risk persons lowers HIV acquisition risk.

- 10 The longer life span conferred by ART has given rise to other medical issues. A wide spectrum of complications associated with older age have become common, some of which overlap with adverse effects from antiretroviral drugs. Medical management of these contemporary HIV complications is constantly evolving.

Acquired immunodeficiency syndrome (AIDS) was first recognized in a cohort of young, previously healthy homosexual men with new-onset profound immunologic deficits, *Pneumocystis carinii* (now *P. jirovecii*) pneumonia (PCP), and/or Kaposi's sarcoma. A retrovirus, human immunodeficiency virus type 1 (HIV-1), is the major cause of AIDS. A second retrovirus, HIV-2, also is recognized to cause AIDS, although it is less virulent, transmissible, and prevalent than HIV-1. These retroviruses are transmitted primarily by sexual contact and by contact with infected blood or blood products. Several risk behaviors for the acquisition of HIV infection have been identified in the United States, most notably the practice of anorectal intercourse and the sharing of blood-contaminated needles by injection-drug users. In many resource-limited countries, the majority of HIV transmission occurs via heterosexual intercourse and from childbearing women to their offspring. Initially, the medical management of HIV consisted of repeated treatments for opportunistic infections (OIs) and eventual palliative care. In the mid-1990s, a new era in the pharmacotherapy for HIV, known as *combination antiretroviral therapy* (ART), was born. ART consists of combinations of antiretroviral agents with different mechanisms of action that potently and durably suppress HIV replication, delay the onset of AIDS, reverse HIV-associated immunologic deficits, reduce HIV transmissions, and significantly prolong survival. Despite the effectiveness of ART, established HIV infection cannot be cured due in part to the integration of the HIV genome into host cells, creating a latent reservoir. Modern antiretroviral drugs and ART regimens have improved upon tolerability and efficacy. Nevertheless, therapeutic challenges remain in the ART era and include the need for continuous adherence to

medication and care, drug–drug interactions, drug-resistant HIV, acute and long-term drug toxicities, and other complications associated with a prolonged life span. Despite progress in the treatment access for this disease, large numbers of HIV-infected persons remain outside of care, nationally and globally. Significant efforts to develop an HIV vaccine have not been fruitful, but prophylactic use of antiretroviral drugs effectively prevents HIV infection in persons exposed to the virus.

EPIDEMIOLOGY

The epidemiologic characteristics of HIV infection differ according to geographic region and depend upon the mode of transmission, governmental prevention efforts and resources, and cultural factors.[1, 2]

1 Infection with HIV occurs through three primary modes: sexual, parenteral, and perinatal. Sexual intercourse, primarily anal and vaginal intercourse, is the most common method for transmission. The probability of HIV transmission depends upon the type of sexual exposure. The highest risk appears to be from receptive anorectal intercourse at about 1.4 transmissions per 100 sexual acts.[3] Transmission risk is lower for receptive vaginal intercourse, and insertive sex acts have lower risk than receptive acts. Condom use reduces risk of transmission by approximately 80%.[3] Other factors that affect the probability of infection include the stage of HIV disease and viral load in the index partner. For example, transmission is significantly higher when the index partner has early or late HIV compared with asymptomatic HIV, as these disease stages are associated with higher viral loads.[3] Individuals with genital ulcers or sexually transmitted diseases are at greater risk for contracting HIV. HIV incidence and prevalence are lower in cultures that advocate male circumcision, which is estimated to reduce risk of male acquisition of HIV approximately 50%.[3] Casual contact with patients with AIDS or HIV infection is not a significant risk factor for HIV transmission.

Prevention of sexual transmission has focused primarily on education that encourages safer sex practices such as use of condoms and reduction of high-risk behavior (eg, intercourse or promiscuity with partners of unknown HIV status).[4] A powerful tool for HIV prevention is combination ART for the infected individual, as this dramatically lowers viral replication and infectiousness, significantly reducing the risk of transmission to others.[3,5] Another effective prevention tool is chemoprophylaxis with antiretroviral drugs, as this significantly reduces HIV acquisition risk among uninfected individuals.[6,7,8] A combined approach has been advocated for optimal prevention.[4] Prevention strategies under investigation include HIV vaccines and topical vaginal/rectal microbicides.[9,10]

Parenteral transmission of HIV broadly encompasses infections due to infected blood exposure from needle sticks, IV injection with used needles, receipt of blood products, and organ transplants. Use of contaminated needles or other injection-related paraphernalia by drug abusers has been the main cause of parenteral transmissions. The risk of HIV transmission from sharing needles is approximately 0.67 per 100 episodes.[3,11] Prevention strategies include stopping drug abuse, obtaining needles from credible sources (eg, pharmacies), never reusing any paraphernalia, using sterile procedures in all injecting activities, and safely disposing of used paraphernalia.[4]

Before widespread screening, HIV was readily transmitted in blood products.[11] However, blood and tissue products in the healthcare system are now rigorously screened for HIV. The estimated risk for receiving tainted blood or blood products in the United States is well below 1:1,000,000 and that for receiving a tainted tissue transplant is 1:55,000.[12,13] Healthcare workers have a small but definite occupational risk of contracting HIV through accidental exposure. Most cases of occupationally acquired HIV have been the result of a percutaneous needle stick injury, which carries an estimated 0.3% risk of transmitting HIV.[3,14] Mucocutaneous exposures (eg, tainted blood splash in eyes, mouth, nose) carries a transmission risk of approximately 0.09%.[14] Significant risk factors for seroconversion with a needle stick include deep injury, injury with a device visibly contaminated with blood, and advanced HIV disease in the index patient (high viral load). The risk of transmission from an HIV-infected healthcare worker to a patient is extremely remote. Comprehensive medical guidelines, including antiretroviral drug prophylaxis, have been developed to minimize the hazard of HIV transmission for healthcare workers and for persons exposed by rape or other means.[11,14]

Perinatal infection, or vertical transmission, is the most common cause of pediatric HIV infection. Most infections occur during or near to the time of birth, although a fraction can occur in utero.[2] The risk of mother-to-child transmission is approximately 25% in the absence of ART. Factors that increase the likelihood of vertical transmission include prolonged rupture of membranes, chorioamnionitis, genital infection during pregnancy, preterm delivery, vaginal delivery, birth weight less than 2.5 kg, illicit drug use and cigarette smoking during pregnancy, and high maternal viral load.[15] Breast-feeding also can transmit HIV. The estimated frequency of breast milk transmission is approximately 5% to 10% in the first 6 months and 15% to 20% through 18 to 24 months.[16] High levels of virus in breast milk and in the mother are associated with higher risk of transmission. Formula feeding prevents breast milk transmission of HIV but may not improve mortality from other causes early in life in resource limited settings.[16] In the United States, HIV-infected mothers are recommended not to breast-feed.[17] A separate and comprehensive set of medical guidelines including antiretroviral drug prophylaxis have been developed to minimize the hazard of mother-to-child HIV transmission.[17]

Persons with HIV infection are broadly categorized as those living with HIV and those with an AIDS diagnosis (stage 3). An AIDS diagnosis is made when the presence of HIV is laboratory-confirmed and the cluster of differentiation 4 (CD4; T-helper cell) count drops below 200 cells/mm^3 (200 × 10^6/L) for those older than or equal to 6 years of age, or after an AIDS indicator condition is diagnosed.[18] Further distinctions regarding the stage of HIV and AIDS (stage 3) are given in the Revised Centers for Disease Control and Prevention (CDC) surveillance case definition (**Table 126-1**).[18] In the United States, the CDC estimates HIV epidemiology using models that rely on surveillance data from state and local health departments.[19] Using these models, the CDC estimates that about 1.2 million individuals are currently living with HIV (all stages) in the United States and that approximately 659,000 have died from complications of HIV infection.[19,20] Importantly, approximately 15% of persons with HIV are unaware of their infection and only approximately 45% of those who are aware of their infection are retained in care. Therefore, a majority of HIV-infected persons (~60%) are not receiving ART regularly, which significantly contributes to the ongoing transmission of HIV infection

in the United States, totaling approximately 50,000 new infections per annum.[20,21]

TABLE 126-1 Surveillance Case Definition for HIV Infection Stage Based on CD4+ T-lymphocyte Counts, United States, 2014

	Age on date of CD4+ T-lymphocyte test					
	<1 year		**1-5 years**		**≥6 years**	
Stage	Cells/μL ($\times 10^6$/L)	%	Cells/μL ($\times 10^6$/L)	%	Cells/μL ($\times 10^6$/L)	%
1	≥1,500	≥34	≥1,000	≥30	≥500	≥26
2	750-1,499	26-33	500-999	22-29	200-499	14-25
3 (AIDS)	<750	<26	<500	<22	<200	<14

AIDS Indicator Conditions

Bacterial infections, multiple or recurrent (specific to children <6 years)
Candidiasis of bronchi, trachea, or lungs
Candidiasis, esophageal
Cervical cancer, invasive (specific to adults, adolescents, children >6 years)
Coccidioidomycosis, disseminated or extrapulmonary
Cryptococcosis, extrapulmonary
Cryptosporidiosis, chronic intestinal (duration >1 month)
Cytomegalovirus disease (other than liver, spleen, or nodes), onset at age > 1 month
Cytomegalovirus retinitis (with loss of vision)
Encephalopathy, HIV-related
Herpes simplex: chronic ulcer(s) (duration >1 month); or bronchitis, pneumonitis, or esophagitis, onset at age > 1 month
Histoplasmosis, disseminated or extrapulmonary
Isosporiasis, chronic intestinal (duration >1 month)
Kaposi's sarcoma
Lymphoma, Burkitt
Lymphoma, immunoblastic
Lymphoma, primary, or brain
Mycobacterium avium complex or *Mycobacterium kansasii*, disseminated or extrapulmonary
Mycobacterium tuberculosis, any site (pulmonary or extrapulmonary)
Mycobacterium, other species or unidentified species, disseminated or extrapulmonary
Pneumocystis jirovecii pneumonia (PCP)
Pneumonia, recurrent (specific to adults, adolescents, children >6 years)
Progressive multifocal leukoencephalopathy
Salmonella septicemia, recurrent
Toxoplasmosis of brain, onset at age >1 month
Wasting syndrome due to HIV

Data from reference 18.

The epidemic in the United States initially was established in men who have sex with men (MSM), and

this population continues to be prominently affected by HIV, accounting for approximately 65% of new cases.[20] Heterosexual transmissions accounted for approximately 25% of new cases and approximately 75% of these are women. Injection drug use make up about 10% of new cases. For women, the main risk factor for transmission is heterosexual intercourse (~84% of cases) and injection-drug use (~16% of cases). For men the main risks are MSM (~78%), heterosexual sex (~10%), and injection-drug use (~10%).[20] African Americans and Hispanics are disproportionately affected by HIV infection. Of new infections in recent years, 44% were African American and 21% were Hispanic although these populations only make up 12% and 17% of the US population respectively. A relatively large proportion of these populations are not well linked to appropriate prevention, care, and treatment services, which represents a significant public health challenge.[19]

The number of individuals living with HIV/AIDS globally has risen to approximately 35 million persons.[1,2] Recent increases are due to a longer lifespan due to wider implementation of ART worldwide. This has reduced the death rate and new infection rate in recent years. For example, the peak number of new infections was 3.3 million per year in 2002 and this has declined to 2.3 million in 2012. New infections in children (mostly due to mother to child transmission) have declined by 38% between 2009 and 2012, and overall deaths have declined by approximately 30% since 2005. Nevertheless, approximately 1.6 million people succumbed to HIV/AIDS in 2012 and HIV/AIDS is still a major contributor to the global burden of disease.[22] The highest concentration of HIV/AIDS cases in the world is in sub-Saharan Africa, where approximately 25 million people are infected. However, new infections have declined there by approximately 38% since 2000 (albeit with regional differences).[1] Heterosexual transmission is the most common mode of transmission in sub-Saharan Africa and worldwide (~80% of cases). Women in sub-Saharan Africa and resource-limited countries are at disproportionately high risk for acquiring HIV because of biological and cultural factors that foster HIV transmission, such as limited ability to refuse sex.[23] Other important epidemiologic features of the HIV epidemic include growing incidence among injection drug users in North Africa and the Middle East, as well as some regions of Eastern Europe and Central Asia (eg, Russia and Ukraine).[1]

ETIOLOGY

HIV is an enveloped single-stranded RNA virus and a member of the Lentivirinae (*lenti*, meaning "slow") subfamily of retroviruses. Lentiviruses are characterized by their indolent infectious cycle. There are two related but distinct types of HIV: HIV-1 and HIV-2. HIV-2, found mostly in western Africa, consists of seven phylogenetic lineages designated as subtypes (clades) A through G. Four groups of HIV-1 are recognized: M (main or major), N (non-M, non-O), and O (outlier) and P (pending the identification of further cases).[2] The nine subtypes of HIV-1 group M are identified as A through D, F through H, and J and K. Mixtures of subtypes are referred to as *circulating recombinant forms*. Group M, subtype B, is primarily responsible for the epidemic in North America and western Europe.[24]

The accumulated evidence suggests that HIV in humans was the result of a cross-species transmission (zoonosis) from primates infected with simian immunodeficiency virus (SIV).[24]

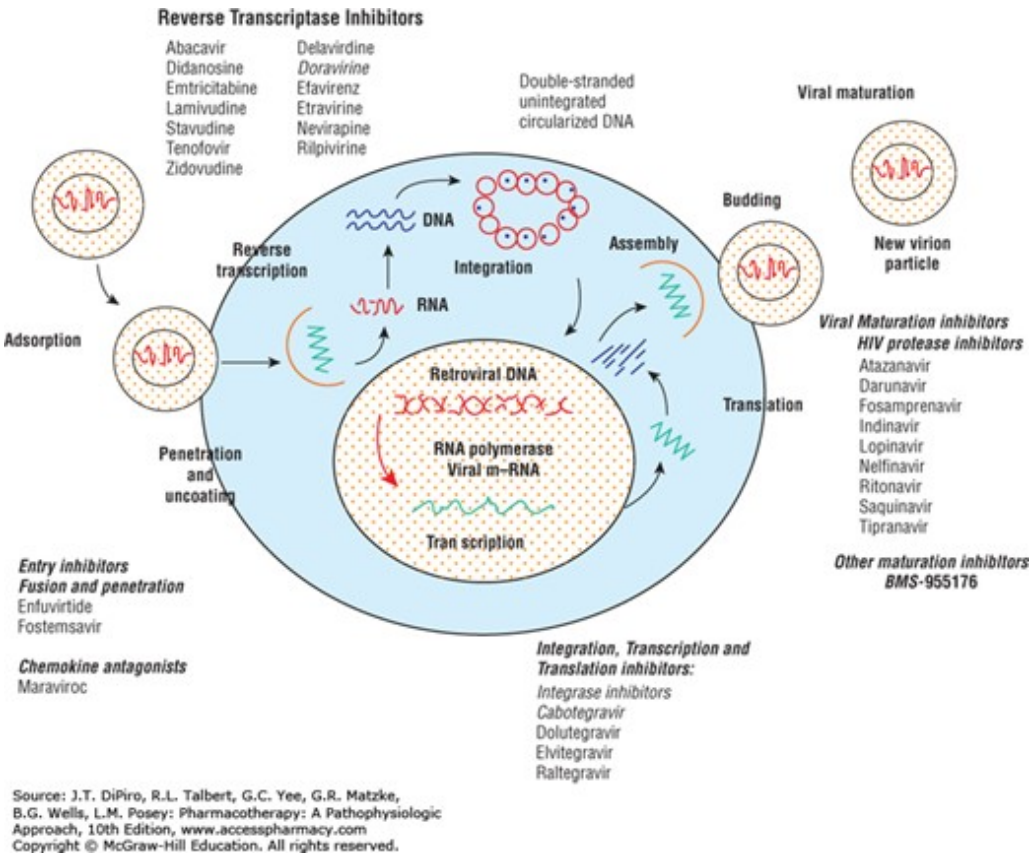
Phylogenetic and geographic relationships suggest that HIV-2 arose from SIV that infects sooty mangabeys and HIV-1 group M and N arose from SIVcpz, a virus that infects chimpanzees (*Pan troglodytes troglodytes*). Groups O and P may have arisen from a SIV variant that infects wild gorillas. Cultural practices, such as preparation and eating of bush meat or keeping animals as pets, may have allowed the virus to cross from primates to humans. The earliest known human infection with HIV has been traced to central Africa in 1959, but cross-species transmissions probably date back to the early 1900s.[24] Modern transportation, promiscuity, and drug abuse have caused the rapid spread of the virus within the United States and throughout the world. This chapter focuses on HIV-1 group M, which is the predominant strain likely to be encountered in the western world.

PATHOGENESIS

2 Understanding the life cycle of HIV (**Fig. 126-1**) is necessary because the current strategies used for treatment of HIV target points in this cycle. Once HIV enters the human body, the outer glycoprotein (gp160) on its surface, which is composed of two subunits (gp120 and gp41), has affinity for CD4 receptors, proteins present on the surface of T-helper lymphocytes, monocytes, macrophages, dendritic cells, and brain microglia. The gp120 subunit is responsible for CD4 binding. Once initial binding occurs, the intimate association of HIV with the cell is enhanced by further binding to chemokine coreceptors. The two major chemokine receptors used by HIV are Chemokine (C–C motif) receptor 5 (CCR5) and chemokine (C-X-C motif) receptor 4 (CXCR4). HIV isolates may contain a mixture of viruses that target one or the other of these coreceptors, and some viral strains may be dual-tropic (ie, can use both coreceptors). The HIV strain that preferentially uses CCR5, R5 viruses, is macrophage-tropic and typically implicated in most cases of sexually transmitted HIV.[25] Individuals with a common 32-base-pair deletion in the CCR5 gene are protected from progression of HIV disease, and those who are homozygous for the 32-base-pair deletion have a degree of resistance to acquisition of HIV-1.[26] The HIV strain that targets CXCR4, designated X4 virus, is T-cell–tropic and often is predominant in the later stage of disease. CD4 and coreceptor attachment of HIV to the cell promotes membrane fusion, which is mediated by gp41, and finally internalization of the viral genetic material and enzymes necessary for replication.

FIGURE 126-1

Life cycle of human immunodeficiency virus with potential targets where replication may be interrupted. Italicized compounds were in development at the time of this writing. *(Reprinted with permission, Courtney V. Fletcher, 2015.)*



After internalization, the viral protein shell surrounding the nucleic acid (capsid) is uncoated in preparation for replication.[27] The genetic material of HIV is positive-sense single-stranded RNA; the virus must transcribe this RNA into DNA (transcription normally occurs from DNA to RNA; HIV works backward, hence the name *retrovirus*). To do so, HIV is equipped with the unique enzyme RNA-dependent DNA polymerase (reverse transcriptase). HIV reverse transcriptase first synthesizes a complementary strand of DNA using the viral RNA as a template. The RNA portion of this DNA–RNA hybrid is then partially removed by ribonuclease H (RNase H), allowing HIV reverse transcriptase to complete the synthesis of a double-stranded DNA molecule. The fidelity of HIV reverse transcriptase is poor, and many mistakes are made during the process. These errors in the final DNA product contribute to the rapid mutation of the virus, which enables the virus to evade the immune response (thus complicating vaccine development), and promotes the evolution of drug resistance during partially suppressive therapy. Following reverse transcription, the final double-stranded DNA product migrates into the nucleus and is integrated into the host cell chromosome by integrase, another enzyme unique to HIV.

The integration of HIV into the host chromosome is critically important. Most notably, HIV can establish a persistent, latent infection, particularly in long-lived cells of the immune system such as memory T lymphocytes. The virus is effectively hidden in these cells, and this characteristic has greatly complicated efforts to cure HIV infection.[28] It also necessitates continuous ART therapy because virus reemerges from this reservoir if therapy is suspended.

After integration, HIV preferentially replicates in activated cells. Activation by antigens, cytokines, or other factors stimulates the cell to produce nuclear factor kappa B (NF-κB), an enhancer-binding protein. NF-κB normally regulates the expression of T-lymphocyte genes involved in growth but also

can inadvertently activate replication of HIV.[29] HIV encodes six regulatory and accessory proteins: Tat, Nef, Rev, Vpu, Vif, and Vpr, which enhance replication and inhibit innate immunity. For example, the Tat protein is a potent amplifier of HIV gene expression; it binds to a specific RNA sequence of HIV that initiates and stabilizes transcription elongation.[29] Vif is a viral protein that binds human ABOBEC 3G, a cytidine deaminase that disrupts the virus' genetic code by converting viral RNA cytosine to uracil thereby providing innate cellular immunity.[30] Vpu inhibits tetherin, a human cellular membrane protein that prevents release of virus particles after budding from infected cells. Assembly of new viral particles occurs in a stepwise manner beginning with the coalescence of HIV proteins beneath the host cell lipid bilayer. The nucleocapsid subsequently is formed with viral single-stranded RNA and other components packaged inside. Once packaged, the virion then buds through the plasma membrane, acquiring the characteristics of the host lipid bilayer. After the virus buds, the maturation process begins. Within the virion, protease, another enzyme unique to HIV, cleaves a large precursor polypeptide (gag-pol) into functional proteins that are necessary to produce a complete and infectious virus. Without this enzyme, the virion is immature and unable to infect other cells.

The natural history of HIV infection exhibits three general phases: acute, chronic, and terminal (AIDS). Initial rounds of HIV replication during acute infection take place largely in the mucosal CD4+ CCR5+ T cell pools in the gut resulting in a massive CD4 T-cell depletion in these tissues.[31] Cells are destroyed by various mechanisms, including cell lysis from newly budding virions, cytotoxic T-lymphocyte–induced cell killing, and induction of apoptosis. Following this destruction of the mucosal CD4 T cell pool, which lasts for 2 to 3 weeks, a state of heightened immune activation ensues during the chronic infection phase, which can last for several years. The activated state is characterized by high levels of activation markers on circulating T cells (eg HLA-DR and CD38) and proinflammatory cytokines, and may result from HIV antigen as well as translocation of microbial antigens from the T-cell depleted gut mucosa. Heightened activation enables further HIV replication and ultimately leads to continued depletion of CD4+ CCR5+ T cells. HIV-1 exhibits a very high turnover rate during this chronic phase, with an estimated 10 billion new viruses produced each day.[32] More than 99% of these viruses are produced in newly infected activated cells. Nevertheless, for much of the chronic phase, the immune system is able to operate well enough to prevent overt OIs that herald AIDS. But eventually, the depletion of CD4 cells and the continuous cellular activation leads to a final collapse of the immune system, or AIDS. HIV may use CXCR4 coreceptor during this last phase of infection and these viruses infect a broader range of CD4 cells (naïve and central-memory) speeding the disease progression. It is this unrelenting destruction of CD4 cells that causes the profoundly compromised immune system and AIDS.

DIAGNOSIS AND CLINICAL PRESENTATION

Detection of HIV and Surrogate Markers of Disease Progression

HIV is diagnosed through a multi-step process.[33] The presence of HIV infection is screened with an enzyme-linked immunosorbent assay (ELISA), which detects antibodies against HIV-1. Although ELISA has been the mainstay of HIV screening for decades, the technology has been evolving to detect infection earlier in the time course of the disease.[34] Older ELISA tests detected IgG (2nd generation

tests) but more modern tests detect IgG and IgM (3rd generation tests) and may further include detection of p24 antigen, an early marker of infection (4th generation tests). These technological advances enable earlier detection of HIV by as much as 15 to 20 days compared with older 2nd generation tests. ELISA tests are generally highly sensitive (less than 99%) and highly specific (greater than 99%), but rare false-positive results can occur particularly in those with autoimmune disorders.[33] False-negative results also occur and may be attributed to the "window-period" before adequate production of antibodies or antigen. This "window period" between HIV acquisition and detection of HIV with 4th and 3rd generation tests is approximately two and three weeks, respectively.[33] Positive screening tests are confirmed with another enzyme immunoassay to specify if the antibodies are to HIV-1 versus HIV-2. (Although HIV-2 is rare in the US, this step ensures proper diagnosis and treatment). If this follow up assay is indeterminant or negative, an HIV nucleic acid test is performed for definitive diagnosis. HIV-RNA is the earliest indicator of infection, detectable ~10 days from acquisition and about one week before 4th generation tests.[34] Several point-of-care screening kits are available for serum, plasma, whole blood, or oral fluids. While oral fluid tests are convenient, they are not as sensitive as blood assays, which may result in false negatives early in infections; this is a particular disadvantage in the setting of HIV testing prior to initiating or continuing preexposure prophylaxis (PrEP).[34]

HIV testing is recommended when HIV infection is suspected because of symptoms and/or high-risk behavior.[35,36] Additionally, the CDC now recommends routine HIV screening in all healthcare settings in persons 13 to 64 years, a policy called "opt-out" testing.[37] A focus of the recommendations is to screen persons at high risk of HIV infection (eg, MSM) at least annually and to screen pregnant women while they are in care. The policy states that consent for medical care will imply consent for HIV testing; however, the person must be informed of the test and can opt out of taking it. Because states may have different HIV consent laws, the local requirements for HIV testing should be consulted. The rationale for the opt-out strategy is to diagnose those who unknowingly carry HIV so as to initiate ART early leading to improved prognosis and reduced forward transmissions.

Once diagnosed, HIV disease is monitored primarily by two surrogate biomarkers, viral load and CD4 cell count.[38] The viral load test quantifies the degree of viremia by measuring the number of copies of viral RNA (HIV RNA) in the plasma. Methods for determining HIV RNA include reverse-transcription polymerase chain reaction (RT-PCR), branched-chain DNA, transcription-mediated amplification, and nucleic acid sequence-based assay. RT-PCR is used more widely than the other techniques.[34] Irrespective of the method used, viral load is reported as the number of viral RNA copies per milliliter of plasma. Each assay has its own lower limit of quantitation, and results can vary from one assay method to the other; therefore, it is recommended that the same assay method be used consistently for each patient. Reductions in viral load often are reported in base 10 logarithm. For example, if a patient presents initially with a viral load of 100,000 copies/mL (10^5 copies/mL or 10^8 copies/L) and subsequently has a viral load of 10,000 copies/mL (10^4 copies/mL or 10^7 copies/L), the decrease is 1 $\log_{10}$. Given that HIV RNA varies within a patient, a perceptible clinical response is generally considered when the decline in viral load is more than 0.5 $\log_{10}$.[38] Viral load is a major prognostic factor for disease progression, CD4 count decline, and death.[38,39] It is also the

predominant way to assess the effectiveness of treatment.

Because HIV attacks and leads to the destruction of cells bearing the CD4 receptor, the number of CD4 lymphocytes (T-helper cells) in the blood is a critical surrogate marker of disease progression and immune system status.[38] The normal adult CD4 lymphocyte count ranges from 500 to 1,600 cells/mm^3 (500 × 10^6-1,600 × 10^6/L), or 40% to 70% of total lymphocytes. CD4 counts in children are age dependent, with younger children having higher CD4 counts (see Table 126-1). The hallmark of HIV disease is depletion of CD4 cells and the associated development of OIs and malignancies especially at lower CD4 cell counts.

Clinical Presentation

3 Clinical presentation of primary HIV infection varies, but most patients (50%-90%) have an acute retroviral syndrome or mononucleosis-like illness, presumably due to the host immune response to the virus (ie, "cytokine storm") (**Table 126-2**).[40] Although many of these symptoms are nonspecific, the presence of aseptic meningitis, oral or genital ulcers, rash, and leukopenia should raise suspicion of acute HIV infection in the setting of a potential exposure. Symptoms often last 2 weeks, and hospitalization may be required for a small fraction of patients. Primary infection is associated with a high viral load (more than 10^6 copies/mL [more than 10^9/L]) and a precipitous drop in CD4 cells. After several weeks an immune response is mounted, the amount of HIV RNA in plasma falls substantially, CD4 cells rebound slightly, and symptoms resolve gradually. However, as described above, this clinically latent period is not virologically latent because HIV replication is continuous (~10 billion viruses per day) and immune system destruction is ongoing. A steady decrease in CD4 cells (approximately 50 cells/μL [50 × 10^6/L] per year) is the most measurable aspect of this immune system deterioration during the asymptomatic phase. Plasma viral load, on the other hand, will appear to have stabilized at a particular level or "set point." The set point correlates strongly with the CD4 cell decline and time to AIDS and morbidity. For example, prior to ART, the Multicenter AIDS Cohort Study measured viral load in 1,604 HIV-positive men and followed them for as long as 11 years. The CD4 cell count decline was approximately twice as fast in those with HIV-RNA above 30,000 copies/mL (30,000 × 10^3/L) compared with those with HIV-RNA less than or equal to 500 copies/mL (less than or equal to 500 × 10^3/L) and mortality rates (within 6 years) were 69.5% versus 0.9%, respectively.[39] Thus, a higher viral set point is associated with faster disease progression and poorer prognosis. Not all individuals infected with HIV progress to AIDS—these so-called "long-term nonprogressors" may be infected with a defective virus (eg, nef-deficient HIV) or may have an intrinsic ability to resist infection (eg, CCR5 mutation).

TABLE 126-2 Clinical Presentation of Primary Human Immunodeficiency Virus Infection in Adults

Signs and Symptoms
Most common: Fever, headache, sore throat, fatigue, GI upset (diarrhea, nausea, vomiting) weight loss, myalgia, morbilliform or maculopapular rash usually involving the trunk, lymphadenopathy, night sweats
Less common: Aseptic meningitis, oral ulcers, leukopenia

Other

High viral load (may exceed 1,000,000 copies per milliliter or 10^9/L)

Persistent decrease in CD4 lymphocytes

Data from reference 40.

Most children born with HIV are asymptomatic. On physical examination, children often present with nonspecific signs, such as lymphadenopathy, hepatomegaly, splenomegaly, failure to thrive, weight loss or unexplained low birth weight (in prenatally exposed infants), and fever of unknown origin.[41] Laboratory findings include anemia, hypergammaglobulinemia (primarily immunoglobulin [Ig]A and IgM), altered mononuclear cell function, and altered T-cell subset ratios. Of note, the normal range for CD4 cell counts in young children is much different from the range in adults (Table 126-1). Children have different susceptibility and/or exposures to OIs compared with adults. Bacterial infections, including *Streptococcus pneumoniae*, *Salmonella* spp., and *Mycobacterium tuberculosis*, may be more prevalent in children with AIDS than in adults with the disease. Kaposi's sarcoma is rare in children. Children with HIV infection may develop lymphocytic interstitial pneumonitis without evidence of *P. jirovecii* or other pathogens on lung biopsy. Some children (~25%) will progress to AIDS rapidly within the first year of life. A presentation of serious OIs such as *P. jirovecii* pneumonia, encephalopathy, failure to thrive, and a precipitous drop in CD4 cells are common in these infants. General management of the HIV-infected child involves principles similar to those used for the adult: ART, treatment and prophylaxis of OIs, and supportive care.[42,43]

TREATMENT

Desired Outcomes

4 The central goals of ART are to decrease morbidity and mortality, improve quality of life, restore and preserve immune function, and prevent further transmission.[38] The most important and effective way to achieve these goals is maximal and durable suppression of HIV replication, which is interpreted as plasma HIV RNA less than the lower limit of quantitation (ie, undetectable; usually less than 50 copies/mL [less than 50 × 10^3/L]). Such a profound reduction in HIV RNA is associated with reduced transmissions and long-term response to therapy (ie, durability), as well as increases in CD4 lymphocytes that closely correlates with a reduced risk for developing OIs. While undetectable HIV RNA almost always corresponds with a rise in CD4 lymphocytes, some patients respond virologically or immunologically without the other.

General Approach to Treatment

5 Combinations of three active antiretroviral agents from two pharmacologic classes profoundly inhibit HIV replication to undetectable plasma levels, prevent and reverse immune deficiency, and substantially decrease morbidity and mortality—constituting the ART era.[44] Principles that serve as a guide for the clinical use of antiretroviral agents are still relevant today[45]:

1. Ongoing HIV replication leads to immune system damage and progression to AIDS. HIV

infection is always harmful, and true long-term survival free of clinically significant immune dysfunction is unusual.

2. Plasma HIV RNA levels indicate the magnitude of HIV replication and its associated rate of CD4 cell destruction, whereas CD4 cell counts indicate the extent of HIV-induced immune damage already suffered.

3. Use of potent combination ART to suppress HIV replication to below the levels of detection of sensitive plasma HIV RNA assays limits the potential for selection of antiretroviral-resistant HIV variants, the major factor limiting the ability of antiretroviral drugs to inhibit virus replication and delay disease progression. Therefore, maximum achievable suppression of HIV replication should be the goal of therapy.

4. The most effective means for accomplishing durable suppression of HIV replication is simultaneous initiation of combinations of effective anti-HIV drugs with which the patient has not been treated previously and that are not cross-resistant with antiretroviral agents with which the patient has been treated previously.

5. Each of the antiretroviral drugs used in combination therapy regimens always should be used according to optimal schedules and dosages.

6. The available effective antiretroviral drugs are limited in number and mechanism of action, and cross-resistance between specific drugs has been documented. Therefore, any change in ART increases future therapeutic constraints.

7. Women should receive optimal ART regardless of pregnancy status.

8. The same principles of ART apply to both HIV-infected children and adults, although treatment of HIV-infected children involves unique pharmacologic, virologic, and immunologic considerations.

9. Persons with acute primary HIV infections should be treated with combination ART to suppress virus replication to levels below the limit of detection of sensitive plasma HIV RNA assays.

The extent to which these principles will continue to stand the test of time is unknown; new information on the pathogenesis and treatment of HIV accrues constantly. As of December 2015, 29 antiretroviral compounds have been approved by the FDA; two (amprenavir and zalcitabine) have since been removed from the market. **Table 126-3** presents the state of the art for treatment of HIV-infected individuals as of December 2015.[38] Treatment is recommended for all HIV-infected persons regardless of CD4 lymphocyte count, as long as the patient is ready to adhere to therapy. Urgent indications for therapy include pregnancy, history of AIDS-defining illness, rapidly declining CD4 counts, HIV-associated nephropathy, or HIV/hepatitis B virus coinfection.

TABLE 126-3 Treatment of Human Immunodeficiency Virus Infection: Antiretroviral Regimens Recommended in Antiretroviral-Naïve Persons

Preferred Regimens	Selected Limitations

	Preferred Regimens	Selected Limitations
HIV PI-based	Darunavir + ritonavir + tenofovir disoproxil fumarate + emtricitabine (AI)	Rash (darunavir has sulfonamide moiety); GI; food requirement; CYP3A4 drug interactions
InSTI-based	Raltegravir + tenofovir disoproxil fumarate + emtricitabine (AI)	Twice daily (not once daily); interactions with polyvalent antacids; creatine kinase increases
	Elvitegravir + cobicistat + tenofovir disoproxil fumarate + emtricitabine (co-formulated) (AI)	Only if CLcr ≥70 mL/min (≥1.17 mL/s); food requirement; interactions with polyvalent antacids; CYP3A4 drug interactions; cobicistat inhibits creatinine secretion increasing Scr - distinguish vs renal dysfunction
	Elvitegravir + cobicistat + tenofovir alafenamide fumarate + emtricitabine (co-formulated) (AI)	Only if CLcr ≥30 mL/min (≥0.5 mL/s); same as above
	Dolutegravir + abacavir + lamivudine (co-formulated) (AI)	Only if HLA-B5701 negative; interactions with polyvalent antacids; dolutegravir inhibits creatinine secretion increasing Scr - distinguish vs renal dysfunction
	Dolutegravir + tenofovir disoproxil fumarate + emtricitabine (AI)	Same as above without HLA-B5701 negative requirement
Selected alternative Regimens (Some Potential Disadvantages vs Preferred Regimens)		
NNRTI-based	Efavirenz + tenofovir disoproxil fumarate + emtricitabine (co-formulated) (BI)	CNS side effects with efavirenz; CYP450 drug interactions; empty stomach dosing; teratogenic in non human primates - avoid in women planning to conceive
	Rilpivirine + tenofovir disoproxil fumarate + emtricitabine (co-formulated) (BI)	Not recommended when HIV-RNA >100,000 copies/mL (>100,000 × 10^3/L) or CD4 <200 cells/µL (<200 × 10^6/L); no proton-pump inhibitors (rilpivirine); food requirement; antacid interactions
HIV PI-based	Atazanavir + ritonavir (or cobicistat) + tenofovir disoproxil fumarate + emtricitabine (BI)	GI; food requirement; CYP3A4 drug interactions; hyperbilirubinemia leading to drug discontinuation especially in those with Gilbert's; only for CLcr ≥ 70 mL/min (≥1.17 mL/s) as cobicistat inhibits creatinine secretion increasing Scr - distinguish vs renal dysfunction
	Darunavir + ritonavir (or cobicistat) + abacavir + lamivudine (BII for ritonavir	Only if HLA-B5701 negative; see issues above

Preferred Regimens	Selected Limitations
and BIII for cobicistat)	
Darunavir + cobicistat + tenofovir disoproxil fumarate + emtricitabine (BII)	Only for CLcr ≥70 mL/min (≥1.17 mL/s) as cobicistat inhibits creatinine secretion increasing Scr - distinguish vs renal dysfunction; see issues above

Selected Regimens or Components that should not be used at any time

Regimen or component	Comment
Any all NRTI regimen (AIBII)	Inferior virologic efficacy
Didanosine + tenofovir (AII)	Inferior virologic efficacy, CD4 declines
Didanosine + Stavudine (AII)	Toxicity including subcutaneous fat loss, peripheral neuropathy, and lactic acidosis
2 NNRTI combinations (AI)	Higher adverse events, drug interactins
Emtricitabine + lamivudine or zidovudine + stavudine (AIIAIII)	Analogs of same nucleobase, No additive benefit (or antagonistic)
Unboosted PIs (ie, darunavir, saquinavir, tipranavir) (AII)	Inadequate bioavailability
Etravirine + selected boosted PIs (AII)	Possible induction of PI metabolism, doses not established
Nevirapine in ARV naïve with higher CD4 counts (>250 for women, >400 for men) (BI)	High incidence of symptomatic hepatotoxicity

Evidence-based rating definition.

Rating strength of recommendation:

A: Strong recommendation.

B: Moderate recommendation.

C: Optional recommendation.

Rating Quality of Evidence Supporting the Recommendation:

I: Evidence from at least one correctly randomized, controlled trial with clinical outcomes and/or validated laboratory endpoints.

II: Evidence from at least one well-designed clinical trial without randomization or observational cohorts with long-term clinical outcomes.

III: Expert opinion.

Lamivudine and emtricitabine are considered interchangeable.

Data from reference 38.

The optimal time to initiate therapy in chronic HIV infection has been a matter of debate for decades. The main arguments for postponing therapy were the concern for cumulative drug toxicity and trepidation for drug resistance and loss of therapeutic options. These concerns were well-founded when older drugs such as lopinavir/ritonavir, stavudine, zidovudine, indinavir, and efavirenz were the mainstay of therapy. Today, the availability of newer medications with different mechanisms of action (eg, InSTI and attachment inhibitors) and significantly improved adverse event profiles helps mitigate these issues.

An additional issue, until recently, was the lack of high-quality evidence of clinical benefits for initiating therapy at higher versus lower CD4 counts (eg, 500 cells/μL [500 × 10^6/L] vs 350 cells/μL [350 × 10^6/L]). This issue was addressed in 2015 with results from two large randomized controlled trials.[46,47] The START trial randomized 4,685 patients with CD4 counts above 500 cells/μL (500 × 10^6/L) to either immediate ART or to delayed ART until the CD4 count reached 350 cells/μL (350 × 10^6/L). Immediate ART resulted in significantly fewer serious AIDS events (HR 0.28, 95% CI 0.15-0.50), and non-AIDS events (HR 0.61, 0.38-0.97) as compared with delaying ART. The TEMPRANO study was conducted in the Ivory Coast where HIV and tuberculosis (TB) co-infection is endemic. The trial randomized 2,056 patients with less than or equal to 800 CD4 cells/μL (less than or equal to 800 × 10^6/L) to immediate ART, immediate ART with isoniazid TB prophylaxis, delayed ART (based upon WHO guidelines), or delayed ART with isoniazid TB prophylaxis. Again, immediate ART resulted in fewer deaths or severe HIV-related illnesses as compared with deferred ART (HR among patients with a baseline CD4 greater than or equal to 500 cells/μL [greater than or equal to 500 × 10^6/L], 0.56; 95% CI, 0.33-0.94). In addition to these important studies, immediate ART is also known to prevent ongoing HIV transmissions by as much as 96% compared with delayed ART.[5] Taken together, these studies provide high-quality evidence that untreated HIV is harmful even at high CD4 counts and immediate ART confers individual- and population-level benefit compared with delayed ART. Major policy-makers now recommend immediate ART regardless of CD4 count, including the WHO and US Department of Health and Human Services.[38,48] An excellent source for information on updated treatment guidelines *www.AIDSinfo.NIH.gov*. Additional guidelines and electronic resources for HIV clinicians are provided in reference 36.[36] Healthcare professionals involved in the care of HIV-infected persons are urged to consult the most current literature on the principles and strategies for ART therapy.

Pharmacologic Therapy

Several methods of therapeutic intervention have been evaluated against HIV including systemic antiretroviral drugs (the focus of this chapter) for direct inhibition of chronic viral replication or prevention of HIV acquisition; vaccination; immunomodulators to help stimulate and restore the immune system; and topical antiretroviral drugs or virucides (chemicals that destroy intact viruses) to prevent HIV infection. The latter three approaches are investigational at this time. Several approaches for an HIV vaccine are in development, including whole killed virus, subunit and peptide vaccination, recombinant live vector, and naked DNA delivery. Historically, vaccine progress has been slow.

Genetic variability in HIV and a nascent understanding of the role of the immune system in suppressing viral replication are significant barriers to the development of an effective HIV vaccine with long-lasting and protective immunity. In the past few years, a randomized placebo-controlled trial demonstrated a modest 30% reduction in HIV transmission in a modified-intention to treat analysis of ALVAC-HIV plus AIDSVAX vaccine in 16,402 volunteers.[49] Efforts are now underway to understand the correlates of protection from this study to inform the vaccine field going forward.[50] Immunomodulators, such as aldesleukin (interleukin-2), provide mild benefits in terms of increased CD4 cells; however, aldesleukin is also associated with significant toxicities and no apparent clinical benefit.[51] Thus, the future is uncertain for immunomodulatory approaches. Topical virucidal or antiretroviral drug formulations for use vaginally or rectally to prevent sexual transmission of HIV are in various phases of development.[9] For example, vaginal application of tenofovir 1% gel before and after intercourse reduced HIV acquisition by 39% in women.[52] However, daily tenofovir 1% gel administered vaginally did not reduce HIV acquisition, an outcome that was driven by poor adherence.[53] Microbicide research is now focusing on long-acting formulations (eg, rings and intra-uterine devices) to mitigate adherence challenges.

Antiretroviral Agents

Systemic delivery of antiretroviral agents for direct inhibition of viral replication has been the most clinically successful strategy for both treatment and prophylaxis. Four general classes of drugs are used today: entry inhibitors, reverse transcriptase inhibitors, InSTIs, and HIV PIs (**Table 126-4**).[38] As a rule, newer agents exhibit significant advantages over first generation drugs in terms of pharmacokinetics, tolerability, safety, and efficacy. This section will highlight specific advantages of newer agents over first generation drugs and will focus the discussion on newer agents used most often today. Updated drug information is available in the Department of Health and Human Services Guidelines including common adverse events and dosing recommendations for hepatic and renal insufficiency for all antiretroviral drugs.[38]

TABLE 126-4 Selected Pharmacologic Characteristics of Selected Antiretroviral Compounds

Drug	*F* (%)	$t_{1/2}$ (h)[a]	Adult Dose[b] (doses/day)	Plasma C_{max}/C_{min} (μM)	Distinguishing Adverse Effect(s)
Integrase Inhibitors (InSTI)					
Dolutegravir	?	14	50 mg (1)	8.3/2.5	Insomnia, headache, rash (can be severe)
Elvitegravir (coformulated with cobicistat)	?	13	150 mg (1)	3.8/1	Diarrhea, nausea
Raltegravir	?	9	400 mg (2)	1.74/0.22	Rash (can be severe), creatine phosphokinase increases
Nucleoside (Nucleotide) Reverse Transcriptase Inhibitors (NtRTIs)					

Drug	*F* (%)	$t_{1/2}$ (h)[a]	Adult Dose[b] (doses/day)	Plasma C_{max}/C_{min} (μM)	Distinguishing Adverse Effect(s)
Abacavir	83	1.5/20	300 mg (2) *or* 600 mg (1)	5.2/0.03 7.4[c]	Hypersensitivity (HLA-B5701 test to predict)
Didanosine	42	1.4/24	200 mg (2) *or* 400 mg (1)	2.8/0.03 5.6[c]	Peripheral neuropathy, pancreatitis
Emtricitabine	93	10/39	200 mg (1)	7.3/0.04	Rarely pigmentation on soles and palms in nonwhites
Lamivudine	86	5/22	150 mg (2) *or* 300 mg (1)	6.3/1.6 10.5/0.5	Headache
Stavudine	86	1.4/7	40 mg (2)	2.4/0.04	Lipoatrophy, peripheral neuropathy
Tenofovir alafenamide	?	35/150 (tenofovir component)	10 mg (1) (when combined with cobicistat)	0.07/0.03	Increased lipids
Tenofovir disoproxil fumarate	25	17/150 (tenofovir component)	300 mg (1)	1.04/0.4	Renal dysfunction (proximal tubulopathy), bone de-mineralization
Zidovudine	85	2/7	200 mg (3) *or* 300 mg (2)	0.2 3[c]	Anemia, neutropenia, myopathy
Nonnucleoside Reverse Transcriptase Inhibitors (NNRTIs)					
Delavirdine	85	5.8	400 mg (3) *or* 600 mg (2)	35/14	Rash, elevated liver function tests
Efavirenz	43	48	600 mg (1)	12.9/5.6	CNS disturbances and potential teratogenicity
Etravirine	?	41	200 mg (2)	1.69/0.86	Rash, nausea

Drug	*F* (%)	$t_{1/2}$ (h)[a]	Adult Dose[b] (doses/day)	Plasma C_{max}/C_{min} (μM)	Distinguishing Adverse Effect(s)
Nevirapine	93	25	200 mg (2)[d]	22/14	Potentially serious rash and hepatotoxicity
Rilpivirine	?	50	25 mg (1)	0.7/0.3	Possibly depression
Protease Inhibitors (PIs)					
Fosamprenavir[e]		8	1,400 mg (1)[e,f]	14.3/2.9	Rash
Atazanavir	68	7	400 mg (1)	3.3/0.23	Unconjugated hyperbilirubinemia
			or		
			300 mg (1)[f]	6.2/0.9	
Darunavir	82	15	800 mg (1)[f]	11.9/6.5	Hepatitis, rash
			or		
			600 mg (2)[f]		
Indinavir	60	1.5	800 mg (3)	13/0.25	Nephrolithiasis
			or		
			400-800 mg (2)[f]		
Lopinavir[g]	?	5.5	800 mg (1)	13.6/7.5	Hyperlipidemia/GI intolerance
			or		
			400 mg (2)		
Nelfinavir	?	2.6	750 mg (3)	5.3/1.76	Diarrhea
			or		
			1,250 mg (2)	7/1.2	
Ritonavir	60	3-5	600 mg (2)[d]	16/5	GI intolerance
			or		
			"Boosting doses"		
Saquinavir	4	3	1,000 mg (2)[f]	3.9/0.55	QT prolongation
Tipranavir	?	6	500 mg (2)[f]	77.6/35.6	Hepatotoxicity, intracranial hemorrhage
Entry Inhibitors—Fusion Inhibitor					
Enfuvirtide	84	3.8	90 mg (2)	1.1/0.73	Injection-site reactions
Coreceptor Inhibitor					
Maraviroc	33	15	300 mg (2)	1.2/0.066	Hepatitis, allergic reaction

C_{max}, maximum plasma concentration; C_{min}, minimum plasma concentration; *F*, bioavailability; $t_{1/2}$, elimination half-life.

[a]NtRTIs: Plasma NtRTI $t_{1/2}$/intracellular (peripheral blood mononuclear cells) NtRTI-triphosphate $t_{1/2}$; plasma $t_{1/2}$ only for other classes.

[b]Dose adjustment may be required for weight, renal or hepatic disease, and drug interactions.

[c]C_{min} concentration typically below the limit of quantification.

[d]Initial dose escalation recommended to minimize side effects.

[e]Fosamprenavir is a tablet phosphate prodrug of amprenavir. Amprenavir is no longer available.

[f]Must be boosted with low doses of ritonavir (100-200 mg).

[g]Available as coformulation 4:1 lopinavir to ritonavir.

Data from reference 38.

Reverse transcriptase inhibitors consist of two classes: those that are chemical derivatives of purine- and pyrimidine-based nucleosides and nucleotides (nucleoside/nucleotide reverse transcriptase inhibitors [NRTIs]) and those that are not (nonnucleoside reverse transcriptase inhibitors [NNRTIs]). NRTIs include the thymidine analogs stavudine (d4T) and zidovudine (AZT or ZDV); the deoxycytidine analogs emtricitabine (FTC) and lamivudine (3TC); the deoxyguanosine analog abacavir sulfate (ABC); and the deoxyadenosine analogs of which didanosine (ddI) is an inosine derivative and tenofovir is a deoxyadenosine-monophosphate nucleotide analog (a nucleotide is a nucleoside with one or more phosphates). **Note that drug abbreviations are provided here and below for reference, but their use is discouraged because they may lead to prescribing or administration errors.** Tenofovir comes in two pro-drug formulations, tenofovir disoproxil fumarate (TDF) and tenofovir alafenamide (TAF). Tenofovir disoproxil fumarate is an ester pro drug that releases tenofovir upon first pass metabolism, producing relatively high systemic concentrations of tenofovir, which confers some risk (usually mild) of proximal tubulopathy and bone de-mineralization. On the other hand, for tenofovir alafenamide, more of the intact pro-drug reaches the systemic circulation and the pro-drug releases tenofovir within lymphoid cells via cathepsin A or hepatic cells via carboxylesterase 1. This strategy results in higher intracellular concentrations, but lower systemic tenofovir concentrations and less change in markers of proximal tubulopathy and bone de-mineralization.[54]

As a class, the NRTIs require phosphorylation to the 5′-triphosphate moiety to become pharmacologically active. Intracellular phosphorylation occurs by cytoplasmic or mitochondrial kinases and phosphotransferases (not viral kinases). The 5′-triphosphate moiety acts in two ways: (a) it competes with endogenous deoxyribonucleotides for the catalytic site of reverse transcriptase, and (b) it prematurely terminates DNA elongation, if taken up and incorporated, as it lacks the requisite 3′-hydroxyl for sugar-phosphate linking. NRTIs are active against both HIV-1 and HIV-2.[38] Emtricitabine, lamivudine, and tenofovir are also active against hepatitis B virus, and a combination of these agents should be used when possible in HIV–hepatitis B coinfected patients.

Although NRTI triphosphates (or diphosphate for tenofovir) are specific for HIV reverse transcriptase,

their adverse effects may be caused in part by inhibition of mitochondrial DNA or RNA synthesis.[55] It is largely this problem that differentiates the first-generation drugs (didanosine, stavudine, and zidovudine) from the agents used most often at this time (tenofovir disoproxil fumarate, tenofovir alafenamide, emtricitabine, lamivudine, abacavir).[38,56] The mitochondrial toxicities include peripheral neuropathy, pancreatitis, lipoatrophy (subcutaneous fat loss), myopathy, anemia, and rarely life-threatening lactic acidosis with fatty liver. The newer agents exhibit less potential to cause these toxicities, but they still have their own adverse event profiles to be considered (see Table 126-4).[38]

The newer NRTI are eliminated by the kidney and dose adjustments are required for renal insufficiency, whereas abacavir is metabolized in the liver and it should not be used in advanced hepatic impairment. Resistance has been reported for all NRTIs, including cross-resistance within the class as multiple and/or specific mutations in the viral genome accrue.[57]

NNRTIs are a chemically heterogeneous group of agents that bind noncompetitively to reverse transcriptase adjacent to the catalytic site, forcing a conformation change to the enzyme. Unlike NRTIs, NNRTIs do not require intracellular activation, do not compete against endogenous deoxyribonucleotides, and do not have intrinsic antiviral activity against HIV-2. Available NNRTIs include delavirdine (DLV), efavirenz (EFV), etravirine (ETR), nevirapine (NVP), and rilpivirine (RPV).[38] As a class, the NNRTIs are generally associated with rash and elevated liver function tests, including life-threatening cases rarely, particularly for nevirapine.[55] The use of first-generation NNRTI (delavirdine, nevirapine, efavirenz) are on the decline largely because of efficacy (delavirdine) or tolerability and/or safety concerns (nevirapine, efavirenz). NNRTIs tend to have long plasma half-lives (except delavirdine) and they are mainly cleared by liver and/or gut-mediated metabolism through the cytochrome P450 (CYP) enzyme system. Caution should be used for those with advanced hepatic insufficiency (nevirapine should not be used in moderate or advanced hepatic insufficiency). NNRTI can be perpetrators of drug–drug interactions, most often associated with induction of CYP metabolism. The NNRTIs are unique in that a single mutation is needed to confer high-level cross-resistance for the class (except etravirine), which has been termed a *low-genetic barrier* to resistance.[58]

The HIV PIs include atazanavir (ATV), darunavir (DRV), fosamprenavir (FPV), indinavir (IDV), lopinavir (LPV), nelfinavir (NFV), ritonavir (RTV), saquinavir (SQV), and tipranavir (TPV). HIV PIs competitively inhibit the cleavage of the gag-pol polyprotein, which is a crucial step in the viral maturation process, thereby resulting in the production of immature, noninfectious virions. HIV PIs have activity against HIV-1 and HIV-2 (particularly darunavir, lopinavir, and saquinavir).[38] HIV PIs are generally associated with GI distress and metabolic changes, such as increased lipids, insulin insensitivity, and changes in body fat distribution. Some of these issues can be traced to formulation problems due to limited aqueous solubility, requiring high levels of excipients and large pill burdens. The first generation HIV PIs (eg, indinavir, nelfinavir, saquinavir, lopinavir) exhibited poor solubility leading to erratic absorption (eg, nelfinavir, saquinavir), crystallization of drug in urine (eg, indinavir), gastrointestinal distress (eg, nelfinavir, lopinavir), and hyperlipidemia (eg, lopinavir). Generally, the newer HIV PIs (eg, darunavir, atazanavir) improve upon (but do not eliminate) these issues. HIV PIs are cleared by liver- and gut-mediated metabolism (mainly CYP3A), and dose adjustments may be required in hepatic insufficiency (tipranavir/ritonavir should not be used in moderate to severe hepatic insufficiency). HIV

PIs are almost always used with low doses of ritonavir or cobicistat, that is, CYP3A inhibitors, to increase the plasma concentrations of the HIV PI of interest. CYP3A-mediated drug interactions with concomitant medications are important considerations for PIs. Resistance to the HIV PIs generally requires the buildup of multiple mutations, termed a *high-genetic barrier*. Multiple mutations can lead to cross-resistance.[57]

There are currently two types of entry inhibitors: fusion inhibitors and CCR5 antagonists. Enfuvirtide (ENF) is the only fusion inhibitor available at this time. Enfuvirtide is a synthetic 36-amino-acid peptide that binds gp41, which inhibits envelope fusion of HIV-1 with the target cell, but does not have activity against HIV-2. Because of the peptide nature of enfuvirtide, oral delivery is impossible, and subcutaneous injection is the preferred route of administration. Injection-site reactions (pain, erythema, nodules) are the most common adverse effect, nearing 100% incidence. Enfuvirtide is cleared via protein catabolism and amino acid recycling, and it appears to have a low genetic barrier to resistance.[57] Maraviroc is a CCR5 antagonist with activity against HIV-1 and HIV-2. Unlike the other available antiretrovirals that interact with a viral target, CCR5 antagonists block a human receptor. The long-term consequences of blocking CCR5 are unknown but may include increased susceptibility to disease by flaviviruses (eg, West Nile virus and tickborne encephalitis virus).[59] One advantage of targeting a human receptor is that resistance to CCR5 antagonists may be more difficult to develop. Because CCR5 antagonists are only effective against R5 virus and not X4 virus, a viral tropism assay must be performed prior to using a CCR5 antagonist. Maraviroc is a CYP3A and P-glycoprotein substrate and is therefore susceptible to drug–drug interactions and caution should be used in those with advanced hepatic insufficiency. Maraviroc has been associated with rash and hepatotoxicity. Resistance mutations have been identified for enfuvirtide, which has a low-genetic barrier to resistance, but assays for maraviroc resistance have not been developed other than the R5 versus X4 tropism test.[38,57]

Among the newer classes of antiretroviral drugs are the InSTI including, raltegravir (RAL), dolutegravir (DTG), and elvitegravir (EVG). InSTI bind to HIV integrase while it is in a specific complex with viral DNA and inhibit the strand transfer that incorporates the proviral DNA into the chromosomal DNA. InSTI are active against HIV-1 and HIV-2. Raltegravir and dolutegravir are primarily glucuronidated by UGT1A1 and are not susceptible to CYP-mediated drug interactions, although other kinds of interactions may be important (**Table 126-3**). Elvitegravir is extensively metabolized by CYP3A and is co-formulated with cobicistat, a potent CYP3A inhibitor, to optimize drug exposure and enable once daily dosing. InSTI are relatively well-tolerated with adverse events that include rash, nausea, and headache. InSTI should be used with caution in advanced hepatic insufficiency. Multiple mutations have been identified conferring resistance to InSTI including cross-resistance as mutations accrue. Dolutegravir appears to have a higher genetic barrier to resistance compared with elvitegravir and raltegravir.[60]

Novel antiviral agents in the classes listed above and novel agents in new drug classes that exploit other steps in the HIV life cycle (see Fig. 126-1) are in development, with a focus on long-lasting activity (eg, nanosuspensions) and/or high activity against drug-resistant virus. In particular, nanosuspensions of a novel InSTI, cabotegravir and rilpivirine are in clinical-phase development as intermittent injections (eg, quarterly) for treatment and prophylaxis.[61,62]

The anti-herpes and anti-hepatitis B antivirals acyclovir, foscarnet, entecavir, and adefovir exhibit modest anti-HIV activity. If these antivirals are used in HIV-infected patients, it should be with suppressive ART therapy.

Drug Interactions

6 Medical use of antiretroviral agents is complicated by clinically significant drug–drug interactions that can occur with many of these agents.[38,63] Some interactions are beneficial and used purposely (eg, ritonavir and cobicistat as pharmacokinetic enhancers); others may be harmful, leading to dangerously elevated or inadequate drug concentrations. Clinicians involved in the pharmacotherapy of HIV must understand the mechanistic basis for these interactions and maintain a current knowledge of drug interactions for these reasons.

Many clinically significant antiretroviral-associated drug interactions involve CYP3A-mediated first-pass metabolism and clearance. The HIV PIs, except nelfinavir, the NNRTIs delavirdine, etravirine, and rilpivirine, the CCR5 antagonist maraviroc, and the InSTI elvitegravir are metabolized by CYP3A. In general, efavirenz, etravirine and nevirapine are inducers of CYP3A, whereas delavirdine and the PIs inhibit CYP3A. Ritonavir is a potent mechanism-based inhibitor of CYP3A-mediated metabolism and is now used exclusively at lower doses as a pharmacokinetic enhancer of other HIV PIs. Similarly, cobicistat, which is an analog of ritonavir without antiretroviral activity, is also a potent mechanism-based inhibitor of CYP3A activity and is used in a similar fashion. Darunavir, lopinavir, saquinavir, and tipranavir must be taken with ritonavir or cobicistat to achieve optimal plasma concentrations. Atazanavir, fosamprenavir, and indinavir are also primarily used with ritonavir or cobicistat for the same reason. Nelfinavir is not effectively boosted by ritonavir given its CYP2C19-mediated metabolism. Many potential concomitant drugs on the market are also metabolized by CYP3A and therefore susceptible to clinically relevant drug interactions with HIV PIs, NNRTIs, and cobicistat. Agents with narrow therapeutic indices and/or that exhibit major changes in pharmacokinetics with CYP3A inhibition are most important in this regard. Examples include, but are not limited to, simvastatin, lovastatin, corticosteroids (including inhaled and intranasal), ergot derivatives, oral hormonal contraceptives, some antiarrhythmics, and some anti-cancer agents.

The drug interaction potential of antimycobacterium agents, specifically the rifamycins, are particularly relevant given the high potential for such infections in HIV-infected patients.[63] Rifampin, a potent inducer of CYP3A metabolism and conjugation enzymes, is contraindicated with use of most HIV PIs, etravirine, rilpivirine, and maraviroc because concentrations are reduced substantially even with ritonavir enhancement. Raltegravir or dolutegravir dose should be doubled in the presence of rifampin; efavirenz is an alternative agent. Ritonavir enhancement generally allows coadministration of HIV PIs with rifabutin.[38] In such cases, the rifabutin dose will require adjustment given its CYP3A-mediated clearance. The herbal product St. John's wort (*Hypericum perforatum*) is a potent inducer of metabolism and is contraindicated with PIs, NNRTIs, and maraviroc.[38] It must be stressed that the pharmacology of CYP3A interactions may be complicated by simultaneous induction/inhibition of drug transporter-mediated (eg, P-glycoprotein) clearance and/or other phase I (eg, CYP 2B6 for RTV) or phase II enzymes.

Some antiretroviral drugs require acidic environments for optimal absorption leading to interactions with antacids, particularly proton-pump inhibitors (eg, atazanavir, rilpivirine). On the other hand, some antiretroviral agents chelate polyvalent cations in antacids, reducing absorption following concomitant dosing (eg, raltegravir, dolutegravir, elvitegravir); dosing can be temporally separated for these cases. Other potential mechanisms for drug interactions include inhibition of renal tubule secretion (eg, TFV and OAT inhibitors), and antagonistic phosphorylation for NRTI of the same nucleobase (eg, lamivudine and emtricitiabine). This list of drug interactions and mechanisms for drug interactions is not complete. Clinicians who treat HIV must stay abreast of antiretroviral drug interaction data. Websites are available that catalog and regularly update HIV drug-interaction information (*http://www.hiv-druginteractions.org/*), and the Department of Health and Human Services guidelines for antiretroviral use provide, and regularly update, excellent summaries of known clinically relevant drug interactions.[38]

Landmarks in the Evolution of Antiretroviral Therapy

7 ART has undergone major changes over the past decades. Illustrating these changes is important for a thorough understanding of current treatment strategies. The fundamental landmarks in the use of antiretroviral agents are as follows:

1. An early study demonstrated that zidovudine monotherapy confers a survival benefit in persons who have AIDS.[64]

2. Combination regimens of two NRTIs (eg, zidovudine and didanosine or zalcitabine) were superior to zidovudine monotherapy in immunologic and virologic parameters, particularly in patients with no previous ART, and conferred a superior survival benefit.[65] This established that NRTI monotherapy was inferior to dual NRTI therapy.

3. Dual NRTI therapy was inferior to triple therapy consisting of 2 NRTIs and the HIV PI indinavir.[66] Use of triple therapy with combinations of two NRTIs with NNRTIs or HIV PIs was associated with a durable response as well as significantly reduced incidence of OIs and improved survival, thus establishing the current paradigm of ART.[67]

4. Evolution of triple-therapy regimens utilizing boosted HIV PIs, co-formulations, new drug classes, and better tolerated agents showed improvements in convenience, tolerability, safety, and virologic efficacy, all helping usher in the current era of ART.[68, 69]

7 Taken together, the pivotal studies described above established that HIV should not be treated with single or dual NRTIs. Recommendations for initial treatment of HIV infection advocate a minimum of three active antiretroviral agents: tenofovir disoproxil fumarate plus emtricitabine with either a ritonavir-enhanced PI (darunavir) or the InSTIs, elvitegravir/cobicistat, dolutegravir, or raltegravir. Additionally, tenofovir alafenamide/emtricitabine plus elvitegravir/cobicistat or abacavir/lamivudine plus dolutegravir are other first-line options (abacavir can only be used in patients who are HLA-B5701 negative). Multiple alternative regimens are also safe and effective, but have one or two disadvantages compared with the preferred regimens such as weaker virologic

responses with high viral loads, lower tolerability, or greater risk of long-term toxicities such as subcutaneous fat loss. Preferred antiretroviral regimens are listed in Table 126-3. Recommended first line ART regimens constantly evolve (as described above) and clinical controversies emerge as data and clinical experience accrue and new strategies come under consideration.

Clinical Controversy…

"Induction-maintenance" therapy is a strategy whereby ART is initiated with three active drugs (conventional ART), but one or two drugs are stopped once undetectable HIV-RNA has been established (ie, maintenance therapy with mono- or dual-drugs). The hope is to reduce cost and long-term drug toxicities, especially related with older NRTIs. This led to maintenance strategies that were NRTI-sparing. Early maintenance regimens led to some elevation in risk for breakthrough viremia, which lowered enthusiasm for this approach. However, new more potent drugs have revived interest. A current example includes a maintenance dual-drug therapy with cabotegravir (investigational InSTI) and rilpivirine (NNRTI), which are under study as intermittent nanosuspension injections.

Adherence

The simplest definition of adherence is the patient's follow through on taking medication as directed. As with any chronic therapy, variable adherence to ART is common, and it significantly impacts virologic response. Factors associated with poor adherence include major psychiatric illnesses, active substance abuse, unstable social circumstances, adverse events, and poor adherence with clinic visits.[38] Most, but not all, modern ART regimens consist of co-formulations and long half-life drugs allowing for once-daily dosing (sometimes without food restrictions), which facilitates adherence compared with multiple dose units, multiple doses per day, and food restrictions with dosing. Average adherence rates range from 60% to 80% for both HIV PI and NNRTI-based regimens including 30% of subjects who miss less than 7 consecutive days of dosing.[70, 71] The odds of persistent or breakthrough viremia are several-fold higher in patients with adherence below 60% to 80%, and the risk mounts with longer dosing "holidays."[72] As clinicians, it is critical to establish a relationship of trust with the patient and to communicate to the patient the importance of proper medication taking. Education should be aimed at understanding the disease process, monitoring, and goals of therapy. An individual's "readiness" to take medications should be clearly established before treatment is initiated.[38] Help from caregivers, friends, and/or family members should be leveraged by the patient because social and psychological support are among the most important factors that influence adherence in this patient population.

Efficacy

Based on clinical trial data, approximately 90% of patients will achieve undetectable viral loads with modern ART regimens.[68,69] The preferred NRTI combination, tenofovir disoproxil fumarate plus emtricitabine, has demonstrated virologic and safety/tolerability advantages compared with zidovudine/lamivudine and abacavir/lamivudine (when combined with atazanavir/ritonavir or efavirenz).[73,74] Its main drawback is renal tubulopathy risk for tenofovir disoproxil fumarate,

especially in those with preexisting renal dysfunction. When combined with dolutegravir, abacavir-lamivudine exhibited superior efficacy rates regardless of baseline viral load compared with efavirenz-tenofovir disoproxil fumarate-emtricitabine.[69] This finding was mainly due to fewer discontinuations arising from adverse events for the abacavir-lamivudine-dolutegravir regimen (most in the other arm were associated with efavirenz). Tenofovir alafenamide was compared with tenofovir disoproxil fumarate both given with emtricitabine- elvitegravir- cobicistat.[68] Similar efficacy was observed but changes in creatinine clearance and bone demineralization was more favorable for tenofovir alafenamide compared with tenofovir disoproxil fumarate. Together, these studies established recommendations for tenofovir disoproxil fumarate -emtricitabine, tenofovir alafenamide -emtricitabine, abacavir-lamivudine as initial NRTI therapy. Note, if abacavir is to be used in any regimen, a test for the presence of human leukocyte antigen (HLA)-B*5701 must be done as its presence has been strongly correlated with the development of abacavir hypersensitivity. Should this test be positive, an abacavir allergy should be added to the patient's chart and abacavir should not be used in the patient, as the hypersensitivity reaction can be life-threatening.

The third active agent of ART regimens has also evolved based on large, randomized, controlled trials. Efavirenz maintained a long history as the recommended third active agent until recently, when comparative trials demonstrated poorer tolerability and more therapy discontinuations for efavirenz versus InSTI.[69,75,76] CNS perturbations such as somnolence, vivid dreams, and depressive symptoms are troublesome issues for efavirenz. Similarly, atazanavir-ritonavir was a recommended third active agent until it showed higher rates of treatment discontinuations compared with raltegravir and darunavir-ritonavir.[77] Atazanavir inhibits the bilirubin conjugating enzyme resulting in asymptomatic hyperbilirubinemia, but in those with Gilbert's disease, the hyperbilirubinemia can be more pronounced leading to drug discontinuation.[78] Together, these studies support recommendations for darunavir-ritonavir and InSTIs as third active agents for preferred initial ART regimens. Many agents are available for inclusion in alternative regimens, including efavirenz and atazanavir-ritonavir, among others. Recommended preferred and alternative regimens are continuously updated as new studies are performed and longer-term follow-up data accrue. Patients with sustained undetectable HIV-RNA taking out-of-date drug regimens may be candidates to simplify to one of the preferred regimens or a more desirable alternative regimen based on past treatment history and other variables. Simplified regimens should continue to include three active drugs.

Resistance

8 Regimen failure is commonly associated with antiretroviral resistance, and testing for such resistance is a useful clinical tool.[57,58] The two types of resistance tests available are phenotype and genotype. A phenotype test determines the concentration of antiretroviral agent necessary to inhibit 50% (IC_{50}) replication of the patient's viral isolate (inhibitory concentration of 50% [IC_{50}]) in a recombinant in vitro viral assay. Results usually are expressed as a fold change in susceptibility (IC_{50}) compared with a wild-type laboratory strain virus. Generally, the fold-change in IC_{50} increases as HIV accumulates additional mutations that confer resistance to a particular drug. However, a single mutation may confer a very high fold-change in IC_{50} for some drugs (eg, lamivudine, emtricitabine, efavirenz, nevirapine) rendering them ineffective after a single mutation. Although small-to-moderate

increases in the fold change suggests reduced susceptibility to that antiretroviral agent, resistance may not be absolute, and partial susceptibility may remain. Theoretically, drug concentrations may be increased to overcome reduced susceptibility. The strengths of phenotypic testing is to provide resistance information for complex mutation patterns, but it is also associated with higher cost, limited number of commercial providers, and slower turnaround time for results. Genotyping assesses genetic mutations and associated codon changes in gp41, reverse transcriptase, integrase, or protease in the patient's virus and compares it with the wild-type sequence. Certain mutations are known to confer resistance to specific drugs. An updated list of drug resistance mutations can be found at (http://www.iasusa.org/resistance_mutations). Mutations are listed by the wild-type amino acid followed by the position in the protein or enzyme and end with the mutation found in the patient's virus. For example, a common mutation caused by lamivudine and emtricitabine is the M184V mutation: a substitution of valine (V) for methionine (M) at the 184 position of reverse transcriptase. Mutations can confer varying degrees of antiretroviral drug resistance and in some cases, weighting algorithms have been developed to predict the relative impact of mutation combinations on antiretroviral activity. Algorithms have also been developed to predict a phenotype from a genotype test (ie, virtual phenotype). Not all mutations, however, are only detrimental—for example, while M184V confers significant resistance to lamivudine and emtricitabine, it is also associated with a less fit virus. Interpretation of genotype resistance tests is complex; therefore, the reader is encouraged to obtain expert advice and consult the most recent guidelines on HIV resistance testing.

Treatment of Special Populations

Pregnancy

Several considerations are relevant to the treatment of pregnant women, including the health of the mother, prevention of HIV transmission to the fetus, potential for teratogenicity, and drug dosing issues based on pharmacokinetic changes during pregnancy. Treatment recommendations should be consulted to address the specific requirements for HIV-infected pregnant women and the prevention of vertical transmission.[17] Generally, pregnant women should be treated as would nonpregnant women, with the goal of maximally suppressing HIV-RNA. Efavirenz should be avoided when possible in women planning to become pregnant or who are not using effective contraception as efavirenz has been associated with neural tube defects in the first trimester, in some but not all studies.[79] Zidovudine is recommended intrapartum depending on the mother's viral load (more than 1,000 copies/mL [more than 1,000 × 10^3/L] or unknown), based on early studies demonstrating clear prophylactic effectiveness as well as extensive familiarity with the side effect profile.[17] Infants born to HIV infected mothers should also receive zidovudine (± several doses of nevirapine) prophylaxis for 4 to 6 weeks after birth. HIV transmission rates to their infants have been reduced to less than 0.5% for women who are treated with ART and when zidovudine prophylaxis is used. Breastfeeding is not recommended in the USA, but in resource-limited settings where lack of clean water makes breastfeeding a more favorable option, infants receive six weeks of once-daily nevirapine for prophylaxis. [17]

Chemoprophylaxis

9 In addition to fetal and infant chemoprophylaxis, protection of healthcare workers from accidental exposure to HIV and in cases of rape or high-risk postcoital and postinjection drug-use episodes are important concerns. The CDC has issued guidelines governing antiretroviral postexposure prophylaxis (PEP) of occupational and other high-risk HIV exposures that should be consulted for updates as the knowledge in this field evolves.[11,14] The principles of the guidelines are to assess the exposure risk and treat as soon as possible after high-risk exposures to prevent HIV infection. Assessing the exposure risk requires knowledge of the HIV-infection status of the source individual, which can be difficult to ascertain. The HIV status of the source should be determined as soon as possible with a rapid HIV test, whenever feasible. However, providers may have to rely on reasonable suspicion when this is not possible, so provider expertise is essential. PEP should not be delayed while waiting on the HIV status of the source, if reasonable suspicion is present. PEP should be considered an urgent medical situation. Both guidelines recommend conventional ART regimens (eg, tenofovir disoproxil fumarate -emtricitabine-rategravir), initiated as soon as possible, ideally within 1 to 2 hours of exposure. Animal studies show reduced PEP efficacy when initiated 72 hours or more after the exposure.[14] The optimal duration of treatment is unknown, but at least 4 weeks of therapy is advocated. Expert consultation is needed when exposure to drug-resistant virus is suspected or confirmed, but this should not delay initial initiation of PEP.

Preexposure prophylaxis (PrEP) involves daily tenofovir disoproxil fumarate–emtricitabine in HIV-negative persons at high risk of HIV acquisition to prevent infection should an HIV-exposure occur.[80] PrEP is effective in MSM, sero-discordant couples, at-risk heterosexual men and women, including those who inject drugs. The key considerations for PrEP are to assess HIV risk for the individual (ie, risk should be elevated) and to document a negative HIV test prior to initiating PrEP, including negative symptoms of acute HIV infection. Reports of drug resistance from PrEP failures were mostly among individuals who initiated PrEP during acute HIV infection, in the window period before the rapid HIV test could detect infection.[81] HIV-testing should be repeated at least every 3 months and renal function should be assessed every 6 months while on PrEP.[80] Promotion of adherence is critical for PrEP effectiveness. The most up-to-date PrEP guidelines should be consulted, as new PrEP strategies are currently under evaluation.

EVALUATION OF THERAPEUTIC OUTCOMES

Two laboratory tests are used to evaluate response to ART: the plasma HIV RNA and the CD4 count.[38] These tests should be performed at baseline, along with a medical history and physical, urinalysis, hematology, chemistries, serologies for coinfections, and patient education about HIV infection. A HIV resistance test is recommended upon initiation of care. After therapy is initiated, patients are generally monitored at 3-month intervals until HIV-RNA reaches undetectable levels. An assessment at 2 to 8 weeks is warranted to document early response. Monitoring may be increased to every 6 months in stabilized patients. The two main indications for a change in therapy are significant toxicity and treatment failure. Should a single agent be responsible for an intolerable side effect, that agent often can be singly changed out of the regimen, for example, the patient who experiences intolerable CNS disturbances during initiation of efavirenz can switch to a boosted PI or inSTI without changing the dual NRTI backbone. Maintaining virologic suppression is an important goal for switching therapy

due to adverse events. Caution must be exercised when drugs in the regimen have overlapping toxicities, which makes changing a single agent problematic. Serious and life-threatening toxicities warrant cessation of the whole regimen before deciding upon a subsequent therapy.

As a general guide, the inability to achieve and maintain less than 200 copies/mL (200 × 10^3/L) of HIV-RNA represents treatment failure and should prompt consideration for changing therapy. This includes the inability to achieve less than 200 copies/mL (200 × 10^3/L) by 24 weeks of therapy initiation (repeat testing is suggested to confirm), or, after HIV RNA suppression, repeated detection of greater than 200 copies/mL (200 × 10^3/L) of HIV-RNA.

Therapeutic Failure

8 The most important measure of therapeutic failure is suboptimal suppression of viral replication. Many reasons may underlie suboptimal suppression of viral replication such as pre-ART disease factors (eg, high viral load or preexisting drug resistance), nonadherence to medication, development of new drug resistance, intolerance to one or more medications, adverse drug–drug or drug–food interactions, or pharmacokinetic–pharmacodynamic variability.[38] In cases of suboptimal suppression of viral replication, these potential causes should be investigated and addressed, if possible. As a general rule, drug resistance develops for regimens that do not maximally suppress HIV replication. Drug resistance testing is recommended while the patient is undergoing the failing regimen or within 4 weeks after stopping the regimen as long as the HIV RNA count is greater than 500 copies/mL (500 × 10^3/L), which is the threshold for resistance assays (~500-1,000 copies/mL [~500 × 10^3-1000 × 10^3/L]). Virus may revert to wild-type if more than 4 to 6 weeks has elapsed between regimen discontinuation and the resistance test. Most clinicians use the genotype assay because it is less expensive and results typically are available sooner compared with the phenotype assay. Resistance results usually require expert interpretation. Treating patients with drug-resistant HIV utilizes the same general treatment approaches described for initial therapy above. Patients should be treated with at least two (preferably three) fully active antiretroviral drugs based on medication history, resistance tests, and new mechanistic drug classes (eg, maraviroc and InSTIs). The goal of therapy is to suppress HIV-RNA to undetectable levels. In cases when undetectable HIV-RNA cannot be attained, maintenance on the regimen is preferred over drug discontinuation so as to prevent rapid immunological and clinical decline.

Several antiretroviral drugs are well-suited for drug-resistant HIV. For example, the HIV PI, tipranavir-ritonavir and the NNRTI, etravirine have demonstrated activity in persons with multidrug-resistant HIV in controlled clinical trials.[82,83] The drugs in the newer classes (ie, inSTI, CCR5 antagonist, and enfuvirtide) are also active against NRTI-, NNRTI-, and PI-resistant viruses in highly treatment experienced patients in controlled trials.[84,85]

Prior to the availability of new drugs and drug classes, other strategies were studied to help manage therapeutic failure including drug holidays, structured or strategic treatment interruptions, and structured intermittent therapy. The overall premise of these strategies was similar: stop all antiretrovirals to spare the patient from drug toxicities and to allow the virus to revert to wild-type. Reinitiation of therapy was intended to reestablish control of viral replication, as wild-type virus

would be expected to predominate, although it was known that resistant virus was archived in long-lived cells, so viral suppression was short-lived. A landmark clinical trial showed that patients randomized to episodic therapy (drug-sparing) guided by the CD4 experienced significantly increased risk of opportunistic disease or death from any cause, including non-AIDS causes.[86,87] This and other studies have established that viral replication is damaging to the immune system and end organs and drug-sparing approaches are not advocated.

Clinical Controversy…

There is a strong theoretical rationale for therapeutic drug monitoring in the treatment experienced patient, but this approach is controversial. Drug susceptibility is founded on the premise that increasing drug concentration corresponds with stronger inhibition of replication up to a maximal effectiveness. This principle holds for drug-resistant variants, except higher drug concentrations are needed for the same levels of inhibition. Therefore, drug concentration monitoring could guide dose adjustments needed to attain the higher target drug concentrations required for optimal viral inhibition.Therapeutic drug monitoring is suggested as a consideration for patients with multidrug-resistant HIV as well as in other select clinical situations. However, limitations to therapeutic drug monitoring include the lack of established target concentrations, unsuitable dose formulations for minor adjustments, intrapatient pharmacokinetic variability, lack of randomized clinical trials proving benefit or cost effectiveness, and few analytical laboratories and experts available for interpretation.

COMPLICATIONS OF HIV INFECTION AND AIDS

3 In the pre-ART era, the major therapeutic focus was prevention and treatment of OIs associated with uncontrolled HIV replication and the steady decline in CD4 cells.[44] Uncontrolled HIV is an insidious disease; persons often present with OIs, a consequence of the weakened immune system rather than HIV per se. Most OIs are caused by organisms that are common in the environment and often represent the reactivation of quiescent, hidden infections common in the population. The probability of developing specific OIs is closely related to CD4 count thresholds (**Fig. 126-2**). These CD4 thresholds serve as a basis for initiating primary OI chemoprevention.

FIGURE 126-2

Natural history of opportunistic infections associated with human immunodeficiency virus infection. CD4 counts expressed as cells/μL can be converted to SI units by multiplying by 10^6/L. *(Reprinted with permission, © Courtney V. Fletcher, 2009.)*

5 In the ART era, the main principle in the management of OIs is treating HIV infection to enable CD4 cell recovery and maintenance above safe levels.[63] Additional important principles regarding management of OIs are as follows:

1. Prevent exposure to opportunistic pathogens
2. Vaccinate to prevent first-episode disease (consult HIV-specific guidelines)
3. Use primary chemoprophylaxis at certain CD4 thresholds to prevent first-episode disease
4. Treat emergent OI
5. Use secondary chemoprophylaxis to prevent disease recurrence
6. Discontinue prophylaxes with sustained ART-associated immune recovery

Several considerations are required for the patient who presents with an OI and is simultaneously diagnosed with HIV and who thus needs both OI and ART treatment. Immediate initiation of ART is indicated for OIs that respond to CD4 recovery, such as cryptosporidiosis, progressive multifocal leukoencephalopathy, and mild-to-moderate Kaposi's sarcoma. Rapid initiation of ART (within days to weeks) is also indicated in the setting of other OIs such as tuberculosis, *Mycobacterium avium* complex (MAC), and PCP, but several potential issues need consideration. First, drug–drug interactions and the complexity of adhering to concomitant ART and OI regimens can be daunting. Careful review of potential interactions and adherence support should be provided. Second, clinicians must be cognizant of potentially overlapping drug toxicities (eg, rash) that creates problems when attempting to stop the perceived culprit drug. Third, an immune reconstitution syndrome (IRIS) has

been associated with initiation of ART in the presence of underlying OIs. IRIS is generally characterized by fever and worsening of OI manifestations in the first few weeks to months after initiating ART.[88] Risk factors for IRIS are a low CD4 count (eg, less than 50 cells/μL [less than 50 × 10^6/L]) and a high antigenic burden. An ART-associated rapid-onset immune reconstitution against the smoldering OI infection, and resulting proinflammatory cytokine cascade, is thought to be the mechanism of IRIS. The most serious IRIS reactions involve neurological OIs such as cryptococcal meningitis, where IRIS can lead to increased morbidity and mortality. For cryptococcal meningitis, it may be prudent to delay ART until completion of the induction or induction/consolidation phase of antifungal therapy (up to 10 weeks).[63] Generally, treatment of IRIS is supportive and may include corticosteroids and/or NSAIDs, depending on the OI. Expert consultation should be used in the management of ART initiation in patients with advanced HIV infection and OIs, and the most up-to-date guidelines should be consulted.[63]

The epidemiology of specific OIs can depend upon geographical region. For instance, TB is particularly endemic on the Africa continent and is considered a major OI in that region, but the incidence of this OI is relatively uncommon in the USA.[89] Major OIs in the USA include PCP, toxoplasmosis, MAC, cytomegalovirus retinitis, and cryptococcal meningitis. All have decreased substantially in incidence with the advent of ART.[44,63,67] Furthermore, primary and secondary chemoprophylaxis for specific OIs have contributed to the same decreases.[44] Nevertheless, opportunistic diseases continue to be complications of HIV disease and occur at low CD4 lymphocyte counts in patients who are unaware of their HIV infection, or who have not responded to ART therapy or OI prophylaxis because of adherence issues or inadequate engagement with the healthcare system.[63]

Selected OIs and example recommended first-line regimens for OI treatment are given in **Table 126-5**, and example recommended therapies for primary OI prophylaxis are given in **Table 126-6**.[63] These recommendations are representative and not as extensive as in the published guidelines, which include multiple additional treatment considerations and alternatives, as well as coverage of less common OIs. The following brief discussion of PCP provides a more in depth overview of the epidemiology, diagnosis, clinical manifestations, and results of treatment and serves as an illustration for the principles discussed above.

TABLE 126-5 Selected Therapies for Common Opportunistic Pathogens in HIV-Infected Individuals

Clinical Disease	Preferred Initial Therapies for Acute Infection in Adults (Strength of Recommendation in Parentheses)	Common Drug- or Dose-Limiting Adverse Reactions
Fungi		
Candidiasis, oral	Fluconazole 100 mg orally for 7-14 days (AI) *or* Nystatin 500,000 units oral swish (~5 mL) four times daily for 7-14 days (BII)	Elevated liver function tests, hepatotoxicity, nausea, and vomiting Taste, patient acceptance

Clinical Disease	Preferred Initial Therapies for Acute Infection in Adults (Strength of Recommendation in Parentheses)	Common Drug- or Dose-Limiting Adverse Reactions
Candidiasis, esophageal	Fluconazole 100-400 mg orally or IV daily for 14-21 days (AI)	Same as above
	or	
	Itraconazole 200 mg/day orally for 14-21 days (AI)	Elevated liver function tests, hepatotoxicity, nausea, and vomiting
Pneumocystis jirovecii pneumonia	Trimethoprim–sulfamethoxazole IV or orally 15-20 mg/kg/day as trimethoprim component in three to four divided doses for 21 days[a] (AI) moderate or severe therapy should be started IV	Skin rash, fever, leucopenia Thrombocytopenia
	or	
	Pentamidine IV 4 mg/kg/day for 21 days[a] (AI)	Azotemia, hypoglycemia, hyperglycemia, arrhythmias
	Mild episodes	
	Atovaquone suspension 750 mg (5 mL) orally twice daily with meals for 21 days[a] (BI)	Rash, elevated liver enzymes, diarrhea
Cryptococcal meningitis	Liposomal amphotericin B 3-4 mg/kg/day IV for a minimum of 2 weeks with flucytosine 100 mg/kg/day orally in four divided doses (AI) *followed by*	Nephrotoxicity, hypokalemia, anemia, fever, chills Bone marrow suppression
	Fluconazole 400 mg/day, orally for 8 weeks or until CSF cultures are negative (AI)[a]	Same as above
Histoplasmosis	Liposomal amphotericin B 3 mg/kg/day IV for 2 weeks (AI) *followed by*	Same as above
	Itraconazole 200 mg orally thrice daily for 3 days then twice daily, for 12 months (AII)[a]	
Coccidioidomycosis	Liposomal amphotericin B 4-6 mg/kg/day IV until clinical improvement (usually after 500-1,000 mg) then switch to azole (AIII)[a]	Same as above
	or	
	Fluconazole 400-800 mg once daily (meningeal disease) (AII)[a]	Same as above
Protozoa		
Toxoplasmic encephalitis	Pyrimethamine 200 mg orally once, then 50-75 mg/day	Bone marrow suppression

Clinical Disease	Preferred Initial Therapies for Acute Infection in Adults (Strength of Recommendation in Parentheses)	Common Drug- or Dose-Limiting Adverse Reactions
	plus	
	Sulfadiazine 1-1.5 g orally four times daily	Rash, drug fever
	and	
	Leucovorin 10-25 mg orally daily for 6 weeks (AI)[a]	
Isosporiasis	Trimethoprim and sulfamethoxazole: 160 mg trimethoprim and 800 mg sulfamethoxazole orally or IV four times daily for 10 days (AII)[a]	Same as above
Bacteria		
Mycobacterium avium complex	Clarithromycin 500 mg orally twice daily, *plus* ethambutol 15 mg/kg/day orally (AI) for at least 12 months	GI intolerance, optic neuritis, peripheral neuritis, elevated liver tests
Salmonella enterocolitis or bacteremia	Ciprofloxacin 500-750 mg orally (or 400 mg IV) twice daily for 14 days (longer duration for bacteremia or advanced HIV) (AIII)	GI intolerance, headache, dizziness
Campylobacter enterocolitis (mild to moderate)	Ciprofloxacin 500-750 mg orally (or 400 mg IV) twice daily for 7-10 days (or longer with bacteremia) (BIII)	Same as above
Shigella enterocolitis	Ciprofloxacin 500-750 mg orally (or 400 mg IV) twice daily for 7-10 days (or 14 days for bacteremia) (AIII)	Same as above
Viruses		
Mucocutaneous herpes simplex	Acyclovir 5 mg/kg IV every 8 hours until lesions regress, then acyclovir 400 mg orally three times daily until complete healing (famciclovir or valacyclovir is alternative) (AIII)	GI intolerance, crystalluria
Primary varicella-zoster	Acyclovir 10-15 mg/kg every 8 hours IV for 7-10 days (severe cases), then switch to oral valacyclovir 1 g three times daily after defervescence (famciclovir or acyclovir is alternative) (AIII)	Obstructive nephropathy, CNS symptoms
Cytomegalovirus (retinitis)	Intravitreal ganciclovir (2 mg) one to four doses over 7-10 days (for sight threatening lesions) *plus* valganciclovir 900 mg twice daily for 14-21 days then once daily until immune recovery from ART (AIII)[a]	Neutropenia, thrombocytopenia

Clinical Disease	Preferred Initial Therapies for Acute Infection in Adults (Strength of Recommendation in Parentheses)	Common Drug- or Dose-Limiting Adverse Reactions
Cytomegalovirus esophagitis or colitis	Ganciclovir 5 mg/kg IV every 12 hours for 21-42 days may switch to valganciclovir 900 mg orally every 12 hours when oral therapy can be tolerated (BI)	Same as above

ART, antiretroviral therapy; CSF, cerebrospinal fluid; HIV, human immunodeficiency virus.

[a]Maintenance therapy is recommended.

See Table 126-3 for levels of evidence-based recommendations.

TABLE 126-6 Therapies for Prophylaxis of Select First-Episode Opportunistic Diseases in Adults and Adolescents

Pathogen	Indication	First Choice (Strength of Recommendation in Parentheses)
I. Standard of care		
Pneumocystis jirovecii	$CD4^+$ count <200/mm^3 (<200 × 10^6/L) *or* oropharyngeal candidiasis	Trimethoprim–sulfamethoxazole, one double-strength tablet orally once daily (AI) or one single-strength tablet orally once daily (AI)
Histoplasma capsulatum	$CD4^+$ count <150/mm^3, (<150 × 10^6/L) endemic geographic area and high risk for exposures	Intraconazole 200 mg orally once daily (BI)
Mycobacterium tuberculosis		
Isoniazid-sensitive	(Active TB should be ruled out): + test for latent TB infection with no prior TB treatment history (AI) *or* – test for latent TB infection, but close contact with case of active tuberculosis (AII)	Isoniazid 300 mg orally plus pyridoxine, 25 mg orally once daily for 9 months (AII) *or* Isoniazid 900 mg orally twice weekly by directly observed therapy (BII) plus pyridoxine 25 mg orally daily for 9 months (BII)
For exposure to drug-resistant TB	Consult public health authorities	
Toxoplasma gondii	Immunoglobulin G antibody to *Toxoplasma* and $CD4^+$ count	Trimethoprim–sulfamethoxazole one double-strength tablet orally once daily

Pathogen	Indication	First Choice (Strength of Recommendation in Parentheses)
	<100/mm^3 (<100 × 10^6/L)	(AII)
Mycobacterium avium complex	CD4$^+$ count <50/mm^3 (<50 × 10^6/L)	Azithromycin 1,200 mg orally once weekly (AI) or 600 mg orally twice weekly (BIII) or clarithromycin 500 mg orally twice daily (AI)
Varicella zoster virus (VZV)	Preexposure: CD4 ≥200/mm^3 (≥200 × 10^6/L), no history of varicella vaccination or infection, or, if available, negative antibody to VZV	Varicella vaccination; two doses, 3 months apart (CIII)
	Postexposure: Significant exposure to chicken pox or shingles for patients who have no history of vaccination or either condition or, if available, negative antibody to VZV	Varicella-zoster immune globulin, 125 IU per 10 kg (maximum of 625 IU) IM, as soon as possible and within 10 days after exposure (AIII)
Streptococcus pneumoniae	Any individual regardless of CD4 count	13-valent polysaccharide vaccine, 0.5 mL intramuscularly once (AI) followed by 23-valent polysaccharide vaccine 0.5 mL 8 weeks later (CIII) Re-vaccinate with 23-valent polysaccharide vaccine every 5 years
Hepatitis B virus	All susceptible patients	HBV vaccine IM (Engerix-B 20 mcg/mL or Recombivax HB 10 mcg/mL), 0, 1, and 6 months (AII) Anti-HBs should be obtained 1 month after the vaccine series completion (BIII)
Influenza virus	All patients (annually, before influenza season)	Inactivated trivalent influenza virus vaccine (annual): 0.5 mL intramuscularly (AIII) (live-attenuated vaccine is contraindicated in all HIV-infected patients)
Hepatitis A virus	All susceptible (anti-hepatitis A virus–negative) patients at increased risk for hepatitis A infection (eg, chronic liver disease, injection drug users, men who have sex with men)	Hepatitis A vaccine: two doses (AII) antibody response should be assessed 1 month after vaccination; with revaccination as needed when CD4 >200 cells/μL (>200 × 10^6/L)(BIII)
Human papillomavirus (HPV) infection	13-26 year old males and females	HPV quadrivalent vaccine months 0, 1-2, and 6 (BIII)

See Table 126-3 for levels of evidence-based recommendations.

Data from reference 63.

***Pneumocystis jirovecii* Pneumonia**

5 *Pneumocystis jirovecii* (*carinii*) pneumonia (PCP) has been and continues to be the most common life-threatening OI in patients with AIDS.[90] *P. jirovecii* was formerly named *P. carinii*; the name change was made to distinguish the organism that infects humans (*P. jirovecii*) from the strain that infects rodents (*P. carinii*). Nevertheless, the acronym PCP is still used today. Early in the AIDS epidemic 80% of patients experienced PCP at some point during their lifetime.[91] Although the incidence of PCP has fallen markedly since the advent of ART and effective prophylaxis for PCP, it still occurs in persons unaware of their HIV infection, and breakthrough PCP can occur in those with variable adherence to ART and/or prophylaxis.

P. jirovecii is a fungus that has protozoan characteristics as well.[90,91] Exposure to *P. jirovecii* is widespread; two thirds of the population have developed serum antibodies by age 2 to 4 years. The organism appears to reside without consequence in humans unless the host becomes immunologically impaired.[92] Disease associated with immunosuppression probably occurs from both new acquisition and reactivation. Ninety percent of PCP cases in AIDS patients occurred in those with CD4 counts less than 200 cells/mm^3 (200 × 10^6/L).[63] Other risk factors include oral thrush, recurrent bacterial pneumonia, unintentional weight loss, and high plasma HIV RNA. Past episodes of PCP increase risk for future episodes, which provides the basis for secondary chemoprophylaxis, as described below.

The presentation of PCP in AIDS often is insidious.[90] Characteristic symptoms include fever and dyspnea. Clinical signs are tachypnea with or without rales or rhonchi and a nonproductive or mildly productive cough occurring over a period of weeks, although more fulminant presentations can occur. Chest radiographs may show florid or subtle interstitial and bilateral infiltrates but occasionally are normal. Arterial blood gases may show minimal hypoxia (PaO_2 80 to 95 mm Hg [10.6-12.6 kPa]) but in more advanced disease may be markedly abnormal. The diagnosis of PCP usually is made by identification of the organism in induced sputum or in specimens obtained from bronchoalveolar lavage. Less commonly, transbronchial or open lung biopsy is used to locate the organism. Diagnostic PCR tests of bronchoavelor lavage is an emerging approach.[63]

Untreated PCP has a mortality rate of nearly 100%. Several potential treatments are available for PCP, but the treatment of choice is trimethoprim–sulfamethoxazole (also called cotrimoxazole), which is associated with a response rate of 60% to 100%.[63] Parenteral pentamidine is equally efficacious but significantly more toxic. Trimethoprim–sulfamethoxazole is also the regimen of choice for primary and secondary prophylaxis of PCP in patients with and without HIV.[63,90]

When used for treatment of PCP, the dose of trimethoprim–sulfamethoxazole is 15 to 20 mg/kg/day (based on the trimethoprim component) as three to four divided doses. Treatment duration typically is 21 days but also must be based on clinical response. Trimethoprim–sulfamethoxazole usually is initiated by the IV route, although oral therapy may suffice in mildly ill and reliable outpatients or for completion of a course of therapy after a response has been achieved with IV administration.[63,90]

Patients with moderate-to-severe PCP (eg, PaO_2 more than 70 mm Hg [more than 9.3 kPa]) should be treated with corticosteroids as soon as possible after starting PCP therapy and certainly within 72 hours, in order to blunt the deterioration seen just after initiation of PCP therapy. Alternative regimens include pentamidine for moderate-to-severe disease and dapsone with trimethoprim, primaquine with clindamycin, and atovaquone for mild-to-moderate PCP.[63] Early initiation of ART (within 2 weeks) is recommended keeping in mind the potential issues described earlier.

Adverse reactions to trimethoprim–sulfamethoxazole and pentamidine are common, occurring in 20% to 85% of patients in this setting.[63] The more common adverse reactions seen with trimethoprim–sulfamethoxazole are rash (rarely including Stevens–Johnson syndrome), fever, leukopenia, elevated serum transaminase levels, and thrombocytopenia. The incidence of these adverse reactions is higher in HIV-infected individuals than in those not infected with HIV. Mild rashes should be watched closely for progression to more severe reactions but are not an absolute contraindication to continuing therapy.[63] This highlights the need for thoughtful consideration of ART components because of overlapping toxicities with some antiretrovirals such as NNRTI, which also are associated with rash and hypersensitivity, including life-threatening cases. For pentamidine, side effects are pronounced and include hypotension, tachycardia, nausea, vomiting, severe hypoglycemia or hyperglycemia, pancreatitis, irreversible diabetes mellitus, elevated serum transaminase levels, nephrotoxicity, leukopenia, and cardiac arrhythmias. Some of these reactions appear to be related to the infusion rate (eg, hypotension and tachycardia) and can be minimized by infusing pentamidine over 1 hour or more.[91] Dosage modification or pharmacokinetic monitoring can reduce the toxicity of both pentamidine and trimethoprim–sulfamethoxazole. Dose reduction of pentamidine from 4 to 3 mg/kg/day appears to be successful in minimizing further rises in serum creatinine levels.[91] As mentioned earlier, early addition of adjunctive corticosteroid therapy to anti-PCP regimens decreases the risk of respiratory failure and improves survival.[63] The adverse effects associated with corticosteroid use for this scenario are minimal, primarily an increased incidence of herpetic lesions, although some concerns exist about the potential for reactivation of tuberculosis or cytomegalovirus and/or long-term effects on bones.[91,93]

Prevention of PCP is clearly a preferable treatment strategy. Primary prophylaxis is recommended for any HIV-infected person who has a CD4 lymphocyte count less than 200 cells/mm^3 (200 × 10^6/L) (or CD4 percentage of total lymphocytes less than14%) or a history of oropharyngeal candidiasis.[63,90] Secondary PCP prophylaxis is recommended for all HIV-infected individuals who have had a previous episode of PCP.

Trimethoprim–sulfamethoxazole is the most effective and least expensive agent and is the preferred therapy for both primary and secondary prophylaxis of PCP in adults and adolescents.[63,90] It also confers cross-protection against toxoplasmosis and many bacterial infections. The recommended dose in adults and adolescents is one double-strength tablet daily, although other regimens, such as one double-strength tablet thrice weekly or one single-strength tablet daily and gradual dose escalation using liquid trimethoprim–sulfamethoxazole, have been used in an attempt to reduce the incidence of adverse reactions and improve compliance. Alternative prophylactic regimens are available if trimethoprim–sulfamethoxazole cannot be tolerated.[63]

In the ART era, the profound reduction in HIV replication and restoration in CD4 cell count to levels rarely associated with the development of OIs provides a basis for the discontinuation of primary and secondary prophylaxis.[63] For PCP, primary prophylaxis should be discontinued in patients receiving and responding to ART who have a CD4 cell count greater than 200 cells/mm^3 (200 × 10^6/L) sustained for at least 3 months, but should be reinstated if the CD4 count drops to less than 200 cells/mm^3 (200 × 10^6/L). The same criteria apply for both discontinuation and reinitiation of secondary prophylaxis of PCP. However, continued secondary prophylaxis should be considered when the original PCP episode occurred at a CD4 count greater than 200 cells/mm^3 (200 × 10^6/L).[63]

Comprehensive recommendations are available for management of PCP and other OIs in the context of HIV infection including prophylaxis, treatment, and removal of prophylaxis with the control of HIV infection.[63] Readers are advised that data continue to emerge on new OI therapies, the safety of stopping primary and secondary prophylaxis, as well as criteria for when to restart secondary prophylaxes. The most current guidelines always should be consulted. Similar OI guidelines have been developed and are updated regularly that are specific to children.[43]

Complications in the ART Era

10 As with any medication, adverse reactions occur with antiretroviral agents that can range from minor intolerances to life-threatening events. Example side effects for each antiretroviral agent are listed in Table 126-4. A comprehensive discussion of all the adverse effects during ART is beyond the scope of this chapter, but can be found in various other sources.[38,55,56] The purpose of this section is to highlight certain medical issues that have emerged in the modern ART era as HIV-infected patients live longer and are exposed to antiretroviral drugs for many years.

Given the life-prolonging effects of ART, as many as half of the HIV-infected population is over 50 years old in resource rich countries.[94] Along with older age come higher rates of well-known chronic and acute illnesses such as osteoporosis and osteopenia, renal and hepatic insufficiency, metabolic syndrome, neurocognitive decline, atherosclerotic disease, frailty, and non-AIDS malignancies. Many of these illnesses occur at higher than expected rates in older HIV-infected patients in the ART era.[95] The cause(s) of these higher rates is the focus of intense study. Initially, adverse events from antiretroviral medications were thought to contribute significantly to these conditions but evidence now suggests that ongoing inflammation and viral persistence play a critical role.[87] Therefore, a theme that emerges in this section is that ART generally protects against non-AIDS events and it is universally recommended to manage these emerging complications.

Non-AIDS malignancies are now a leading cause of mortality in the ART era.[96] While contemporary ART has reduced the incidence of HIV-related cancers such as Kaposi's sarcoma and non-Hodgkin's lymphoma, other non-AIDS-related malignancies impact HIV-infected individuals at significantly elevated rates such as Hodgkin's lymphoma and anal, lung, skin, and hepato-carcinoma.[97] Part of this risk may be attributed to elevated exposures to, or susceptibilities to human papillomavirus (oral and anal cancer), smoking (lung carcinoma), and chronic hepatitis B and/or C coinfection (liver cancer), which are modifiable risk factors. For example, primary care guidelines advocate HPV vaccination for

younger HIV infected individuals, as well as increased screening for anal cancer in those with existing genital or anal warts.[36] Concern has been raised that antiretroviral drugs may contribute directly to these increased cancer rates, as some agents have been associated with cancers in retrospective studies, or were associated with cancer in laboratory animals.[98,99] However, there are similar elevated cancer rates in organ transplant recipients with medication-induced immunosuppression, suggesting it is the impairment to the immune system and/or inflammation associated with HIV-infection that is driving much of these higher cancer rates.[100] While the approach to treatment of non-AIDS-related malignancies in HIV-infected patients is similar to that in non-HIV-infected patients, treatment is complicated by drug–drug interactions that may exist between the antiretrovirals and the oncolytics.[101]

Cardiovascular disease has also emerged as a major concern for HIV infected patients. Patients with HIV infection exhibit an approximately 1.5-fold higher risk of cardiovascular disease compared with matched HIV-negative individuals.[94] This increased risk is similar in magnitude to other well-established risk factors such as hypertension and hyperlipidemia. Elevated systemic inflammation and its impact on endothelial structure and function and the clotting cascade is thought to underlie much of this risk, as elevations in circulating IL-6 and D-dimer correlate with clinical outcomes.[102] Antiretroviral drugs may contribute to risk, given the well-known relationships between PIs, efavirenz, and the thymidine analog NRTIs and dyslipidemia (increased triglycerides and low-density lipoproteins [LDL] and decreased high-density lipoproteins [HDL]), abnormal glucose homeostasis (insulin resistance and impaired glucose tolerance), body fat abnormalities (lipoatrophy of the face and extremities and central lipoaccumulation), and lactic acidosis with hepatosteatosis (all the NRTIs).[103] Many agents within these drug classes are less associated with these complications including atazanavir and darunavir for the PIs, nevirapine and rilpivirine for NNRTIs, and lamivudine, emtricitabine, tenofovir, and abacavir for the NRTIs.[103,104] The same appears to be true for InSTI and maraviroc.[104] Retrospective studies have found an association between myocardial infarction and abacavir and didanosine use, but other studies have not, so this association is controversial.[105,106] This controversy highlights the difficulty in using observational and retrospective data to attribute risk to these emerging medical conditions.

Metabolic abnormalities such as hyperlipidemia and hyperglycemia should be treated according to national guidelines for those conditions with the caveat to intensively screen for potential drug–drug interactions.[36] For instance, there is a long history of using β-hydroxy-β-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitor (statin) therapy for HIV or ART-associated hyperlipidemia. Examples of serious drug–drug interactions include the PIs and lovastatin and simvastatin where plasma area under the concentration–time curve of these statins can be increased more than 10-fold, potentially increasing the risk for rhabdomyolysis.[38] Generally, fluvastatin, pitavistatin, and pravastatin are recommended as alternatives. Atorvastatin or rosuvastatin should be used with caution including initiation with low doses with careful monitoring. There is growing interest for using statins for their anti-inflammatory effects in HIV infected individuals, given the strong relationships between inflammation and cardiovascular disease in this population.[107]

A relevant problem for HIV infected individuals with years of ART experience is body fat

abnormalities, as older ART was associated with changes in body fat distribution.[108] The thymidine analogs, particularly stavudine, were associated with lipoatrophy of the subcutaneous fat in the extremities and face, and these agents and older PIs were associated with hypertrophy of the deep abdominal fat depot. Collectively these fat abnormalities were termed HIV lipodystrophy. Newer agents such as abacavir, tenofovir, emtricitabine, darunavir, and InSTI appear to be less associated with lipodystrophy compared with older agents such as stavudine, zidovudine, and indinavir. In patients still taking older ART regimens, this provides a basis for switching therapy to newer regimens, which may result in small gains in subcutaneous fat in those with existing lipoatrophy. Small controlled studies have demonstrated modest but inconsistent gains in subcutaneous fat with thiazolidinedione therapy. Central fat accumulation is difficult to treat. Lifestyle changes, such as reducing calorie intake and increasing aerobic exercise, should be the first-line approach. Metformin reduces central fat accumulation, but lean body mass and subcutaneous fat may exhibit unwanted declines. Tesamorelin, a growth hormone releasing analog was approved to safely reduce central adiposity, although a drawback is that visceral fat returns within months of discontinuation.[108] Unfortunately, both lipoatrophy and fat accumulation eventually may lead to reconstructive surgery strategies in severe or refractory cases. The best management of body fat changes is prevention through initiation of preferred regimens less likely to cause such changes (see current recommendations for initial therapy).[38]

Functional declines of end organs such as kidney, liver and brain (cognition) are another important problem for older HIV infected patients. Like above, these declines appear to be related with HIV infection itself, and some improvement may be seen with therapy, particularly for neurocognitive function.[109,110] However, certain drugs may also exacerbate these issues.[111] The NNRTI efavirenz, for instance, is commonly associated with central nervous system perturbations including somnolence, attention deficits and psychiatric issues. These effects exacerbate neurocognitive impairment, although this is controversial and difficult to disentangle from the effects of HIV.[112] The most important defense against HIV associated neurocognitive decline is durable suppression of viral replication.[111]

HIV also causes a nephropathy (termed HIVAN), most commonly a glomerulopathy that can lead to end stage renal disease in the absence of ART.[113] The incidence of this condition has declined by approximately 60% in the ART era, demonstrating that ART is the most important intervention against HIVAN. African-Americans are more likely to experience HIVAN compared with those of European ancestry. Some antiretroviral drugs impact renal health and these may exacerbate the effects of HIV. For example, atazanavir and lopinavir may crystallize in urine leading to obstruction, whereas tenofovir may injure the proximal tubule leading to fanconi syndrome in rare cases.[114] The newer tenofovir alafenamide pro-drug appears to be less likely to cause proximal tubulopathy—via lower plasma exposures of tenofovir—compared with tenofovir disoproxil.[54] Renal function should be monitored routinely in all HIV-infected patients including consideration for more frequent monitoring for patients receiving the drugs mentioned above.[38]

HIV infected patients experience co-infection with hepatitis B (HBV) and hepatitis C virus (HCV) relatively commonly, and this can influence hepatic declines in this population.[115] For example, up to

30% of HIV-infected patients in the United States have HIV–HCV (approximately 300,000 individuals) including as many as 90% of injection–drug users and 90% of hemophiliacs. HIV worsens the prognosis of HCV by reducing the chance of HCV clearance and accelerating HCV progression. With chronic HCV infection, progression to fibrosis, cirrhosis, and liver failure is several-fold faster in HIV–HCV patients versus HCV-monoinfected patients. ART reduces progression to hepatic decompensation and, among HIV–HCV coinfected population on ART, progression is faster in those who do not fully suppress HIV replication.[115,116] For these reasons, ART is recommended for HIV–HCV coinfected patients and HCV therapy should be offered according to HCV guidelines.[117] The most important consideration for co-treatment is potential drug–drug interactions between ART and HCV therapies. Again, the most recent information should be consulted in reviewing potential interaction.[38,117]

The same general principles extend to HIV-HBV coinfected patients, who comprise approximately 10% of the HIV infected population. [118] However, two unique considerations are relevant for HIV-HBV coinfection. First, the ART regimen should include tenofovir plus either lamivudine or emtricitabine given the HBV activity of these agents. Second, hepatic flares and decompensation has been reported when tenofovir-based therapy was interrupted or discontinued. If discontinuation is necessary, close monitoring of hepatic function is indicated.

PERSONALIZED PHARMACOTHERAPY

Whether the patient will ultimately mount a durable response to ART depends upon adherence, convenience/tolerability, and pharmacologic effectiveness. As discussed throughout this chapter, a great number of considerations go into choosing the optimal ART for a given patient. These factors include: pre-ART disease characteristics (eg, resistance testing, viral load and CD4 count), ART characteristics (eg, co-formulations, food requirements, drug–drug interactions, etc), co-morbid conditions (eg, preexisting renal dysfunction), potential for pregnancy (eg, efavirenz may be excluded), HLA-B5701 and/or tropism testing (if abacavir or maraviroc are being considered), and co infections (eg, TB infection). Thus, the clinician's knowledge of HIV pathophysiology and pharmacologic principles of ART will help determine therapeutic success.

ACKNOWLEDGMENT

This work was supported by Grants U01 AI106499, UM1 AI06701, R01AI093319, and R01 AI124965 from the National Institute of Allergy and Infectious Disease.

DISCLOSURES

Thomas Kakuda is an employee of Alios Biopharma, a Johnson & Johnson company and a stock holder of Johnson & Johnson.

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

AIDS	acquired immunodeficiency syndrome
ART	antiretroviral therapy
CCR5	chemokine (C–C motif) receptor 5
CD	cluster of differentiation
CDC	Centers for Disease Control and Prevention
CXCR4	Chemokine (C-X-C motif) Receptor 4
CYP	cytochrome P450
DHHS	Department of Health and Human Services
ELISA	enzyme-linked immunosorbent assay
FDA	Food and Drug Administration
gp	glycoprotein
HCV	hepatitis C virus
HDL	high density lipoprotein
HIV	human immunodeficiency virus
HLA	human leukocyte antigen
IC_{50}	concentration of antiretroviral agent necessary to inhibit 50% of viral replication
Ig	immunoglobulin
InSTI	integrase strand transfer inhibitor
IRIS	immune reconstitution syndrome
LDL	low-density lipoprotein
LTR	long-terminal repeat
MAC	*Mycobacterium avium* complex
MSM	men who have sex with men
NNRTI	nonnucleoside reverse transcriptase inhibitor
NRTI	nucleoside/nucleotide reverse transcriptase inhibitor
OI	opportunistic infection
PCP	*Pneumocystis jirovecii* (*carinii*) pneumonia
PCR	polymerase chain reaction
PI	protease inhibitor
PEP	postexposure prophylaxis
PrEP	preexposure prophylaxis
RT-PCR	reverse-transcription polymerase chain reaction
SIV	simian immunodeficiency virus
TB	tuberculosis
TDF	tenofovir disoproxil fumarate
WHO	World Health Organization

Chapter 127: Cancer Treatment and Chemotherapy

Stacy S. Shord; Lisa M. Cordes

INTRODUCTION

KEY CONCEPTS

- 1 Carcinogenesis is a multistep process that includes initiation, promotion, conversion, and progression.
- 2 Cancer cells demonstrate unique traits that distinguish them from normal cells. Cancer cells can stimulate their own growth, resist inhibitory signals, avoid programmed cell death, grow new blood vessels (angiogenesis), invade local tissues, and spread to distant sites (ie, metastases).
- 3 Screening programs are designed to detect cancers in asymptomatic people who are at risk of a specific cancer.
- 4 Diagnosis and staging informs the treatment goals and helps select the most appropriate anticancer therapy. The treatment goal may be cure, control, or palliation. The therapy typically includes a combination of surgery, radiation therapy, and systemic anticancer agents. Systemic anticancer agents include chemotherapy, targeted drugs, and biologic therapies.
- 5 Chemotherapy inhibits cancer growth by killing rapidly proliferating cells. These agents can be identified as either cell-cycle phase-specific, targeting one specific phase of the cell cycle, or cell-cycle phase-nonspecific, targeting all proliferating cells regardless of their place in the cell cycle. Cell-cycle phase-specific chemotherapy is generally given more frequently or as a continuous infusion and cell-cycle phase-nonspecific chemotherapy is usually given as a single dose.
- 6 Targeted drugs are small molecular weight drugs that inhibit kinases or enzymes responsible for the activation of various proteins that form intracellular signaling cascades. These drugs treat a cancer by correcting a dysregulated signaling pathway.

- 7 Biologic therapies include cytokines, vaccines, growth factors, and monoclonal antibodies (mAb) with most biologic therapies classified as a mAb. mAb recognize an antigen that is expressed preferentially on cancer cells or target growth factors responsible for cancer growth. These antibodies induce cell death by a variety of mechanisms that involve the host immune system. These antibodies can also be used to deliver drugs, radioisotopes, or toxins to the antigen-expressing cells.

- 8 Various factors can affect the response and toxicities a patient may experience with anticancer therapy. When determining the optimal therapy, the clinician should carefully consider patient-specific factors, tumor-specific factors, and treatment goals.

- 9 Myelosuppression is a common acute dose-limiting toxicity for chemotherapy agents. Dose-limiting toxicities are not commonly identified for targeted drugs and biologic therapies. The common toxicities associated with these latter systemic therapies are typically related to the interference with an intracellular signaling pathway and may occur several months after starting therapy.

Cancer is a group of more than 100 different diseases that are characterized by uncontrolled cellular growth, local tissue invasion, and distant metastases. It is the second leading cause of death in Americans. Nearly 1.7 million cases of cancer are projected for 2016 with an estimated 600,000 lives claimed in the United States.[1] **Figure 127-1** shows the estimated incidence of common cancers and cancer-related deaths. The most common cancers are prostate, breast, and lung cancer. The most common cause of cancer-related deaths in the United States is lung cancer, which accounts for about 160,000 deaths each year. These cancers are discussed in further detail in the subsequent chapters.

FIGURE 127-1

Health professionals treating patients with cancer should have a thorough understanding of the pharmacokinetic, pharmacodynamic, and pharmacogenomic properties of all available anticancer drugs, in addition to the reported safety and efficacy of each drug in each cancer population. Health professionals should be able to critically evaluate, summarize, and communicate the essential information to other health professionals, patients, and caregivers. This chapter defines the etiology, pathology, diagnosis, staging, screening, and treatment; provides general information on how to safely administer systemic anticancer drugs; and presents an overview of common supportive care measures for patients with cancer undergoing anticancer treatment.

ETIOLOGY OF CANCER

Normal healthy cells are strictly regulated, with stimulatory and inhibitory signals in a delicate balance. For normal cells to become cancer cells, it is believed that a physical, chemical or biological agent must damage the cell and cause a genetic or epigenetic alteration that is subsequently propagated during cell division. Cancer cells eventually acquire multiple alterations and these alterations lead to unlimited growth, invasion, and metastases.

Carcinogenesis

1 The mechanisms by which cancers occur are incompletely understood. A cancer is thought to develop from a cell in which the normal mechanisms that control cell growth and proliferation are

altered. Current evidence supports the concept of carcinogenesis as a multistage process that is genetically regulated.[2,3] The first step in this process is *initiation*, which requires exposure of normal cells to carcinogens. These carcinogens produce genetic alterations that, if not repaired, results in irreversible cellular changes. The changed cell may subsequently have an altered response to their environment that provides a selective growth advantage and permits the development of a clonal population of cancer cells. During the second step, known as *promotion*, carcinogens or other factors alter the environment to favor growth of the altered cell population compared to normal cells. Promotion could be affected by chemoprevention strategies (strategies to lower cancer risk), including changes in lifestyle and diet. At some point, the altered cell becomes cancerous (*conversion* or *transformation*). Depending on the cancer, 5 to 20 years may elapse between the initiation and the development of a clinically detectable cancer. The final stage, called *progression*, involves further genetic alterations that lead to increased cell proliferation. The critical elements of this phase include invasion into local tissues and the development of metastases.

Substances that may act as carcinogens include a myriad of chemical, physical, and biologic agents.[2] Chemical exposures may occur by occupational and environmental means or by lifestyle habits. Some chemicals associated with cancer include aniline dye, asbestos, and benzene. Aniline dye is a known cause of bladder cancer; benzene is a known cause of leukemia and asbestos is a known cause of mesothelioma. Some drugs and hormones used for therapeutic purposes are also classified as carcinogens (**Table 127-1**). Physical agents that act as carcinogens include ionizing radiation and ultraviolet light; radiation induces mutations by forming free radicals that damage deoxyribonucleic acid (DNA) and other cellular components. Biologic agents that are associated with certain cancers, include natural compounds (ie, viruses) or pollutants. The Epstein-Barr virus (EBV) may be an important factor in the initiation of Burkitt lymphoma. Likewise, infection with human papilloma virus (HPV) is a cause of cervical and head and neck cancers. Hereditary factors, age, and gender may also contribute to the development of cancer.

TABLE 127-1 Selected Drugs and Hormones Known to Cause Cancer in Humans

Drug or Hormone	Type of Cancer
Alkylating agents (eg, chlorambucil, mechlorethamine, melphalan, and nitrosoureas)	Leukemia
Anabolic steroids	Liver
Analgesics containing phenacetin	Renal, urinary bladder
Anthracyclines (eg, doxorubicin)	Leukemia
Antiestrogens (tamoxifen)	Endometrium
Coal tars (topical)	Skin
Nonsteroidal estrogens (diethylstilbestrol)	Vagina or cervix, endometrium, breast, testes
Steroidal estrogens (estrogen replacement therapy, oral contraceptives)	Endometrium, breast, liver
Epipodophyllotoxins (etoposide, teniposide)	Leukemia
Immunosuppressive drugs (cyclosporine, azathioprine)	Lymphoma, skin

Drug or Hormone	Type of Cancer
Oxazaphosphorines (cyclophosphamide, ifosfamide)	Urinary bladder

Genetic Alterations

Clinical Controversy…

Can an anticancer drug be selected for an individual patient based on an observed genetic alteration regardless of the underlying disease? For example, a kinase inhibitor has shown to improve survival in a specific cancer. Will this drug prove effective in an individual patient with the same genetic alteration but different underlying cancer?

In recent years, there has been marked progress in our understanding of the genetic changes that lead to the development of cancer.[2,3] Two types of genes play an important role in the development of cancer: oncogenes and tumor suppressor genes. **Figure 127-2** illustrates the acquired capabilities of cancer cells that differ from normal cellular function.[4]

FIGURE 127-2

Functional capabilities acquired by cancer cells, including angiogenesis, self-proliferation, insensitivity to antigrowth signals and limitless growth potential, metastasis, and antiapoptotic effects. It is thought that most, if not all, cancer cells acquire these functions through a variety of mechanisms, including activation of oncogenes and mutations in tumor suppressor genes. (*Reprinted from Cell, Vol 144(5), Hanahan D, Weinberg RA, The Hallmarks of Cancer: The Next Generation, Copyright © 2011, with permission from Elsevier.*)

Oncogenes

Oncogenes develop from normal genes, called proto-oncogenes. Proto-oncogenes are present in all cells and are essential regulators of normal cellular functions. Genetic alterations of the proto-oncogene through point mutation, chromosomal rearrangement, or gene amplification can activate the oncogene. Carcinogens may cause these genetic alterations or these alterations may be inherited (germ-line mutations). After activation, the oncogene produces either excessive amounts of the normal gene product or an abnormal gene product. The result is dysregulation of normal cell growth and proliferation, which imparts a distinct growth advantage to the cell and increases the probability of transformation. For example, the erythroblastic leukemia viral oncogene (ErbB) family members are oncogenes that mediate cell proliferation and differentiation through activation of intracellular signaling pathways. As an oncogene, the ErbB gene product is typically mutated, overexpressed, or amplified, resulting in excessive cellular proliferation, invasion, and metastasis and increased cell survival in several cancers. **Table 127-2** lists examples of oncogenes by their cellular function.

TABLE 127-2 Examples of Oncogenes and Tumor Suppressor Genes

Gene	Associated Human Cancer
Oncogenes	
ALK	Lung cancer, lymphomas, neuroblastoma, and ovarian cancer
BCR-ABL	Acute lymphoblastic leukemia, chronic myeloid leukemia
BCL-2	B-cell lymphomas
BRAF	Colon cancer, lung cancer, melanoma, ovariancancer, thyroid cancer
ERBB1	Colon cancer, glioblastoma multiforme, lung cancer
ERBB2	Breast cancer, gastric cancer, lung cancer

Gene	Associated Human Cancer
KIT (CD117)	Acute leukemia, gastrointestinal stromal tumor, and gastrointestinal stromal tumor
MYC	Acute myeloid leukemia, breast cancer, lung cancer, pancreatic cancer, retinoblastoma, T-cell lymphomas
PI3KCA	Lung cancer, ovarian cancer
RAS (NRAS, HRAS, KRAS)	Colon cancer, melanoma, ovarian cancer, thyroid cancer
RET	Lung cancer, thyroid cancer
Tumor Suppressor Genes	
APC	Colon cancer, thymus cancers
BRCA1, BRCA2	Breast cancer, ovarian cancers
MSH2, MLH1, PMS1, PMS2, MSH6	Colon cancer
NF1, NF2	Leukemias, melanoma
TP53	Multiple cancers
PTEN	Lung cancer, ovarian cancer
RB1	Bladder cancer, retinoblastoma, sarcoma
VHL	Renal cell cancer

Data collated from My Cancer Genome found at http://www.mycancergenome.org/.

Tumor Suppressor Genes

Tumor suppressor genes regulate and inhibit inappropriate cellular growth and proliferation.[3] Genetic alterations result in loss of control over normal cell growth. Retinoblastoma (Rb1) and TP53 are examples of tumor suppressor genes. Mutation of TP53 is one of the most common genetic alterations associated with cancer. The normal gene product of TP53 is responsible for negative regulation of the cell cycle (ie, a series of cellular events that lead to the division and duplication of a cell), allowing the cell cycle to halt for repairs, corrections, and responses to other external signals. Inactivation of TP53 following a genetic alteration removes this checkpoint, allowing genetic alterations to accumulate within a cell. Mutation of TP53 is linked to a variety of cancers. For example, a germline mutation in which an individual has only one functional copy of TP53 is associated with Li-Fraumeni syndrome, a syndrome characterized by multiple cancers by early adulthood. Another important function of TP53 may be modulation of cytotoxic drug effects; loss of TP53 is associated with anticancer drug resistance.

DNA Repair Genes

Another important type of gene that plays a role in the development of cancer is the DNA repair genes. Their normal function is to repair DNA that is damaged by environmental factors or errors in DNA that occur during replication.[3] If not corrected, these errors can result in alterations that activate

oncogenes or inactivate tumor suppressor genes. Subsequently, more genetic alteration saccumulate within a cell and the risk for transformation increases for the altered cell population. Specifically, DNA repair genes can affect mismatch repair, single-strand break repair, and double-strand break repair. For example, poly ADP ribose polymerase (PARP) is a family of proteins that are responsible for DNA repair and programmed cell death by affecting multiple repair mechanisms.[5] PARP1 is a member of the PARP family that plays a role in repairing single-strand DNA breaks. Deficiencies in DNA repair genes have been discovered in breast, colon, and ovarian cancers.

Accumulation of Genetic Alterations

It has become evident that a single genetic alteration is probably insufficient to initiate cancer.[2,3] Most cancers acquire multiple somatic genetic alterations; some alterations may make no contribution to the development of the cancer (eg, passenger mutations), while other alterations likely support the ongoing survival of the cancer (eg, driver mutations). Scientists postulate that combinations of alterations are required for carcinogenesis and that each alteration is inherited by the next generation of cells. Thus, several detectable genetic alterations may be present in a cancer. Whereas early alterations are found in both premalignant lesions and established cancers, later alterations are found only in an established cancer. This theory of sequential genetic alteration resulting in cancer has been demonstrated in colon cancer. In colon cancer, the initial genetic alteration is believed to be loss of the adenomatous polyposis coli (APC) gene, which results in formation of a small benign polyp (ie, abnormal tissue growth in a mucus membrane). An oncogenic mutation of ras genes is often the next step, leading to enlargement of the polyp. Loss of function of DNA mismatch repair enzymes may occur at many points during the transformation. Loss of TP53 and another gene, believed to be the deleted in colorectal cancer (DCC) gene, completes the transformation. Loss of TP53 may be a late event in the development and progression of colon cancer, as well as other cancers.

Identification of genes and proteins involved in carcinogenesis has several important clinical implications. For example, the identification of the involvement of a gene product in the development of a cancer may lead to the development of new screening tools or anticancer drugs. As another example, specific genetic alterations may also aid in diagnosing specific cancers or identifying the most appropriate anticancer therapy. Many genetic markers have become important prognostic or predictive markers. For example, ErbB2 (also known as, human epidermal growth factor receptor 2 [HER2]) overexpression or amplification predicts response to trastuzumab in breast and gastric cancer and predicts overall survival in women with breast cancer.

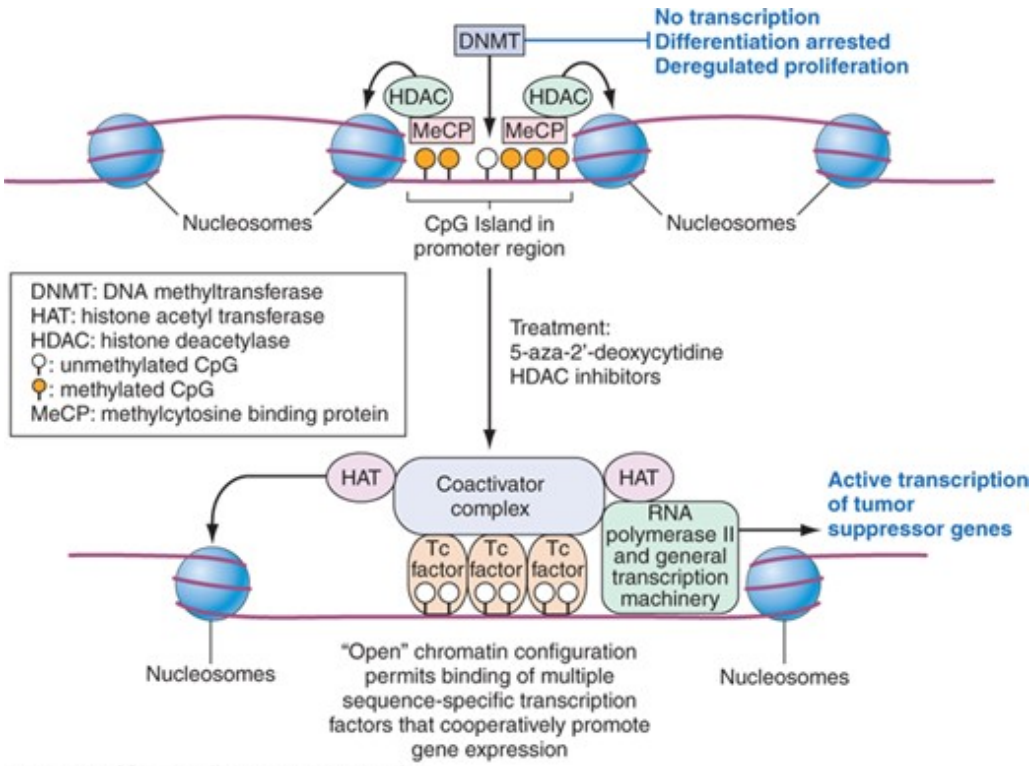
Epigenetic Alterations

Epigenetics refers to changes in gene expression that occur without altering the DNA sequence.[6] The two most common mechanisms of epigenetic regulation include methylation and histone modification. DNA methylation commonly occurs at CpG dinucleotides (or islands) and is catalyzed by DNA methyltransferases (DNMTs). Histones are basic proteins associated with DNA in the nucleosome. These proteins may be modified by acetylation, methylation, or phosphorylation on their N-terminal tail. These modifications play a role in transcriptional regulation. For example,

histone deacetylases (HDAC) repress transcription and histone acetylases activate transcription. Epigenetic changes may be involved in the development of cancer by either priming the cell or making it susceptible to genetic alterations associated with the development of cancer. As an example, hypermethylation at CpG dinucleotides found near tumor suppressor genes can switch these genes off and promote the development of cancer. Anticancer drugs, identified as inhibitors of DNMT or HDAC, target these modifications. **Figure 127-3** shows the effects of these inhibitors on methylation, chromatin formation, and transcription.

FIGURE 127-3

Epigenetic regulation of gene expression in cancer cells. CpG islands within the promoter and enhancer regions of the gene are methylated, resulting in the complexes with HDAC activity. Chromatin is in a condensed conformation that inhibits transcription (upper figure). Inhibitors of DNMT with inhibitors of HDAC confer a chromatin structure that allows transcription (lower figure). *(Reproduced with permisson from Longo DL. Cancer Cell Biology and Angiogenesis. In: Longo DL, Fauci AS, Kasper DL, et al. eds. Harrison's Principles of Internal Medicine, 18th ed. New York, NY: McGraw-Hill, 2012.)*



PATHOLOGY OF CANCER

2 Cancer cells demonstrate several characteristics that differentiate them from normal cells. These traits include unlimited growth in which the cell cycle is no longer strictly regulated. Genetic alterations permit activation of multiple oncogenes and suppression of various tumor suppressor genes, releasing the cancer cells from the strict regulation observed with healthy cells. The cancer

cells subsequently undergo multiple cell divisions, allowing the tumor size to increase exponentially. Cancer cells also resist programmed cell death by inhibiting apoptosis and senescence. Lastly, cancer cells grow new blood vessels, invade new local tissue, and spread to distant sites.

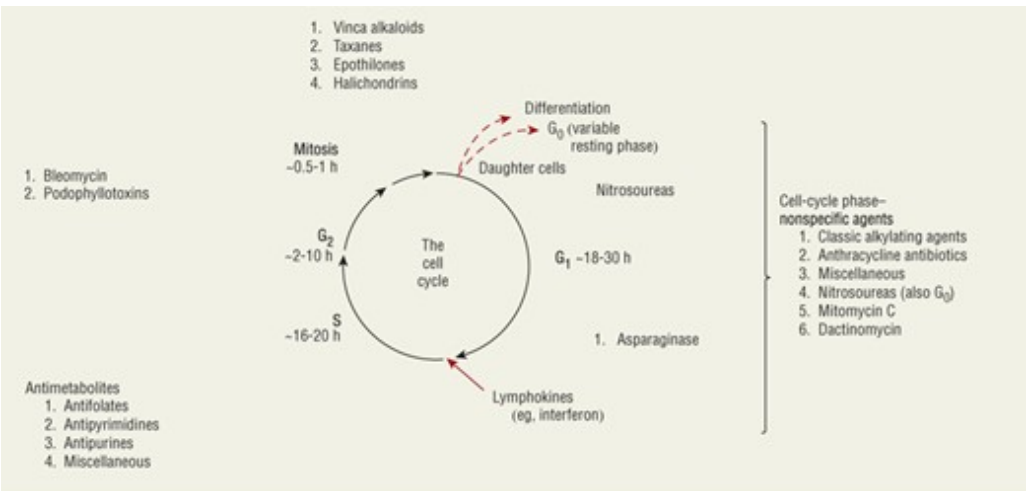
Cell Cycle

The cell cycle incorporates a series of events by which normal and cancer cells divide and make new cells. This process is strictly regulated in healthy cells. Oncogenes and tumor suppressor genes provide the stimulatory and inhibitory signals that regulate the cell cycle. These signals converge on a molecular system in the nucleus known as the cell-cycle clock. The function of the clock in healthy cells is to integrate the signal input and to determine if the cell cycle should proceed. The clock is composed of a series of interacting proteins, the most important of which are cyclins and cyclin-dependent kinases (CDKs). Cyclins and CDK promote entry into the cell cycle and are overexpressed in several cancers. CDK inhibitors have been identified as important negative regulators of the cell cycle.

The cell cycle proceeds from one cell division to the next. The cycle involves five phases: DNA replication (S phase), cell division (M phase), two resting phases (G_1 and G_2), and a nondividing state (G_0 phase). In the first resting phase G_1, the cell grows in size and decides to commit to the cell cycle or remain in a resting state. If the cell is normal, the cell will move into the S phase to synthesize its DNA. Next, the cell enters the second resting phase G_2, in which the cell prepares to divide. In the M phase, the cell enters mitosis and yields two daughter cells. If the cell is not healthy the cell can stop dividing and initiate apoptosis. **Figure 127-4** depicts the cell cycle and the phases of activity for some chemotherapy agents.

FIGURE 127-4

Cell-cycle activity for chemotherapy. Cell-cycle phase-specific chemotherapy are most active during a particular phase. Cell-cycle phase-nonspecific chemotherapy may have activity in more than one phase. In many cases, it is likely that chemotherapy cytotoxicity involves multiple intracellular sites of action and may not be linked to specific cell-cycle events.



Four checkpoints exist within the cell cycle, one in each phase of the cell cycle, and these checkpoints serve as quality control checkpoints. The cell will not proceed to the next phase unless all requirements for the current phase are met. Complexes of cyclin and CDK regulate these checkpoints. These complexes lead to the activation of other proteins that are responsible for the specific events of each phase of the cell cycle. The first checkpoint is called the restriction site. Rb complexed to a transcription factor called E2F controls the restriction site. The presence of this complex prevents cell cycle progression. A cell can proceed beyond the G_1 restriction site and continue into the S phase, when cyclin–CDK complexes phosphorylate Rb and target it for degradation. A cell may alternatively withdraw into the G_0 phase in the presence of anti-mitogenic or the absence of mitogenic factors.

Defense Systems

When the normal regulatory mechanisms for cell growth fail, backup defense systems may be activated. The secondary defenses include apoptosis (programmed cell death or suicide) and cellular senescence (aging). Apoptosis is a normal mechanism of cell death required for tissue homeostasis. This process is regulated by oncogenes and tumor suppressor genes and is also a mechanism of cell death after exposure to cytotoxins. Overexpression of oncogenes responsible for apoptosis may produce an "immortal" cell, which has increased potential for malignancy. For example, the B-cell lymphoma 2 (BCL-2) is normally located on chromosome 18, but it may be translocated to chromosome 14 in proximity to the immunoglobulin heavy chain gene. This translocation leads to overexpression of BCL-2 in lymphoid malignancies, which decreases apoptosis and confers a survival advantage. As another example, loss of TP53 disrupts normal apoptotic pathways, imparting a survival advantage. Apoptosis may also play an important role as a mechanism of inherent resistance to some chemotherapy agents.

Cellular senescence is another important defense mechanism.[3] Laboratory studies demonstrate that after a cell population has undergone a preset number of doublings, growth stops, and cells die. This is known as senescence, a process that is regulated by telomeres. Telomeres are the DNA segments or caps at the ends of chromosomes. They are responsible for protecting the end of the DNA from damage. With each replication, the length of the telomeres is shortened. After the telomeres are shortened to a critical length, senescence is triggered. In this way, telomeres tally and limit the number of cell doublings. In cancer cells, the function of telomeres is overcome by overexpression of an enzyme known as telomerase. Telomerase replaces the portion of the telomeres that is lost with each cell division, thereby avoiding senescence and permitting an infinite number of cell doublings.

Cancer Growth

The study of cancer growth forms the foundation for many of the basic principles of modern chemotherapy. The growth of most cancers is illustrated by the Gompertzian growth curve (**Figure 127-5**).[3] Gompertz was an insurance actuary who described the relationship between age and expected death. This mathematical model also approximates cancer cell proliferation. In the early stages, cancer growth is exponential, which means that the cancer takes a constant amount of time to double its size. During this early phase, most cancer cells are actively dividing. This population of cells is called the growth fraction. The doubling time, or time required for the cancer to double in

size, is very short. Because systemic anticancer drugs typically have a greater effect on rapidly dividing cells, cancers are most sensitive to their effects when the cancer is small and the growth fraction is high. As the cancer grows, the doubling time is slowed. The growth fraction decreases, probably owing to the cancer outgrowing its blood and nutrient supply or the inability of blood and nutrients to diffuse throughout the mass. Wide variability exists in measured doubling times for different cancers. The doubling time of most solid tumors is about 2 to 3 months, but some cancers have doubling times of only days (eg, aggressive non-Hodgkin lymphoma [NHL]).[3]

Tumor burden impacts diagnosis and treatment (Fig. 127-5). Regarding diagnosis, it takes about 10^9 cancer cells (1 g mass, 1 centimeter in diameter) for a cancer to be clinically detectable by palpation or radiography. A cancer of this size has likely undergone about 30 doublings in cell number. It only takes 10 additional doublings for this 1 g mass to reach 1 kg in size. A cancer possessing 10^{12} cells (1 kg mass) is considered lethal. Thus, a cancer is clinically undetectable for most of its life span. Tumor burden also impacts treatment. The cell kill hypothesis states that a certain percentage of cells will be killed with each treatment course. For example, if a cancer consists of 1,000 cells and the first treatment kills 90% of the cells, then 10% or 100 cells remain. The second treatment kills another 90% of cells, and again only 10% or 10 cells remain. According to this hypothesis, the tumor burden will never reach zero. Cancers consisting of less than 10^4 cells are believed to be small enough for elimination by host factors, including immunologic mechanisms. The limitations of this theory are that it assumes all cancers are equally responsive to treatment and that resistance to anticancer drugs and the development of metastases do not occur.[3]

Invasion and Metastasis

As the cancer grows, cancer cells break away or shed from the primary site to invade surrounding tissue and metastasize to distant sites.[2,7] Metastatic disease is associated with a poorer prognosis and shortened survival compared to earlier disease. The cancer cells invade adjacent tissue or metastasize to distant sites by hematogenous or lymphatic spread but, not all of the shed cells result in a metastatic lesion. The shed cells must first find an environment suitable for growth.[7] The onset and time course for the development of metastasis depends largely on the individual cancer, as illustrated by the diverse patterns of metastasis observed for different cancers. Breast cancer, for example, tends to metastasize very early. As another example, prostate cancer commonly metastasizes to bone and colon cancer commonly metastasizes to the liver. Other less common modes of disease spread include dissemination via cerebrospinal fluid and transabdominal spread within the peritoneal cavity.

For a cancer cell to break away from the primary tumor site, the shed cell and surrounding host tissue must first secrete substances that stimulate angiogenesis.[8] The shed cells must then detach from the primary tumor by expressing proteins that degrade the extracellular matrix, such as matrix metalloproteases, and invade surrounding blood and lymph vessels. The cells must then attach to the vascular endothelium. The cells may proliferate within the lumen of the vessel, but most commonly extravasate into the surrounding tissue. The local microenvironment may provide growth factors that can serve as fertilizer to potentiate the development of a metastatic site. At every step, the potential metastatic cell must fight the host immune system. Finally, the metastasis must again initiate angiogenesis to ensure continued growth and proliferation.

Angiogenesis is the development of new blood vessels.[9] This process becomes unregulated in several cancers and supports growth, invasion, and metastasis. Angiogenesis is regulated by pro- and anti-angiogenic growth factors, which are released in response to hypoxia and other stresses to the cell. Pro-angiogenic growth factors include vascular endothelial growth factor (VEGF), fibroblast growth factor, platelet-derived growth factor (PDGF) and tumor necrosis factor-alpha (TNF-α). Anti-angiogenic growth factors include interleukin-12 (IL-12), interferon (IFN), and tissue inhibitors of metalloproteinases. The best studied pro-angiogenic factor is VEGF, whose elevated levels have been associated with a poor prognosis and an increased risk of metastases in many cancers, including breast cancer, non-small cell lung cancer (NSCLC), ovarian cancer, and colon cancer. Similar to other growth factors, VEGF binds to specific receptors located on the extracellular domain: VEGFR1, 2, and 3. VEGFR1 and VEGFR2 are expressed primarily in endothelial cells and in some cancer cells and mediate the biologic effects of VEGF. Each of the receptors induces a different signal transduction pathway. These pathways eventually result in the generation of proteases that are necessary for the breakdown of the extracellular matrix. Inhibiting the development of new blood vessels with biologic therapies and targeted drugs can limit or prevent tumor growth.

DIAGNOSIS OF CANCER

Tumors may be either benign or malignant. Benign tumors are noncancerous growths that are often encapsulated, localized, and indolent. Benign tumors are named for the cell or tissue of origin

followed by the suffix-oma. The tumor cells resemble the cells from which they developed. These masses seldom metastasize and rarely recur after being removed. In contrast to benign tumors, malignant tumors or cancers invade and destroy the surrounding tissue. The cancer cells are genetically unstable and loss of normal cell architecture results in cells that are atypical of their tissue or cell of origin. These cells lose the ability to perform their usual functions. This loss of structure and function is called anaplasia. Cancers tend to metastasize and consequently, recurrences are common after removal or destruction of the primary tumor. Cancers arising from epithelial cells are called carcinomas and those arising from muscle or connective tissue are called sarcomas. **Table 127-3** lists common nomenclature by tissue type.[3]

TABLE 127-3 Tumor Classification by Tissue Type

Tissue of Origin	Benign	Malignant
Epithelium		
Surface epithelium	Papilloma	Carcinoma (squamous, epidermoid)
Glandular tissue	Adenoma	Adenocarcinoma
Connective tissue		
Fibrous tissue	Fibroma	Fibrosarcoma
Bone	Osteoma	Osteosarcoma
Smooth muscle	Leiomyoma	Leiomyosarcoma
Striated muscle	Rhabdomyoma	Rhabdomyosarcoma
Fat	Lipoma	Liposarcoma
Lymphoid tissue and hematopoietic cells		
Bone marrow elements		
Lymphoid tissue		Hodgkin and non-Hodgkin lymphoma
Plasma cell		Multiple myeloma
Neural tissue		
Glial tissue	"Benign" gliomas	Glioblastoma multiforme, astrocytoma
Nerve sheath	Neurofibroma	Neurofibrosarcoma
Melanocytes	Pigmented nevus	Melanoma
Mixed tumors		
Gonadal tissue	Teratoma	Teratocarcinoma

Screening

3 Because cancers are most curable before they metastasize, early detection and treatment have obvious potential benefits. Cancer screening programs are designed to detect cancers in individuals

who have not yet developed symptoms, but they are only available for a few cancers, such as colon, prostate, breast, and cervical cancers. Available screening tools include the Papanicolaou (Pap) smear test for cervical cancer and mammography for breast cancer. Limitations of the available screening tests include false-negative test results (related to the sensitivity of the test), false-positive test results (related to the specificity), and overdiagnosis (true positives not likely to become clinically significant). For example, most abnormal test results identified by a screening mammography are false-positive, although the specificity of a mammogram exceeds 90%. For most cancers, lack of effective screening methods and inaccessible anatomic sites limit the availability of screening methods. Public education on the early warning signs of common cancers is therefore extremely important for facilitating early detection. The American Cancer Society publishes yearly guidelines for routine screening examinations (**Table 127-4**).[10]

TABLE 127-4 Screening Guidelines for Early Detection of Cancer in Average-Risk, Asymptomatic Individuals

Cancer	Test or Procedure	Age (y)	Frequency
Breast[a]	Breast self-examination	≥20	Monthly[b]
	Clinical breast examination	20-39	Every 3 years
		≥40	Every year
	Mammography	≥40	Every year
Cervical[c]	Pap test (conventional or liquid based)	21-29	Every 3 years
		30-65	Every 3 years
	Pap test and HPV DNA test	30-65	Every 5 years
Colorectal	One of the following examination schedules should be followed:		
	Guaic-based fecal occult blood test (FOBT) or fecal immunochemical test (FIT)[d]	≥50	Every year
	Stool DNA test	≥50	Every 3 years
	Flexible sigmoidoscopy	≥50	Every 5 years alone or with FOBT or FIT
	Double contrast barium enema	≥50	Every 5 years
	Colonoscopy	≥50	Every 10 years
	Computed tomography colonography	≥50	Every 5 years
Endometrial	Information on risks and symptoms	Menopause	Once
Lung	Low-dose helical computed tomography	55-74 years	Annually[e]
Prostate	Digital rectal examination and prostate-specific antigen (PSA) blood test	≥50 (average-risk) or ≥45 (high-risk)	Not specified[f]

[a]Annual screening mammography and magnetic resonance imaging (MRI) starting at age 30 years is

recommended for women with a known BRCA mutation, women who are untested but have a first-degree relative with a BRCA mutation or other high risk genetic syndrome with known penetrance, or women with an approximately 20% to 25% or greater lifetime risk of breast cancer based on specialized breast cancer risk estimation models capable of pedigree analysis of first degree and second-degree relatives on both the maternal and paternal sides.

[b]Beginning in their early 20s, women should be told about the benefits and limitations of breast self-examination (BSE). The importance of prompt reporting of any new breast symptoms to a healthcare professional should be emphasized. It is acceptable for women to choose not to do BSE or to do BSE irregularly or irregularly.

[c]Women age 65 years and older who have had three or more normal Pap test results and no abnormal Pap tests within the last 10 years and women who have undergone a total hysterectomy may choose to stop cervical cancer screening. Women at any age should NOT be screened annually by any screening method.

[d]Testing at home with adherence to manufacturer's recommendation for collection techniques and number of samples is recommended. FOBT with the single stool sample collected on the clinician's fingertip during a digital rectal examination in the health care setting and guaiac-based toilet bowl FOBT tests also are not recommended.

[e]Clinicians with access to high-volume, high-quality lung cancer screening and treatment centers should initiate a discussion about annual lung cancer screening with apparently healthy patients who have at least a 30 pack-year smoking history and who currently smoke or have quit within the past 15 years. A process of informed and shared decision making with a clinician related to the potential benefits, limitations, and harms associated with screening should occur before any decision is made to initiate annual lung cancer screening. Smoking-cessation counseling remains a high priority for clinical attention in discussions with current smokers.

[f]Menwho have at least a 10-year life expectancy should have an opportunity to make an informed decision with their healthcare provider about whether to be screened for prostate cancer, after receiving information about the potential benefits, risks, and uncertainties associated with prostate cancer screening. Prostate cancer screening should not occur without an informed decision-making process.

Adapted from Smith RA, Manassaram-Baptiste D, Brooks D, et al.. Cancer screening in the United States, 2015: A review of current American Cancer Society guidelines and issues in cancer screening. CA Cancer J Clin 2015;65(1):30-54.

Diagnosis

4 The presenting signs and symptoms vary widely and depend on the type of cancer. The presentation in adults may include any of the seven warning signs listed in **Table 127-5**, as well as headaches, weight loss, chronic pain, fatigue, or anorexia.[11] The warning signs of cancer in pediatrics

are different and reflect the cancers more common in this population (**Table 127-6**).[12] The definitive diagnosis of cancer relies on the procurement of a tissue sample and pathologic assessment of this sample. This sample can be obtained by numerous methods, including an excisional, core, or needle aspiration biopsy. A tissue diagnosis is essential, because many benign tumors can masquerade as cancers and most tumors are not cancer. The diagnosis may include evaluation for genetic alterations commonly found in some tumors, such as hormone receptor status in breast cancer or epidermal growth factor receptor (EGFR) status in NSCLC.

TABLE 127-5 Cancer's Seven Warning Signs

Change in bowel or bladder habits
A sore that does not heal
Unusual bleeding or discharge
Thickening or lump in the breast or elsewhere
Indigestion or difficulty in swallowing
Obvious change in wart or mole
Nagging cough or hoarseness
If YOU have a warning signal, see your doctor!

Adapted from American Cancer Society Study Communicating Cancer Information Through Mass Distribution Leaflets–an American Cancer Society Study. CA Cancer J Clin 1967;17:291-293.

TABLE 127-6 Cancer's Warning Signs in Children

Continued, unexplained weight loss
Headaches with vomiting in the morning
Increased swelling or persistent pain in bones or joints
Lump or mass in abdomen, neck, or elsewhere
Development of a whitish appearance in the pupil of the eye
Recurrent fevers not caused by infections
Excessive bruising or bleeding
Noticeable paleness or prolonged tiredness

Staging

Following a pathologic diagnosis, cancers should be staged to determine the extent of disease (ie,

tumor location and size) before starting treatment. Staging provides information on prognosis and guides treatment selection. A staging workup may involve physical examination, biopsy, imaging tests (ie, computed tomography scans, magnetic resonance imaging, and positron emission tomography scans), and laboratory tests. The laboratory tests may include tumors markers, antigens or other substances produced by the cancer but, tumor markers are often nonspecific and may be elevated in many different cancers or in patients with nonmalignant diseases. As a result, tumor markers are generally more useful for monitoring response and detecting recurrence than as diagnostic tools. For example, human chorionic gonadotropin (hCG) and alpha-fetoprotein (AFP) in testicular cancer or prostate-specific antigen (PSA) in prostate cancer are useful markers to monitor response or recurrence.[3] After starting treatment, the staging workup is usually repeated to evaluate the effectiveness of the treatment.

The most common staging system for solid tumors is the TNM system that describes the tumor (T), nodes (N) and metastases (M). A numerical value is assigned to each letter to indicate the size or extent of disease. The T describes the size of the primary tumor and spread to adjacent tissues, the N specifies the size, location and number of regional lymph nodes affected by the cancer, and the M describes the presence or absence of metastases. Each letter is followed by an Arabic number that uniquely describes that tumor, node or metastases. After the individual T, N, and M are determined; their values are combined to provide an overall stage that is identified using Roman numerals ranging from stage I to stage IV. For example, stage T_3 N_1 M_0, which describes a moderate- to large-sized primary mass with regional lymph node involvement and no distant metastases, is typically a stage III cancer. This simplified staging system allows health professionals to easily identify the extent of disease. For example, stage I usually indicates localized cancer, stages II and III typically indicate local and regional disease, and stage IV typically indicates distant metastases. The criteria for classifying disease extent are quite specific for each different cancer.[12] Alternative staging systems that are used in clinical practice for leukemias and lymphomas as discussed in subsequent chapters.

TREATMENT MODALITIES

Three modalities are used to treat cancer: surgery, radiation, and systemic anticancer agents. These modalities may be used alone, but are typically given sequentially or concurrently to treat a specific cancer. The timing of the different modalities relative to one another is typically based on the outcomes of a clinical trial.

Surgery is the oldest treatment modality and it plays a major role in diagnosis and treatment. It may be curative if the primary cancer has not metastasized. Surgery remains the treatment of choice for most early stage cancers, such as breast and colon cancers. Surgery typically involves removal of the primary tumor and adjacent lymph nodes. This modality may also be used to remove isolated metastases and relieve symptoms associated with metastatic disease. For example, hepatic metastases may be removed for patients with colon cancer.

Radiation therapy can be used alone for localized cancer or for cancer that may encompass a single radiation field. It was first used to treat cancer in the late 1800s and remains a mainstay of treatment for some cancers. Radiation therapy may also be used to alleviate symptoms associated with vena

cava syndrome, bone metastases, spinal cord compression, and brain tumors. This modality typically damages normal tissue surrounding the cancer, but the normal tissue typically repairs itself more readily than the cancer cells. Several different types of radiation therapy are available including external beam radiation therapy, stereotactic radiation, brachytherapy, and radioisotopes. Both early and late toxicities associated with radiation therapy are dependent on the organs within the radiation field. For example, mucositis is commonly observed in patients with head and neck cancer. Secondary cancers are a devastating late toxicity that can occur following radiation therapy.

Systemic anticancer agents include chemotherapy, targeted drugs, and biologic therapies. The specific agents will be discussed later in this chapter. In general, systemic anticancer agents have been developed to destroy cancer cells while minimizing effects to healthy cells.

Combined Modality Treatment

As stated earlier in the chapter, a cancer may be treated with multiple modalities. For example, systemic anticancer agents are often administered to patients with local disease (ie, early stage) following surgery or radiation therapy, because most patients with local disease have undetectable metastatic disease (ie, micrometastases) at diagnosis. Localized anticancer treatment alone would likely fail to completely eliminate the cancer. *Adjuvant* therapy is systemic therapy administered to eradicate micrometastatic disease after surgery or radiation. The goal of adjuvant therapy is to reduce recurrence rates and prolong long-term survival. Thus, adjuvant therapy is given to patients with potentially curable cancers who have no clinically detectable disease after surgery or radiation. Because adjuvant therapy is given at a time when the cancer is undetectable (ie, no measurable disease), its effectiveness is evaluated by recurrence rates and survival. The value of adjuvant therapy has been established for the treatment of colorectal and breast cancers. As another example, systemic therapy called *neoadjuvant* or preoperative therapy may be given to patients before surgery or radiation therapy to reduce tumor burden and destroy micrometastases. Neoadjuvant therapy has been given to women with breast cancer to reduce the size of the primary tumor and allow for a less invasive surgical procedure.

The management of hematologic malignancies typically involves the use of systemic anticancer therapies and radiation therapy. Since these cancers are systemic diseases that cannot be effectively treated with localized modalities. Systemic therapy that is administered to eradicate the cancer cells is called *induction* therapy. When a complete remission (the disappearance of all signs of the cancer) is documented, postremission, or *consolidation* therapy is administered. These therapies are designed to eradicate any remaining disease, similar to adjuvant therapy for solid tumors, and can include systemic therapy, a hematopoietic stem cell transplant, or radiation therapy. *Maintenance* therapy is sometimes administered after consolidation therapy. This therapy is given to prevent the cancer from recurring and may include combination chemotherapy. Not all treatment phases are employed for a hematological malignancy.

Goals of Treatment

The goals of treatment depend on the cancer stage and patient factors, such as comorbidities. When an anticancer agent is administered to patients with local or regional disease, the treatment (ie,

adjuvant therapy) is often administered to cure the patient and may be labeled as *curative* therapy. When the cancer has metastasized to distant sites, a cure is usually not possible. Anticancer therapy may be administered to patients with metastatic disease to slow the progression of cancer (ie, control) and prolong survival by months to years. If anticancer therapy is given to patients with the goal of reducing symptoms, the treatment is often called *palliative* therapy.

SYSTEMIC ANTICANCER AGENTS

Chemotherapy

5 Chemotherapy was first administered in 1941 when Goodman and Gilman gave nitrogen mustard to patients with lymphoma. These agents typically target DNA. As discussed later in the chapter, a chemotherapy agent is typically given as part of a combination regimen, in which multiple anticancer agents with different mechanisms of action and toxicities are given together. Most chemotherapy agents target rapidly proliferating cells (both normal and cancer cells) and these agents might act at one or more phases of the cell cycle. A chemotherapy agent that demonstrates major activity in a particular phase of the cell cycle is known as a cell-cycle phase-specific agent. For example, antimetabolites exert their effect during the S phase. Cell-cycle phase-specific agents may be less active in other phases of the cell cycle. A cell-cycle phase-nonspecific agent has significant activity in multiple phases. Alkylating agents, such as nitrogen mustards, are examples of cell-cycle phase-nonspecific agents. Despite this classification, it is believed that most chemotherapy agents provide cytotoxic effects following interactions with other intracellular activities, not just specific cell-cycle events. Knowledge of cell-cycle specificity has been used to optimize treatment schedules. For example, a cell-cycle phase-specific chemotherapy agent is typically administered as a continuous infusion or in multiple repeated fractions to maximize the number of cancer cells in the sensitive cell cycle phase. Thus, a cell-cycle phase-specific chemotherapy agent is also termed schedule dependent. In contrast, cell-cycle phase-nonspecific chemotherapy is active in many phases and consequently these agents are not schedule dependent. The activity of these chemotherapy agents depends on the dose, so these chemotherapies are termed dose-dependent. Chemotherapy agents are typically given in a defined repeating schedule called a cycle. The cycle length typically depends on the toxicities associated with the chemotherapy agent, such that sufficient time elapses between doses to allow a patient to adequately recover from a serious adverse event (eg, neutropenia). The number of cycles depends, in part, on the treatment goals. The number of cycles is typically defined by prior clinical trials for early stage disease, while the number of cycles is typically defined by individualized treatment response and tolerability for locally advanced or metastatic disease.

Targeted Drugs and Biologic Therapies

Biologic therapies and targeted drugs interfere with cancer cell proliferation in a different manner compared with chemotherapy. These agents stop cancer progression by blocking aberrant intracellular signaling pathways that govern cell responses, movement, and division. Some of these agents can cause cancer cell death by inducing apoptosis or stimulating the immune system to destroy the cancer cells.

The first targeted drug was developed in the late 1980s. Targeted drugs are small molecular weight drugs (less than 1,000 daltons) that have been specifically designed to interact with extracellular receptors or interfere with intracellular signaling pathways. These drugs are typically given orally once or twice daily until disease progression or unacceptable toxicity. Since resistance commonly develops with targeted drugs, some targeted drugs are administered with other anticancer agents.

Biologic therapies include growth factors, cytokines, enzymes, vaccines, and monoclonal antibodies (mAb). These agents treat cancer by boosting the host immune system and causing the patient's own body to eradicate the cancer. The most common biologic anticancer therapy is a mAb. The first mAb and cytokine for the treatment of cancer were approved in the 1990s. Similar to targeted drugs, most biologic therapies are administered with other anticancer drugs. Both mAbs and targeted drugs have been developed to interfere with intracellular signaling. Whereas mAbs target the extracellular receptors or their natural ligands and prevent ligand binding to the receptor, targeted drugs typically inhibit intracellular kinases. The net effect of both strategies is to interfere with intracellular signal transduction and decrease cell proliferation (**Figure 127-6**). Some common receptors and pathways affected by available targeted drugs and mAbs include ErbB2 family, mitogen-activated protein kinase (MAPK) pathway and phosphatidylinositide 3-kinase (PI3K) pathway.

FIGURE 127-6

Common elements of intracellular signaling pathways and targeted strategies that inhibit these pathways, such as (1) mAb against the growth factor receptor, (2) mAb against a growth factor, (3) targeted drugs that inhibit intracellular kinases and prevent subsequent activation of downstream signals, and (4) targeting downstream signals. All targeted drugs have the same goal of decreasing cell proliferation and increasing cancer cell death. (MAPK, mitogen-activated protein kinase.)

ErbB Family

The ErbB family of receptors contains four known members: ErbB1 (EGFR), ErbB2 (HER2), ErbB3, and ErbB4. EGFR and HER2 are overexpressed in several cancers, including breast, lung, gastric, and colon cancers. The roles of the other receptors in cancer growth and proliferation are still under investigation. Members of this family are inactive by themselves and must form a dimer (a molecule composed of two subunits) either with a member of the same family (homodimer) or with a member of a different ErbB family (heterodimer). Dimerization of the receptor leads to kinase phosphorylation and subsequent activation of downstream pathways required to activate signal transduction and cell growth.

Intracellular Signaling Pathways

Well-described intracellular signaling pathways include PI3K, JAK-STAT (Janus kinase–signal transducers and activators of transcription), and MAPK. When these pathways are activated, they promote cell proliferation and survival. These pathways consist of a chain of proteins that ultimately communicate a signal to the DNA found in the nucleus from a cell surface receptor. A protein within a signaling pathway communicates by adding a phosphate group to its neighboring protein; the phosphate groups act as an “on” or “off” switch for the pathway. In cancer, a mutated protein permits

the pathway to remain in the “on” or “off” position. The downstream effectors of these pathways also initiate cell cycle progression by promoting the expression of cyclins and repressing the expression of CDK inhibitors.

The MAPK signaling pathway regulates many fundamental cellular processes, including cell differentiation, proliferation, and senescence. These pathways relay the intracellular signals through a series of ras, raf, MEK (mitogen-activated protein kinase-extracellular signal-regulated kinase), and ERK (extracellular signaling receptor kinase) proteins that subsequently phosphorylate and regulate nuclear and cytoplasmic structures. Some of these proteins are commonly altered in pancreatic, melanoma, colorectal, hepatocellular, and other solid tumors.[13]

The PI3K signaling pathway also regulates cell proliferation, growth, survival, and mobility. PI3K becomes activated in response to growth hormones, and it ultimately activates protein kinase B (AKT), a serine–threonine kinase that serves as a master switch for the cell cycle progression. Fully activated AKT translocates to the nucleus, where it can inhibit pro-apoptotic signals and activate anti-apoptotic substrates. It can also phosphorylate mammalian target of rapamycin (mTOR). After being activated, mTOR stimulates protein synthesis by phosphorylating translation regulators. mTOR also contributes to protein degradation and angiogenesis.[14] Phosphatase and tensin homolog (PTEN) is a tumor suppressor gene that blocks intracellular signaling through this pathway and is frequently inactivated in several solid tumors.[15]

The JAK-STAT signaling pathway helps regulate the immune system. This pathway contains three main components: extracellular receptors, JAKs, and STAT. The pathway is initiated when cytokines or growth factors bind to the receptor, activate JAK, and subsequently recruit STAT. The STAT proteins then translocate to the nucleus and modify gene expression. Altered JAK signaling has been associated with JAK mutations in patients with myelofibrosis.[16]

Combination Therapy

Although a single anticancer agent may be administered to a cancer patient, the more common approach to systemic therapy is to administer multiple agents. Initially, this approach was based on the Goldie-Coldman hypothesis, which addresses the issue of cancer cell heterogeneity and the inevitable development of drug resistance. The individual agents selected for combination therapy should have different mechanisms of action and adverse event profiles. For example, myelosuppressive agents are typically combined with nonmyelosuppressive agents to minimize myelosuppression and other sequela. The individual agents should each have significant activity against the cancer and the combination therapy should have known clinical benefit in the cancer to be treated. Combination regimens that include multiple chemotherapy agents with or without a targeted drug or biologic therapy have been used to successfully manage many cancers for decades. More recently, two targeted drugs have been given together for the treatment of melanoma. Predictive markers, such as HER2 and BRAF, may be used to identify which patients may benefit from combination therapy.

CHEMOTHERAPY

Since all chemotherapy agents interfere with the cellular synthesis of DNA, ribonucleic acid (RNA), and proteins, chemotherapy agents are commonly categorized by their mechanism of action. For example, akylators exert their effects on DNA and protein synthesis by binding to DNA and preventing the unwinding of the DNA molecule. As another example, antimetabolites resemble nucleotide bases or inhibit enzymes involved in the synthesis of DNA and proteins. **Figure 127-7** shows the sites of action of common categories of anticancer agents.

The following sections discuss the biochemical classification system and the individual agents within each classification. The clinical uses, mechanisms of action, common toxicities, and practical patient management for most available chemotherapy agents are detailed below. **Table 127-7** summarizes dose modifications of individual chemotherapy agents.

FIGURE 127-7

Mechanisms of action of commonly used anticancer agents. (ATRA, all-trans-retinoic acid) *(Reproduced with permission from Chabner BA. General Principles of Chemotherapy. TABLE 127-7 Monitoring of Anticancer Drugs[a]

Agent	Major Adverse Effects	Monitoring Parameters	Comments

Agent	Major Adverse Effects	Monitoring Parameters	Comments
Antimetabolites			
Capecitabine	Diarrhea; hand-foot syndrome (palmar–plantar erythema); mild nausea and vomiting	Stool count; hands and feet for early signs of skin breakdown	Adjust dose for renal impairment Oral prodrug of FU Warfarin results in increased anticoagulant effects; may require phenytoin dose reduction
Cladribine	Myelosuppression; fever (onset by day 6, persisting for about 3 days); immunosuppressive; severe opportunistic infections occur	CBC; signs of infection	Risk of opportunistic infections necessitate prophylactic antibiotics for PJP and other infections
Clofarabine	Myelosuppression; elevated liver enzymes; nausea and vomiting; TLS	CBC; liver function; uric acid	
Cytarabine and liposomal cytarabine for intrathecal use	Myelosuppression; nausea and vomiting; diarrhea; mucositis; TLS; flu-like syndrome; rash HDAC toxicities: worsening of above and cerebellar toxicity; conjunctivitis	CBC; signs of infection; renal function; neurologic examinations (signs of confusion)	HDAC infusions should be administered over 2-3 hours to decrease risk of CNS toxicity; use eye drops during treatment and for 48 hours after treatment to prevent conjunctivitis with HDAC Increased HDAC neurotoxicity with impaired renal function
Fludarabine	Myelosuppression, including decreased T cells; diarrhea; rare CNS toxicity: somnolence, peripheral neuropathy, hearing and visual changes, altered mental status, seizures; pulmonary toxicity; TLS	CBC; signs of infection; renal function; neurologic examinations	Adjust dose for renal impairment Risk of opportunistic infections necessitate prophylactic antibiotics for PJP and HSV
Fluorouracil	Mucositis; diarrhea; hand-foot syndrome;	CBC; stool count; hands and feet for	Deficiency of DPD correlates with increased toxicity

Agent	Major Adverse Effects	Monitoring Parameters	Comments
	myelosuppression; nausea and vomiting; hyperpigmentation; photosensitivity; ocular toxicity; myocardial ischemic symptoms	early signs of skin breakdown	Drug interaction with warfarin: increased anticoagulant effect
Gemcitabine	Myelosuppression; flu-like syndrome; rash; elevations in liver transaminases; nausea and vomiting	CBC; liver function	Rash may respond to topical steroids; fevers may respond to acetaminophen
6-Mercaptopurine	Myelosuppression; dry skin; rash; photosensitivity; hepatotoxicity; jaundice and hyperbilirubinemia; nausea and vomiting	CBC; liver function	Allopurinol increases the toxicity of 6-MP by interfering with metabolism 6-MP reduces anticoagulant effects of warfarin
Methotrexate	Myelosuppression; mucositis; renal failure at high doses; nausea and vomiting; CNS toxicity (more severe with IT administration); hepatotoxicity	CBC; liver function; renal function; urine pH and methotrexate drug levels with high-dose therapy	Adjust dose or avoid use with renal impairment; avoid drugs that decrease renal excretion of methotrexate (eg, NSAIDs, PPIs, sulfas and penicillins) Distributes readily into third-space fluids (ascites, pleural effusions), prolonging exposure and increasing toxicity; may be contraindication for use Monitor methotrexate levels with high-dose administration; these must include leucovorin rescue to prevent excessive myelosuppression; sodium bicarbonate also given for high-dose therapy to prevent nephrotoxicity (maintain urine pH >7) Use preservative-free

Agent	Major Adverse Effects	Monitoring Parameters	Comments
			preparations for IT and high-dose administration Avoid with renal impairment Avoid NSAIDs during administration
Pemetrexed	Myelosuppression; stomatitis; pharyngitis; rash; desquamation	CBC; renal function; skin examinations	Supplement with folic acid (400 mcg daily starting 1 week before first dose; continued days after last dose) and vitamin B_{12} (1,000 mcg IM during week before first dose and even cycles thereafter) to decrease myelosuppression Premedicate with dexamethasone (day before, the day of, and day after) to decrease incidence of rash
Trifluridineand tipiracil	Anemia, neutropenia, asthenia/fatigue, nausea, thrombocytopenia, decreased appetite, diarrhea, vomiting, abdominal pain, and pyrexia	CBC; renal function	Consider dose modifications for moderate renal impairment
Microtubule-Targeting Drugs			
Cabazitaxel	Myelosuppression; infection; hypersensitivity reactions; diarrhea; asthenia; renal failure; nausea and vomiting	CBC; signs of infection; stool count; renal function; signs of hypersensitivity reactions; liver function	Avoid with hepatic impairment Premedicate with H_1 and H_2 antagonist plus dexamethasone to decrease risk of hypersensitivity
Docetaxel	Myelosuppression; fluid retention and edema; pleural effusions; ascites; alopecia; rash; peripheral neuropathy; hypersensitivity reactions	CBC; fluid status; liver function	Contraindicated with hepatic impairment (hyperbilirubinemia, elevated transaminases, or elevated alkaline phosphatase)

Agent	Major Adverse Effects	Monitoring Parameters	Comments
			Premedicate with dexamethasone 8 mg orally twice daily for 3 days (starting 1 day before docetaxel) to lower risk of fluid retention
			Avoid or adjust dose with hepatic impairment
Paclitaxel and nab-paclitaxel	Myelosuppression; infection; hypersensitivity reactions; peripheral neuropathy; myalgias or arthralgias; mucositis; cardiac arrhythmias; alopecia	CBC; signs of infection; signs of hypersensitivity reactions; liver function	Premedicate with dexamethasone, diphenhydramine, and ranitidine 30 minutes before paclitaxel; nab-paclitaxel associated with decreased hypersensitivity reactions and does not require premedication
			Neurotoxicity may require discontinuation
			Products are not interchangeable
Vinblastine and vinorelbine	Myelosuppression; mucositis; neurotoxicity; less common than with vincristine; myalgias; SIADH (rarely); vesicant	CBC; liver function	Adjust dose with elevated bilirubin
			Treat extravasation injury with warm soaks and injection of hyaluronidase
			Adjust dose with elevated bilirubin
Vincristine	Peripheral neuropathy (highest of vinca alkaloids); motor, sensory, autonomic, and cranial nerves may be affected (paresthesias, ileus, urinary retention, facial palsies) and can be irreversible; SIADH; vesicant	Signs of neurotoxicity (tingling in extremities; constipation, CNS toxicity); liver function	Treat constipation aggressively to prevent ileus
			Doses are commonly capped at 2 mg to minimize neurotoxicity
			LETHAL if administered IT
			Treat extravasation similar to

Agent	Major Adverse Effects	Monitoring Parameters	Comments
			vinblastine
Eribulin	Myelosuppression; peripheral neuropathy; asthenia; alopecia; nausea; constipation	CBC; liver function; renal function; potassium and magnesium levels	Dose reduce for Child-Pugh class A or B hepatic impairment and moderate renal impairment May cause QT prolongation in patients with electrolyte or congenital abnormalities (avoid other drugs that may prolong QT interval)
Ixabepilone	Myelosuppression; peripheral neuropathy; hypersensitivity reactions; asthenia; arthralgias; alopecia	CBC; signs of infection; signs of hypersensitivity reactions; liver function	Avoid or adjust dose with hepatic impairment CYP3A4 substrate, levels may be effected by inducers or inhibitors, avoid use or dose adjustment to ixabepilone may be necessary Premedicate with H_1 and H_2 antagonist
Topoisomerase Inhibitors			
Irinotecan	Diarrhea: acute (within 1 hour of completion; related to cholinergic effects) and delayed (>12 hours after administration; usually after the second or third dose); nausea and vomiting; myelosuppression (neutropenia); alopecia; fatigue; increased liver enzymes; pulmonary toxicity: diffuse infiltrates, fever, dyspnea	CBC; GI symptoms (bowel movements); fluid and electrolytes	Acute diarrhea is best treated or prevented with atropine; delayed diarrhea is managed with antimotility agents Adjust dose (or discontinue) with elevated total bilirubin or UGT1A1 deficiency
Topotecan	Myelosuppression (neutropenia and thrombocytopenia); mucositis; reversible	CBC; liver function; renal function	Adjust dose for renal impairment

Agent	Major Adverse Effects	Monitoring Parameters	Comments
	increased liver enzymes		
Daunorubicin and liposomal daunorubicin	Myelosuppression (dose related); mucositis; nausea and vomiting; alopecia; vesicant: severe extravasation injury; cardiac toxicities: acute—not related to cumulative dose; arrhythmias, pericarditis; chronic—cumulative injury to myocardium (total dose >550 mg/m^2)	CBC; LVEF; liver function	Adjust dose for elevated bilirubin LVEF should be >50% to administer safely Liposomal form: decreased risk of cardiac and vesicant toxicity
Doxorubicin and liposomal doxorubicin	Similar to daunorubicin; cardiac toxicity associated with cumulative doses >450-550 mg/m^2; radiation recall reactions	CBC; LVEF; liver function	Adjust dose for elevated bilirubin LVEF should be >50% to administer safely May discolor urine (red-orange) Liposomal form: decreased risk of cardiac and vesicant toxicities
Epirubicin	Similar to daunorubicin; cardiac toxicity associated with cumulative doses >900 mg/m^2	CBC; LVEF; liver function	Adjust dose for elevated bilirubin LVEF should be >50% to administer safely Adjust dose for renal impairment
Etoposide	Myelosuppression; nausea and vomiting: may be worse with oral and high-dose regimens; alopecia; mucositis; hypotension: infusion rate–related; hypersensitivity reactions	CBC; blood pressure	Requires large volumes of fluid for IV administration because of limited solubility (maximum concentration, 0.4 mg/mL) Available orally in liquid-filled gelatin capsules; ~50% bioavailability, but absorption is variable and

Agent	Major Adverse Effects	Monitoring Parameters	Comments
			greater at lower oral doses
	Similar to daunorubicin		
Idarubicin	Total cumulative dose not well established; >150 mg/m^2 reported to be associated with decreased LVEF	CBC; LVEF; liver function	Adjust dose for elevated bilirubin LVEF should be >50% to administer safely
Mitoxantrone	Myelosuppression; nausea and vomiting; mucositis; alopecia; less cardiotoxic than the anthracyclines	CBC; LVEF; liver function	Not a vesicant (may cause vein irritation but not associated with severe tissue injury such as anthracyclines) May discolor urine blue-green
Alkylating Agents			
Bendamustine	Myelosuppression; infection; dermatologic reactions, including Stevens-Johnson syndrome; TLS; infusion reactions	CBC; signs of infection; signs of dermatologic toxicity; uric acid	Not studied in renal impairment Allopurinol may increase risk for Stevens-Johnson's syndrome
Busulfan	Myelosuppression; skin hyperpigmentation; pulmonary fibrosis; gynecomastia; adrenal insufficiency High (HSCT) dose toxicities: seizures; hepatic venoocclusive disease; severe nausea and vomiting	CBC; pulmonary status; liver function; signs of edema (weight gain, fluid status)	Bone marrow recovery may be delayed (3-6 weeks); pulmonary fibrosis associated with >3 years exposure, prior chest radiation Seizure prophylaxis with HSCT doses Pharmacokinetic monitoring is required with IV busulfan IV and oral preparations are not interchangeable; put tablets in gelatin capsules for easier administration with high-dose administration

Agent	Major Adverse Effects	Monitoring Parameters	Comments
Carboplatin	Myelosuppression (thrombocytopenia); nausea and vomiting (acute and delayed); risk of hypersensitivity reactions at higher cumulative doses (frequently results in cross-hypersensitivity to cisplatin)	CBC; renal function	Calvert formula used to dose carboplatin Lower incidence of nephrotoxicity, neurotoxicity, and nausea and vomiting than cisplatin Administer on an empty stomach; food decreases absorption
Chlorambucil	Myelosuppression; increased liver enzymes; skin rash; menstrual irregularities; pulmonary toxicity; risk of secondary malignancies; causes infertility and sterility; teratogenic	CBC; liver function; pulmonary function	May be dosed in low daily-dosing regimens or in higher dose, "pulse," or intermittent dosing schedules administered biweekly or monthly; pulse dosing may require patients to take several tablets (eg, 10-20 tablets) per dose Adjust dose or avoid with renal impairment
Cisplatin	Nephrotoxicity; potassium and magnesium wasting; severe nausea and vomiting (acute or delayed onset); peripheral neuropathy that is cumulative and dose related; ototoxicity; anemia seen with chronic dosing	Renal function; potassium and magnesium levels; GI symptoms (nausea and vomiting)	Hydration required (1-2 L of 0.9% sodium chloride) minimum before and after administration; ensure good urine output >100 mL/h); potassium chloride and magnesium sulfate in IV fluid to replace losses; dose reduce or consider carboplatin with impaired renal function Aggressive antiemetics required pretreatment and for 3-5 days after to prevent delayed nausea and vomiting

Agent	Major Adverse Effects	Monitoring Parameters	Comments
			Amifostine chemoprotective agent may reduce cisplatin renal toxicity Doses should not exceed 100 mg/m^2 (maximum single dose and per-cycle dose) Adjust dose for renal impairment Hydration needed to prevent hemorrhagic cystitis (oral or IV ~3 L/day × 72 h); mesna may be required with high-dose regimens (see ifosfamide)
Cyclophosphamide	Hemorrhagic cystitis; nausea and vomiting (acute and delayed); myelosuppression; alopecia; SIADH: typically with high doses (>2 g/m^2); risk of secondary malignancies causes infertility and sterility	CBC; renal function; urinalysis	Instruct patients to take oral tablets Administer in the morning to allow for elimination of toxic metabolite; absorbed through skin: avoid spills Drug interactions: CYP450 inducers (eg, barbiturates) may increase formation of toxic metabolites; CYP450 inhibitors (eg, cimetidine) may increase myelosuppression
Ifosfamide	Hemorrhagic cystitis; nephrotoxicity; myelosuppression; CNS effects: somnolence, confusion, disorientation, cerebellar symptoms that are dose-related; nausea and vomiting (acute and delayed); alopecia	CBC; daily urinalysis for blood; renal function	Adjust dose for renal impairment 3-4 L/day fluid for hydration; potassium, magnesium, and phosphate may be required to replace losses Mesna is always given (typically 60%-100% of ifosfamide dose), may be

Agent	Major Adverse Effects	Monitoring Parameters	Comments
			delivered in same IV bag CNS toxicity and nausea and vomiting may be more severe with rapid infusion; case reports suggest methylene blue may be effective treatment for CNS toxicity
Mechlorethamine	Myelosuppression; severe nausea and vomiting; vesicant; secondary malignancies; sterility and infertility	CBC; GI symptoms (nausea and vomiting)	Antidote for extravasation is sodium thiosulfate Bone marrow recovery may require 6-8 weeks
Nitrosoureas (carmustine and lomustine)	Myelosuppression; severe nausea and vomiting; cumulative nephrotoxicity; pulmonary fibrosis; facial flushing during infusion	CBC; renal function; pulmonary function	Carmustine is a vein irritatant, and facial flushing may be related to alcohol vehicle; also available in wafer form for implantation into brain tumor cavities after resection Lomustine is administered orally
Oxaliplatin	Peripheral neuropathy >50% patients: acute form: <14 days, rapid onset, reversible, exacerbated by cold; chronic form: onset >14 days and may be permanent; pharyngolaryngeal dysesthesias; nausea and vomiting; anaphylaxis risk	CBC; renal function; acute and chronic neuropathies	Adjust dose for renal impairment 1 g of magnesium and calcium before and after may be used to prevent neuropathies Avoid exposure to cold
Procarbazine	Myelosuppression; diarrhea; neurotoxicity; neuropathy; flu-like syndrome; infertility and sterility; secondary	CBC	Administer as a single daily dose on an empty stomach MAOIs that interact with tyramine-rich foods and may

Agent	Major Adverse Effects	Monitoring Parameters	Comments
	malignancies		precipitate hypertensive crisis; drug interactions: TCAs and SSRIs, sympathomimetics; disulfiram-like reaction with alcohol
Thiotepa	Myelosuppression; nausea and vomiting; mucositis; pruritus and dermatitis	CBC; dermatologic toxicities	Most commonly used in HSCT preparative regimens
Trabectedin	Myelosuppression; rhabdomyolysis; hepatotoxicity; nausea and vomiting; diarrhea or constipation; cardiomyopathy	CBC; creatine phosphokinase; liver function	Extravasation may lead to tissue necrosis
Triazenes (dacarbazine and temozolamide)	Myelosuppression; severe nausea and vomiting; increased liver enzymes; flu-like syndrome (may last for several days after dacarbazine administration); facial flushing; photosensitivity	CBC; liver function	Dispense in a lightproof bags Temozolamide crosses the blood–brain barrier; may cause lymphosuppression when given with radiation therapy; requires PJP prophylaxis
Miscellaneous Agents			
Arsenic trioxide	Differentiation syndrome (pulmonary infiltrates, respiratory distress, fever, and hypotension); QT prolongation; electrolyte abnormalities (hypokalemia or hyperkalemia and hypomagnesemia); hyperglycemia; rash; lightheadedness; fatigue; musculoskeletal pain	ECG and serum electrolytes (calcium, magnesium, potassium) before each course; renal function	Differentiation syndrome must be treated promptly with corticosteroids Do not give if QTc >500 msec Replace electrolytes before therapy
Bleomycin	Anaphylaxis and hypersensitivity reactions; fever and flu-like symptoms; mucositis; pulmonary fibrosis	Obtain PFTs before use and if signs of pulmonary toxicity develop; monitor for anaphylactic	Adjust dose for renal impairment Test dose (1 unit) is recommended but

Agent	Major Adverse Effects	Monitoring Parameters	Comments
			controversial; premedicate for subsequent doses with acetaminophen
		reactions	Pulmonary toxicity associated with cumulative dose >400 units and preexisting pulmonary disease
Hydroxyurea	Myelosuppression; rash; skin hyperpigmentation; TLS; secondary leukemias	CBC; uric acid	Dose may need to be adjusted with renal impairment (use with caution) Used to decrease white blood cell counts rapidly to prevent adverse effects of leukocytosis
Mitomycin C	Myelosuppression (delayed and prolonged); mucositis; nausea and vomiting; vesicant; pulmonary fibrosis; hemolytic anemia and uremic syndrome	CBC; renal function; pulmonary function	Apply ice or cold packs to site for extravasation
Omacetaxine	Myelosuppression (Thrombocytopenia, increased risk of hemorrhage; anemia and neutropenia); diarrhea; nausea; fatigue; asthenia; injection site reaction; pyrexia; infection; lymphopenia; hyperglycemia	CBC; blood glucose	Active in T315I-resistant CML
Retinoids			
Bexarotene	Peripheral edema; insomnia; headache; fever; increased triglycerides and cholesterol; hypothyroidism; leukopenia and anemia; dry skin; increased liver	CBC; liver function; cholesterol and triglyceride levels; thyroid function	Avoid gemfibrozil to treat elevated triglycerides Limit vitamin A supplements May cause hypoglycemia in patients receiving insulin,

Agent	Major Adverse Effects	Monitoring Parameters	Comments
			sulfonylureas, or metformin
	enzymes; pancreatitis; photosensitivity		Teratogenic; contraindicated in pregnancy; female patients should be educated about proper contraceptive measures
Tretinoin (ATRA)	Headache; differentiation syndrome; "ATRA syndrome" consisting of pulmonary symptoms, fever, hypotension, and pleural effusions; dry skin and mucous membranes; mucositis; increases in liver enzymes and bilirubin	CBC; liver function; signs of differentiation syndrome	Differentiation syndrome must be treated promptly with corticosteroids Teratogenic; contraindicated in pregnancy; female patients should be educated about proper contraceptive measures
ALK Inhibitors			
Alectinib	Fatigue; bradycardia; hepatotoxicty; anemia; constipation; edema; myalgia; visual disturbances	CBC; liver function; heart rate; creatine phosphokinase	Administer with food
Ceritinib	Gastrointestinal toxicity; increases in liver enzymes; fatigue; visual disturbances; QT prolongation; bradycardia; hyperglycemia	CBC; renal function; liver function, blood glucose; pancreatic enzymes; cardiac monitoring; electrolytes	Administer on an empty stomach
Crizotinib	Nausea and vomiting; diarrhea; constipation; fatigue; increases in liver enzymes; visual disorders; edema; ILD; QT prolongation; bradycardia	CBC; renal function; liver function; HR and BP; cardiac monitoring; electrolytes; pulmonary symptoms	Visual disorders (visual impairment, blurred vision, and photopsia) occur in approximately half of patients
BCR-ABL Inhibitors			
Bosutinib	Nausea and vomiting; edema; pleural effusions and ascites; myelosuppression; CHF; arthralgias; rash; diarrhea;	CBC; liver function; electrolytes; Philadelphia chromosome levels; signs of edema	Adjust dose for hepatic impairment Avoid antacids and PPIs Maintenance dose based on

Agent	Major Adverse Effects	Monitoring Parameters	Comments
	increased liver enzymes; hypophosphatemia		CBC
Dasatinib	Nausea and vomiting; edema; pleural effusions and ascites; myelosuppression; CHF; arthralgias; fatigue; rash; diarrhea; increased liver enzymes; QT prolongation; hypophosphatemia and hypocalcemia	CBC; liver function; electrolytes; signs of edema; Philadelphia chromosome levels	Avoid antacids, H_2 antagonists and PPIs Maintenance dose based on CBC
Imatinib	Nausea and vomiting; edema; pleural effusions and ascites; myelosuppression; CHF; arthralgias; rash; diarrhea; increased liver enzymes; hypophosphatemia	CBC; liver function; electrolytes; Philadelphia chromosome levels; signs of edema	Dose adjustments should be considered with severe liver and moderate renal impairment May increase warfarin effects Maintenance dose based on CBC Take with meals and a full glass of water
Nilotinib	Nausea and vomiting; edema; myelosuppression; increased lipase; hyperglycemia; arthralgias; rash; diarrhea; increased liver enzymes; QT prolongation	CBC; liver function; serum lipase; serum glucose; electrolytes; Philadelphia chromosome levels	Adjust dose for hepatic impairment Take on an empty stomach CYP3A4 substrate, avoid inhibitors Maintenance dose based on CBC
Ponatinib	Myelosuppression; hypertension; rash; abdominal pain; fatigue; headache; dry skin; constipation; arthralgia; nausea; pyrexia; thromboembolic events; hepatotoxicity; congestive heart failure; pancreatitis;	Cardiac monitoring (CHF, arrhythmias); BP; pancreatic enzymes; fluid retention; CBC; liver function	May need to decrease or hold therapy if hepatotoxicity develops Avoid antacids and drugs that decrease gastric pH

Agent	Major Adverse Effects	Monitoring Parameters	Comments
	hemorrhage (secondary to thrombocytopenia); fluid retention		
BRAF Inhibitors			
Dabrafenib	Papilloma; arthralgia; alopecia; fatigue; headache; HFSR; pyrexia	CBC; serum glucose; electrolytes; renal function; dermatologic evaluations	Take on an empty stomach
Vemurafenib	Papilloma; arthralgia; alopecia; fatigue; headache; photosensitivity reaction; hypersensitivity reactions; QT prolongation	Liver function; electrolytes; cardiac monitoring; dermatologic evaluations	Radiation sensitization/recall
BTK Inhibitor			
Ibrutinib	Diarrhea; fatigue; musculoskeletal pain; nausea; rash; atrial fibrillation; hemorrhage; tumor lysis syndrome; bone marrow suppression	CBC; renal function; hepatic function; uric acid levels; electrolytes; cardiac monitoring	Reduce dose with hepatic impairment
CDK Inhibitor			
Palbociclib	Thromboembolic events; infection; bone marrow suppression; gastrointestinal toxicity	CBC; infection	Administer with food
DNA Methyltransferase Inhibitors			
Azacitidine and decitabine	Myelosuppression and infection; constitutional symptoms; musculoskeletal symptoms (arthralgias); cough; dyspnea	CBC; infection	
EGFR Inhibitors			
Afatinib	Rash; diarrhea; ILD; keratitis	Liver function; renal function; dermatologic evaluations; electrolytes; LVEF in patients with cardiac	Administer on an empty stomach

Agent	Major Adverse Effects	Monitoring Parameters	Comments
		risk factors; pulmonary symptoms	
			Dose reductions or delays may be required for rash, but supportive care should be attempted first
Erlotinib	Rash; diarrhea; ILD, hepatic and renal failure reported	Liver function; renal function; electrolytes; pulmonary symptoms; dermatologic evaluations	Major interaction with warfarin, leading to increased bleeding risk H_2 antagonists, PPIs, and antacids may decrease drug levels Administer on an empty stomach as food increases absorption and possibly toxicity
Gefitinib	Similar to erlotinib	Liver function; renal function; electrolytes; pulmonary symptoms; dermatologic evaluations	Similar precautions and drug interactions as with erlotinib
Lapatinib	Diarrhea; rash; nausea; vomiting; fatigue; decreases in LVEF; hepatotoxicity; QT prolongation; ILD	Liver function; cardiac monitoring (LVEF, QT, MUGA); electrolytes; pulmonary symptoms	Adjust dose for severe hepatic impairment Administer on empty stomach Avoid strong CYP3A4 inhibitors, (if unavoidable, consider dose reduction); avoid strong CYP3A4 inducers (if unavoidable, consider gradual dose increases)
Osimertinib	Gastrointestinal toxicity; dermotologic toxicity; ILD/pneumonitis;	Cardiac monitoring (LVEF, QT); pulmonary	Avoid strong CYP3A4 inhibitors and inducers

Agent	Major Adverse Effects	Monitoring Parameters	Comments
	pneumonia; pulmonary embolism; cardiomyopathy; QT prolongation	symptoms; dermatologic evaluations	
Hedgehog Inhibitors			
Sonidegib	Fatigue; alopecia; amenorrhea; musculoskeletal toxicity; teratogenic effects	Pregnancy status; creatine phosphokinase; renal function; liver function	Boxed waring for severe birth defects and embryo-fetal death; advise females to use contraception during treatment and for 20 months after the last dose; advise males to use condoms during treatment and for at least 8 months after the last dose; do not donate blood during treatment and for 20 months after the last dose; do not donate sperm during treatment and for 8 months after the last dose Avoid strong and moderate CYP3A modulators; moderate CYP3A inhibitors may be used for short-term
Vismodegib	Muscle spasms; alopecia; dysgeusia; fatigue; nausea; vomiting; diarrhea; decreased appetite; constipation; arthralgias; teratogenic effects	Pregnancy status	Boxed warning for severe birth defects and embryo-fetal death; patients should not donate blood or blood products while receiving vismodegib and for at least 7 months after the last dose; verify pregnancy status within 7 days prior to treatment initiation; do not donate sperm during treatment and for 3 months after the last dose
Histone Deacetylase Inhibitors			

Agent	Major Adverse Effects	Monitoring Parameters	Comments
Belinostat	Pyrexia; nausea; fatigue; anemia; hepatotoxicity; infection; tumor lysis syndrome	Liver function; renal function; CBC; electrolytes, uric acid levels	
Panobinostat	Cardiotoxicity; nausea; vomiting; diarrhea; hemorrhage; infection; hepatotoxicity	Cardiac monitoring; electrolytes, CBC; liver function; pregnancy status	Boxed warnings for cardiovascular events and gastrointestional events
Romidepsin	Neutropenia; lymphopenia; thrombocytopenia; infection; nausea; fatigue; vomiting; anorexia; anemia; ECG T-wave changes	CBC; cardiac monitoring (ECG); electrolytes	Monitor INR if patient on warfarin Avoid or adjust dose for hepatic impairment
Vorinostat	Diarrhea; fatigue; nausea; thrombocytopenia; anorexia; dysgeusia; thromboembolic events; hyperglycemia	CBC; electrolytes; serum glucose; renal function	Increase in INR with concomitant warfarin Severe thrombocytopenia and GI bleeding have been reported with concomitant use with vorinostat and other HDAC inhibitors (eg, valproic acid)
JAK Inhibitor			
Ruxolitinib	Thrombocytopenia; anemia; bruising; dizziness; headache; infections; cardiovascular abnormalities	CBC; renal function; liver function; cardiac monitoring	Consider adjust dose for renal and hepatic impairment
MEK Inhibitor			
Trametinib	Diarrhea; lymphedema; hemorrhage; venous thromboembolism; febrile reactions; cardiomyopathy; dermatologic toxicity; hyperglycemia; hypertension; ophthalmic events	CBC; liver function; LVEF; ophthalmologic evaluation; dermatologic evaluation; BP	Capsules are stored refrigerated Administer on an empty stomach

Agent	Major Adverse Effects	Monitoring Parameters	Comments
Cobimetinib	Dermatologic toxicity; nausea and vomiting; pyrexia; hemorrhage; new primary malignancies; cardiomyopathy; ophthalmic events; hepatotoxicity; rhabdomyolysis	CBC; liver function; signs of bleeding; dermatologic evaluation; ophthalmologic evaluation; LVEF; creatine phosphokinase; electrolytes	Avoid coadministration with strong or moderate CYP3A inducers or inhibitors
mTOR Inhibitors			
Everolimus	Rash; asthenia; stomatitis; nausea; edema; anorexia; anemia; pneumonitis; hyperglycemia; hyperlipidemia; hypertriglyceridemia; hypophosphatemia; elevated liver enzymes; elevated Scr; lymphopenia; thrombocytopenia; leukopenia; infection	Blood glucose; cholesterol and triglyceride levels; CBC, renal function; liver function; electrolytes; pulmonary symptoms	Adjust dose for hepatic impairment Initiation or increase in cholesterol or diabetic medications often needed CYP3A4 and Pgp substrate, may require dose adjustment based on concurrent medication
Temsirolimus	Similar to everolimus with addition of infusion-related reactions	Similar to everolimus; infusion reactions	Adjust dose for hepatic impairment Requires diphenhydramine premedication
Multikinase Inhibitors			
Axitinib	Diarrhea; rash; HFSR; bleeding; thrombotic events; hypertension; hepatotoxicity; hypothyroidism; proteinuria; GI perforation; fatigue; rare reports of progressive multifocal leukoencephalopathy	CBC; liver function; BP; thyroid function; urine protein; neurologic evaluation; dermatologic evaluation	Adjust dose for hepatic impairment Substrate of CYP3A4, may require dose adjustment based on concurrent medication administered
Cabozantinib	Diarrhea; stomatitis; HFSR; decreased weight; decreased appetite; nausea; fatigue; oral pain; hair color changes; dysgeusia;	Signs and symptoms of bleeding; BP; urine protein; CBC; liver function; thyroid function; electrolytes,	Administer on an empty stomach CYP3A4 substrate, monitor for drug interactions

Agent	Major Adverse Effects	Monitoring Parameters	Comments
	hypertension; abdominal pain; constipation; increased liver enzymes; proteinuria; lymphopenia; neutropenia; thrombocytopenia; hypocalcemia; hypophosphatemia; GI perforations and fistulas and hemorrhage have been reported	dermatologic evaluation	
Lenvatinib	Hypertension; fatigue; diarrhea; proteinuria; stomatitis; HFSR; hypothyroidism; hepatotoxicity; thromboembolic events; renal toxicity; hypocalcemia	Liver function; renal function; thyroid function; BP; electrolytes	Adjust dose for in severe hepatic and renal impairment
Pazopanib	Diarrhea; hypertension; hair/skin hypopigmentation; nausea; anorexia; vomiting; decreased weight; fatigue; musculoskeletal pain; dysguesia; dyspnea; hypothyroidism; proteinuria; fatal hepatotoxicity; thromboembolic events	Liver function; cardiac monitoring (ECG); BP; thyroid function; urine protein; dermatologic evaluation	Adjust dose for hepatic impairment Take on empty stomach Reduce dose when administered with strong CYP3A4 inhibitors; avoid CYP3A4 inducers; concomitant use with simvastatin increases liver enzymes
Regorafenib	Asthenia; fatigue; decreased appetite; HFSR; diarrhea; mucositis; weight loss; infection; hypertension; dysphonia; hepatotoxicity; hemorrhage	Liver function; BP; dermatologic evaluation	Administer with food, low-fat breakfast that contains <30% fat Monitor INR closely if on concomitant warfarin because of an increased risk of hemorrhage with regorafenib
Sorafenib	Diarrhea; rash; HFSR; fatigue; hypertension; prolonged QT interval;	BP; liver function; cardiac monitoring; electrolytes;	Administer on an empty stomach May increase the

Agent	Major Adverse Effects	Monitoring Parameters	Comments
	cardiac events (including MI); drug-induced hepatitis	dermatologic evaluation	anticoagulation effects of warfarin
Sunitinib	Diarrhea; rash; bleeding; CHF and cardiac effects; QT prolongation; fatigue; hypertension; hepatotoxicity; thyroid dysfunction	CBC; liver function; BP; thyroid function; cardiac monitoring (CHF, ECG); electrolytes	CYP3A4 substrate, may require dose adjustment based on concurrent medication administered
Vandetanib	Diarrhea; rash; acne; nausea; hypertension; headache; fatigue; upper respiratory tract infections; decreased appetite; abdominal pain; prolonged QT interval, torsades de pointes, and sudden death; ILD; hemorrhage; increased liver enzymes	Liver function; electrolytes; cardiac monitoring (QT); BP; pulmonary symptoms; dermatologic evaluation	REMS program for QT prolongation/sudden death Adjust dose for renal impairment Avoid other medications that prolong the QT interval Advise patients to wear sunscreen and protective clothing when exposed to sun
PARP Inhibitor			
Olaparib	Fatigue; musculoskeletal pain; dermatitis; nausea/vomiting; upper respiratory infections; anemia; pneumonitis; secondary malignancies (MDS/AML)	CBC; pulmonary symptoms	
PI3K Inhibitor			
Idelalisib	Gastrointestional disorders; pneumonitis; neutropenia; fever; rash; elevated liver enzymes; dermatologic toxicity	Liver function; CBC; dermatologic evaluation; pulmonary symptoms	Boxed warnings for hepatotoxicity, diarrhea, colitis, pneumonitis, intestinal perforation
Proteasome Inhibitors			
Bortezomib	Fatigue or malaise; nausea; diarrhea; anorexia; constipation; vomiting; myelosuppression, especially	CBC; thyroid function; symptoms of neuropathy; electrolytes	Adjust dose for hepatic impairment Administer IV or subcutaneous

Agent	Major Adverse Effects	Monitoring Parameters	Comments
			(subcutaneous administration has been shown to decrease neuropathies)
	thrombocytopenia; hyponatremia; hypokalemia; peripheral neuropathy, cumulative and dose-related; fever		Increased risk of severe neuropathy with preexisting neuropathy
			Co-administration with strong CYP3A4 inhibitors can increase bortezomib concentrations
Carfilzomib	Fatigue; anemia; thrombocytopenia; nausea; diarrhea; dyspnea; pyrexia; infusion-related reactions; rare reports of cardiac arrest, CHF, and MI	Symptoms of dyspnea; CBC; liver function; cardiac monitoring; infusion reactions	Premedicate with dexamethasone before all cycle 1 doses, during the first cycle of dose escalation, and if infusion reaction symptoms develop
Ixazomib	Gastrointestinal toxicity; thrombocytopenia; perhipheral neuropathy; edema; back pain; cutaneous reactions	CBC; liver function; dermatologic evaluation	Administer on an empty stomach Reduce starting dose for hepatic or renal impairment Avoid use with strong CYP3A4 inducers
Miscellaneous Small Molecule Inhibitors			
Lanreotide	Abdominal pain; musculoskeletal pain; vomiting; headache; injection site reaction; hypertension; hypo- and/or hyperglycemia; gallstones; hypothyroidism (mild)	HR and BP; blood glucose; thyroid function; gall bladder ultrasonography	
Thalidomide, lenalidomide, and pomalidomide	Thalidomide: somnolence; constipation; dizziness or orthostatic; hypotension; rash; peripheral neuropathies; thromboembolic events	CBC; signs of thrombosis; signs of peripheral neuropathies; pregnancy status	REMS program for fetal toxicity For lenalidomide, adjust dose for renal impairment Prophylactic anticoagulation

Agent	Major Adverse Effects	Monitoring Parameters	Comments
	Lenalidomide: fatigue; peripheral neuropathy; neutropenia and thrombocytopenia; thromboembolic events		may be required
Monoclonal Antibodies that Target CD20			
Ibritumomab tiuxetan	Must consider toxicities of rituximab; delayed hematologic toxicity; infusion-related reactions; asthenia; nausea; chills; fever; tumor pain	Infusion-related reactions; CBC	Radiopharmaceutical; prepared and administered only by personnel trained in radiopharmaceuticals; patients must be trained in precautions to decrease radiation exposure Antimicrobial, antiviral, and antifungal prophylaxis in select patients
Obinutuzumab	Infusion reactions; myelosuppression; nausea; diarrhea; Progressive Multifocal Leukoencaphalopathy; HBV reactivation	CBC; hepatitis B screening at baseline; renal function; electrolytes; infusion reaction; fluid status	Antihyperuricemic prophylaxis and hydration if risk for tumor lysis syndrome HBV reactivation Premedicate with acetaminophen, an antihistamine, and a glucocorticoid Premedicate with acetaminophen, antihistamine, and corticosteroid
Ofatumumab	Neutropenia; pneumonia; pyrexia; cough; diarrhea; anemia; fatigue; dyspnea; rash; nausea; bronchitis; upper respiratory infection	Infusion-related reactions; CBC; hepatitis B screening at baseline	For dose 1 initiate infusion at a rate of 3.6 mg/h, dose 2 initiate rate at 24 mg/h, and for doses 3-12 initiate infusion at a rate of 50 mg/h; in the absence of infusional toxicity, the rate of infusion may be increased every 30 minutes

Agent	Major Adverse Effects	Monitoring Parameters	Comments
Rituximab	Hypersensitivity reactions and infusion-related reactions; TLS (especially with large tumor burden); myelosuppression and infection; rare reports of progressive multifocal leukoencephalopathy; severe skin reactions; myalgias; tachycardia	Infusion-related reactions; CBC; neurologic examination; hepatitis B screening at baseline; electrolytes, HR, BP	Patients at high risk of hepatitis B should be screened for before therapy Infusion-related reactions may be severe; increase rate of infusion gradually and premedicate with acetaminophen and diphenhydramine; use meperidine IV as needed for rigors
Tositumomab	Myelosuppression (especially thrombocytopenia and neutropenia) that is severe and prolonged; abdominal pain; diarrhea; infusion reactions; anaphylaxis may occur; hypothyroidism; asthenia; myalgias; cough; rash	Infusion-related reactions; CBC; thyroid function	Similar radiation safety procedures as ibritumomab Premedicate with acetaminophen and antihistamine Thyroprotective regimen required
Monoclonal Antibodies that Target Cell Surface Receptors			
Alemtuzumab	Myelosuppression and immunosuppression; autoimmune conditions; infection; infusion-related reactions; nausea and vomiting; fever; hypotension; rash; headache; fatigue; secondary malignancies	CBC; infusion-related reactions; CMV; $CD4^+$ counts; HR; BP; autoimmune symptoms; symptoms of infection	Restricted distribution through REMS program to mitigate risks of autoimmune conditions, infusion reactions, and secondary malignancies Patients should be started on antiviral and PJP prophylaxis during and 6 months posttreatment
Blinatumomab	Infusion reactions; cytokine release syndrome; neurologic toxicities; infections; fever; headache; peripheral edema; rash; tumor lysis syndrome; hepatotoxicity; bone	CBC; liver function; neurological examination; uric acid levels; electrolytes	Boxed warnings for cytokine release syndrome and neurological toxicities Premedicate with dexamethasone prior to the first dose of each cycle, prior

Agent	Major Adverse Effects	Monitoring Parameters	Comments
			to a step dose or when restarting therapy after an interruption >4 hours
	marrow suppression		Administered as a continuous intravenous infusion over 28 days
Brentuximab vedotin	Neutropenia; peripheral neuropathy; fatigue; nausea or vomiting; anemia; diarrhea; rash; thrombocytopenia; infusion-related reactions; TLS; rare reports of progressive multifocal leukoencephalopathy	CBC; symptoms of neuropathy; infusion-related reactions; uric acid levels, electrolytes	
Daratumumab	Infusion-related reactions; pyrexia; fatigue; upper respiratory tract infection; nausea; myelosuppression	CBC; actue or delayed infusion-related reactions	Type and screen patients prior to starting treratment as daratumumab may interfere with crossmatching and red blood cell antibody screening
Dinutuximab	Infections; infusion reactions; hyookalemia; hypotension; capillary leak syndrome; hypotension; neurological ocular toxicity; pain; bone marrow suppression; hemolytic uremic syndrome	CBC; electrolytes; renal function; BP; infusion reaction	Boxed warnings for infusion reactions and severe peripheral neuropathy Premedicate with analgesics (such as morphine), an antihistamine, acetaminophen, and intravenous hydration
Monoclonal Antibodies that Target Growth Factor Receptors and Their Ligands			
Ado-Trastuzumab Ematansine	Cardiac toxicity; thrombocytopenia; hemorrhage; hepatotoxicity; infusion reactions; peripheral neuropathy; ILD	CBC; liver function; pregnancy status; cardiac monitoring (LVEF); pulmonary symptoms	Boxed warnings for cardiotoxicity, hepatotoxicity, and embryo-fetal death Ado-Trastuzumab Ematansine and Trastuzumab are NOT interchangeable

Agent	Major Adverse Effects	Monitoring Parameters	Comments
Bevacizumab	GI bleeding or perforation, sometimes with intraabdominal abscess formation; impaired wound healing; hypertension; proteinuria; thrombotic events; rare severe pulmonary hemorrhage; rare reports of progressive multifocal leukoencephalopathy	BP; urine protein; neurologic examination; signs of GI perforation; symptoms of thromboembolism	Boxed warnings for gastrointestinal perforation, wound dehiscence, and hemorrhage
Cetuximab, Necitumumab, and Panitumumab	Rash; paronychial cracking in fingers or toes; asthenia; abdominal pain; nausea; constipation; diarrhea; infusion and hypersensitivity reactions; electrolyte wasting; cardiopulmonary arrest	Electrolytes; infusion reactions; dermatologic evaluation	Dose reductions or delays may be required for rash but supportive care should be attempted first Decreased risk of infusion-related reactions to panitumumab and does not appear to be cross reactive; therefore, a patient can receive panitumumab if they react to cetuximab
Pertuzumab	Diarrhea; nausea; alopecia; rash; neutropenia; fatigue; peripheral neuropathy; embryo and fetal toxicity; left ventricular dysfunction; infusion-related reactions	LVEF; infusion reactions; pregnancy status	Given with trastuzumab
Ramucirumab	GI bleeding or perforation; impaired wound healing; hypertension; proteinuria; thyroid dysfunction; thromboembolic events; hemorrhage	BP; urine protein; thyroid function, liver function	Boxed warnings for gastrointestinal perforation, wound dehiscence, and hemorrhage
Trastuzumab	Cardiac toxicity: congestive cardiomyopathy, usually reversible with medical management; infusion-related reactions	Infusion-related reactions; cardiac monitoring (LVEF)	Do not administer with anthracyclines because of increased cardiotoxicity
Immunomodulatory Monoclonal Antibodies			

Agent	Major Adverse Effects	Monitoring Parameters	Comments
Denosumab	Arthralgia; headache; nausea; hypocalcemia; osteonecrosis of the jaw	Dental evaluations; electrolytes	A dental examination prior to initiation of therapy
Elotuzumab	Fatigue; pyrexia; diarrhea or constipation; respiratory infections; peripherial neuropathy; hepatotoxicity; infusion-related reactions; second primary malignancies	Liver function; infusion-related reactions; infections	May interfere with the assay used to monitor M-protein which can impact the determination of complete response
Ipilimumab	Fatigue; diarrhea; pruritus; rash; immune-mediated reactions (enterocolitis, dermatitis, neuropathy, endocrinopathy, hepatitis)	Thyroid function; electrolytes; liver function; renal function; dermatologic evaluations; gastrointestional symptoms	Treat severe immune-mediated reactions with corticosteroids
Nivolumab and Pembrolizumab	Fatigue; immune-mediated toxicities (pneumonitis, colitis, hepatitis, nephritis, thyroid dysfunction)	Liver function; renal function, thyroid function; GI symptoms	Treat severe immune-mediated reactions with corticosteroids
Siltuximab	Pruritis, weight gain, hyperuricemia, infection; gastrointestinal perforation	CBC; uric acid levels; cytokine release reactions	Do not administer live vaccines while being treated with siltuximab HIV-positive and HHV-8-positive patients excluded from the clinical trials
Cytokines			
Interferon-alfa	Flu-like symptoms; fatigue; serious or fatal neuropsychiatric (eg, depression, suicide), autoimmune, ischemic, and infectious complications; pulmonary symptoms; thyroid disorders; hyperglycemia	Neurological evaluation; infection; pulmonary and cardiac monitoring; blood glucose; thyroid function	Fatigue and Flu-like symptoms tend to decrease with duration of therapy Exists in a pegylated form that has a prolonged half-life

Agent	Major Adverse Effects	Monitoring Parameters	Comments
Interleukin-2	Flu-like syndrome: fevers, chills, malaise; vascular or capillary leak syndrome: hypotension, pulmonary and peripheral edema; GI: nausea and vomiting, diarrhea; nephrotoxicity; myelosuppression (thrombocytopenia and leukopenia); bacterial infections; CNS: somnolence, confusion; arrhythmias; rash; itching	Intense monitoring required; electrolytes; liver function; renal function; CBC; thallium stress test; pulmonary function tests; cardiac monitoring during IL-2 administration, BP, HR	Vasopressor support and fluid resuscitation may be necessary during treatment because of hypotension Pulmonary edema can be managed with cautious use of diuretics; short courses of albumin may also be beneficial Itching may respond to treatment with antihistamines; emollient skin creams or occlusive agents are effective for dry, peeling skin Avoid corticosteroids because they may counteract the antitumor effects of IL-2 Patients on beta-blockers will need to be tapered off before initiation of aldesleukin
Enzymes			
L-asparaginase	Hypersensitivity reactions (fever, hypotension, rash, dyspnea in 25%), much lower risk with polyethylene glycol form and asparaginase *E. chrysanthemi;* pancreatitis; decreased synthesis of proteins, clotting factors; CNS: lethargy	Pancreatic enzymes; liver function; coagulation parameters (fibrinogen, PT, PTT); hypersensitivity reactions; blood glucose; CBC	Skin test before administration of *E. coli*–derived asparaginase; anaphylaxis precautions Pegaspargase complexes with polyethylene glycol to decrease immunogenicity and prolong duration of action Asparaginase *E. chrysanthemi* was developed for patients who have developed hypersensitivity

Agent	Major Adverse Effects	Monitoring Parameters	Comments
			to *E. coli*–derived asparaginase
Fusion Proteins			
Denileukin diftitox	Pyrexia; nausea; fatigue; rigors; vomiting; diarrhea; headache; peripheral edema; cough; dyspnea; pruritus; infusion reactions; capillary leak syndrome; loss of visual acuity	Infusion reactions; fluid status; BP; serum albumin; ophthalmologic evaluation	Serum albumin should be ≥3 g/dL (30 g/L) before initiating therapy Premedicate with an antihistamine and acetaminophen
Ziv-aflibercept	Neutropenia; diarrhea; proteinuria; increases in liver enzymes; stomatitis; fatigue; thrombocytopenia; hypertension; weight decreased; decreased appetite; epistaxis; abdominal pain; dysphonia; serum creatinine increased; headache; hemorrhage; GI perforation; compromised wound healing; arterial thromboembolic events; fistula formation	BP; urine protein; signs and symptoms of hemorrhage; CBC; liver function; renal function	Should be held at least 4 weeks before elective surgery and restarted at least 4 weeks after major surgery and until the surgical wound is fully healed
Vaccines			
Sipuleucel-T	Infusion reactions; chills; fatigue; back pain; nausea; joint ache; headache; thromboembolic events have occurred	Infusion reaction	Physicians and patients must be registered Premedicate with an antihistamine and acetaminophen
Talimogene laherparepvec	Fatigue; chills; pyrexia; nausea; influenza-like illness; injection site pain; cellulitis; risk of herpetic infection	Herpetic infections; injection- site complications; immune-mediated events	Administered directly into the cutaneous, subcutaneous and/or nodal lesion(s) Precautions for accidental exposure of healthcare works and close contacts

ATRA, all-*trans*-retinoic acid; BP, blood pressure; CBC, complete blood count; CHF, congestive heart

failure; CML, chronic myeloid leukemia; CMV, cytomegalovirus; CNS, central nervous system; CrCL, creatinine clearance; CYP, cytochrome P450 isoenzyme; DPD, dihydropyrimidine dehydrogenase; DVT, deep vein thrombosis; ECG, electrocardiogram; GI, gastrointestinal; G6PD, glucose-6-phosphate dehydrogenase; HDAC, high-dose cytarabine; HSV, herpes simplex virus; H_1 and H_2, histamine 1 and 2; HDAC, histone deacetylase; HSCT, hematopoietic stem cell transplantation; ILD, interstitial lung disease; INR, international normalized ration; IT, intrathecal; IM, intramuscular; LVEF, left ventricular ejection fraction; MAOI, monoamine oxidase inhibitor; MI, myocardial infarction; mTOR, mammalian target of rapamycin; MUGA, multigated acquisition scan; NSAID, nonsteroidal antiinflammatory drug; PE, pulmonary embolism; PFT, pulmonary function tests; Pgp, P-glycoprotein; PJP, *Pneumocystis jiroveci* pneumonia; PPI, proton pump inhibitor; PT, prothrombin time; PTT, partial thromboplastin time; SC, subcutaneous; Scr, serum creatinine; SIADH, syndrome of inappropriate secretion of antidiuretic hormone; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant; TLS, tumor lysis syndrome; TSH, thyroid-stimulating hormone; UGT1A1, Uridine 5′-diphospho-glucuronosyltransferase (UDP-glucuronosyltransferase).

[a]Only approximate guidelines can be given. Consult current references before dispensing as not all dose adjustments and monitoring parameters are provided in the table.

Antimetabolites

Antimetabolites are similar to the nucleotides that make up DNA and RNA. The body mistakes these chemotherapy agents for the naturally occurring nucleotide bases and metabolizes these agents as the natural nucleotides. These chemotherapy agents ultimately disrupt replication and cell division by interfering with the production of nucleic acids, DNA, and RNA. Unfortunately, these compounds are not selective for cancer cells and rapidly dividing normal cells may be affected by an antimetabolite. The most common toxicities associated with the antimetabolites are secondary to their effect on rapidly dividing normal cells, such as cells of the bone marrow and gastrointestinal tract. The three major classes of antimetabolites include pyrimidine analogs, purine analogs, and folate antagonists.

Pyrimidine Analogs

Cytarabine

Cytarabine is a cytidine analogue commonly used to treat acute myeloid leukemia (AML), acute lymphoblastic leukemia (ALL), and NHL. It is phosphorylated to its active phosphates within cancer cells and inhibits DNA polymerase, an enzyme responsible for strand elongation. It is also incorporated directly into DNA, where it inhibits the replication of DNA and acts as a chain terminator to prevent DNA elongation. Deaminase enzymes, particularly cytidine deaminase, degrades cytarabine.[17]

Cytarabine may be given intravenously or intrathecally. Intrathecal administration allows for cytotoxic concentrations of cytarabine to be maintained in the central nervous system (CNS) for several hours

after administration of traditional cytarabine formulations and for more than 2 weeks after administration of a depot formulation. It may be given to patients with leukemia.

The dose-limiting toxicities are leukopenia and thrombocytopenia. Other common toxicities include nausea, vomiting, mucositis, and diarrhea. Following administration of high-dose cytarabine (greater than 1 g/m^2 per dose), cerebellar syndrome may occur presenting with dysarthria, nystagmus, and ataxia. The risk of cerebellar syndrome is strongly correlated with advanced age and renal dysfunction. Renal dysfunction permits accumulation of high levels of the triphosphate, which is believed to be neurotoxic. Hepatic dysfunction, high cumulative doses, and bolus dosing may also increase the risk of neurotoxicity.[17] Conjunctivitis or keratitis is another common toxicity associated with high-dose cytarabine. Prophylactic steroid or saline eye drops should be administered with high-dose cytarabine to minimize irritation as discussed later in this chapter. Allopurinol may be given with high-dose cytarabine to minimize the risk of tumor lysis syndrome, a group of metabolic complications that occur following the breakdown of dying cancer cells.

Fluoropyrimidines

Fluorouracil (FU or 5-FU) is a fluorinated uracil analog that was originally synthesized in the late 1950s. It acts as a false pyrimidine and undergoes sequential phosphorylation to a mono-, di-, and triphosphate similar to natural nucleotide bases. In the presence of folates, the monophosphate binds tightly to and interferes with the function of thymidylate synthase. The triphosphate metabolite is incorporated into RNA as a false base and interferes with its function. The interference with both thymidine formation and RNA function both contribute to its cytotoxic effects. FU is commonly used to treat gastrointestinal tract and head and neck cancers.

The dosage and administration influences both the mechanism of action and toxicity profile.[17] With continuous-infusion regimens, thymidylate synthesis inhibition plays a greater role and dose-limiting toxicities are hand-foot syndrome and diarrhea. Comparatively, the incorporation into RNA plays a greater role with intermittent bolus schedules. The dose-limiting toxicity commonly associated with a bolus administration is myelosuppression.

Several pharmacologic strategies have been attempted to increase its cytotoxicity against cancer cells and decrease its toxicity to normal cells. The most common strategy combines FU with the reduced folate leucovorin. Folates increase the reduced folate pool, stabilize the monophosphate–thymidylate synthase complex and prolong the inhibition of thymidylate synthase. Clinical trials suggest that combining reduced folates with FU provides greater anticancer activity and improves tolerability.[17]

Dihydropyrimidine dehydrogenase (DPD) is a pyrimidine catabolic enzyme that is responsible for about 80% of the catabolism of FU. Reduced expression of this enzyme has been associated with drug accumulation and serious adverse events.[18] DPD deficiency is an autosomal recessive genetic disorder, with genetic variation in the DYPD gene associated with reduced enzyme activity. DPD deficiency occurs in up to 5% of the overall population. FU is contraindicated in patients with known DPD deficiency.

Capecitabine is an oral pyrimidine uracil analog used to treat breast and colon cancers. Because

capecitabine is enzymatically converted to FU, it shares the same mechanisms of action. Capecitabine is typically taken twice daily with food for the first 14 days of a 21-day treatment cycle. Because chronic twice-daily oral dosing produces sustained FU levels similar to those observed with continuous infusions, hand-foot syndrome and diarrhea are the dose-limiting toxicities.

Uridine triacetate is approved for the emergency treatment of adult and pediatric patients following a FU or capecitabine overdose regardless of the presence of symptoms, or who exhibit early-onset, severe or life-threatening toxicity affecting the cardiac or central nervous system and/or early-onset, unusually severe adverse reactions within 96 hours following the FU or capecitabine administration. It is not recommended for the nonemergent treatment of adverse reactions. The safety and efficacy has not been established when more than 96 hours has elapsed following the end of FU or capecitabine administration. Few adverse events have been reported, but the most common adverse reactions are vomiting, nausea and diarrhea.

Gemcitabine

Gemcitabine is a fluorine-substituted deoxycytidine analog that is related structurally to cytarabine and is used to treat pancreatic, nonsmall cell lung, breast, and bladder cancers. Its activation and mechanism of action are similar to those of cytarabine. Gemcitabine is incorporated into DNA, where it inhibits DNA polymerase activity. It also inhibits ribonucleotide reductase, which is the enzyme required to convert ribonucleotides into the deoxyribonucleotides that are needed for both DNA synthesis and repair. Compared with cytarabine, gemcitabine achieves intracellular concentrations about 20 times higher, secondary to increased penetration of cell membranes and greater affinity for the activating enzyme deoxycytidine kinase. Gemcitabine that is incorporated into DNA has a prolonged intracellular half-life. Its stereoconfiguration causes another normal base pair to be added next to the fraudulent gemcitabine base pair in the DNA strand. This “masked chain termination” protects the gemcitabine from excision and elimination. Flu-like symptoms are commonly associated with gemcitabine. These symptoms may last several days and may be treated with acetaminophen.

Trifluridine and Tipiracil

Trifluridine and tipiracil are combined in a molar ration of 1:0.5 in one tablet that is approved for the treatment of metastatic colorectal cancer. Trifluridine is a thymidine-based nucleoside analogue and tipiracil is a thymidine phosphorylase inhibitor. Following uptake into cancer cells, trifluridine is incorporated into DNA, interferes with DNA synthesis and inhibits cell proliferation. Inclusion of tipiracil increases trifluridine exposure by inhibiting its metabolism by thymidine phosphorylase. The dose-limiting toxicity is myelosuppression; patients older than 65 years of age may be at greater risk for grade 3 or higher myelosuppression. Other common toxicities include asthenia/fatigue, nausea, decreased appetite, diarrhea, vomiting, abdominal pain, and pyrexia.

Purine Analogs

Cladribine and Pentostatin

Cladribine and pentostatin are purine nucleoside analogs with slightly different mechanisms of action. Both agents are used to treat hairy cell leukemia. Cladribine is resistant to inactivation by adenosine deaminase and is triphosphorylated to an active form that is incorporated into DNA that inhibits DNA synthesis and early chain termination. Its anticancer activity is unusual for an antimetabolite in that it affects both actively dividing and resting cancer cells. Pentostatin is a potent inhibitor of adenosine deaminase. Adenosine deaminase is an enzyme critical in purine base metabolism and is found in high concentrations in lymphatic tissue. Both agents have immunosuppressive effects that place patients at risk for serious opportunistic infections and require the administration of prophylactic antibiotics.

Fludarabine

Fludarabine is an adenine analogue used to treat chronic lymphocytic leukemia (CLL) and indolent NHL. Similar to cytarabine, fludarabine interferes with DNA polymerase, causing chain termination. Fludarabine also incorporates into RNA, resulting in inhibition of transcription. Fludarabine is immunosuppressive; it has been associated with the development of opportunistic infections, secondary to its effect on T-cells and subsequent decrease in CD4 counts. Prophylactic antibiotics and antiviral medications are recommended and should continue until CD4 counts normalize.[17]

Mercaptopurine and Thioguanine

6-Mercaptopurine (6-MP) and its analog thioguanine are oral antimetabolites used for the treatment of ALL. These antimetabolites are rapidly converted to ribonucleotides that inhibit purine biosynthesis or undergo purine interconversion reactions needed to supply purine precursors for synthesis of nucleic acids. Clinical cross-resistance is generally observed.[17] Both antimetabolites are metabolized by thiopurine methyltransferase (TPMT) and hypoxanthine phosphoribosyl transferase to produce multiple metabolites that contribute to the observed anticancer activity, hepatotoxicity, and myelosuppression. Certain genetic alterations within the TPMT gene can lead to a reduction of loss of TPMT enzyme activity. Therefore, patients who are homozygous or heterozygous for a genetic alteration that affects TPMT enzyme activity may lead to an accumulation of toxic metabolites and an increased risk of severe myelosuppression. The Clinical Pharmacogenetics Implementation Consortium (CPIC) provides primary dosing recommendations for patients with altered TPMT gene.

6-MP depends on xanthine oxidase for an initial oxidation step. Its metabolism is markedly decreased by coadministration of the xanthine oxidase inhibitor allopurinol, which may lead to the development of serious adverse events. If allopurinol is given concurrently with 6-MP to minimize tumor lysis syndrome, the dose of 6-MP must be reduced.[17]

6-MP is now available as tablets or suspension for oral administration to facilitate dosing in pediatrics.

Folate Antagonists

Methotrexate

Methotrexate is commonly used to treat ALL and some lymphomas. It inhibits dihydrofolate reductase (DHFR), which results in the depletion of intracellular pools of reduced folates (tetrahydrofolates) essential for thymidylate and purine synthesis. Folates are essential cofactors for DNA and RNA synthesis and thus, lack of either thymidine or purines prevents DNA or RNA synthesis.

Chemotherapy regimens may contain low-, intermediate- or high-dose methotrexate and may incorporate methotrexate given orally, intravenously or intrathecally. High-dose methotrexate defined as doses greater than 500 mg/m^2 given intravenously as prophylaxis or treatment of CNS disease can cause severe myelosuppression and gastrointestinal toxicity. The development of these toxicities is related to both the maximal concentrations and the time that concentrations remain above 0.02 mg/L (50 nmol/L). These effects may be neutralized by supplying reduced folates exogenously, such as leucovorin (folinic acid), which bypasses the metabolic block induced by DHFR inhibitors.[19] Leucovorin should be administered until levels fall below the threshold and various dosing algorithms are available to guide leucovorin dosing based on methotrexate level. As an alternative to leucovorin, levoleucovorin may be given with high-dose methotrexate. Vigorous hydration with sodium biocarbonate to alkalinize the urine should be given to decrease the risk of renal failure. Patients with third space fluids may require prolonged leucovorin rescue, since these fluids influence methotrexate volume of distribution and elimination half-life.

Glucarpidase has been approved for the treatment of toxic plasma methotrexate concentrations in patients with delayed methotrexate clearance because of impaired renal function. It is important to note that methotrexate concentrations within 48 hours after glucarpidase administration can only be reliably measured by chromatographic methods. Immunoassays can overestimate methotrexate concentration because of interference from metabolites.

Methotrexate is highly protein bound and drugs, such as sulfonamides, salicylates, phenytoin, and tetracyclines, may displace methotrexate from albumin. Increased toxicity may be observed. Nonsteroidal anti-inflammatory drugs (NSAIDs) and vitamin C may also affect methotrexate disposition and prolong methotrexate elimination half-life. Although the exact mechanism is uncertain, proton pump inhibitors are thought to inhibit methotrexate elimination and thereby potentially increase methotrexate toxicity.

Pemetrexed

Pemetrexed is a multi-targeted antifolate that is used to treat nonsquamous NSCLC and mesothelioma. It inhibits at least three biosynthetic pathways in thymidine and purine synthesis. In addition to inhibiting DHFR, it also inhibits thymidine synthase and glycinamide ribonucleotide formyltransferase, decreasing the risk of the development of drug resistance. Severe hematologic toxicity and deaths associated with neutropenic sepsis have been reported in clinical trials. Elevated baseline cystathionine or homocysteine concentrations correlated with this unexpected toxicity. Routine supplementation of folic acid and vitamin B_{12} lowers levels of these substances and lowers the risk of mortality related to neutropenic sepsis. The approved labeling of pemetrexed requires administration of folic acid and vitamin B_{12} prior to initiating pemetrexed and throughout the duration of treatment. Oral or intravenous dexamethasone should be given with pemetrexed to

minimize the risk of rash.

Pralatrexate

Pralatrexate is an antifolate drug approved for patients with relapsed or refractory peripheral T-cell leukemias. It competitively inhibits DHFR and polyglutamylation by the enzyme folylpolyglutamyl synthetase. This inhibition results in the depletion of thymidine and other synthesis of biological molecules that depends on single carbon transfer.[20] The most common adverse events resulting in dose reductions are pyrexia, mucositis, febrile neutropenia, sepsis, and thrombocytopenia.

Microtubule-Targeting Drugs

Microtubules are an integral part of the cytoskeleton and help maintain the shape of a cell. These structures are also involved in chromosome separation during mitosis and form the mitotic spindle responsible for separating chromosomes during cell replication. Several chemotherapy agents affect microtubule function, including epipodophyllotoxins, taxanes, vinca alkaloids, epitholones, and macrolides.

Eribulin

Eribulin is a fully synthetic antimicrotubule analogue of the macrolide halichondrin B. Eribulin inhibits tubulin polymerization by inhibiting microtubule growth, but it does not shorten or promote depolymerization of microtubules.[21] Additionally, eribulin only binds to the β-tubulin subunit and has demonstrated the ability to overcome taxane resistance conferred by β-tubulin mutations.[21] The most common toxicities are similar to other microtubule inhibitors, but eribulin demonstrates a decreased incidence of neuropathy compared with vincristine and taxanes. Eribulin is approved for the treatment of metastatic breast cancer and unresectable or metastatic liposarcoma.

Estramustine

Estramustine is approved for the treatment of metastatic prostate cancer. It structurally combines the alkylating agent nor-nitrogen mustard with estradiol. It was designed with the intent that the estradiol portion of the molecule would facilitate uptake of the alkylating agent into hormone-sensitive prostate cancer cells. Despite the inclusion of an alkylator, estramustine does not function as an alkylating agent. The estradiol is released after its administration and it is responsible for most of the toxicity associated with estramustine; the estradiol is not believed to contribute to its anticancer activity. In the mid-1980s, estramustine was redefined as an antimicrotubule agent. It binds covalently to microtubule-associated proteins that are part of the structural support for microtubules. The binding causes the separation of microtubule-associated proteins from the microtubules, inhibiting microtubule assembly and eventually causing their disassembly. Observed toxicities include gastrointestinal disorders, edema, gynecomastia, thromboembolic events, and cardiovascular events.

Ixabepilone

Ixabepilone is a synthetic epothilone approved for the treatment of metastatic breast cancer. Its binding to microtubules appears distinct from other microtubule inhibitors, such as the taxanes. Dose-limiting toxicities are leukopenia and neuropathy, consistent with other microtubule inhibitors. Other toxicities include anemia, thrombocytopenia, diarrhea, myalgia and alopecia. Premedication with antihistamines must be administered; a corticosteroid may be co-administered with the antihistamines if a patient experiences a hypersensitivity reaction to a previous dose.

Taxanes

Paclitaxel and docetaxel are taxane plant alkaloids with antimitotic activity used to treat many different solid tumors.[22] Paclitaxel and docetaxel both act by binding to tubulin, but they do not interfere with tubulin assembly. Instead, the taxanes promote microtubule assembly and interfere with microtubule disassembly. They induce tubulin polymerization, resulting in formation of inappropriately stable, nonfunctional microtubules. The stability of the microtubules damages cells by disrupting the dynamics of microtubule-dependent structures required for mitosis and other cellular functions. Taxanes also have some nonmitotic actions that can promote cancer cell death, such as inhibition of angiogenesis.

Resistance to the antitumor effects of the taxanes is attributable to alterations in tubulin or tubulin binding sites or to P-glycoprotein (Pgp)-mediated multidrug resistance. Although paclitaxel and docetaxel have very similar mechanisms of action, cross-resistance between the two chemotherapy agents is incomplete.[22]

Myelosuppression is common with both taxanes, but other toxicities differ. While fluid retention is seen with docetaxel, neurotoxicity and hypersensitivity reactions are seen with paclitaxel.[22] Both require premedications with corticosteroids; paclitaxel also requires premedication with antihistamines to decrease the likelihood of hypersensitivity reactions.

Two paclitaxel drug products are available. The original drug product contains Cremephor and ethanol. The subsequent drug product contains paclitaxel bound to albumin (nab-paclitaxel); this drug product does not contain the Cremophor excipient that is believed to contribute to the hypersensitivity reactions and exacerbate myelosuppression with the original drug product. In clinical trials, nab-paclitaxel has shown comparable activity to the original drug product with a lower incidence of hypersensitivity reactions. Peripheral neuropathy remains a common adverse event with nab-paclitaxel. Nab-paclitaxel is approved for the treatment of metastatic breast, NSCLC and pancreatic cancer. Of note, the dose differs from the original paclitaxel drug product.

Cabazitaxel is a semisynthetic derivative of docetaxel that has demonstrated anticancer activity in hormone refractory prostate cancer that has progressed following treatment with docetaxel-based chemotherapy despite having the same mechanism of action. This is partially because of its lack of affinity for Pgp that allows cabazitaxel to remain inside the cancer cells. Toxicities and premedications are similar to docetaxel.[23]

Vinca Alkaloids

Vincristine, vinblastine, and vinorelbine are natural alkaloids derived from the periwinkle (vinca) plant. These agents act as mitotic inhibitors or spindle poisons. Although these alkaloids have a very similar structure, they have different activities and patterns of toxicity. These agents are used to treat different cancers. For example, vinblastine may be used to treat testicular cancer and Hodgkin lymphoma, vincristine may be used to treat NHL and Hodgkin lymphoma, and vinorelbine may be used to treat NSCLC and breast cancer. Vinorelbine and vinblastine are associated with dose-limiting myelosuppression, while vincristine is associated with dose-limiting neurotoxicity, including constipation and paralytic ileus. All vinca alkaloids are vesicants upon extravasation; the application of local heat allows dispersal or dilution of the alkaloid to minimize the tissue damage.

Vinca alkaloids should never be administered intrathecally. Accidental overdose is associated with a very high mortality rate. It is recommended to avoid administration of intravenous and intrathecal chemotherapy on the same day to avoid accidental intrathecal administration of these alkaloids.

Vinca alkaloids bind to tubulin and disrupt the normal balance between polymerization and depolymerization of microtubules, which inhibits assembly of microtubules and disrupts microtubule dynamics. This interferes with formation of the mitotic spindle and causes cells to accumulate in mitosis. These agents also disturb a variety of microtubule-related processes in cells and induce apoptosis. Resistance to the vinca alkaloids develops primarily from Pgp-mediated multidrug resistance, which decreases drug accumulation and retention within cancer cells.[22]

Topoisomerase Inhibitors

Topoisomerases (I and II) are essential enzymes involved in maintaining DNA topologic structure during replication. During replication, these enzymes cleave DNA strands and form intermediates with the strands, producing a gap through which DNA strands can pass, and then reseal the strand breaks. Topoisomerase I produces single-strand breaks and topoisomerase II produces double-strand breaks.[24] Several important anticancer agents interact with topoisomerase enzymes: anthracyclines, camptothecins, and podophyllotoxins.

Anthracyclines

The anthracyclines include doxorubin, daunorubicin (daunomycin), idarubicin, and epirubicin. These agents share a common, four-membered anthracene ring complex with an attached aglycone or sugar portion. The ring complex is a chromophore and accounts for the intense colors of these derivatives.[24] Anthracyclines are classified as antitumor antibiotics, but they have multiple mechanisms of action, including intercalation into DNA and inhibition of topoisomerase II.[24] The production of free radicals following their metabolism may also contribute to their anticancer activity. These agents are used to treat many cancers, including leukemias, lymphomas, and multiple other cancers.

Although the dose-limiting toxicity is myelosuppression, development of cardiomyopathy is a significant concern with these agents. All patients should have a baseline study to evaluate left ventricular ejection fraction. Since the probability of congestive heart failure increases with the

cumulative dose, a maximum cumulative dose has been identified for each anthracycline. The relatively low level of defensive enzymes found in cardiac muscle that scavenge against oxygen free radicals may account for the relative risk of cardiomyopathy compared to other organs. Oxygen free-radical formation likely contributes to extravasation injury associated with these agents, as well. Other common toxicities include nausea, vomiting and alopecia. Doxorubicin also causes a discoloration of the urine. Resistance to anthracyclines is usually secondary to Pgp-mediated multidrug resistance, but altered topoisomerase II activity may also contribute to the development of resistance.

Mitoxantrone is a closely related chemotherapy agent identified as an anthracendione. It was synthesized in an attempt to develop a chemotherapy agent with comparable antitumor activity to doxorubicin but with an improved safety profile. Similar to the anthracyclines, mitoxantrone is an intercalating topoisomerase II inhibitor, but its potential for free-radical formation is much less than that of the anthracyclines. This decreased tendency for free-radical formation may explain the reduced risks of cardiac toxicity and ulceration after extravasation. Mitoxantrone may be used with other anticancer agents to treat leukemias and lymphomas. Common toxicities include nausea, vomiting, alopecia and discolored urine.

Camptothecins

Topotecan and irinotecan, through its active metabolite SN-38, inhibit topoisomerase I enzyme activity. Topoisomerase I enzymes stabilize DNA single-strand breaks and inhibit strand resealing.[24] Topotecan is available for oral and intravenous administration and it is used to treat ovarian cancer and small cell lung cancer. Irinotecan is used for the treatment of colorectal cancer. Irinotecan's active metabolite SN-38 undergoes metabolism by the polymorphic enzyme uridine diphosphate glucosyltransferase. Although variant tandem repeats in the promoter of this gene have been associated with a higher risk of diarrhea and neutropenia, genotyping has not been widely adopted in clinical practice.

Liposomal irinotecan is approved for the treatment of patients with metastatic adenocarcinoma of the pancreas whose disease has progressed following gemcitabine-based therapy with FU and leucovorin. The common toxicities associated with irinotecan have been observed with liposomal irinotecan, including gastrointestinal toxicity and myelosuppression. The recommended dose is lower for patients homozygous for the UGT1A1*28 allele.

Etoposide and Teniposide

Etoposide and teniposide are semisynthetic podophyllotoxin derivatives that bind to tubulin and interfere with microtubule formation. Etoposide and teniposide also damage cancer cells by causing strand breakage through inhibition of topoisomerase II.[24] Resistance may be caused by differences in topoisomerase II levels, increased cell ability to repair strand breaks, or increased levels of Pgp. Etoposide and teniposide are usually clinically cross-resistant. They are cell-cycle phase-specific and arrest cells in the S or early G_2 phase. As a result, activity is much greater when they are administered in divided doses over several days rather than in large single doses. Etoposide may be used to treat

testicular cancer and small cell lung cancer and teniposide is used to treat pediatric ALL. Both agents are associated with dose-limiting myelosuppression, as well as nausea, vomiting and alopecia.

Alkylating Agents

The alkylating agents are among the oldest and most useful classes of chemotherapy agents. Their clinical use evolved from the observation of myelosuppression and lymph node shrinkage in soldiers exposed to sulfur mustard gas warfare during World War I. In an effort to develop similar agents that might be useful in treating lymphomas, less reactive derivatives were synthesized. Their anticancer activity was confirmed by clinical trials in the mid-1940s.

All alkylating agents work by covalently bonding to highly reactive alkyl groups or substituted alkyl groups with nucleophilic groups of proteins and nucleic acids. Some agents react directly with biologic molecules, but others form an intermediate compound that reacts with these molecules. The most common binding site for alkylating agents is the seven-nitrogen group of the DNA base guanine. These covalent interactions result in cross-linking between two DNA strands or between two bases in the same strand of DNA and prevent the separation of DNA strands that needs to occur during replication. Reactions between DNA and RNA and between drug and proteins may also occur. Alkylating agents are cell-cycle phase-nonspecific, but their greatest effect is seen in rapidly dividing cells.

As a class, alkylators are cytotoxic, mutagenic, teratogenic, carcinogenic, and myelosuppressive. Resistance to these chemotherapies can occur from increased DNA repair capabilities, decreased entry into or accelerated exit from cells, increased inactivation inside cells, or lack of cellular mechanisms to result in cell death after DNA damage. They are inactivated by hydrolysis, making spontaneous degradation an important component of their elimination.[25]

Nitrogen Mustards

Bendamustine

Bendamustine is an alkylating agent with a benzimidazole ring that demonstrates only partial cross-resistance in vitro with other alkylating agents.[26] It is used primarily to treat lymphoid malignancies, such as CLL and NHL. Bendamustine is incompatible with polycarbonate or acrylonitrile-butadiene-styrene found in syringes and adapters and has been shown to minimize the integrity of syringes and adapters. Typical adverse events associated with alkylating agents have been observed with bendamustine, but it appears to cause less alopecia.

Cyclophosphamide and Ifosfamide

Cyclophosphamide and ifosfamide are nitrogen mustard derivatives and are widely used in the treatment of solid tumors and hematologic malignancies. These mustards are closely related in structure, clinical use, and toxicity. Neither agent is active in its parent form and must be activated by cytochrome P450 enzymes. One of the active metabolites of cyclophosphamide is phosphoramide

mustard and of ifosfamide is ifosfamide mustard. The cytochrome P450-mediated metabolites 4-hydroxycyclophosphamide and 4-hydroxyifosfamide are also cytotoxic compounds. Acrolein, a metabolite of both cyclophosphamide and ifosfamide, has little anticancer activity, but is responsible for the hemorrhagic cystitis associated with ifosfamide and high-dose cyclophosphamide. Encephalopathy after ifosfamide can occur within 48 to 72 hours after the infusion and is reversible once the infusion is stopped. Methylene blue has been administered to manage neuropathy, but no clinical trials are available to support its routine use. The increased production of dechloroethylated metabolites after administration of ifosfamide compared with cyclophosphamide may explain the increased risk of CNS toxicity associated with ifosfamide.

Nitrosoureas

Carmustine and Lomustine

Carmustine (BCNU) and lomustine (CCNU) are characterized by their lipophilicity and their ability to cross the blood–brain barrier; both agents are used to treat brain cancers. Carmustine is also used to treat multiple myeloma and lymphoma and in preparation for a bone marrow transplant. It is available as an intravenous preparation and as a drug-impregnated biodegradable wafer for direct application to residual tumor tissue after surgical resection of brain tumors. Both agents cause dose-limiting myelosuppression, but the nadir is typically delayed to 4 to 6 weeks after administration. The nitrosoureas decompose to reactive alkylating metabolites and to isocyanate compounds that have several effects on reproducing cells.[25]

Nonclassic Alkylating Agents

Several other chemotherapy agents appear to act as alkylators, although their structures do not include the classic alkylating groups. These agents are capable of binding covalently to cellular components and include procarbazine, dacarbazine, temozolomide, and platinum analogues.[25]

Dacarbazine and Temozolomide

Dacarbazine and temozolomide undergo demethylation to the same active intermediate (monomethyl triazeno-imidazole-carboxamide [MTIC]) that interrupts DNA replication by causing methylation of guanine. Unlike dacarbazine, temozolomide does not require the liver for activation and is chemically degraded to MTIC at physiologic pH. Both agents inhibit DNA, RNA, and protein synthesis.[25]

Important pharmacokinetic differences exist between these two agents. Dacarbazine is poorly absorbed and must be administered by intravenous infusion. Temozolomide is rapidly absorbed after oral administration; it demonstrates nearly 100% bioavailability when given under fasted conditions. Dacarbazine penetrates the CNS poorly, but temozolomide readily crosses the blood–brain barrier, achieving therapeutically active concentrations in cerebrospinal fluid and brain tumor tissues.[25] Temozolomide is approved for the treatment of glioblastoma multiforme and dacarbazine was commonly used to treat melanoma. Common adverse events include nausea and vomiting, alopecia,

and myelosuppression.

Platinum Analogs

The platinum derivatives—cisplatin, carboplatin, and oxaliplatin—are chemotherapy agents with remarkable usefulness in cancer treatment. Recognition of cisplatin's cytotoxic activity was the result of a serendipitous observation that bacterial growth in culture was altered when an electric current was delivered to the media through platinum electrodes. The growth change was noted to be similar to that produced by alkylating agents and radiation. It was found that a platinum–chloride complex, now known as cisplatin, generated by the current was responsible for the changes. Carboplatin is a structural analog of cisplatin in which the chloride groups of the parent compound are replaced by a carboxycyclobutane moiety. It shares a similar spectrum of clinical activity with cisplatin and cross-resistance is common. Oxaliplatin is an organoplatinum compound in which the platinum is complexed with an oxalate ligand as the leaving group and to diaminocyclohexane. Its spectrum of activity differs substantially from the other platinum compounds and includes notable activity against colorectal cancers.[25]

The cytotoxicity of the platinum derivatives depends on platinum binding to DNA and the formation of intrastrand cross-links or adducts between neighboring guanines. These intrastrand links cause a major bending of the DNA. These agents may cause cellular damage by distorting the normal DNA conformation and preventing bases that are normally paired from lining up with each other. Interstrand cross-links also occur.[25]

The aquated species differ among these platinum compounds, but all of these species contribute to the anticancer activity. The cytotoxic form of cisplatin is the aquated species in which hydroxyl groups or water molecules replace the two chloride groups. This reaction occurs readily in low concentrations of chloride, such as the concentrations present within cells, and produces a positively charged compound that can react with DNA. The aquated species is responsible for both the efficacy and toxicity of cisplatin. Carboplatin also undergoes aquation but at a slower rate. Oxaliplatin becomes active when the oxalate ligand is displaced in physiologic solutions.[25]

Resistance to the therapeutic effects of platinum compounds may occur through several mechanisms. The ability to repair platinum-induced DNA damage may be increased or the compounds may be inactivated by increased levels of intracellular glutathione, metallothioneins, or other thiol-containing proteins. Altered uptake into cells may also affect sensitivity to platinum compounds.[25]

The dose-limiting toxicities differ substantially among these compounds. Cisplatin can cause serious nephrotoxicity, ototoxicity, peripheral neuropathy, emesis, and anemia, but its significant anticancer activity in many tumors makes it a valuable agent despite these toxicities. Most of these toxicities can be prevented or managed with aggressive supportive care measures. Intravenous hydration, mannitol and diuretics have been used to minimize the risk of nephrotoxicity, but it appears intravenous hydration alone is adequate to minimize the risk of nephrotoxicity. In contrast, carboplatin administration is limited by hematologic toxicity. Patients with compromised renal function require dose reductions to limit myelosuppressive toxicity.[25] The most widely used dosage schema, the

Calvert formula, uses a target area-under-the-curve and renal function parameters to estimate the carboplatin dose. Carboplatin's potential to cause renal damage, peripheral neuropathy, ototoxicity, and nausea and vomiting is much less than that of comparable cisplatin doses.[25] Oxaliplatin is not nephrotoxic or ototoxic, but it can cause peripheral neuropathies and unique cold-induced neuropathies. Intravenous calcium and magnesium were commonly used to minimize the risk of neuropathy, but these measures do not appear to decrease the risk of acute neurotoxicity or cumulative sensory neurotoxicity based on the results of a controlled trial.[27] All of the platinum derivatives have potential to cause hypersensitivity reactions, including anaphylaxis, after a threshold exposure is reached. De-sensitization protocols may be successful in re-establishing tolerance to these agents.

Trabectedin

Trabectedin is an alkylating drug that binds guanine residues in the minor groove of DNA. Subsequently, adducts form and cause a bending of the DNA helix towards the major groove. It is approved for the treatment of patients with unresectable or metastatic liposarcoma or leiomyosarcoma who have received a prior anthracycline-containing regimen. Possible risks associated with trabectedin include neutropenic sepsis, rhabdomyolysis, cardiomyopathy, hepatotoxicity, anaphylaxis, and extravasation leading to tissue necrosis.

Endocrine Therapies

Endocrine therapies are perhaps the earliest successful approach to target the growth processes of cancer cells. Endocrine manipulation is an option for management of cancers in which its growth is under gonadal hormonal control, such as breast, prostate, and endometrial cancers. These cancers may regress if the feeding hormone is eliminated or antagonized. Major organ system toxicity is uncommon from endocrine therapies. Specific anticancer agents such as the selective estrogen receptor modulators (SERM) and aromatase inhibitors (AI) have increased the utility of endocrine therapies in the treatment of cancer.[28,29] These therapies are discussed in detail in Chapters 128 and 131.

Corticosteroids

Corticosteroids are also useful anticancer agents because of their lymphotoxic effects. These drugs are primarily used to treat hematologic malignancies and together with chemotherapy or targeted therapy for hormone-refractory prostate cancer. In addition to their cytotoxic effects, corticosteroids have many other applications as part of supportive care measures and in the management of oncologic emergencies. Short-term corticosteroid regimens are generally well tolerated.

Miscellaneous Agents

Arsenic Trioxide

Arsenic is an organic element and a well-known poison that is an effective treatment for acute

promyelocytic leukemia (APL).[30] As an anticancer agent, arsenic trioxide acts as a differentiating agent, inducing the growth progression of cancer cells into mature, more normal cells. It also induces apoptosis. This anticancer agent is discussed in more detail in Chapter 134.

Bleomycin

Bleomycin is an antitumor antibiotic used with other anticancer agents to treat Hodgkin lymphoma and testicular cancer and for pleurodesis to prevent recurrence of a pleural effusion. It is a mixture of peptides from fungal Streptomyces species. Its strength is expressed in units of drug activity and one unit is roughly equal to 1 mg of polypeptide protein. The predominant peptide is bleomycin A2, which makes up about 70% of the commercial drug product. Its cytotoxicity is secondary to DNA strand breakage, which it produces via free-radical formation. Cytotoxicity depends on binding of the bleomycin–iron complex to DNA. The bleomycin–iron complex then reduces molecular oxygen to free oxygen radicals that cause primarily single-strand breaks in DNA. Bleomycin has greatest effect on cells in the G2 and M phases of the cell cycle.

Bleomycin is inactivated within cells by the enzyme aminohydrolase. This enzyme is widely distributed, but is present in only low concentrations in the skin and the lungs, explaining the predominant toxicities of bleomycin to those sites. Baseline pulmonary function tests and monitoring for pulmonary toxicity are necessary. The presence of hydrolase enzymes in cancer cells is the primary mechanism of resistance to bleomycin. Cells can also become resistant by repairing the DNA breaks produced by bleomycin.

Hydroxyurea

Hydroxyurea is a unique drug that inhibits ribonucleotide reductase. Cells accumulate in the S phase, because DNA synthesis is inhibited and only abnormally short DNA strands are produced.[30] This anticancer agent was used to treat chronic myeloid leukemia (CML) because of its ability to cause a rapid decline in white blood cells.

Mitomycin C

Mitomycin C is a natural product that is sometimes classified as an antitumor antibiotic.[25] It has similarities to nitrogen mustards and may function as an alkylating agent, although its toxicity pattern differs from conventional alkylating agents. It is used to treat bladder cancer. Mitomycin C may be given intravenously or as an instillation directly into the bladder. Mitomycin C causes delayed myelosuppression, so treatment is typically given every six weeks.

Omacetaxine mepesuccinate

Omacetaxine mepesuccinate is a natural ester of the alkaloid cephalotaxine. It inhibits protein translation and thus prevents the initial elongation step of protein synthesis. It is given subcutaneously for treatment of patients with CML who have failed two or more approved targeted drugs for this disease. Additionally, synergy with these approved targeted drugs has been

demonstrated in a few clinical studies and additional combination trials are ongoing.[31] The most common serious adverse reactions are myelosuppression, hemorrhage and hyperglycemia.

Radium-223

Radium-223 is for the treatment of patients with castration-resistant prostate cancer, who have symptomatic bone metastases and no known visceral metastatic disease. It is an alpha-particle emitting radiotherapy that mimics calcium and forms complexes with hydroxyapatite at areas of increased bone turnover, such as bone metastases. Radium-223 shows minimal myelosuppression with gastrointestinal adverse reactions the most common toxicities observed following its administration.

Retinoids

Three retinoids are available to treat patients with cancer. Tretinoin (all-trans-retinoic acid), a naturally occurring derivative of vitamin A (retinol), is used to treat APL. Other retinoids indicated for the treatment of cancers include alitretinoin (9-cis-retinoic acid) gel for topical management of Kaposi's sarcoma lesions and bexarotene gel or capsules for treatment of cutaneous T-cell lymphoma.

Retinoids are classified as morphogens, small molecules released from one type of cell that can affect the growth and differentiation of neighboring cells. Their normal roles in the human body are to induce differentiation of some cells, stop the differentiation of others, and both suppress and induce apoptosis in different cell types. Their diverse actions come from the diversity of their receptors. The two classes of retinoid receptors are retinoid X receptors (RXR) and retinoic acid receptors (RAR). RXR are versatile; they bind to RAR and to other nuclear receptors, such as thyroid hormone receptors. After being activated, the receptors act as transcription factors that in turn regulate the expression of genes that control cellular growth and differentiation.

Tretinoin binds primarily to the RAR-α receptors. Alitretinoin is considered a pan-agonist, which means that it binds to all known retinoid receptors, producing diverse regulatory effects. Bexarotene is synthetic and is classed as a rexinoid. It is the first RXR-selective retinoid agonist. The exact mechanism of action of alitretinoin and bexarotene as anticancer agents is unknown.

The common adverse events differ for these three agents. Tretinoin may be associated with retinoic acid syndrome. This syndrome manifests with dyspnea, fever, weight gain, or peripheral edema following cytokine release from the differentiating promyelocytes. Corticosteroids should be administered to manage this syndrome. Aliretinoin is associated with pain, itching and rash and bexarotene is associated with skin reactions, thyroid disorders, hypercholesterolemia and hyperlipidemia.

TARGETED DRUGS

6 Targeted drugs are a class of small molecule drugs (molecular weight less than 1,000 daltons) that are typically identified as kinases inhibitors. Kinases are enzymatic proteins that constitute the

intracellular signaling pathways, such as the JAK-STAT and MAPK/ERK pathways described earlier. Following ligand binding to an extracellular receptor, these kinases transmit signals to the cell interior that stimulates activation of the pathway. The targeted drugs turn off or inhibit these pathways by inhibiting the adenosine triphosphate (ATP) binding domain of the kinases.[32] Most of the approved kinase inhibitors are promiscuous, such that they inhibit more than one kinase. The binding to multiple kinases typically leads to off-target effects or toxicities; some toxicities are attributed to specific kinase families. For example, the VEGF family is associated with hypertension, poor wound healing and proteinuria. Although most inhibitors are given orally continuously for months to years, their anticancer activity is typically limited by the development of resistance. Some targeted drugs require identification of the target within the cancer with a companion diagnostic test before initiation of therapy.

Anaplastic Lymphoma Kinase (ALK) Inhibitors

Crizotinib

Crizotinib binds to the ATP intracellular domain of activated ALK, thereby inhibiting phosphorylation and subsequent downstream signaling. ALK rearrangements were first identified in large cell lymphomas and later in NSCLC. In NSCLC, the most common rearrangement involves inversion of chromosome 2p that is primarily fused to the echinoderm microtubule-like protein 4 (EML4), which forms the ALK-EML4 oncogene fusion protein. This rearrangement leads to the activation of downstream signaling pathways and inhibition of apoptosis.[33] ALK-EML4 has a higher prevalence in younger patients, Asians, never or light smokers and adenocarcinoma. Crizotinib also inhibits other kinases, such as ROS1, RON, and MET. Crizotinib is approved for the treatment of patients with locally advanced or metastatic NSCLC that is ALK-positive as detected by an FDA (Food and Drug Administration)-approved test.

The most common toxicities reported in patients taking crizotinib include nausea, vomiting, diarrhea, constipation, fatigue, and elevated transaminases. Visual disorders occur in about half of patients and usually occur within the first weeks of therapy. Edema is also commonly seen and is most likely attributed to the inhibition of MET. Crizotinib has been associated with interstitial lung disease/pneumonitis, hepatotoxicity, QT interval prolongation, and bradycardia.

Many patients with ALK- positive NSCLC initially respond to crizotinib, but most patients will develop resistance. Possible reasons for resistance include the development of brain metastases or development of genetic alterations in ALK.

Alectinib and Ceritinib

Alectinib and ceritinib are second-generation ALK inhibitors that are approved for the treatment of patients with metastatic ALK-positive NSCLC resistant or intolerant to crizotinib. Similar to crizotinib, alectinib and ceritinib inhibit autophosphorylation of ALK and subsequent downstream signaling. In addition to ALK, ceritinib also inhibits insulin-like growth factor 1 receptor (IGF-1R) although to a lesser extent.[34]

Toxicities that are seen with both alectinib and ceritinib include fatigue, bradycardia, and hepatotoxicity. Additional adverse effects seen in patients taking alectinib include anemia, constipation, edema, and myalgia. Patients taking ceritinib should be monitored for QT interval prolongation, gastrointestinal toxicity, pancreatitis, and hyperglycemia. Visual disturbances have been reported with alectinib and ceritinib although to a much lesser extent when compared to crizotinib. Whereas crizotinib may be taken without regard to food, alectinib should be taken with food and ceritinib should be taken on an empty stomach.

Breakpoint Cluster Region-Abelson (BCR-ABL) Inhibitors

Imatinib

Imatinib is a selective inhibitor of the tyrosine kinase activity of BCR-ABL fusion gene, the product of the Philadelphia chromosome. The Philadelphia chromosome is the hallmark finding of CML and it is a translocation of genetic material between chromosomes 9 and 22. Imatinib binds to the kinase-binding site of the BCR-ABL gene, competitively blocking access to ATP. This prevents tyrosine-kinase phosphorylation of the gene and downstream activation of cellular proliferation. An additional effect of imatinib is its ability to inhibit stem-cell factor receptor (KIT) and platelet-derived growth factor receptor (PDGFR).

Imatinib is a standard treatment option for newly diagnosed Philadelphia chromosome–positive (Ph^+) CML and for gastrointestinal stromal tumors (GIST). A major advantage of imatinib is that it can eliminate the Philadelphia chromosome, resulting in cytogenetic responses (ie, elimination of the genetic defect). Imatinib and other BCR-ABL inhibitors are further discussed in Chapter 135. Imatinib is also approved for the treatment of Ph^+ALL and other rare diseases.

Potential serious adverse events observed with imatinib include fluid retention and rash. Severe fluid retention (ie, pleural effusion, pericardial effusion, and ascites) occurs in fewer than 10% of patients taking imatinib, but patients should be monitored regularly for early signs and symptoms of fluid retention and instructed to call their health professionals when symptoms first develop. A rash may require early intervention, because Stevens-Johnson syndrome has been reported with imatinib and may require permanent discontinuation.

Dasatinib, Nilotinib, and Bosutinib

These targeted drugs are next-generation kinase inhibitors that share the same binding site on the BCR-ABL kinase ATP-binding domain with imatinib.[35,36] These inhibitors maintain clinical activity in patients with CML with some mutations in the BCR-ABL binding site that confer imatinib resistance, but none of these inhibitors are active against the genetic alteration identified as T351I. Nilotinib and dasatinib are approved for the treatment of CML and Ph^+ALL. Bosutinib is approved for the treatment of patients resistant or intolerant to the other inhibitors. Both bosutinib and dasatinib also inhibit a family of kinases called sarcoma (Src) kinases that are believed to mediate cellular differentiation, proliferation, and survival; Src kinases have been implicated in modulating multiple oncogenic signal transduction pathways.[36]

These inhibitors have a toxicity profile similar to that of imatinib with myelosuppression, nausea, vomiting, headache, and fluid retention being commonly reported. Bosutinib does not inhibit the KIT or PDGFR, which may account for its reported decrease in myelosuppression.[36]

Ponatinib

As mentioned earlier, the T351I mutation, often referred to as the gatekeeper mutation, confers resistance to the above BCR-ABL inhibitors. Ponatinib was developed with a computational chemistry-based approach to inhibit this mutated conformation of BCR-ABL and provide an effective treatment for this traditionally resistant tumor.[37] Ponatinib is also approved for the treatment of Ph^+ALL that is resistant or intolerant to prior therapy. The more common toxicities reported are similar to other BCL-ABL inhibitors, such as hypertension, rash, headache, constipation, fever, and nausea. Arterial thrombosis and hepatotoxicity have also been observed.

BRAF Inhibitors

BRAF is mutated in a variety of solid tumors with most mutations occurring at codon 600. This codon is in the activation loop of BRAF and increases downstream activity at MEK then ERK, which results in proliferation and survival of cancer cells. BRAF mutations occur in up to 50% of melanomas. The most common mutations are the V600E mutation, which replaces valine with glutamic acid at codon 600 and is seen in about 80% of BRAF mutated melanomas and the V600K mutation, which replaces valine with lysine at this codon and occurs in about 8% of BRAF mutated melanomas. Dabrafenib and vemurafenib inhibit BRAF V600E thereby blocking the MAPK pathway in BRAF-mutated cells. Both inhibitors are approved for the treatment of unresectable or metastatic melanoma with the BRAF V600E mutation as detected by an FDA-approved test. Common toxicities seen with dabrafenib and vemurafenib include papilloma, arthralgia, alopecia, fatigue, and headache. Hand-foot skin reaction (HFSR) and pyrexia are commonly seen with dabrafenib, whereas photosensitivity reactions, hypersensitivity reactions, and QT prolongation are more commonly reported with vemurafenib. Patients should be monitored for the development of new cutaneous malignancies and noncutaneous squamous cell carcinoma that have been associated with dabrafenib and vemurafenib-induced paradoxical activation of the MAPK pathway.[39]

Bruton's Tyrosine Kinase (BTK) Inhibitor

BTK is involved in the B-cell receptor (BCR) signaling pathway that leads to B-cell proliferation and differentiation upon its activation. In B-cell malignancies, the BCR signaling pathway is thought to promote disease progression although the exact mechanism of BCR stimulation has not been determined. Ibrutinib forms an irreversible covalent bond with a cysteine residue of BTK resulting in the inhibition of malignant B-cell proliferation and survival.[40] Ibrutinib is approved for the treatment of the following B-cell malignancies: Waldenstrom's macroglobulinemia; mantle cell lymphoma (MCL), and CLL. Patients should be monitored for hemorrhage, infections, cytopenias, atrial fibrillation, and tumor lysis syndrome. Additional common toxicities include diarrhea, fatigue, musculoskeletal pain, nausea, and rash.

CDK Inhibitor

As discussed earlier in this chapter, CDK play an important role in the cell cycle progression. Specifically, CDK 4/6 and cyclin D1 regulate transition from the G1 phase to the S phase by phosphorylating the retinoblastoma protein (pRb). Palbociclib reversibly inhibits CDK 4/6, which results in the blockade of pRb hyperphosphorylation and ultimately G1 arrest.[41] In breast cancer, it has been demonstrated that cyclin D1 expression and subsequent pRb phosphorylation can be maintained despite estrogen receptor (ER) antagonism. Therefore, inhibiting CDK 4/6 with palbociclib may overcome acquired resistance to hormonal therapy observed in ER-positive breast cancer.[42]

Palbociclib is approved for use with letrozole for the initial treatment of postmenopausal women with ER-positive, HER2-negative advanced breast cancer. Patients receiving palbociclib should be monitored for hematologic toxicities, infections, and pulmonary embolisms.

DNA Methyltransferase Inhibitors

Azacitidine and decitabine are approved for the treatment of patients with myelodysplastic syndrome (MDS), a disorder of hematopoietic cell maturation that can progress to AML. These inhibitors are nucleoside analogs that demonstrate dose-dependent effects. At lower doses, these analogs exert their effects by directly incorporating into DNA and inhibiting DNMT, which leads to cellular differentiation and apoptosis.[6] At higher doses, these agents might cause the formation of covalent adducts between DNMT and active drug being incorporated into DNA, particularly in cells actively dividing. Hypomethylation also appears to normalize the function of genes that control cell differentiation and proliferation, promoting normal cell maturation.[43]

These inhibitors have demonstrated efficacy in slowing the progression of MDS to AML, reducing transfusion requirements, and allowing for the improvement of normal hematopoiesis over time. The primary toxicity is myelosuppression, particularly during early phases of treatment as the malignant clone driving the MDS is cleared from the bone marrow and normal hematopoiesis is slowly restored. As a result, infections occur frequently.

EGFR Inhibitors

Erlotinib

Erlotinib is an oral first generation selective EGFR kinase inhibitor. By competing with ATP for its binding site on the EGFR kinase cytosolic domain, it blocks intracellular downstream signaling and ultimately interferes with the proliferation and growth of cancer cells. Erlotinib is approved for the first-line treatment of patients with metastatic NSCLC whose tumors have EGFR exon 19 deletions or exon 21 (L858R) substitution mutations as detected by an FDA-approved test. In addition, erlotinib is approved for the treatment of locally advanced or metastatic NSCLC as a second-line agent or as maintenance treatment for patients with NSCLC whose disease has not progressed after first-line therapy with a platinum-based regimen. Although erlotinib appears effective in patients with or without EGFR-activating mutations, it appears to be more effective in patients with these

mutations.[44] Erlotinib is also approved for use in pancreatic cancer with gemcitabine.

The most common adverse events that occur with erlotinib result from the abundance of EGFR in skin and mucosa and include acneiform rash and diarrhea.[45] Some studies suggest that the development of a rash may be predictive of a response to therapy and correlates with clinical benefit.[46] Interstitial lung disease is a rare adverse event reported in patients taking erlotinib.

Afatinib

Unlike erlotinib which reversibly binds to EGFR, afatinib irreversibly blocks all kinases of the ErbB family by covalently binding to the intracellular kinase domain, which subsequently inhibits tumor growth.[47] Afatinib shares the same indication as erlotinib for patients with NSCLC and exon 19 deletions or exon 21 substitution. The safety and efficacy of afatinib have not been established in patients whose tumors have other EGFR mutations. Toxicities are similar to those seen with erlotinib, although one study reported an increased incidence of rash and diarrhea with afatinib.[47]

Gefitinib

Gefitinib similarly blocks the promotion of the development of lung cancer cells with specific EGFR mutations (exon 19 deletions and exon 21 substitution). This inhibitor was initially approved in 2003, but it was subsequently withdrawn in 2005 when the confirmatory clinical trial failed to demonstrate an improvement in survival. In 2015, gefitinib was approved for the first-line treatment of metastatic NSCLC whose tumors harbor specific types of EGFR gene mutations, as detected by an FDA-approved test. The second approval was based on a clinical trial that demonstrated an improvement in response in this population, which was supported by a retrospective analysis of another trial.[48] Gefitinib has similar adverse events compared to other EGFR inhibitors, including diarrhea and skin reactions.

Lapatinib

Lapatinib is a 4-anilinoquinazoline kinase inhibitor that inhibits the intracellular kinase domains of both EGFR (ErbB1) and HER2 (ErbB2). It has demonstrated clinical activity with capecitabine in patients with breast cancer whose tumors overexpress HER2 and who have previously received therapy with trastuzumab, an anthracycline, and a taxane. Lapatinib is also approved for use with letrozole in postmenopausal women for the treatment of hormone receptor-positive metastatic breast cancer that overexpresses HER2. Common adverse events include an increased incidence of diarrhea, hepatotoxicity, rash, and QT interval prolongation. Two specific mutations observed in the HLA-DQA and HLA-DRB genes have been associated with an increased risk of hepatotoxicity.[49,50]

Osimertinib

Osimertinib is approved for the treatment of patients with metastatic EGFR T790M mutation-positive NSCLC, as detected by an FDA-approved test, who have progressed on or after EGFR tyrosine kinase inhibitor. This mutation, referred to as the EGFR gatekeeper mutation, occurs in about 50% of

patients who develop acquired resistance to first-line therapy with erlotinib or gefitinib.[37] Gastrointestinal and dermatologic toxicities are commonly reported with osimertinib. Serious adverse events include interstitial lung disease/pneumonitis, pneumonia, and pulmonary embolism.

Hedgehog Inhibitors

Sonidegib and vismodegib are oral inhibitors of the Hedgehog signaling pathway that is abnormally activated in basal cell carcinoma and medulloblastoma. Through binding to smoothened (SMO) receptor, sonidegib and vismodegib prevent downstream signaling and activation of the Hedgehog pathway leading to the inhibition of tumor growth.[51] Vismodegib is approved for metastatic or locally advanced basal cell carcinoma, while sonidegib is approved only for locally advanced disease.

The Hedgehog pathway is essential for early embryogenesis. Therefore, both sonidegib and vismodegib have been shown to be embryotoxic, fetotoxic, and teratogenic in animals. The approved labeling for both drugs contains specific recommendations regarding contraception for women of child bearing potential and for men with a pregnant partner or a female partner of child bearing potential, as well as limitations regarding blood and sperm donation during treatment and for several months following the last dose. Vismodegib is generally well tolerated and toxicities include muscle spasm, alopecia, dysgeusia, fatigue, and nausea. Sonidegib is associated with an increased risk of serious musculoskeletal toxicities and the probability of developing this adverse event appears to rise with increasing sonidegib exposure. Grades 3 and 4 serum lipase and creatine kinase elevations occurred in at least 5% of patients given the approved dose of 200 mg daily. Sonidegib uniquely has a very long elimination half-life of 28 days compared to vismodegib and other small molecular targeted drugs.

HDAC Inhibitors

Belinostat

The mechanism of HDAC inhibitors was discussed earlier in the chapter. Belinostat is an HDAC inhibitor that is approved for the treatment of relapsed or refractory peripheral T-cell lymphoma. Ongoing trials are evaluating the administration of belinostat with other anticancer agents. The most common toxicities seen with belinostat include pyrexia, nausea, fatigue, and anemia.

Panobinostat

Panobinostat is an HDAC inhibitor that has been shown to improve progression-free survival with bortezomib and dexamethasone in patients with multiple myeloma who have received at least two prior regimens, including bortezomib and an immunomodulatory agent.[52] Since severe cardiac toxicities have been reported with panobinostat, an electrocardiograph (ECG) and electrolytes should be monitored at baseline and during treatment. Nausea, vomiting, and severe diarrhea are often seen with panobinostat.

Romidepsin and Vorinostat

Similar to belinostat and panobinostat, romidepsin and vorinostat inhibit HDAC. Romidepsin is approved for the treatment of patients with cutaneous or peripheral T-cell lymphoma who have received at least one prior therapy and vorinostat is approved for the treatment of cutaneous T-cell lymphoma who have received at least two prior therapies. Patients receiving romidepsin should be monitored for myelosuppression, ECG changes, and infections. Reactivation of DNA viruses, including EBV and hepatitis B virus (HBV), have been reported with romidepsin.[53] Serious adverse events reported with vorinostat include venous thromboembolism, dose-related thrombocytopenia, and anemia.

JAK Inhibitor

Ruxolitinib is an oral inhibitor of JAK1 and JAK2 of the JAK-STAT signaling pathway; these kinases are involved in the regulation of blood and immunologic functioning. In myelofibrosis and polycythemia vera, JAK1 and JAK2 activity is dysregulated. Ruxolitinib has been shown to modulate the affected JAK1 and JAK2 activity resulting in clinical responses and symptomatic improvement.[54] Approved indications for ruxolitinib include the treatment of intermediate or high-risk myelofibrosis and the treatment of polycythemia vera in patients who have had an inadequate response to or are intolerant of hydroxyurea. The most common toxicities include thrombocytopenia, anemia, bruising, dizziness, and headache.

MEK Inhibitors

Reported resistance mechanisms of the BRAF inhibitors dabrafenib and vemurafenib include reactivation of the MAPK pathway. The combination of BRAF and MEK inhibition has demonstrated delayed resistance and decreased incidence of secondary cancers.[42] Trametinib is approved as a single agent and with dabrafenib for the treatment of unresectable or metastatic melanoma with BRAF V600E or V600K mutations as detected by an FDA-approved test. Common toxicities reported with trametinib include rash, diarrhea, and lymphedema. Serious toxicities reported with the combination dabrafenib and trametinib include hemorrhage, venous thromboembolism, and febrile reactions.

Unlike trametinib, cobimetinib is not approved as a single agent; it is only approved for the treatment of unresectable or metastatic melanoma with BRAF V600E or V600K mutations with vemurafenib. Common toxicities include diarrhea, nausea, vomiting, photosensitivity reaction, and pyrexia. Serious risks with the use of cobimetinib are new primary malignancies, hemorrhage, cardiomyopathy, severe dermatologic reactions, serous retinopathy and retinal vein occlusion, hepatotoxicity, and rhabdomyolysis.

mTOR Inhibitors

Temsirolimus

Temsirolimus and its primary active metabolite, sirolimus, bind to the intracellular protein 12-kilodalton FK506 binding protein (FKBP-12) and this protein–drug complex inhibits mTOR by

blocking its kinase activity.[55] mTOR inhibition suppresses the production of proteins that regulate progression through the cell cycle resulting in G1 phase arrest. Temsirolimus is approved for the treatment of advanced renal cell carcinoma.

The most common adverse reactions with temsirolimus are rash, asthenia, mucositis, nausea, edema, and anorexia. Infusion reactions may occur and pre-treatment with an antihistamine is recommended. Lab abnormalities are common with temsirolimus including hyperglycemia and hyperlipidemia. Rare but potentially serious adverse events include interstitial lung disease, immunosuppression, and renal failure.

Everolimus

Similar to temsirolimus, everolimus is an mTOR inhibitor that reduces protein synthesis and cell proliferation by binding to FKBP-12. Everolimus has the following indications: treatment of advanced renal cell carcinoma after treatment failure with sunitinib or sorafenib; hormone receptor-positive, HER2-negative breast cancer with exemestane after letrozole or anastrozole failure in postmenopausal women; subependymal giant cell astrocytoma with tubular sclerosis complex (TSC); renal angiomyolipoma with TSC; and unresectable or metastatic pancreatic neuroendocrine tumors. Dosage forms for everolimus include traditional oral tablets and tablets for oral suspension, but it is important to note that the tablets for oral suspension do not have the same FDA approved indications. Stomatitis is one of the most common toxicities with everolimus while other adverse reactions are similar to those of temsirolimus.

Multikinase Inhibitors

Axitinib, Pazopanib, Sorafenib and Sunitinib

Several kinase inhibitors inhibit multiple kinases, such as axitinib, pazopanib, sorafenib and sunitinib. Sunitinib and sorafenib inhibit multiple growth factor receptors (VEGFR2 and PDGFR), cell surface proteins (KIT), and cytokine receptors (FLT3) and thus, disrupt multiple aberrant intracellular signaling pathways. In addition, sorafenib inhibits Raf, which is part of the MAPK signaling pathway.[56] Sunitinib is approved for GIST, pancreatic neuroendocrine tumors and advanced renal cell carcinoma and sorafenib is approved for unresectable hepatocellular carcinoma, advanced renal cell carcinoma, and locally recurrent or metastatic, progressive, differentiated thyroid carcinoma refractory to radioactive iodine treatment.

Pazopanib and axitinib are second-generation inhibitors. Pazopanib inhibits all VEGFR kinases with additional activity against KIT and PDGFR. Axitinib has enhanced potency and selectivity to all VEGFR kinases with minor activity against PDGFR and KIT.[57] Pazopanib is approved for the treatment of advanced renal cell carcinoma and axitinib is approved for the same indication after failure of one prior systemic therapy. Pazopanib has an additional indication for patients with advanced soft tissue sarcoma who have received prior chemotherapy.

Gastrointestinal toxicities such as diarrhea are common with these drugs, as are rash, fatigue, and hypertension. Patients should also be monitored for the development of thyroid dysfunction and

hepatotoxicity.

Cabozantinib

Cabozantinib is a small molecule inhibitor of numerous receptor kinases, most importantly RET (rearranged during transfection), VEGFR2, and MET membrane receptor.[58] MET is required for several important processes during embryogenesis (eg, angiogenesis) and leads to abnormal growth and proliferation of several tumors. Medullary thyroid cancers express mutated RET as well as VEGFR2 and MET. Cabozantinib is approved for the treatment of metastatic medullary thyroid cancers. Toxicities reported in clinical trials included diarrhea, HFSR, lymphopenia, hypocalcemia, hypertension, transaminitis, and stomatitis.

Lenvatinib

Lenvatinib primarily inhibits VEGFR1, -2, and -3, but it can also inhibit other kinases including fibroblast growth factor receptor (FGFR) and PDGFR-alpha, KIT, and RET. Lenvatinib is approved for the treatment of locally recurrent or metastatic, progressive, radioactive iodine-refractory differentiated thyroid cancer. Common toxicities seen with lenvatinib include hypertension, fatigue, diarrhea, proteinuria, stomatitis, and HFSR.

Regorafenib

Regorafenib is multikinase inhibitor that blocks the activity of several protein kinases, including those involved in the regulation of tumor angiogenesis (VEGFR1, -2, and -3), oncogenes and downstream targets (KIT, RET, RAF1, and BRAF), as well as PDGFR and FGFR.[59] Because many of these targets are important in colon cancer and GIST, regorafenib is approved for the treatment of metastatic colorectal cancer and for advanced or metastatic GIST in patients who have previously received imatinib and sunitinib. Serious adverse events reported with regorafenib include hepatotoxicity, hemorrhage, gastrointestinal perforation, and reversible posterior leukoencephalopathy syndrome. Regorafenib should be stopped prior to surgery as wound-healing complications may occur. Common adverse reactions with regorafenib include asthenia, hypertension, mucositis, gastrointestinal toxicities, and HFSR. Regorafenib should be given with a low-fat evening meal, as the toxicities anecdotally appear minimized when given at night.

Vandetanib

Vandetanib is a small molecule inhibitor of RET, VEGFR2 and -3, and EGFR.[60] Most medullary thyroid tumors express mutated RET and vandetanib has demonstrated activity in this tumor. It is approved for the treatment of metastatic medullary thyroid cancer. Toxicities observed with vandetanib include diarrhea, hypertension, and rash. Vandetanib can prolong the QT interval and cases of Torsades de pointes and sudden death have been reported. Because of this risk, vandetanib is only available through a risk evaluation and mitigation strategy (REMS) program where prescribers and pharmacies must be certified through the program to prescribe and dispense vandetanib.

PARP Inhibitor

PARP is essential for the repair of single-stranded DNA breaks through the base-excision-repair pathway. Tumors with breast cancer gene 1 (BRCA1) or BRCA2 mutations are highly sensitive to the blockade of single-strand DNA breaks (through PARP inhibition), because they exhibit a compromised ability to repair double-strand DNA breaks. This concept is known as *synthetic lethality* and occurs when there is a lethal synergy between two nonlethal events. Olaparib inhibits PARP and induces synthetic lethality in BRCA1 and BRCA2 deficient tumor cells.[61,62] Olaparib is indicated for the treatment of deleterious or suspected deleterious germline BRCA mutated advanced ovarian cancer who have been treated with three or more prior lines of chemotherapy.

Patients receiving olaparib should be monitored for hematological toxicity as MDS/AML has been reported with olaparib. Common toxicities include fatigue, musculoskeletal pain, dermatitis, nausea and vomiting, upper respiratory infections, and anemia.

PI3K Inhibitor

Malignant B-cell proliferation and survival depend on PI3K signaling. The p110δ isoform is highly expressed in malignant lymphoid B-cells and plays a direct role in activation of the PI3K pathway. Through the selective inhibition of p110*δ*, idelalisib induces apoptosis.[63] Idelalisib is approved for the treatment of relapsed CLL with rituximab. Other indications include relapsed follicular B-cell NHL and small lymphocytic lymphoma in patients who have received at least two prior systemic therapies.

Boxed warnings for idelalisib include hepatotoxicity, severe diarrhea or colitis, pneumonitis, and intestinal perforation. Common adverse reactions include neutropenia, fever, rash, and elevated liver enzymes.

Proteasome Inhibitors

The proteasome is an enzyme complex that is responsible for degrading proteins that control the cell cycle. Some of the proteins degraded by proteasomes regulate critical functions for cancer growth, such as regulation of the cell cycle, transcription factors, apoptosis, angiogenesis, and cell adhesion.[64]

Bortezomib

Bortezomib has specific affinity for the catalytic portion of the 26S proteasome. It is a specific inhibitor of this proteasome, which results in accumulation of IκB, an inhibitor of the major transcription factor nuclear factor κB (NF-κB). NF-κB induces transcription of genes that block cell death pathways and promote cell proliferation. Its activity depends on its release from its inhibitory partner protein, IκB, in the cytoplasm and its move to the nucleus. When IκB fails to degrade, through the actions of bortezomib, NF-κB remains in the cytoplasm, preventing it from transcribing the genes that promote cancer growth. Bortezomib is approved for the treatment of multiple myeloma and MCL.[64]

The most commonly reported toxicities with bortezomib include fatigue, nausea, diarrhea, thrombocytopenia, and fever. Peripheral neuropathy may develop or worsen with the use of bortezomib. Subcutaneous administration of bortezomib has been associated with a lower incidence of peripheral neuropathy when compared with intravenous administration. Caution should be used when treating patients with existing heart disease as cardiac failure has been reported. Patients should also be monitored for hypotension and acute respiratory syndrome. At least 72 hours should elapse between consecutive doses of bortezomib to minimize cumulative toxicity by permitting the restoration of proteasome function between doses.

Carfilzomib

Carfilzomib is a second-generation proteasome inhibitor approved for relapsed or refractory multiple myeloma. Whereas bortezomib exhibits reversible inhibition of multiple proteasome targets, the inhibition with carfilzomib is irreversible. As a result, carfilzomib produces more sustained inhibition of the proteasome. Carfilzomib is a more potent and selective inhibitor of the chymotrypsin-like activity of the proteasome and immunoproteasome and has been demonstrated to overcome bortezomib resistance in cell lines.[65]

Ixazomib

Ixazomib is an oral proteasome inhibitor approved with lenalidomide and dexamethasone for the treatment of patients with multiple myeloma who have received at least one prior therapy. Common adverse reactions are gastrointestinal toxicity, thrombocytopenia, peripheral neuropathy, peripheral edema, and back pain. Ixazomib has a unique administration schedule for an oral agent (given on days 1, 8, and 15 of a 28-day cycle) and should be taken on an empty stomach.

Miscellaneous

Thalidomide, Lenalidomide, and Pomalidomide

Thalidomide, the infamous drug that caused severe limb deformities when used by pregnant women as a nonprescription sedative in the 1960s, is approved for treatment of leprosy and multiple myeloma. Thalidomide is a glutamic acid derivative and is broadly classified as an immunomodulatory drug. Lenalidomide and pomalidomide are analogs of thalidomide with similar therapeutic activity but different adverse event profiles. Lenalidomide is approved for the treatment of multiple myeloma, transfusion-dependent anemia caused by MDS with a specific mutation and MCL whose disease has relapsed or progressed after two prior therapies, including bortezomib. Pomalidomide has been approved for the treatment of multiple myeloma with disease progression after at least two prior therapies including lenalidomide and a proteasome inhibitor.

These drugs have many potential mechanisms of action, but the most important is thought to be angiogenesis inhibition, an action also linked to their teratogenic effects. Other possible mechanisms include direct inhibition of cancer cells, free radical oxidative damage to DNA, interference with adhesion of cancer cells, inhibition of TNF-α production, or alteration of cytokine secretion that

affects the growth of cancer cells.

The most common toxicities for thalidomide include somnolence, constipation, dizziness, orthostatic hypotension, rash, and peripheral neuropathies. In contrast, lenalidomide is associated with much less somnolence and neuropathies compared with thalidomide. Neutropenia, thrombocytopenia, and thrombotic events are prevalent with thalidomide, lenalidomide and pomalidomide. To avoid embryo-fetal exposure and to inform health professionals and patients of the teratogenic potential, these drugs are only available under a REMS program.

Lanreotide

As an octapeptide analog of somatostatin, the mechanism of lanreotide is believed to be similar to that of natural somatostatin through the inhibition of neuroendocrine functions. Somatostatin analogues are commonly used to treat hypersecretion syndromes associated with neuroendocrine tumors, but only recently have been proven to have an antitumor effect associated with prolonged progression-free survival. Lanreotide is approved for the treatment of unresectable, well or moderately differentiated, locally advanced or metastatic gastroenteropancreatic neuroendocrine tumors. Common toxicities include abdominal pain, musculoskeletal pain, vomiting, headache, injection site reaction, and hypertension. Patients should be monitored for hypoglycemia, hyperglycemia and gallstones.

Clinical Controversy…

Numerous targeted agents and biologic therapies have been recently approved and although this is a very exciting time for the world of oncology, many of these new agents come at a high financial cost to the patient. What is an acceptable cost of a small increase in survival and who should make that determination? “Financial toxicity” of anticancer agents is an important conversation oncology health professionals should have with their patients and caregivers.

BIOLOGIC THERAPIES

7 Biologic therapies include cytokines, mAbs, growth factors, and vaccines. The mAb are the most common biologic therapy available to treat patients with cancer.

Monoclonal Antibodies

The mAbs are designed to target pathways critical for the survival and growth of cancer cells and improve outcomes while minimizing toxicities. The mAb can bind to either the extracellular receptor or to its natural ligand and prevent the activation of the downstream intracellular signaling. Several antibodies are available to treat both solid tumors and hematologic malignancies.

The mAbs consist of immunoglobulin sequences that are known to recognize a specific antigen or protein on the surface of cells. There are five classes of immunoglobulins, but IgG is the most commonly used therapeutically. Similar to endogenous antibodies, the Fab portion is composed of heavy and light chains that are responsible for binding to antigens and the constant region

determines the effector function of the antibody. The mAb may be naked (unconjugated) or conjugated to toxin (immunotoxin), chemotherapy agent (antibody drug conjugate), or radioactive particle (radioimmunoconjugate).

Standardized nomenclature exists for naming mAbs. The suffix -mab is used for all antibodies and it is always preceded by the identification of the animal source of the product. The letters o, u, xi, and zu before the -mab suffix indicate murine, human, chimeric, and humanized, respectively. The general disease state the antibody is treating precedes the source and is identified using a code. Most approved antibodies used to treat cancer have the code -tu(m) that designates it for use against miscellaneous tumors. If the product is conjugated, a separate word is added to identify the toxin, chemotherapy, or radioactive particle. For example, the antibody-drug conjugate of trastuzumab and mertansine is named ado-trastuzumab ematansine.

The first mAb used in humans were murine, but most of the antibodies used today are humanized or human. These agents differ in the amount of foreign component. Hypersensitivity and infusion-related reactions, with or without the development of antiproduct antibodies (APA), are generally greatest with murine antibodies and least with humanized antibodies. The severity of these reactions can range from mild (eg, fever, chills, nausea, and rash) to severe, life-threatening anaphylaxis with cardiopulmonary collapse. Patients with a hypersensitivity or infusion-related reaction may also experience chest or back pain during the infusion. Patients with circulating cancer cells in the bloodstream are at highest risk for more severe reactions. Patients must be monitored closely during infusion. The reactions tend to be more severe with the initial infusion, and subside with subsequent treatments. Some mAbs require premedication, including antihistamines, acetaminophen, or steroids, to minimize hypersensitivity reactions. Recommended infusion rates may be lower for the initial dose, with incremental increases as tolerated by the patient. For patients experiencing signs or symptoms of infusion-related reactions, the infusion should be interrupted and prompt treatment with antihistamines, corticosteroids, and other supportive measures should be initiated. Other adverse events are typically determined by the selectivity of the target antigen. mAbs against antigens found on normal and cancer cells will have increased toxicity compared with tumor-specific antigens found only on tumor tissues.

Unconjugated mAbs that target antigens on the cell surface of cancer cells may induce death of cancer cells by several mechanisms. These mAbs could directly mediate cell killing through complement-dependent cytotoxicity (CDC), antibody-dependent cell-mediated cytotoxicity (ADCC), or inhibiting intracellular signaling. CDC occurs when the Fc portion of the antibody activates the complement system, leading to tumor cell lysis and ADCC occurs when effector cells that contain Fc receptors bind to the Fc portion of the antibody and either lyses or phagocytizes the antibody-containing cell. Natural killer cells, monocytes, and macrophages are all capable of mediating ADCC. Finally, antibody binding may result in the transmission of signals that induce apoptosis, or programmed cell death in the targeted cell.

Immunoconjugates deliver a payload, typically a chemotherapy agent, toxin, or radioactive particle to a cell targeted by the antibody. After the antibody binds the target antigen, the payload is internalized by the target cell and kills cancer cells through traditional mechanisms of action. In addition to killing the target cell, radioimmunoconjugates are capable of killing antigen-negative

cancer cells sometimes termed the bystander effect. Theoretically, immunoconjugates conjugates deliver therapy to specific sites of disease while limiting systemic exposure to the chemotherapy, radiation, or toxin. The mAb might also contribute to the observed anticancer effects.

Monoclonal Antibodies that Target B-lymphocyte Antigens

Rituximab

Rituximab is a chimeric antibody directed against the cluster of differentiation (CD)20 antigen found on the surface of normal and cancerous B-cells. The Fab domain of rituximab binds to the CD20 antigen on B lymphocytes and the Fc domain recruits immune effector functions to mediate B-cell lysis. Possible explanations for its anticancer effect include CDC and ADCC of malignant B-cells and possibly a direct apoptotic effect.

Rituximab is approved for the treatment of low-grade or follicular, CD20-positive, B-cell NHL in multiple settings. It is also approved for the treatment of CD20-positive CLL with standard chemotherapy. Rituximab is also indicated for the treatment of a variety of immune-mediated diseases, including rheumatoid arthritis, granulomatosis with polyangiitis, and microscopic polyangiitis.

Most of the infusion-related reactions associated with rituximab occur during the first infusion and are components of an infusion-related complex secondary to the amount of circulating B- cells. After the first infusion, the incidence and the severity of these reactions decrease dramatically. Premedication and additional supportive care medications may be required depending on indication. The most common events with the infusion-related complex are transient fever, chills, nausea, asthenia, and headache. Additionally, rituximab may cause HBV reactivation and should not be administered in patients with severe, active infections.

Ofatumumab

Ofatumumab is a type I human mAb that also targets the CD20 antigen. Its mechanism of action is similar to that of rituximab, but ofatumumab targets a different epitope than rituximab, has greater affinity for the antigen, and dissociates from the epitope slower than rituximab.[66] Specifically, ofatumumab binds to two regions of the CD20 antigen, the small extracellular loop and the N-terminal region of the large extracellular loop. This allows it to demonstrate anticancer activity in patients who have progressed on rituximab in a variety of B-cell cancers.[66]

Ofatumumab is approved as a single agent for refractory, recurrent or progressive CLL and with other anticancer agents for treatment-naive CLL. Adverse reactions are similar to rituximab with fewer infusion-related reactions and a higher rate of infectious complications.

Obinutuzumab

Obinutuzumab is a type II humanized anti-CD20 mAb approved with chlorambucil. When compared with the type I anti-CD20 antibodies such as rituximab, type II agents exhibit a different elbow hinge

angle and therefore bind CD20 in a different orientation. Furthermore, the Fc portion of obinutuzumab has been glycoengineered to reduce fucosylation resulting in improved receptor affinity and enhanced ADCC potency.[67,68]

Adverse events associated with obinutuzumab include infusion reactions, myelosuppression, nausea, and diarrhea. HBV reactivation and Progressive Multifocal Leukoencephalopathy (PML) have been reported with obinutuzumab use.

Ibritumomab Tiuxetan

Ibritumomab tiuxetan is a radioimmunoconjugate that consists of the murine anti-CD20 antibody ibritumomab and a linker chelator tiuxetan that allows the attachment of indium-111 (used for imaging and dosimetry) or yttrium-90 (active radiotherapy). Yttrium-90-ibritumomab is the therapeutic radiation isotope and selectively delivers radiation to B-cells that express the CD20 antigen.

The radiation-induced cytotoxicity delivered by yttrium -90-ibritumomab not only affects the cancer cells it binds but also other cells that are within the path length of the radioisotope's emissions (ie, bystander effect). Consequently, yttrium-90-ibritumomab can induce cell death in CD20-positive and -negative cancer cells and eradicates a large number of cancer cells. Ibritumomab tiuxetan also induces ADCC, CDC, and apoptosis. Ibritumomab tiuxetan is indicated to be given with rituximab for the treatment of relapsed or refractory, low-grade or follicular B-cell NHL and for previously untreated follicular NHL who achieved a response to first-line chemotherapy. The therapeutic regimen consists of two steps. Rituximab is administered on day 1, and about one week later (day 7, 8, or 9), an additional dose of rituximab is administered followed by yttrium-90-ibritumomab within 4 hours after completion of the rituximab infusion.

Adverse reactions include severe infusion-related reactions. Myelosuppression is common with ibritumomab tiuxetan as a consequence of the radioisotope. Ibritumomab tiuxetan results in prolonged thrombocytopenia and neutropenia and dose modifications are necessary based on baseline neutrophil and platelet blood counts. The median durations of thrombocytopenia and neutropenia were 24 days and 22 days, respectively. Monitoring and management of cytopenias, along with their complications is necessary for up to 3 months after completing treatment.

Tositumomab

Tositumomab is a murine anti-CD20 radioimmunoconjugate similar to ibritumomab tiuxetan. One important difference is that tositumomab is combined with the radioisotope I-131, which has therapeutic and safety implications. The mechanisms of cell death are similar to ibritumomab as is the indication for refractory NHL. The tositumomab regimen consists of four components in two steps: a dosimetric step to assess the radiation dose and a therapeutic step.

Most adverse events are similar to ibritumomab tituxetan, including infusion-related reactions and myelosuppression. Complete blood counts should be obtained weekly for 10 weeks to 12 weeks to assess recovery of normal blood counts. To prevent iodine uptake by the thyroid gland and

subsequent delivery of ionizing radiation to the thyroid gland, thyroid protective agents (eg, saturated solution of potassium iodide) should be given before starting the tositumomab dosing regimen and continued for 14 days after the therapeutic dose.

Monoclonal Antibodies that Target Other Cell Surface Receptors

Alemtuzumab

Alemtuzumab is a recombinant humanized mAb that is directed against CD52. CD52 is expressed on the surface of B and T lymphocytes, natural killer cells, monocytes, and macrophages.[69] Its anticancer activity comes from binding to the CD52 antigen present on leukemic lymphocytes and inducing cell lysis and death. Alemtuzumab is indicated as a single agent for the treatment of B-cell CLL.

Alemtuzumab is associated with severe infusion-related reactions, hematologic toxicity, and opportunistic infections.[69] Hematologic toxicity consisting of severe prolonged neutropenia and thrombocytopenia occurs in most patients. Health professionals should monitor complete blood counts prior to each dose to determine the need for dose modification. Because CD52 is expressed on lymphocytes, alemtuzumab can induce profound lymphopenia including a decrease in CD4 and CD8 counts. Patients should receive prophylaxis for *Pneumocystis jiroveci* pneumonia and herpes virus, which should be continued for a minimum of 2 months after completing alemtuzumab therapy or until recovery of CD4 counts. Alemtuzumab is only available through a restricted distribution program and has a REMS program to mitigate the risks of autoimmune conditions, infusion reactions, and malignancies associated with the use of alemtuzumab.

Blinatumomab

Blinatumomab is a bispecific T-cell engaging antibody against a B-lymphocyte-specific molecule CD19. Through the formation of a synapse between CD19 on malignant B-cells and CD3 on T-cell receptors, blinatumomab potentiates T-cell induced cytotoxic cell killing. Blinatumomab is indicated for the treatment of Philadelphia chromosome-negative relapsed or refractory B-cell precursor ALL.[70]

Due to its short half-life (~2 hours) and mechanism of action, blinatumomab is administered as a continuous intravenous infusion over 28 days. In addition to possible decreased efficacy, early trials that utilized shorter infusion durations also reported a higher rate of neurologic toxicities and cytokine-release syndrome.[70] Patients receiving blinatumomab are usually hospitalized for the first 9 days of cycle 1 and the first 2 days of cycle 2 to monitor for infusion reactions. Patients receiving blinatumomab should be monitored for infusion reactions, cytokine release syndrome, neurological toxicities, and infections. Common toxicities include fever, headache, peripheral edema, and rash.

Brentuximab Vedotin

Brentuximab vedotin is an antibody–drug conjugate that targets the CD30 antigen found on cancer cells. Upon binding to the CD30 antigen, brentuximab vedotin is internalized by endocytosis, and the dipeptide bond that links the naked mAb to the chemotherapy monomethylauristatin E (MMAE) is

cleaved.[71] MMAE then binds to microtubules and acts as an inhibitor of microtubule polymerization. It may also induce apoptosis by inhibiting NF-κB. Brentuximab vedotin is indicated for Hodgkin lymphoma after failure of autologous hematopoietic stem cell transplant and relapsed anaplastic large cell lymphoma. Infusion reactions, peripheral neuropathy, and neutropenia are common toxicities seen with brentuximab vedotin administration; these toxicities are common with other microtubule inhibitors.

Daratumumab

Daratumumab is a mAb that inhibits the growth of CD38 expressing tumor cells by inducing apoptosis directly through Fc mediated cross linking and immune-mediated tumor cell lysis through CDC, ADCC, and antibody dependent cellular phagocytosis. Myeloid derived suppressor cells and a subset of regulatory T cells express CD38. It is approved for the treatment of patients with multiple myeloma who have received at least three prior lines of therapy.

The most frequently reported adverse reactions were infusion reactions, fatigue, nausea, back pain, pyrexia, cough, upper respiratory tract infection, and myelosuppression. Pre-medications (corticosteroid, antipyretic, and an antihistamine) and post-infusion medications (corticosteroid) are recommended to prevent acute and delayed infusion reactions. Since daratumumab interferes with blood bank crossmatching, specifically with Indirect Antiglobulin Tests, it is recommended that a type and screen be performed prior to treatment initiation. If a blood transfusion is necessary, inform the blood bank that the patient has received daratumumab.

Dinutuximab

Glycolipid GD2 is expressed primarily on the cell surface of neuroblastoma cells and on normal tissues including neurons and peripheral sensory nerve fibers.[72,73] The function of the GD2 carbohydrate antigen is not completely understood, but is thought to play a role in the attachment of tumor cells to extracellular matrix proteins.[72] Dinutuximab is a chimeric mAb that binds GD2 inducing cell lysis through ADCC and CDC. This activity is thought to be enhanced when dinutuximab is given with granulocyte-macrophage colony-stimulating factor (GM-CSF) and IL-2.[73] Dinutuximab is approved to be given with GM-CSF, IL-2, and 13-cis-retinoic acid for the treatment of pediatric patients with high-risk neuroblastoma who achieve at least a partial response to prior first-line multiagent, multimodality therapy. Serious toxicities associated with dinutuximab include infections, infusion reactions, hypokalemia, hypotension, and capillary leak syndrome.

Monoclonal Antibodies That Target Growth Factor Receptors and Their Ligands

EGFR Inhibitors

Cetuximab is a chimeric mAb that binds specifically to the extracellular domain of EGFR on both normal and cancer cells and competitively inhibits the binding of epidermal growth factor and other ligands, such as transforming growth factor-α. Binding of cetuximab to the EGFR inhibits cell growth, induces apoptosis, and inhibits VEGF production. Cetuximab may be given as a single agent or with

other anticancer agents to treat metastatic KRAS wild-type colorectal cancer and squamous cell head and neck cancer. Acneiform rash and skin reactions occur in most patients receiving cetuximab, as observed with the targeted drugs that inhibit EGFR.[46] Multiple follicular or pustular lesions generally appear within the first 2 weeks of therapy and usually resolve after cessation of treatment. Resolution can be slow, continuing beyond 28 days in nearly half of cases. In patients who develop a severe rash, dose modifications may be necessary. Interestingly, a trend for improved responses with increasing severity of skin reactions has been reported and requires further research to assess the clinical importance of these reactions.[46]

Panitumumab is a mAb that also binds to the cell surface EGFR. It is an IgG2 antibody and the first human mAb approved to treat cancer. Panitumumab is currently approved to treat KRAS wild-type metastatic colon cancer with chemotherapy for first-line treatment or as a single agent following disease progression after prior treatment. Adverse reactions are similar to cetuximab, although severe reactions appear to be less common because panitumumab does not have a murine component.

Both antibodies appear to be more effective in patients with tumors that are RAS wild type, than patients with tumors that are RAS mutation positive. Therefore, patients with metastatic colorectal cancer should not receive anti-EGFR antibody therapy if a RAS mutation is detected.[74] Genetic testing of colorectal cancers is discussed in further detail in Chapter 130.

Necitumumab is a next-generation mAb that binds to the human EGFR and blocks the binding of EGFR to its ligands. It is approved for first-line treatment of patients with metastatic *squamous* NSCLC with gemcitabine and cisplatin. Serious and clinically significant adverse events include cardiopulmonary arrest, hypomagnesemia, thromboembolic events, dermatologic toxicities, and infusion reactions. Since increased toxicity and mortality was observed when necitumumab was given with pemetrexed and cisplatin for the treatment of nonsquamous NSCLC, patients with metastatic nonsquamous NSCLC should not receive necitumumab.

HER2 Inhibitors

Trastuzumab

Trastuzumab is a humanized mAb that selectively binds to HER2. HER2 is overexpressed in about 33% of breast cancers, in about 22% of gastroesophageal junction and gastric cancers, and to varying degrees in other malignancies.[75] Trastuzumab inhibits cell cycle progression by decreasing cells entering the S phase of the cell cycle, which leads to downregulation of HER2 receptors on cancer cells and decreased cell proliferation.[74] Trastuzumab also leads to ADCC and CDC and directly induces apoptosis in cells overexpressing HER2. In addition, synergy between trastuzumab and chemotherapy has been demonstrated, resulting in trastuzumab often being used in combination regimens. Trastuzumab is approved for the treatment of HER2-positive early stage and metastatic breast cancer and metastatic gastric or gastroesophageal junction adenocarcinoma. The tumor should overexpress HER2 as measured by diagnostic tests that can quantify gene amplification or protein expression.

The most serious adverse reactions caused by trastuzumab include cardiomyopathy, infusion-related reactions, hypersensitivity reactions, and increased myelosuppression. An evaluation of cardiac function should be performed before administration and extreme caution should be exercised in patients with preexisting cardiac dysfunction and in those who have received prior anthracyclines. In patients who develop a clinically significant decrease in left ventricular function (defined as greater than 16% decrease in ejection fraction from pretreatment levels or an ejection fraction below normal limits and greater than 10% decrease from baseline), discontinuation of therapy should be considered. Similar to most mAbs, the symptoms associated with a hypersensitivity reaction are most common with the initial infusions and occur infrequently thereafter. Myelosuppression is infrequent with trastuzumab alone, but the incidence of neutropenia and febrile neutropenia is higher when trastuzumab is given with myelosuppressive chemotherapy.

Ado-Trastuzumab Ematansine

Ado-trastuzumab ematansine is indicated for the treatment of HER2-positive, metastatic breast cancer previously treated with trastuzumab and a taxane. Ado-trastuzumab ematansine is an antibody–drug conjugate that consists of the humanized anti-HER2 monoclonal antibody trastuzumab covalently linked to the microtubule inhibitory drug DM1 (derivative of maytansine 1).[76] Ematansine refers to the linker-payload complex. It is important to note that ado-trastuzumab ematansine and trastuzumab are not interchangeable and should not be substituted for one another. The adverse events associated with ado-trastuzumab ematansine include adverse events reported with trastuzumab and microtubule inhibitors.

Pertuzumab

Pertuzumab is a humanized mAb that targets the HER2 receptor. It is synergistic with trastuzumab and is effective in tumors that have developed resistance to trastuzumab. Pertuzumab binds to extracellular domain II of HER2, a site distinct from trastuzumab, and inhibits ligand-dependent HER2–HER3 dimerization, which subsequently decreases tumor proliferation and resistance pathways.[77] Dual targeting of the HER2 receptor allows for increased efficacy against variant forms of the HER2 receptor, including truncated HER2 receptors. Similar to trastuzumab, it appears to induce ADCC in cancer cells. Pertuzumab is approved to treat HER2 overexpressed locally advanced, inflammatory or early stage breast cancer in the neoadjuvant setting or for the treatment of refractory metastatic breast cancer.

VEGF Inhibitors

Bevacizumab

Bevacizumab is a humanized mAb directed against circulating VEGF. It binds to all biologically active circulating isoforms of VEGF and prevents the activation and promotion of angiogenesis. Bevacizumab is approved to treat metastatic colorectal cancer and as first-line treatment of advanced nonsquamous NSCLC. Additional indications include the following: metastatic renal cell carcinoma to be given with interferon alfa; progressive glioblastoma as a single agent; persistent, recurrent, or

metastatic cervical cancer with paclitaxel and cisplatin or paclitaxel and topotecan; and for platinum-resistant recurrent ovarian, fallopian tube or primary peritoneal cancer with chemotherapy.

Several serious adverse events have been associated with bevacizumab, including hypertension, bleeding, and thrombotic events. Hypertension is more common in patients with a history of hypertension and responds to oral antihypertensive medications. Although the most common bleeding episodes are transient epistaxis, fatal CNS, and gastrointestinal hemorrhages have been reported. The product labeling includes a box warning regarding the risk of gastrointestinal perforation, wound dehiscence, and hemorrhage. Bevacizumab is not recommended for use within 28 days of major surgery and patients should be instructed to report abdominal pain (an initial sign of gastrointestinal hemorrhage) to their health professionals immediately. Paradoxically, bevacizumab also has been associated with thrombotic events, including deep vein thrombosis, pulmonary embolism, and myocardial infarction, especially in elderly patients with a history of cardiac events. Another potentially serious adverse event associated with bevacizumab is proteinuria/nephrotic syndrome, and patients should be monitored for the development or worsening of proteinuria with serial urine dipsticks. Patients with a 2+ or greater urine dipstick should undergo further assessment.

Ramucirumab

Ramucirumab is a human mAb that binds to VEGFR2 resulting in the inhibition of ligand-induced proliferation. Whereas bevacizumab binds the circulating ligand (ie, VEGF), ramucirumab inhibits angiogenesis through the specific blockade of VEGFR2.[78] Ramucirumab is approved for the treatment of advanced gastric or gastroesophageal junction adenocarcinoma as a single agent or with paclitaxel. Other indications include treatment of metastatic NSCLC with docetaxel after progression with platinum-based chemotherapy and for the treatment of metastatic colorectal cancer in the second-line setting. When administered as a single agent, the most common toxicities associated with ramucirumab are hypertension and diarrhea. Boxed warnings for ramucirumab are the same as for bevacizumab. Patients should also be monitored for thromboembolic events, hypertension, proteinuria, and thyroid dysfunction.

Immunomodulatory Monoclonal Antibodies

Denosumab

Denosumab is a human mAb with affinity for the receptor activator of nuclear factor kappa-B ligand (RANKL). Giant cell tumors of bone are benign osteolytic tumors whose osteoclast-like giant cells express the receptor activator of nuclear factor kappa-B (RANK) receptor. Activation of RANK contributes to osteolysis and tumor growth.[79] Denosumab binds to RANKL thereby preventing the activation of RANK on osteoclast-like giant cells. It is approved for the treatment of adults and skeletally mature adolescents with giant cell tumor of bone that is not amenable to surgery. The most common toxicities include arthralgia, headache, nausea, and hypocalcemia. A dental examination should be performed prior to initiation of therapy and patients should be monitored for symptoms of osteonecrosis of the jaw.

Ipilimumab

Ipilimumab is a human mAb that blocks cytotoxic T-lymphocyte antigen 4 (CTLA-4) and is approved for the treatment of metastatic melanoma and adjuvant treatment of cutaneous melanoma with pathologic involvement of regional lymph nodes. CTLA-4 acts as a negative regulator of T-cell function, decreasing the ability of the immune system to mount an antitumor response. By binding to CTLA-4, ipilimumab allows for enhanced T-cell stimulation, proliferation, and antitumor activity.[80] Ipilimumab can take longer than chemotherapy to demonstrate a response because its mechanism depends on harnessing the immune system. Based on its enhanced immune response, several severe and fatal immune-mediated adverse reactions have been observed, including enterocolitis, hepatitis, dermatitis, neuropathy, and endocrinopathy.

Nivolumab

The programmed death-1 (PD-1) receptor is expressed by activated T cells and serves as an immunologic checkpoint. The PD-1 ligand (PD-L1) is expressed on numerous human tumors including melanoma and lung. Through the interaction of PD-L1 with PD-1, T-cell activity is limited and the tumor evades immunosurveillance. It has been suggested that PD-L1 expression is associated with increased tumor aggressiveness. Nivolumab, a fully human IgG4 mAb, binds to and blocks PD-1 from interacting with its receptor resulting in the restoration of T-cell activity.[81]

Nivolumab is approved for the treatment of metastatic NSCLC with progression on or after platinum-based chemotherapy, unresectable or metastatic melanoma, and metastatic renal cell carcinoma. Nivolumab is also approved with ipilimumab for the treatment of patients with BRAF V600 wild-type, unresectable or metastatic melanoma. Patients receiving nivolumab must be monitored for immune-mediated toxicities including pneumonitis, colitis, hepatitis, nephritis, and thyroid dysfunction. Depending on the severity of the reaction, corticosteroids should be administered.

Elotuzumab

Elotuzumab is an IgG mAb directed against Signaling Lymphocytic Activation Molecule Family 7 (SLAMF7). It is approved with lenalidomide and dexamethasone for the treatment of patients with previously treated multiple myeloma. The most common adverse reactions reported include fatigue, diarrhea, constipation, pyrexia, peripheral neuropathy, decreased appetite, cough, and respiratory infections. Patients should also be monitored for infusion reactions, infections, second primary malignancies, and hepatotoxicity. Of note, elotuzumab can be detected in the serum protein electrophoresis and immunofixation assays of M-protein, which may interfere with the ability to assess complete response.

Pembrolizumab

Pembrolizumab is a highly selective humanized IgG4 mAb. Similar to nivolumab, pembrolizumab binds to the PD-1 receptor thereby reversing T-cell suppression. Pembrolizumab is approved for the treatment of unresectable or metastatic melanoma. Given its similar mechanism of action, toxicities

reported with pembrolizumab are similar to those reported with nivolumab.

Siltuximab

Siltuximab is an anti-IL-6 chimeric mAb approved for the treatment of multicentric Castleman Disease (MCD) who are human immunodeficiency virus (HIV)-negative and human herpes virus-8 (HHV-8)-negative. MCD is a rare lymphoproliferative disorder and although it is not considered a form of cancer, many patients with this disease develop lymphomas and it is therefore often treated with chemotherapy. Hyperplastic lymph nodes of patients with MCD produce IL-6, a cytokine that induces B-cell differentiation, and it is thought that dysregulated IL-6 plays a critical role in the manifestation of the disease. Siltuximab is an antibody to endogenous IL-6 and is not thought to bind to viral IL-6. Therefore, HIV-positive and HHV-8-positive patients were excluded from the clinical trials. The most common toxicities associated with siltuximab include pruritus, increased weight, and hyperuricemia. Patients should also be monitored for infections and siltuximab should be held in patients who develop a severe infection.

Cytokines

Interferons

Recombinant interferon-alfa is approved for hairy cell leukemia, melanoma, Kaposi's sarcoma, and CML. A pegylated interferon-alpha identified as peginterferon-alfa has been approved for adjuvant treatment of metastatic melanoma. The mechanisms by which IFNs exert their anticancer effects is unknown, but IFNs exert their effect by binding to specific membrane receptors and initiating various intracellular signaling pathways.[82] The most frequent toxicities are flu-like symptoms and elevated transaminases. Potentially serious toxicities include neuropsychiatric, autoimmune, ischemic, and infectious disorders.

Interleukin-2 (Aldesleukin)

Interleukin-2 (IL-2) is a cytokine produced by recombinant DNA technology that promotes B- and T-cell proliferation and differentiation and initiates a cytokine cascade with multiple interacting immunologic effects. The IL-2 receptor is expressed in increased amounts on activated T-cells and mediates most of the effects of aldesleukin. Anticancer activity depends on proliferation of cytotoxic immune cells that can recognize and destroy cancer cells without damaging normal cells. Some of these cytotoxic cells are natural killer cells, lymphokine-activated killer cells, and tumor-infiltrating lymphocytes.[83] Aldesleukin is approved for the treatment of metastatic renal cell carcinoma and melanoma.

Aldesleukin is a toxic therapy that requires vigorous supportive care under the supervision of experienced healthcare professionals. The most common dose-limiting toxicities are hypotension, fluid retention, and renal dysfunction. Aldesleukin decreases peripheral vascular resistance, producing peripheral vasodilation, tachycardia, and hypotension. A characteristic vascular or capillary leak syndrome produces fluid retention, which in turn can cause respiratory compromise. These toxicities

require administration of vasopressors in most patients, judicious use of fluid support and diuretics, and supplemental oxygen. Patients with underlying cardiovascular or renal abnormalities are more susceptible to these toxicities, making careful patient selection important.[83] Most patients treated with aldesleukin experience thrombocytopenia, anemia, eosinophilia, reversible cholestasis, and skin erythema with burning and pruritus, and some have neuropsychiatric changes, hypothyroidism, and bacterial infections.[83] In general, the toxicities from aldesleukin reverse quickly after therapy is stopped and can be managed or prevented by careful prospective monitoring and supportive care.

Enzymes

l-Asparaginase is unique among anticancer agents in its unusual mechanism of action, patterns of toxicity, and source. It is an enzyme produced by Escherichia coli or Erwinia chrysanthemi. l-Asparagine is a nonessential amino acid that can be synthesized by most mammalian cells except cells with certain lymphoid malignancies, which have no or limited synthetase levels required for l-asparagine formation. l-Asparagine is degraded by the enzyme l-asparaginase, which depletes existing supplies and inhibits protein synthesis. Increased l-asparagine synthetase activity within cancer cells causes resistance to l-asparaginase treatment. l-Asparaginase is a component of combination chemotherapy regimen used for the treatment of ALL and multiple products are available.

Fusion Proteins

Denileukin Diftitox

Denileukin diftitox is a recombinant fusion protein that combines the active sections of both IL-2 and diphtheria toxin. Unconjugated diphtheria toxin is much too toxic to administer to humans. As the payload of the fusion protein, however, its cytotoxic effects are directed toward cells that express the high-affinity form of the IL-2 receptor, such as cancer cells of some patients with cutaneous T-cell lymphoma. When denileukin diftitox interacts with IL-2 receptors, the toxin inhibits protein synthesis in the cancer cells and causes cell death. It is approved for the treatment of cutaneous T-cell lymphomas.

Although denileukin diftitox is directed therapy, its targeting of cells that express high-affinity IL-2 receptors is not specific because these receptors are expressed on cells other than cancer cells. Denileukin diftitox produces acute hypersensitivity reactions, flu-like symptoms, diarrhea, visual impairment, and vascular leak syndrome. It differs from the vascular leak syndrome produced by high-dose aldesleukin in that it occurs in fewer patients, is delayed in onset, is usually self-limited, and does not consistently recur on retreatment.[83] Patients with an albumin concentration less than 3 g/dL (30 g/L) are at increased risk for vascular leak syndrome and use in these patients is not recommended.

Ziv-Aflibercept

Ziv-aflibercept is a soluble recombinant fusion protein that was designed to block multiple signals

that stimulate the angiogenic process. It was developed by fusing sections of the VEGFR1 and VEGFR2 immunoglobulin domains to the Fc portion of human IgG1. Ziv-aflibercept blocks VEGFA, VEGFB, and phosphatidylinositol-glycan biosynthese class F by “trapping” the ligands before they get to the native transmembrane receptors and thus decreasing proangiogenic signaling and tumor growth. It is approved with chemotherapy for resistant or progressive metastatic colorectal cancer and has toxicities similar to other anti-VEGF therapies.

Vaccines

Sipuleucel-T

Sipuleucel-T is the first therapeutic vaccine approved by the FDA and has paved the way for numerous vaccines currently being investigated. Sipuleucel-T is classified as an autologous cellular immunotherapy that is indicated for the treatment of asymptomatic or minimally symptomatic metastatic castrate-resistant prostate cancer. Through leukapheresis, a patient’s dendritic cells are collected and isolated then cultured ex vivo. The fusion protein (PAP-GM-CSF) is composed of prostate acid phosphatase (PAP) and GM-CSF. PAP is selectively expressed on prostatic tissues and GM-CSF is included to enhance the immune response. Antigen-presenting cells take up this antigen and are then re-infused into the donor patient to stimulate a T-cell response.[84]

Treatment with sipuleucel-T consists of three infusions separated by approximately 2 weeks. Due to the leukapheresis, ex vivo cell manipulation, and re-infusion, treatment with sipuleucel-T can be logistically challenging. Premedication consisting of acetaminophen and an antihistamine should be given prior to each infusion to decrease the chance of an infusion reaction. Common toxicities include chills, fatigue, back pain, nausea, joint ache, and headache.

Talimogene Laherparepvec

Talimogene laherparepvec (T-VEC) is an oncolytic viral therapy based on a modified herpes simplex virus (HSV) type 1. T-VEC is modified through the deletion of two HSV genes, ICP34.5 and ICP47, and is designed to lyse tumor cells and promote antitumor immunity. It is indicated for the local treatment of unresectable cutaneous, subcutaneous, and nodal lesions in patients with melanoma recurrent after initial surgery. T-VEC is injected directly into the cutaneous, subcutaneous or nodal lesion. The most common toxicities are fatigue, chills, pyrexia, nausea, influenza-like illness, and injection site pain. Pyrexia, chills, and influenza-like illness can occur any time during treatment, but were more frequent during the first 3 months of treatment. Cellulitis is the most commonly reported serious adverse event.

RESPONSE CRITERIA

The response to anticancer agents and other treatment modalities could be described as a cure, complete response (CR), partial response (PR), stable disease, or progression. A cure implies that the patient is entirely free of disease and has the same life expectancy as a cancer-free individual. Because of our inability to detect small numbers of cancer cells, we can never be absolutely certain

that an individual patient is cured. Cancers that are curable with treatment are characterized by a stable plateau in the survival curve where the risk of relapse is very low. For most curable cancers, the survival curve has plateaued by about 5 years. Therefore, patients with a curable cancer who are alive 5 years from the time of diagnosis without disease recurrence are often considered "cured", but patients with some malignancies, such as breast cancer and melanoma, are still at significant risk for relapse after 5 years.

Response Evaluation Criteria for Solid Tumors

In an attempt to simplify and unify response definitions in clinical practice, clinical trials, and published reports, the response evaluation criteria in solid tumors (RECIST) criteria were developed in 2000 and revised in 2009 (RECIST 1.1).[85] At baseline, overall tumor burden and measurable disease is assessed. Target lesions are identified and measured at baseline and are later re-evaluated to determine objective tumor response. Nontarget lesions are also assessed. A CR means disappearance of all target lesions and any pathological lymph nodes must be reduced in short axis to less than 10 mm. A PR is defined as a 30% or greater decrease in the sum of diameters of target lesions from baseline. Overall objective response rates for a given treatment are calculated by adding the CR and PR rates. Progressive disease is defined as a 20% or greater increase in the sum of diameters of target lesions when compared to the smallest sum since treatment initiation. The development of one or more new lesions while receiving treatment is also considered progressive disease. A patient whose tumor size neither grows nor shrinks by the above criteria is termed to have stable disease.[85] Some patients may experience subjective improvement in cancer-related symptoms without a defined response. Although clinically important, this does not indicate an objective response. Although RECIST 1.1 is the most widely accepted criteria for the assessment of tumor response in solid tumors, it does not come without shortcomings. The modified RECIST (mRECIST) assessment may be more accurate for the evaluation of tumor burden in some cancers.[86]

Furthermore, the emergence of immunotherapy in oncology has led to the need for revised response criteria that accounts for the mechanism of immunotherapeutic agents. RECIST neglects to take into account the pseudo-progression effect ("flare") that can be seen with these agents which may result in declaring progressive disease too early. The immune-related response criteria (irRC) and immune-related RECIST (irRECIST) have been proposed to overcome the challenges of RECIST 1.1 with immunotherapy.[87,88]

The response definitions described above are applicable to solid tumors, but leukemias and multiple myeloma are not characterized by discrete, measurable masses. Responses in these cancers are measured by elimination of abnormal cells (eg, return to normal hematology parameters and normal bone marrow in leukemia), return of tumor markers to normal levels (eg, normal serum protein electrophoresis in multiple myeloma), or improved function of affected organs (eg, improved renal function after obstructive uropathy). Cytogenetic markers and molecular techniques have an increasingly important role in determining whether all cancer has been truly eliminated. For example, in CML, the Philadelphia chromosome can be detected by polymerase chain reaction techniques even when no leukemia is evident in the bone marrow or bloodstream. Patients without evidence of the Philadelphia chromosome are classified as having a complete cytogenetic response. Measuring

cytogenetic responses is increasingly common in patients with known cytogenetic abnormalities, and the absence of complete cytogenetic responses may predict disease relapse.

Factors Affecting Treatment Response

8 Factors affecting response include tumor burden, cancer cell heterogeneity, drug resistance, dose intensity, and patient-specific factors. The significance of tumor burden was discussed earlier in the Principles of Tumor Growth section. Tumors consist of a heterogeneous population of cells. Because of the genetic instability of cancer cells compared with normal cells, genetic alterations commonly occur during cell division. Large tumors have therefore undergone many cell divisions and express multiple genetic alterations, resulting in genetically varied populations.[3] In 1979, Goldie and Coldman proposed that these cytogenetic changes were not completely random and were highly associated with the development of the ability of tumors to develop drug resistance. The probability of developing resistant cell populations increases as tumor size increases. It is believed that a small percentage of resistant cancer cells may survive initial therapy. Resistant populations later proliferate and eventually become the dominant population, which could explain the common pattern of an initial response to therapy followed by progressive tumor regrowth despite continuing the same treatment.

Drug resistance may be either acquired or inherited. Mechanisms of drug resistance include altered drug transport systems, metabolism, and target enzymes; inability to repair drug-induced damage; and insensitivity to drug-induced apoptosis.[3] For example, multidrug resistance has been observed with natural chemotherapies (eg, anthracyclines, vinca alkaloids, epipodophyllotoxins, and taxanes), and it occurs when some cancer cells are exposed to increasing concentrations of a specific chemotherapy. Surprisingly, these same cells also become resistant to other structurally unrelated chemotherapies and are therefore considered multidrug resistant. The resistant cancer cells overexpress the drug transporter Pgp, which enhances the export of these chemotherapies. Other potential mechanisms of drug resistance include inactivation of chemotherapy by glutathione metabolism, upregulation of drug targets, alternative intracellular signaling pathways, and decreased apoptosis. The last mechanism can be mediated by overexpression of bcl-2 or loss of TP53, as discussed earlier in the chapter.

The relationship between dose and response has been extensively explored for chemotherapy agents,[1] because dose is believed to be a critical factor in determining response for many cancers. Dose intensity is defined as the dose delivered to the patient over a specified period of time. The three main variables that determine delivered dose intensity are the dose per course, the interval between doses, and the total cumulative dose. Dose density refers to shortening of the usual interval between doses (eg, every 2 weeks instead of every 3 weeks) and is designed to maximize the effects of therapy on tumor growth kinetics. This strategy has been most extensively studied in breast cancer, with positive results from adjuvant therapy given to patients with high-risk node-positive disease. The delivery of optimal dose intensity is often compromised by the toxicities of the anticancer agent. Treatment cycles are commonly delayed because of inadequate recovery from toxicity, especially myelosuppression. Subsequent doses of the anticancer agents are often reduced to prevent or reduce the severity of these toxicities. The impact on patient outcome has been proven

in studies showing reduced rates of response and survival in individuals receiving less-than-optimal doses. Understanding the pathophysiology of toxicities has led to the development of more effective agents to prevent and manage these toxicities. The development of chemoprotective agents has facilitated application of dose-intensity principles. For example, colony-stimulating factors minimize neutropenia and permit delivery of dose-intensive or dose-dense regimens that are myelosuppressive. The issue of dose intensity is particularly important in the setting of high-dose chemotherapy with autologous hematopoietic stem cell support. Although lethal myelosuppression is avoided by administering hematopoietic stem cells, other severe end-organ toxicities emerge as doses of the anticancer agents are increased.

Patient-specific factors create unpredictable variability in response to anticancer therapy. For example, interindividual variations in absorption, distribution, or elimination could lead to sub- or supratherapeutic levels of anticancer agents and their metabolites. The genetic alterations that resulted in the cancer can also affect response. For example, breast cancers that overexpress HER2 are often sensitive to anthracycline-based regimens. As a result, both efficacy and tolerability can be affected. Health professionals in oncology may modify doses based on variations in body size, blood counts, and organ function. Prospective dose modifications based on these parameters are still very important to optimize the effectiveness of therapy and minimize toxicity. But more specific tools are becoming available as we learn how to identify and apply differences in the genetic makeup of the patient and cancer to their anticancer therapy. Pharmacogenomics is the study of the role of inheritance in individual variation in drug response. In oncology, several clinically relevant genetic polymorphisms or variations have been identified that can affect pharmacokinetics and pharmacodynamics. Examples include polymorphisms in genes responsible for the activity of the enzymes DPD (responsible for FU metabolism), TPMT (responsible for thiopurine metabolism), and UGT1A1 (responsible for irinotecan metabolism). Patients with deficiencies in these enzymes can experience significant, and possibly life-threatening, toxicity. Identifying these genetic variants could permit individualization of regimens containing these agents to avoid toxicity. Monitoring concentrations of anticancer agents could also improve the therapeutic index. For example, pharmacokinetic and pharmacodynamic modeling is associated with improved responses and decreased toxicity in children with ALL.

The presence of other disease states (eg, comorbidities) may also affect response to treatment by limiting treatment options. The overall functional status of a patient may be assessed using performance status scales, such as the Karnofsky Performance Status (KPS) and Eastern Cooperative Oncology Group (ECOG) scales. These scales can be used to predict patient tolerance of anticancer therapy and to assess the effects of therapy on the patient's level of activity and quality of life. For many cancers, performance status at diagnosis is the most important prognostic indicator.

Today's oncology health professionals have a wealth of information to consider when designing a personalized treatment approach. Patient-specific factors (eg, performance status, comorbidities, organ function, and pharmacogenomics), tumor-specific factors (eg, pathology, stage, and molecular profile), and treatment goals (eg, palliation and cure) are all considered when determining the best treatment option. Treatment cost can also be an important consideration.

ADMINISTRATION

Dosing and Administration

Health professionals should monitor all clinical and laboratory values that are affected by a specific anticancer agent at baseline and periodically during treatment. For example, a complete blood count should be evaluated weekly while receiving myelosuppressive chemotherapy. In general, a neutrophil count of 3,000 cells/mm^3 (3×10^9/L) or above or an absolute neutrophil count (ANC) of 1,500 cells/mm^3 (1.5×10^9/L) or above and a platelet count of 100,000 cells/mm^3 (100×10^9/L) or above are usually required before administering myelosuppressive agents. In addition, a chemistry panel is drawn to assess organ function, especially for agents eliminated or metabolized via those routes. Table 127-7 lists agents that require dosing adjustments and require specific laboratory tests before administration; failure to follow these recommendations may result in overdosing and excessive toxicity.

Anticancer agents might be dosed based on body size (such as body weight or body surface area [BSA]) or as a fixed dose. Chemotherapy is generally dosed based on BSA. BSA is commonly used as an estimate of cardiac output and subsequent distribution to the liver and kidneys, the primary determinants of drug elimination. The most common methods used to determine BSA are the Mosteller and DuBois formulas. Body-sized dosing is also commonly used for mAbs, but the effect of body size on interpatient variability should be explored to determine the optimal dosing approach. In contrast, most oral targeted agents are based on a fixed-dose approach based on the available tablet or capsule strengths.

Other dosing methods are being used to improve tolerability and anticancer activity. For example, carboplatin is dosed based on the patient's estimated glomerular filtration rate (GFR). This method is known as the Calvert formula and has been demonstrated to achieve adequate levels of carboplatin while minimizing excessive toxicity. The dose might also be based on drug levels (eg, methotrexate) and health professionals should be proficient in these calculations before dosing and administering any chemotherapy agent. A healthcare provider should complete diagnostic tests recommended before administering some anticancer agents, such as tamoxifen, trastuzumab, vemurafenib, and crizotinib, which are only prescribed to patients whose tumor expresses a specific protein or gene. Additionally, health professionals need to be aware of the diagnostic tests associated with the drug approval and how to interpret the findings from the various tests. For example, some tests may identify if a tumor is mutation positive or negative, whereas other tests may identify the specific genetic alteration identified in the tumor.

Safety and Handling

All anticancer agents regardless of the route of administration should be handled with care to avoid inadvertent exposure of health professionals and caregivers. Consequently, all healthcare facilities should have written procedures for safely handling these agents and all personnel should be oriented to these procedures. Additionally, health professionals should provide information about safe handling and disposal to patients and their families when a patient is prescribed an oral anticancer

agent. Safe handling includes avoiding skin contact and inhalation, but patient-centered guidelines regarding safe handling of oral anticancer agents have not been developed.[89]

The United States Pharmacopeia Chapter 797 regulates the preparation of extemporaneously compounded sterile preparations and should be used by providers that prepare intravenous chemotherapy. Chapter 800 is currently in draft form and should be available in the near future. The most common avenue of exposure is via inhalation or skin absorption. Individuals preparing intravenous chemotherapy should work in an International Organization for Standardization (ISO) Class 5 biologic safety cabinet and wear appropriate personal protective equipment including a gown, face mask, eye protection, hair covers, shoe covers, and double sterile chemo-type gloves. Closed-system vial-transfer devices should be used when possible. Negative-pressure techniques should be used in drug preparation to minimize aerosolization. Health professionals administering chemotherapy should take similar precautions to avoid exposure. Double chemotherapy-tested gloves, protective gowns, and protective eyewear (if there is potential for splashing) should be worn whenever handling or administering hazardous drugs. Kits for cleaning up chemotherapy spills should be located in all areas where chemotherapy is handled. Cytotoxic waste should be disposed of properly, and patients should be informed of proper methods for disposing of potentially contaminated body excreta and cytotoxic waste.

SUPPORTIVE CARE

9 The treatment of cancer is complicated by the risk of multiple serious adverse events, many of which may be life-threatening. Adverse events (or toxicities) are commonly graded on a scale from no toxicity (grade 0) to death (grade 5) with the Common Terminology Criteria for Adverse Events (CTCAE) developed by the National Cancer Institute (NCI). Specific toxicities observed with individual anticancer agents were listed earlier in the chapter. Toxicities such as myelosuppression, mucositis, nausea and vomiting, and alopecia are commonly observed with chemotherapy because these agents target rapidly dividing normal and cancer cells. Other toxicities associated with chemotherapy are infertility and carcinogenesis. The adverse event profile with biologic therapies and targeted agents typically differ from chemotherapy. The events observed with these anticancer agents depend on the altered intracellular signaling. For example, rash has been observed with agents that inhibit EGFR intracellular signaling and hemorrhage and thrombosis have been observed with agents that affect the VEGFR intracellular signaling pathway. Nutritional support and pain management are also important supportive care issues for all patients with cancer. The management of chemotherapy-induced nausea and vomiting and the basic principles of nutritional support and pain management are discussed in detail in other chapters. The basic principles for the management of some common toxicities or adverse events are described below.

Hematologic

Myelosuppression is the most common dose-limiting toxicity observed with chemotherapy, but myelosuppression may be seen with kinase inhibitors (eg, sunitinib). The risk of myelosuppression increases when chemotherapy is administered concurrently with radiation to the chest or pelvic region. The effects of myelosuppression are usually not observed immediately after administration

because the currently circulating blood cells must first be consumed. For example, neutropenia is typically observed before thrombocytopenia, because white blood cells have a short life span of 6 to 12 hours compared to platelets with a life span of 5 to 10 days. Anemia typically occurs a few months after the first dose, since erythrocytes have a relatively long life span of 120 days. The lowest blood cell count (or nadir) typically occurs 10 to 14 days after chemotherapy administration, with a recovery in cell counts by 3 to 4 weeks after administration; however, the nadir commonly occurs later following administration of nitrosoureas, mitomycin C, and radiolabeled antibodies (about 4-6 weeks). Subsequent doses should be delayed until the minimum suggested blood counts are achieved to minimize additional toxicity and morbidity. Patients with leukemia or receiving a hematopoietic stem cell transplant may have a more rapid nadir of about 5 to 7 days.

A dose reduction should be considered if a patient develops severe myelosuppression such as anemia necessitating a transfusion or neutropenia with a fever. A dose reduction may be considered empirically before the first dose if the patient has a low baseline neutrophil or platelet count, has diminished bone marrow reserve, has impaired drug elimination, or is to receive a combination of several myelosuppressive agents; these patients may be at an increased risk of developing severe myelosuppression. A decreased bone marrow reserve has been observed in patients who have received multiple prior courses of myelosuppressive chemotherapy or extensive radiation therapy.

A dose reduction should be carefully balanced with the treatment goals, since reduced dose can compromise anticancer activity in some tumors (eg, breast cancer and lymphoma).[1] In patients who are responding well to treatment, some myelosuppression is accepted by most health professionals if it is not compromising the patient's quality of life and the cancer is responding to therapy. In these patients, empiric use of hematopoietic growth factors provides an alternative to dose reduction.

Anemia

Although usually not life threatening, anemia is the most common hematologic complication of chemotherapy.[90] The incidence of anemia depends on several factors, including the type and duration of therapy and the type and stage of the underlying malignancy. For example, carboplatin is more commonly associated with anemia than other chemotherapy agents. Multiple conditions can cause anemia, including gastrointestinal blood loss, nutrient deficiency (eg, iron and folate), chemotherapy and radiation therapy, bone marrow invasion, hemolysis, renal dysfunction, and anemia of chronic disease. Of all the signs and symptoms of anemia, fatigue is most common in patients with cancer. In fact, fatigue is the most commonly reported symptom overall in patients undergoing anticancer therapy. Of note, other common causes of fatigue include insomnia, depression, unrelieved pain, and the underlying malignancy.

The underlying cause of the anemia should be identified before treatment for anemia is started. Red blood cell transfusions are the mainstay of treatment, but erythropoiesis-stimulating agents (epoetin alfa and darbepoetin alfa) may be considered for patients with underlying kidney disease and for patients receiving palliative treatment. Serious adverse events related to erythropoiesis-stimulating agents include thrombosis and myocardial infarction. These events have generally occurred when the target hemoglobin of 12 g/dL (120 g/L; 7.45 mmol/L) is exceeded or the hemoglobin rises too

quickly.[90] Various studies have demonstrated an increased risk of mortality with the use of erythropoiesis-stimulating agents in patients with cancer. For these reasons, epoetin alfa and darbepoetin alfa must be prescribed and used under a REMS program. Other rare and generally mild toxicities include pain at injection site, rash, flu-like symptoms, seizures, and hypertension. The presence of functional iron deficiency should be determined before administering these products. If the functional iron deficiency is identified, intravenous iron should be considered, as oral iron is poorly tolerated and absorbed in patients with cancer. Clinical practice guidelines for the treatment of cancer- and chemotherapy-related anemia are available.[90]

Neutropenia

Neutropenia in patients with cancer is associated with an increased risk of infection. The probability of developing an infection increases when ANC falls below 500 cells/mm^3 (0.5×10^9/L) or when the duration of neutropenia is prolonged.[91] Other risk factors for infection include alteration in the integrity of physical defense barriers and the functional integrity of the leukocytes. Neutrophil function can be affected by the underlying cancer, anticancer agent, or radiation therapy.

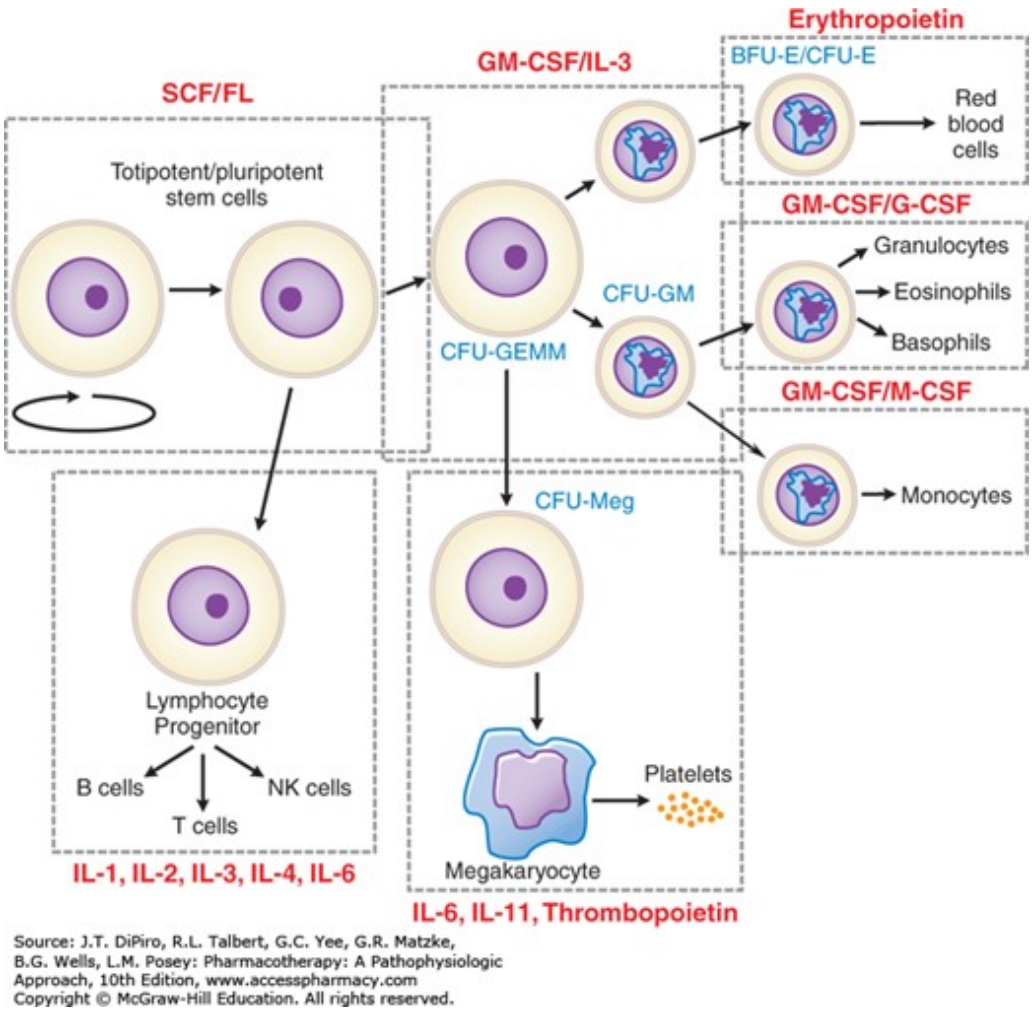
In the neutropenic patient, it can be difficult to identify an infection, as the usual signs and symptoms of infection, such as pus, abscesses, and infiltrates on chest radiography, are often absent. Subsequently, health professionals must rely on fever as an indicator of infection in these patients. Definitive culture results may take days and a septic neutropenic cancer patient can die within hours if not treated. Therefore, empiric antibiotics are promptly initiated based on reliable coverage of the most likely organisms, antibiotic sensitivities at the institution, the patient's signs and symptoms (if present), and possible adverse events.[91] The most common source of infection in these patients is self-infection with body flora, which includes both gram-positive and gram-negative bacteria. Specific treatment of infections in immunocompromised hosts is discussed in Chapter 122.

Colony-stimulating factors (CSF) may minimize the severity of neutropenia and subsequently, reduce the risk of infection.[91] These factors are naturally occurring proteins that are essential for the normal growth and maturation of blood cell components (**Figure 127-8**). For example, filgrastim specifically stimulates the production of neutrophilic granulocytes and sargramostim promotes the proliferation of granulocytes (neutrophils and eosinophils), monocytes and macrophages.[92] Although sargramostim stimulates megakaryocytes, no consistent effect on platelet production has been observed in clinical trials. Both factors initially enhance demargination and mobilization of mature cells from the marrow and then provide constant stimulation of stem cell progenitors. Pegfilgrastim is a peglyated filgrastim that has a substantially longer half-life compared to filgrastim. Whereas multiple daily doses of filgrastim are typically needed to increase neutrophil count, only a single dose of pegfilgrastim is needed to similarly increase neutrophil counts. Filgrastim-sndz (a biosimilar to filgrastim) and tbo-filgrastim have recently been approved for use with myelosuppressive chemotherapy.

FIGURE 127-8

Sites of action of hematopoietic growth factors in the differentiation and maturation of marrow cell

lines. A self-sustaining pool of marrow stem cells differentiates under the influence of specific hematopoietic growth factors to form a variety of hematopoietic and lymphopoietic cells. Stem cell factor (SCF), FTL-3 ligand (FL), interleukin-3 (IL-3), and granulocyte-macrophage colony-stimulating factor (GM-CSF), together with cell–cell interactions in the bone marrow, stimulate stem cells to form a series of burst-forming units (BFU) and colony-forming units (CFUs): CFU-GEMM, CFU-GM, CFU-Meg, BFU-E, and CFU-E (GEMM, granulocyte, erythrocyte, monocyte, and megakaryocytes; GM, granulocyte and macrophage; Meg, megakaryocyte; E, erythrocyte). After considerable proliferation, further differentiation is stimulated by synergistic interactions with growth factors for each of the major cell lines—granulocyte colony-stimulating factor (G-CSF), monocyte/macrophage-stimulating factor (M-CSF), thrombopoietin, and erythropoietin. Each of these factors also influences the proliferation; maturation; and, in some cases, the function of the derivative cell line. (NK, natural killer.) *(Reproduced with permission from Kaushansky K, Kipps TJ. Hematopoietic agents: Growth factors, minerals and vitamins. In: Brunton LL, Chabner BA, Knollman BC (eds). Goodman & Gilman's The Pharmacologic Basis of Therapeutics, 12th ed. New York: McGraw-Hill, 2010.)*



These growth factors may be used as primary or secondary prophylaxis of neutropenia. Primary prophylaxis refers to the use of these factors to prevent neutropenia with the first cycle of chemotherapy. The National Comprehensive Cancer Network (NCCN) recommends this strategy for patients who are receiving a chemotherapy regimen with a 20% or higher risk of febrile neutropenia.[93] These guidelines also recommend primary prophylaxis for patients with risk factors

receiving a chemotherapy regimen with a 10% to 20% risk of febrile neutropenia. Patient risk factors include age 65 years or older, previous chemotherapy or radiation, pre-existing conditions, poor performance status, poor organ function, and HIV-positive patients. Secondary prophylaxis refers to the use of growth factors to prevent recurrent neutropenia in patients who had experienced neutropenia with the prior cycle of chemotherapy. It is recommended that secondary prophylaxis be reserved for patients with chemosensitive cancers when a dose reduction may affect survival.

The role of these factors in the treatment of established neutropenia is less well defined. Some guidelines suggest that the administration of these factors may be considered in select patients with established neutropenia. High-risk patients with fever and neutropenia may include those with neutropenia for more than 10 days, ANC less than 100 cells/mm^3 (0.1×10^9/L), age greater than 65 years, and infectious complications (pneumonia, sepsis, or invasive fungal infections) as well as those who are hospitalized at the time of the development of neutropenic fever.[91]

Both filgrastim and sargramostim have also proven effective in accelerating hematopoietic engraftment and in treating graft failure after hematopoietic stem cell transplantation. Other uses for the factors include peripheral blood stem cell mobilization and congenital or idiopathic neutropenia. Growth factors should not be used in patients receiving concomitant chemotherapy and radiotherapy, especially if the radiation involves the mediastinum. These patients appear to experience more significant thrombocytopenia.

At currently recommended doses, these factors are well tolerated. Toxicities are more commonly seen with sargramostim and may be related to its ability to enhance binding of neutrophils to endothelial cells or to activation of monocytes or macrophages, which may stimulate the release of cytokines such as IL-1 and TNF-α.[92] The most common adverse event with these factors is bone pain. Other toxicities include constitutional symptoms, such as low-grade fever, myalgia, arthralgia, lethargy, and mild headache. At higher sargramostim doses, pleural and pericardial effusions, capillary leak syndrome, and thrombus formation may occur. Both factors may produce mild erythema at subcutaneous injection sites, as well as a generalized maculopapular rash. The toxicities observed with pegfilgrastim are similar to those of filgrastim.

The dosing and administration of these factors for the prophylaxis of chemotherapy-induced neutropenia is as follows: a single dose of pegfilgrastim 6 mg or daily doses of filgrastim 5 mcg/kg or sargramostim 250 mcg/m^2 until the ANC reaches a pre-specified target following the nadir. Alternative doses are used in other settings, such as mobilization. These factors should be started between 24 and 72 hours after chemotherapy. Filgrastim and sargramostim can be stopped the day before chemotherapy, but pegfilgrastim should be administered at least 14 days before the next dose of chemotherapy due to its extended half-life. Both sargramostim and filgrastim may be given intravenously, but subcutaneous administration is preferred. Because of the high cost of these agents, doses are commonly rounded to the nearest product vial size to minimize waste.

Thrombocytopenia

Thrombocytopenia increases the risk for significant bleeding. To date, platelet transfusions remain the mainstay of management. At most centers, platelet transfusions are reserved for patients with a

platelet count of less than 10,000 cells/mm^3 (10×10^9/L) unless the patient is actively bleeding, must undergo a surgical procedure, or has documented infections or fever. For patients with nonmyeloid malignancies who experience significant thrombocytopenia with chemotherapy, oprelvekin (IL-11) may be considered as secondary prophylaxis in subsequent cycles.[95] When used after chemotherapy that is associated with a high risk of thrombocytopenia, oprelvekin decreased the need for platelet transfusions, as well as the number of platelets required for transfusion. Unfortunately, oprelvekin is associated with some significant toxicities, mostly related to fluid retention (eg, edema, dilutional anemia, dyspnea, and pleural effusions). Cardiac toxicity, especially tachycardia, and atrial fibrillation and flutter also have been observed. Prophylactic oprelvekin is significantly more expensive than platelet transfusions. Considering the modest clinical benefit, the toxicities, and the high cost, oprelvekin use should be reserved for patients who are at high risk for severe thrombocytopenia from chemotherapy when dose reduction is expected to compromise disease response.

Gastrointestinal

Nausea and vomiting are common toxicities observed with chemotherapy agents and some targeted drugs. Medications to minimize the risk of nausea and vomiting are typically given before administration of the anticancer drug. The medications selected depend on the underlying risk of nausea and vomiting associated with the anticancer drug. Medications should also be given for patients to take as needed if nausea or vomiting occurs at home after administration is complete. The underlying pathophysiology and available antiemetic regimens are discussed further in Chapter 35.

The gastrointestinal mucosa is a common site of toxicity associated with anticancer therapy. The subsequent inflammation (mucositis) can lead to painful ulcerations, local infection, and an inability to eat, drink, or swallow. Disruption of the gastrointestinal mucosal barrier may also provide an avenue for systemic microbial invasion. Anticancer agents most commonly associated with mucositis include FU, doxorubicin, methotrexate, multikinase inhibitors, and mTOR inhibitors. Currently, the most effective means of preventing mucositis is through good oral hygiene. Patients who are at high risk for this toxicity (those with poor dentition, high-dose chemotherapy, or radiation therapy involving the oropharynx) should be evaluated by a dentist before starting therapy and should be instructed to rinse their mouths frequently with baking soda and salt water or plain saline rinses during therapy. Clinical practice guidelines for the prevention and treatment of anticancer therapy-induced mucositis are available.

A better understanding of the pathophysiology of mucositis has resulted in identification of promising new agents that may minimize the risk of developing mucositis. The keratinocyte growth factor palifermin is approved for use in patients receiving myelotoxic therapy before hematopoietic stem cell transplantation. Palifermin is administered at a dose of 60 mcg/kg/day intravenously for 3 consecutive days immediately before the initiation of conditioning therapy and then again for 3 days after hematopoietic stem cell transplantation. The effect of palifermin on solid tumor growth is unknown, and its use in nonhematologic cancers is not recommended.

After mucositis has developed, treatment is mainly supportive, including use of topical or systemic analgesics and oral hygiene. Numerous formulations of “magic mouthwash” are commercially

available or compounded and often include viscous lidocaine, diphenhydramine, and Maalox. These mouthwashes are commonly used in clinical practice, but data is currently lacking to support their use. Severe cases of mucositis may lead to dehydration and require intravenous hydration and opioid analgesics. Local infections caused by Candida species and HSV are common in these patients. Suspicious lesions should be cultured and appropriate antifungal or antiviral treatment should then be initiated. Antifungal therapy may be delivered topically for mild infections (thrush) with clotrimazole troches or nystatin oral suspension. For more severe oral or esophageal fungal infections, systemic treatment with oral or intravenous antifungals is indicated.

Mucosal damage can occur at any point along the entire length of the gastrointestinal tract. In the lower portion of the gastrointestinal tract, this damage is usually manifested as diarrhea (mild to life threatening) and abdominal pain. Intravenous fluids and electrolyte supplementation should be initiated promptly in severe cases. After infectious causes have been ruled out, diarrhea can safely be treated with agents such as diphenoxylate/atropine or loperamide. The somatostatin analog octreotide has also been used successfully to treat severe cases of chemotherapy-induced diarrhea; guidelines are available to assist health professionals in treating chemotherapy-induced diarrhea. It is important to note that patients receiving immunotherapy may experience diarrhea that is immune-mediated and corticosteroids should be administered in severe cases.

Dermatologic

Chemotherapy-induced cutaneous reactions are generally reversible and self-limiting upon dose reductions or delays. Common reactions include localized rash, photosensitivity, skin hyper- or hypopigmentation, nail changes, and HFSR or hand-foot syndrome.

Alopecia

Many patients find alopecia to be one of the most distressing toxicities associated with anticancer therapy. Alopecia from chemotherapy is usually temporary and the degree of hair loss varies widely. Hair loss is not limited to the scalp; any area of the body may be affected. Patients receiving a taxane as part of their chemotherapy regimen are especially prone to total body alopecia. Hair loss usually begins 1 to 2 weeks after chemotherapy and regrowth may begin before completing treatment. Cryotherapy (local application of ice) and scalp tourniquets have both been investigated as methods of preventing alopecia. Both techniques produce vasoconstriction, resulting in decreased exposure of hair follicles to the chemotherapy. These techniques are not uniformly effective and are contraindicated in patients with cancer whose cancer can metastasize to the scalp, such as leukemia and lymphoma.

In addition to alopecia, other hair changes may occur that may be distressing to patients. Notably, some kinase inhibitors (such as pazopanib) have been associated with hair depigmentation. This loss of pigmentation (white color) is thought to be the result of the inhibition of KIT signaling which decreases melatonin synthesis.

Extravasation

Vesicants are agents that may cause severe tissue damage if they escape from the vasculature.[94] These agents include the anthracyclines, the vinca alkaloids, the taxanes, and others. The anthracyclines are the most notorious agents and the most extensively investigated. The tissue damage may result in prolonged pain, tissue sloughing, infection, and loss of mobility. Prompt initiation of the appropriate interventions is important to minimize morbidity. Unfortunately, most information on extravasation management is anecdotal and few controlled clinical trials have been conducted to determine optimal intervention strategies. Consequently, prevention is the focus of extravasation management. The most important method of prevention is good administration technique, but extravasations may occur despite optimal administration.[94] The vein selected for administration should be on the distal portion of the arm. The large veins of the forearm are desirable because if a drug does extravasate, there is adequate soft tissue coverage to protect crucial structures such as nerves and tendons and joint function is not put at risk. The healthcare provider administering the vesicant should verify needle stability and adequate blood return regularly throughout the administration. A central venous catheter is highly recommended for the intravenous infusion of vesicants of longer duration. For extravasation of anthracyclines, antitumor antibiotics, and alkylating agents, apply ice packs to the affected area. Only a few antidotes to vesicant agents are used clinically. Topical dimethyl sulfoxide (DMSO) or intravenous dexrazoxane are recommended as antidotes for anthracycline extravasation. Topical DMSO may also be given for mitomycin C extravasation. Dry, warm compresses and hyaluronidase are recommended for the extravasation of vinca alkaloids and taxanes. Clinical practice guidelines for the management of extravasation are available.[96]

HFSR and Hand-Foot Syndrome

Although the terms HFSR and hand-foot syndrome are commonly interchanged, it is important to note that these adverse reactions are distinct in both cause and presentation. HFSR is associated with multikinase inhibitors and characteristically localizes to areas of pressure or friction on the hands and feet. Hand-foot syndrome, also known as palmar-plantar erythrodysesthesia, is associated with chemotherapy including FU, capecitabine, and liposomal doxorubicin. Hand-foot syndrome typically presents with diffuse edema and redness on the palms and soles of the feet. Both HFSR and hand–foot syndrome can be uncomfortable and interfere with daily activities. Topical moisturizers may aid in prevention. Urea cream, topical steroids, and pain medication (such as gabapentin or NSAID) may be beneficial for treatment.

Rash

Rash has been observed with some targeted drugs. For example, rash is one of the most common toxicities associated with therapy that inhibits EGFR signaling pathways. Some studies suggest that the rash may be a surrogate marker of response to these agents. Therefore, extensive patient counseling is required to prevent drug discontinuation. Patients should also be instructed to prophylactically apply sunscreen and avoid alcohol-containing skin products. Rash occurs in up to two-thirds of patients taking EGFR inhibitors, most commonly in the first month of treatment with the typical site of presentation being the face and upper torso. Anecdotal reports indicate that emollients help if patients present with dry skin, topical and systemic antibiotics may help if the rash becomes

infected, and steroids may help prevent itching and inflammation.

Endocrine

Blood Glucose Dysregulation

Both hyper- and hypoglycemia have been reported with numerous targeted drugs. Hyperglycemia is most commonly associated with mTOR inhibitors. Fasting blood glucose and hemoglobin A1C should be monitored closely especially in diabetic patients. Standard guidelines should be used to adjust anti-diabetic medications as necessary. Hypoglycemia has been commonly reported with multikinase inhibitors and bexarotene. Fasting blood glucose should be closely monitored and doses of anti-diabetic medications reduced as required.

Hypothyroidism

Hypothyroidism is a common adverse event that is seen with multikinase inhibitors. Thyroid stimulating hormone (TSH) and free T4 should be measured at baseline and periodically throughout treatment. Most symptoms are mild and can be reversed with thyroid supplementation. Bexarotene has also been associated with hypothyroidism. It rapidly suppresses TSH levels and affects thyroid hormone metabolism. Free T4 levels should be monitored closely and supplementation is usually required.

Miscellaneous

Numerous other toxicities are seen with both targeted drugs and chemotherapy agents and many of these are discussed in other chapters. A few common toxicities including hypertension and ocular toxicities are discussed here.

Hypertension

Many anticancer agents, especially those that inhibit the VEGF signaling pathway, are associated with hypertension. Although the exact mechanism has yet to be established, it is thought that VEGF inhibition leads to a decrease in nitric oxide and prostacyclin production, resulting in an increase in vascular resistance and blood pressure.[97] Prior to treatment initiation, blood pressure should be well-controlled according to standard guidelines. If hypertension develops, antihypertensive therapy should be initiated or adjusted. Anticancer treatment should be held with persistent or severe hypertension.

Ocular

A broad spectrum of ocular toxicities is seen with both targeted and chemotherapy agents. Common ocular toxicities seen with a variety of anticancer agents include blurred vision, photophobia, conjunctivitis, cataracts, abnormal lacrimation, dry eye, keratitis, optic neuropathy, and retinopathy.

The ALK inhibitor, crizotinib, has been associated with common complaints of visual disturbances

including blurred vision, photophobia, and vitreous floaters, among others. Although common, the ocular effects associated with crizotinib are usually self-limiting and have a minimal impact on daily activities.

It is well documented that high-dose cytarabine can cause reversible corneal toxicity. This ocular toxicity is thought to be due to the high concentration of cytarabine in tears. Ophthalmic corticosteroids or saline are recommended to prevent this toxicity. Other ocular toxicities that are associated with anticancer agents include the following: cataracts with anastrozole and tamoxifen; uveitis and retinal vein occlusion with vemurafenib; and cortical blindness with vincristine.

Thrombosis

Patients with cancer have a relatively high risk of developing a venous thromboembolism. The factors that may affect a patient's risk of developing a thromboembolism include the specific cancer (ie, lung cancer, pancreatic cancer, gastric cancer), tumor burden, anticancer treatment (ie, antiangiogenic agents and endocrine therapies) and surgical interventions. Other risk factors might include familial thrombophilia, previous venous thromboembolism, immobilization, age and indwelling catheters. Thromboembolism increases morbidity and mortality, with thromboembolic events a leading cause of death in patients with cancer.

Routine primary prophylaxis is not recommended for most patients, but it should be considered for patients undergoing major surgery or for immobilized hospitalized patients. Unfractionated heparin or a low molecular weight heparin is recommended for patients undergoing major surgery. As an example, enoxaparin or dalteparin may be administered subcutaneously daily for up to one month post-surgery. Unfractionated or low molecular weight heparin or fondaparinux is recommended for immobilized patients with cancer (ie, hospitalization). As discussed earlier in the chapter, thromboprophylaxis is recommended with thalidomide and its analogues.

For patients who develop a venous thromboembolism, treatment goals include preventing a pulmonary embolus, recurrent venous thromboembolism and long-term complications. The American College for Chest Physicians recommend treatment with a low molecular weight heparin.[99] For patients with severe renal impairment, anti-Xa activity monitoring or unfractionated heparin is recommended and dose modifications may be necessary. Treatment with oral vitamin K antagonists, such as warfarin, or other oral anticoagulants are not currently recommended as first-line treatment. The optimal duration of antithrombotic therapy for the prevention of recurrence has not been specifically studied and is often determined based on patient-specific factors including the underlying disease and anticancer treatment. Treatment duration may be a minimum of 3 to 6 months or indefinite.

Survivorship

Advances in the treatment of some cancers, such as Hodgkin lymphoma and testicular cancer, have produced long-term survivors and the opportunity to examine the late consequences of chemotherapy. Survivors should be assessed for long-term psychosocial and physical effects and survivorship guidelines are available for health professionals through the NCCN.[99] Infertility and

secondary cancers have emerged as important late effects.

Infertility

The gonadal toxicities of chemotherapy have not received much attention in the past because they are not life threatening. High rates of fertility deficits and sexual dysfunction have been noted for both men and women. In men, chemotherapy can produce severe oligospermia or azoospermia, as well as infertility. Serum testosterone levels are rarely altered. The recovery of spermatogenesis after completing therapy is unpredictable. Men receiving combination chemotherapy appear to sustain more long-lasting toxicities on fertility than do men receiving single-agent chemotherapy. Age, total dose, duration of therapy, and the chemotherapy mechanism are other important variables. In women, toxic effects on the ovaries result clinically in amenorrhea, vaginal epithelial atrophy, and menopausal symptoms. These effects are related to dose and age. Younger patients are more resistant to the effects on the ovaries. As with men, the recovery of fertility is unpredictable, but women younger than 25 years of age appear to have the best outcomes. The effects of the alkylating agents on fertility have been extensively studied. These agents exert profound and consistently detrimental effects on reproductive function. The impact of this drug-induced amenorrhea on patient survival has been less clear with some trials demonstrating a benefit to patients who achieve chemotherapy-induced amenorrhea. Trial results have been mixed, however, and conclusive statements cannot be made at this time. Less is known about commonly used agents such as doxorubicin, taxanes, and platinum compounds. The risk of infertility should be discussed with all patients before they receive anticancer agents, and they should be informed about options for fertility preservation.

Secondary Malignancies

Secondary cancers induced by chemotherapy and radiation are serious long-term complications.[100] Some targeted drugs may also be associated with development of secondary cancers. Although many solid tumors have been reported as chemotherapy-induced malignancies, AML and MDS are the most common secondary cancers and have been reported after successful treatment of Hodgkin lymphoma and NHL, acute leukemias, multiple myeloma, breast cancer, and advanced ovarian cancer. For curable cancers, the relatively small risk for occurrence of secondary malignancies is far outweighed by the benefits of survival in large numbers of patients. The issue of secondary malignancies is of particular concern in patients receiving adjuvant chemotherapy. As with the late complication of infertility, the anticancer agents primarily associated with secondary cancers are the alkylating agents. Etoposide, teniposide, radioimmunoconjugates, and the anthracyclines also are linked to secondary leukemias. Solid tumors as secondary malignancies occur more commonly after treatment with radiation than with chemotherapy.

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

6-MP	6-mercaptopurine

ADCC	antibody-dependent cell-mediated cytotoxicity
AFP	alpha-fetoprotein
AI	aromatase inhibitor
ALL	acute lymphoblastic leukemia
ALK	anaplastic lymphoma kinase
AML	acute myeloid leukemia
ANC	absolute neutrophil count
APA	antiproduct antibodies
APC	adenomatous polyposis coli
APL	acute promyelocytic leukemia
ATP	adenosine triphosphate
BCNU	carmustine
BCL-2	B-cell lymphoma 2
BCR	B-cell receptor
BCR-ABL	breakpoint cluster region-Abelson
BSA	body surface area
BTK	Bruton's tyrosine kinase
CCNU	lomustine
CD	cluster of differentiation
CDC	complement-dependent cytotoxicity
CDK	cyclin-dependent kinase
CLL	chronic lymphocytic leukemia
CML	chronic myeloid leukemia
CNS	central nervous system
CPIC	Clinical Pharmacogenetics Implementation Consortium
CR	complete response
CSF	colony-stimulating factor
CTCAE	Common Terminology Criteria for Adverse Events
CTLA-4	cytotoxic T-lymphocyte antigen 4
DCC	deleted in colorectal cancer
DHFR	dihydrofolate reductase
DM1	derivative of maytansine 1
DMSO	dimethyl sulfoxide
DNA	deoxyribonucleic acid
DNMT	DNA methyltransferase
DPD	dihydropyrimidine dehydrogenase
EBV	Epstein-Barr virus

ECG	electrocardiograph
ECOG	Eastern cooperative oncology group
EGFR	epidermal growth factor receptor
EML4	echinoderm microtubule-like protein 4
ER	estrogen receptor
ErbB	erythroblastic leukemia viral oncogene
ERK	extracellular signal-regulated kinase
FDA	Food and Drug Administration
FGFR	fibroblast growth factor receptor
FKBP-12	12-kDa FK506-binding protein
FU	fluorouracil
GFR	glomerular filtration rate
GIST	gastrointestinal stromal tumor
GM-CSF	granulocyte-macrophage colony stimulating factor
HBV	hepatitis B virus
hCG	human chorionic gonadotropin
HDAC	histone deacetylase
HER2	human epidermal growth factor receptor 2
HFSR	hand-foot skin reaction
HHV	human herpes virus
HIV	human immunodeficiency virus
HPV	human papilloma virus
HSV	herpes simplex virus
IL	interleukin
IFN	interferon
IGF-1R	insulin-like growth factor 1 receptor
irRC	immune-related response criteria
irRECIST	immune-related RECIST
ISO	International Organization for Standardization
JAK	Janus kinase
JAK-STAT	Janus kinase–signal transducers and activators of transcription
mAb	monoclonal antibody
MAPK	mitogen-activated protein kinase
MCD	multicentric Castleman's Disease
MCL	mantle cell lymphoma
MDS	myelodysplastic syndrome
MEK	mitogen-activated protein kinase- extracellular signal-regulated kinase

MMAE	monomethylauristatin E
mRECIST	modified RECIST
MTIC	monomethyl triazeno-imidazole-carboxamide
mTOR	mammalian target of rapamycin
NCCN	National Comprehensive Cancer Network
NCI	National Cancer Institute
NSAID	nonsteroidal anti-inflammatory drug
NSCLC	nonsmall cell lung cancer
NF-κB	nuclear factor-κB
NHL	non-Hodgkin lymphoma
Pap	Papanicolaou
PAP	prostate acid phosphatase
PARP	poly ADP ribose polymerase
PD-1	programmed death-1
PD-L1	programmed death ligand-1
PDGF	platelet-derived growth factor
PDGFR	platelet-derived growth factor receptor
Pgp	p-glycoprotein
Ph^+	Philadelphia chromosome-positive
PI3K	phosphatidylinositide 3-kinases
PML	progressive multifocal leukoencephalopathy
PR	partial response
pRb	retinoblastoma protein
PSA	prostate-specific antigen
PTEN	phosphatase and tensin homolog
RANK	receptor activator of nuclear factor kappa-B
RANKL	receptor activator of nuclear factor kappa-B ligand
RAR	retinoic acid receptor
Rb	retinoblastoma
RECIST	response evaluation criteria in solid tumors
REMS	risk evaluation and mitigation strategy
RET	rearranged during transfection
RNA	ribonucleic acid
RXR	retinoid X receptor
SERM	selective estrogen receptor modulator
SMO	smoothened
STAT	signal transducers and activators of transcription

T-VEC	talimogene laherparepvec
TNF-α	tumor necrosis factor-alpha
TPMT	thiopurine methyltransferase
TSC	tubular sclerosis complex
TSH	thyroid stimulating hormone
VEGF	vascular endothelial growth factor
VEGFR	vascular endothelial growth factor receptor

Chapter 128: Breast Cancer

Chad M. Barnett; Bonnie Lin Boster; Laura Boehnke Michaud

INTRODUCTION

KEY CONCEPTS

- 1 Breast cancer is usually diagnosed in the early stages when it is a highly curable malignancy.
- 2 Although controversial, regular screening mammography in women younger than 50 years of age is beneficial, and many national and international studies demonstrate a reduction in the breast cancer mortality rate from annual or biennial screening mammography in women ages 50 to 74 years.
- 3 Local therapy of early-stage breast cancer consists of modified radical mastectomy or lumpectomy plus external-beam radiation therapy. The surgical approach to the ipsilateral axilla may consist of a lymph node mapping procedure with sentinel lymph node biopsy or a full level I/II axillary lymph node dissection.
- 4 Adjuvant endocrine therapy reduces the rates of relapse and death in patients with hormone receptor–positive early breast cancer. Adjuvant chemotherapy reduces the rates of relapse and death in all patients with early-stage breast cancer.
- 5 The choice of the most appropriate chemotherapy, endocrine therapy, and anti-*HER2* therapy regimen is complex and rapidly changing as results from ongoing randomized clinical trials are reported.
- 6 Neoadjuvant chemotherapy and biotherapy are appropriate for selected patients with early breast cancer and most patients with locally advanced breast cancer and inflammatory breast cancer followed by local therapy and further adjuvant systemic therapy as indicated.
- 7 Whereas the goal of adjuvant and neoadjuvant chemotherapy is curative, the goal of chemotherapy in the metastatic setting is palliative.
- 8 Anti-*HER2* therapies and other biologic or targeted agents (eg, everolimus, palbociclib) in

combination with chemotherapy or endocrine therapy have significantly improved outcomes for selected patients with metastatic breast cancer (MBC).

- 9 Initial therapy of metastatic breast cancer in most women with hormone receptor–positive tumors should include endocrine therapy.

- 10 About 60% of women with metastatic breast cancer will respond to chemotherapy regimens; anthracycline- and taxane-containing regimens are the most active.

Breast cancer is the most common site of cancer and is second only to lung cancer as a cause of cancer death in American women. It was estimated that 249,260 new cases of breast cancer will be diagnosed and that 40,890 people will die of breast cancer in 2016.[1] In addition to invasive breast cancers, it was estimated that 61,000 cases of noninvasive, or in situ, cancer will be diagnosed among women in the United States in 2016.[1]

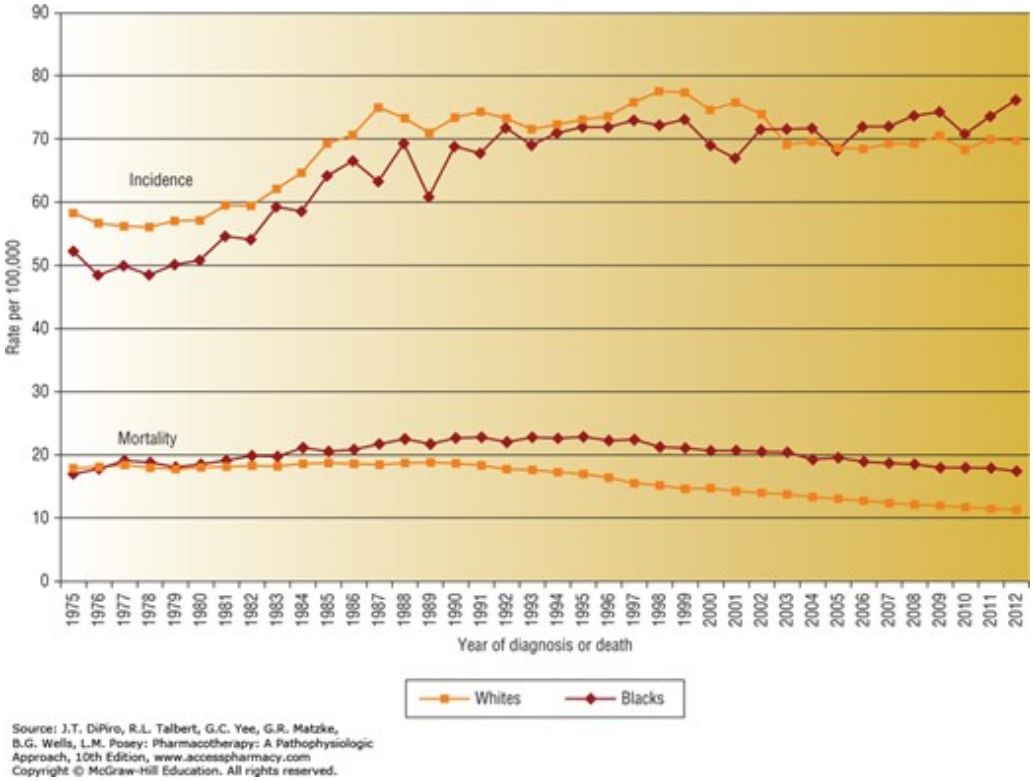
Female breast cancer incidence rates have increased for all women combined since 1980, although the rate of increase slowed in the 1990s and has decreased starting in 2000 after peaking in 1999. The decrease in breast cancer incidence of about 7% from 2002 to 2003 is thought to be related to decreased use of menopausal hormone therapy, also known as hormone replacement therapy (HRT), in postmenopausal women.[2] Incidence rates were stable from 2007 to 2011. The incidence of DCIS also increased rapidly between the early and late 1980s and continues to increase. The increase in DCIS is largely attributed to an increased use of screening mammography because most cases of DCIS manifest solely as clustered microcalcifications seen on mammography.[2]

Female breast cancer incidence rates vary considerably across racial and ethnic groups. The average annual age-adjusted incidence rate from 2008 to 2012 was 128.1 cases per 100,000 among whites, 124.3 cases among African Americans, 91.9 cases in Hispanics, 91.9 cases in American Indians and Alaska Natives, and 88.3 cases among Asian Americans and Pacific Islanders.[1] Reasons for the higher incidence rates in whites than in other racial and ethnic groups may include differences in reproductive and lifestyle factors and access to and use of screening.

1 For all racial and ethnic groups, most breast cancers are diagnosed at an early stage when tumors are small and localized. However, a higher proportion of disease is diagnosed at more advanced stages in African American and other minority women than in white women. The death rate is also higher among African American women than white women despite the lower incidence. From 2008 to 2012, the breast cancer death rate was highest in African Americans (31.0 cases per 100,000 women) followed by whites (21.9), American Indians and Alaska Natives (15.0), Hispanics (14.5), and Asian Americans and Pacific Islanders (11.4).[1] The cause of this disparity between white and African American women is widely debated and multifactorial, with possible explanations including access to care, socioeconomic status, cultural differences, higher stage at diagnosis, and more aggressive biologic features. Despite these differences, overall mortality rates from breast cancer in the United States have declined since 1990. These declines have been attributed to improvements in early detection and in treatment.[1] **Figure 128-1** shows the temporal trends in incidence and mortality by race.

FIGURE 128-1

Breast cancer incidence and mortality rates by race, 1975 to 2009. *(Data from Howlader N, Noone AM, Krapcho M, et al. SEER Cancer Statistics Review, 1975-2012, National Cancer Institute. Bethesda, MD, http://seer.cancer.gov/csr/1975_2012/, based on November 2014 SEER data submission, posted to the SEER web site, April 2015.)*



The median age at diagnosis for breast cancer is 61 years of age.[3] Although lung cancer is the leading cause of cancer deaths for women regardless of age, breast cancer is the leading cause of cancer deaths for females between the ages of 20 and 59 years.[1]

EPIDEMIOLOGY AND ETIOLOGY

The two variables most strongly associated with the occurrence of breast cancer are gender and age. Although one commonly thinks of breast cancer as a disease confined to women, about 2,600 cases of male breast cancer were estimated to be diagnosed in the United States in 2016.[1] Male gender had been considered a poor prognostic factor in some investigations, but it is now believed that higher mortality rates in men are attributable to more advanced disease at the time of diagnosis. When stage and other known prognostic factors are controlled for, the clinical outcome for men with breast cancer is comparable to that of women.[4] Treatment of breast cancer in men is similar to treatment of breast cancer in women.

The incidence of breast cancer increases with advancing age. A frequently quoted breast cancer statistic is that one in eight women will develop breast cancer during her lifetime. It should be emphasized that this is a cumulative lifetime risk of developing the disease from birth to death. The

one-in-eight women figure is often misinterpreted by women who assume that it translates into one in eight women being diagnosed with breast cancer each year. A more useful method of presenting the risk data is based on age intervals.[5] **Table 128-1** shows that the risk of a woman developing breast cancer before the age of 50 years is about one in 53, and more than half the risk occurs after age 60 years.

TABLE 128-1 Risk of Developing Breast Cancer, Women, All Races, 2009-2011

Age Interval	Probability (%) of Developing Invasive Breast Cancer During the Interval
Birth-49 y	1.9 or 1 in 53
50-59 y	2.3 or 1 in 44
60-69 y	3.5 or 1 in 29
70 y and older	6.7 or 1 in 15
From birth to death	12.3 or 1 in 8

Data from reference 2.

An understanding of the relationship between age and the incidence of breast cancer is particularly relevant when one discusses "risk factors" or factors other than age that increase a woman's probability of developing breast cancer. The RR of developing breast cancer for an individual woman in a defined risk group is usually multiplied by the probability of a woman developing breast cancer during her lifetime, and this figure is taken as the cumulative lifetime risk of that individual developing breast cancer. However, the risk of developing breast cancer depends on age. Therefore, a more meaningful way to counsel patients regarding their risk of developing breast cancer based on the presence of a known risk factor incorporates an age-specific incidence rate, not cumulative lifetime risk. For example, if a 40-year-old woman with a strong family history of breast cancer has a RR ratio of 2.0, her risk of developing breast cancer by the age of 50 years is only 4.6% (2 × 2.3), not 24.6% (2 × 12.3) (Table 128-1). It is also important to note that recognized risk factors are not additive in a simple mathematical sense. Finally, most women with breast cancer have no identifiable major risk factor, indicating that the search for the etiology of this disease is largely incomplete.

A number of calculators are available to estimate a patient's risk of developing breast cancer. The National Cancer Institute (NCI) has an online version of the Breast Cancer Risk Assessment Tool (*www.cancer.gov/bcrisktool/Default.aspx*). This tool is based on a statistical model known as the Gail model, derived from data from the Breast Cancer Detection and Demonstration Project, a mammography screening project conducted in the 1970s. The Breast Cancer Risk Assessment Tool was designed for healthcare professionals to project a woman's individualized risk for invasive breast cancer over a 5-year period and over her lifetime. This model has been shown to provide accurate estimates in white women, but it has not been validated for other racial and ethnic groups and other subgroups, including those with genetic risk factors. Other risk assessment models also exist, each taking into account different risk factors. Gail and colleagues have developed a similar model for assessing the risk of developing breast cancer in African American women.[6] These empiric models may not be as useful for women with a history suggestive of hereditary breast cancer. Thus, no one model is appropriate for every patient.

Endocrine Factors

A number of endocrine factors have been linked to the incidence of breast cancer.[7,8] Many of these relate to the total duration of menstrual life. Early menarche, generally defined as menstruation beginning before age 12 years, increases the cumulative lifetime risk of breast cancer development. Similarly, a late age of natural menopause (age 55 years or later) increases the risk of breast cancer development, although to a lesser degree than early menarche.[7] Conversely, bilateral oophorectomy before age 40 years reduces the risk of developing breast cancer.

Nulliparity and a late age at first birth (greater than or equal to 30 years) are reported to increase the lifetime risk of developing breast cancer. It is suggested that the period between the onset of menses and the age of first pregnancy provides a "window of initiation" for the development of breast cancer. This is a time when an unbalanced hormonal environment reacts with the abundant and highly responsive breast tissue. Investigators postulate that international differences in age of menarche, age at menopause, and childbearing may account for a substantial part of the international differences in the incidence of breast cancer.

Many studies have evaluated the relationship between exogenous hormones and the development of breast cancer. Postmenopausal HRT has been the subject of several epidemiologic studies and meta-analyses, with conflicting results. The NCI–funded Women's Health Initiative (WHI) is a series of clinical trials designed to investigate the risks and benefits of treatment strategies that could affect women's health issues, such as breast cancer. The estrogen plus progestin trial randomized more than 16,000 postmenopausal women to take conjugated equine estrogen combined with medroxyprogesterone or a placebo.[9] This study reported an increased risk of breast cancer (38 vs 30 cases per 10,000 person-years; RR ratio = 1.26; 95%; CI, 1.00–1.59) in women taking combined estrogen and progestin for an average of 5.2 years compared with those receiving placebo. Analysis of the NCI's Surveillance, Epidemiology, and End Results (SEER) registries showed that the age-adjusted incidence rate of breast cancer in women in the United States in 2003 fell by 6.7% compared with 2002.[10] This decrease in breast cancer incidence seems to be temporally associated with the first report of the WHI study and subsequent decrease in estrogen and progestin HRT use among postmenopausal women. Additional follow-up of patients in this trial confirms a decrease in breast cancer incidence after cessation of estrogen and progestin.[11] In the estrogen alone trial, more than 10,000 women who had a hysterectomy and therefore did not require progestin therapy because of a decreased risk of endometrial carcinoma were randomized to estrogen alone or placebo.[12] The risk of breast cancer was not increased in women who received estrogen alone compared with those who received placebo. With additional follow-up, the incidence of breast cancer in women in this study was actually lower in patients who received estrogen compared with those who received placebo.[13] However, the authors concluded that estrogen alone may not reduce the incidence of breast cancer in patients at increased risk and therefore should not be used specifically for breast cancer risk reduction. Unresolved issues remain as to whether lower doses or short-term use of estrogen or estrogen–progestin for menopausal symptoms can be safe and effective. A longer duration of HRT and concurrent use of progestins appear to contribute to breast cancer risk. In addition, the impact of HRT use on breast cancer risk also varies according to race, body mass index

(BMI), and breast density.[14] The use of postmenopausal HRT in women with a history of breast cancer is generally contraindicated. Women who are considering HRT should carefully consider the risks versus benefits (see Chapter 82).

Epidemiologic studies of oral contraceptives do not show a consistent relationship between use of birth control pills and breast cancer risk. Results are conflicting, and assessment of the studies should consider the particular oral contraceptive products involved, daily and cumulative doses of the hormones administered, and latency period for development of breast cancer. A meta-analysis of 13 prospective cohort studies conducted between the years of 1989 and 2010 reported a nonsignificant increase in breast cancer incidence for patients who used oral contraceptives compared with those who had never used oral contraceptives.[15] Newer formulations of oral contraceptives contain lower hormone concentrations, and the authors of this meta-analysis were not able to differentiate breast cancer risk based on the formulations of oral contraceptives. It is also important to note that oral contraceptives are known to reduce the risk of ovarian and endometrial cancers. Most experts believe that the safety and benefits of low-dose oral contraceptives currently outweigh the potential risks.

Genetic Factors

Both personal and family histories influence a woman's risk of developing breast cancer. A personal history of breast cancer is associated with an increased risk of developing contralateral breast cancer. Cancers of the uterus and ovary are also associated with an increased risk of developing breast cancer. A number of cancer family syndromes include breast cancer in association with other types of cancers.

Many women have "lumpy breasts" or have a clinical diagnosis of fibrocystic breast disease or benign breast disease. Nonproliferative lesions, such as cysts or simple fibroadenomas, do not increase the risk of breast cancer. Proliferative lesions without atypia, such as intraductal papillomatosis, are associated with a mildly elevated breast cancer risk of about 1.5 to 2.0 times that of the general population. Atypical hyperplasias are classified as either ductal or lobular units, and these lesions may increase a woman's risk for breast cancer to about 4.0 times that of the general population.[16]

Dense breast tissue reduces the sensitivity of mammography in detecting breast cancer and is associated with an increased risk of breast cancer. The risk of breast cancer in women with dense breasts (defined by mammography) has been estimated to be between four to five times that of women of the same age with little density.[17] Many variables, including age, BMI, menopausal status, HRT, parity, and the ratio of fibroglandular to fatty tissue, can influence mammographic breast density. This ratio can be expressed as the percentage dense area and the absolute dense area, both of which are risk factors for breast cancer.[17] Genetic factors may also play a role in this finding because mammographic breast density has been shown to have high heritability and is also strongly associated with a positive family history of breast cancer.

The percentage of all breast cancers in the U.S. population that can be attributed to family history is about 10%. Empirical estimates of the risks associated with particular patterns of family history of breast cancer indicate the following:[18]

1. Having any first-degree relative with breast cancer increases a woman's risk of breast cancer about 1.5- to 3-fold. Risk increases with increasing numbers of affected first-degree relatives.

2. The risk is affected by both a woman's own age and the age of the relative when diagnosed. A higher risk is seen when a woman and her relative at diagnosis are younger than 50 years.

3. The risk associated with having any second-degree relative with breast cancer is complex and depends on other family history patterns. However, the risk is generally lower than that of first-degree relatives.

4. Affected family members on both the maternal and the paternal sides are important to consider in evaluation of risk.

Although women with a family history of breast cancer are at increased risk for the disease, the diagnosis of breast cancer is still uncommon in young women even with a positive family history.

Germ-line mutations in either *BRCA1* or *BRCA2* are associated with an increased risk for breast and ovarian cancer. These genes function as tumor suppressor genes, maintaining genomic integrity and DNA repair. Compared with an average woman's 13% lifetime risk of developing breast cancer, the probability of developing breast or ovarian cancer by the age of 70 years in women with a *BRCA1* or *BRCA2* mutation is estimated to be 57% and 49% for breast cancer and 40% and 18% for ovarian cancer, respectively.[19]

The probability of being a *BRCA* gene mutation carrier is related to ethnicity and family history. Jewish people of Eastern European decent (Ashkenazi Jews) have an unusually high (2.1%) carrier rate of germ-line mutations in *BRCA1* and *BRCA2* compared with the rest of the U.S. population. Conversely, it is estimated that clinically significant *BRCA* mutations occur at a frequency of about one in 300 to 500 persons in the general, non-Jewish U.S. population.[20] Testing for *BRCA1* and *BRCA2* mutations is now widely available, but testing is generally recommended only when there is personal or family history suggestive of hereditary cancer, when the test results can be adequately interpreted, and when results will assist with diagnosis and management. The decision to test an individual for a genetic mutation related to breast cancer risk is complex, and several organizations have published recommendations on genetic susceptibility testing for individuals who meet the criteria for increased risk.[20,21,22]

Although most genetic causes of breast cancer are attributed to *BRCA1* and *BRCA2,* other genes that have been identified as being associated with hereditary breast cancer include *TP53*, *CHEK2*, *PALB2*, *PTEN*, *ATM*, and others.[23]

Environmental and Lifestyle Factors

Breast cancer incidence rates vary considerably among countries, which suggests that environmental and lifestyle factors play an important role in the etiology. Compelling evidence is derived from studies of Asian women who migrated to the United States. Although the incidence of breast cancer in Asian women is quite low, the incidence of breast cancer in Asian women who were born in the

United States or who migrated from Asia to the United States gradually increases over the individual's lifetime to equal that of the white population in the same geographic area.[24]

Diet is an important and modifiable environmental risk factor. Possible relationships between fat intake and steroid hormone metabolism have led to an emphasis on dietary fat as a possible etiologic agent for breast cancer. Epidemiologic data show a positive correlation between higher dietary fat intake and breast cancer risk, which is stronger in postmenopausal than in premenopausal women. In a meta-analysis of 31 case-control and 14 cohort studies on dietary fat and breast cancer, Boyd et al. reported a small but significant RR ratio of 1.13 (95% CI, 1.03-1.25) when comparing the highest and lowest fat intake categories.[25] To confirm this association prospectively, the hypothesis that low dietary fat intake reduces breast cancer risk was further tested in the WHI Randomized Controlled Dietary Modification Trial.[26] More than 48,000 postmenopausal women were randomized to a dietary intervention that consisted of reducing total fat intake to 20% of energy and consuming at least five servings of fruits and vegetables daily and six servings of grains daily versus a comparison group without any dietary interventions. Over an 8-year mean follow-up period, the incidence of invasive breast cancer was not significantly different between the two groups (annualized incidence rate, 0.42% vs 0.45%; HR, 0.91; 95% CI, 0.83-1.01). Although there is still much to be learned about the effects of diet on the risk of developing breast cancer, a low-fat diet seems to be a reasonable approach to potentially reduce the risk of breast cancer.

An additional dietary factor to be explored in the breast cancer population includes food-derived heterocyclic amines, which are known carcinogens found commonly in cooked red meat or processed meat. Studies of red or processed meat ingestion and breast cancer incidence are inconsistent, and no association was reported in one meta-analysis.[27]

Many studies have also examined the association between breast cancer and intake of dietary fiber and micronutrients, including β-carotene, and vitamins A, C, and E. The relationship between vitamins and breast cancer is unclear. No consistent benefit of fruits or vegetable consumption and the risk of breast cancer has been demonstrated.[27]

Another dietary factor that deserves mention is the possible effect of phytoestrogens on breast cancer risk. Phytoestrogens are natural plant estrogens found in soybean products, seeds, berries, and nuts. The two most studied classes of dietary phytoestrogens are isoflavones and lignans; isoflavones are richer in Asian diets, and lignans are the main source of phytoestrogens in the Western diet.[28,29] Because these compounds exhibit weak estrogenic properties, some experts believe that they may function as relative antiestrogens by displacing natural estradiol. However, studies have also reported a potential stimulatory effect on breast tissue. A meta-analysis of observational studies that evaluated phytoestrogen use and the risk of breast cancer suggests that any potential associated risk reduction is modest and may be limited to postmenopausal patients.[28] Nonetheless, the effect of phytoestrogens on breast cancer is very controversial, and further research is needed.

Both body weight and height are associated with the incidence of breast cancer. Most studies of premenopausal women show either no relationship with body weight or slightly declining breast

cancer risks with increasing body weight. Most studies in postmenopausal women show increasing breast cancer risks with increasing body weight. Accordingly, a meta-analysis by Renehan et al. found that an increase in BMI was associated with an increase in the risk of breast cancer for postmenopausal women (RR, 1.12; 95% CI, 1.08-1.16; $P<0.0001$) but had the opposite effect in premenopausal women (RR, 0.92; 95% CI, 0.88-0.97; $P<0.001$).[30] An increase in circulating estrogen is postulated to be the most likely explanation for these results. Although height is not a modifiable risk factor, weight and body composition are modifiable and should be studied further. Maintaining a healthy weight and body composition appear to be beneficial and promote many different health benefits but requires further study in association with the incidence of breast cancer.

Many studies report an inverse association between physical activity and breast cancer risk.[31] A review of 7 cohort and 14 case-control studies suggests that the association is stronger for postmenopausal breast cancer than for premenopausal breast cancer. Exercise may provide modest protection against breast cancer, but the relationship is complex. Possible explanations include the effects of physical activity on menstrual characteristics (in premenopausal women), body size, weight, and serum hormone levels. Estrogen-related pathways or other metabolic hormones such as insulin and insulin-like growth factors may influence this relationship. Making healthy choices appears to be the best health advice for women.

Many epidemiologic studies have evaluated the relationship between alcohol and breast cancer. Studies indicate both a modest positive association between alcohol and breast cancer and a dose–response relationship.[32] The risk increases with consumption of alcohol in general regardless of the beverage type or woman's menopausal status. Although the exact mechanism is unknown, the most plausible biologic hypothesis relates to increased levels of estrogen or other reproductive steroid hormones caused by impaired liver function. Although a causal relationship between alcohol consumption and breast cancer has not been proven in a prospective trial, the weight of the available evidence suggests that a relationship (direct or indirect) may exist. Because alcohol consumption is a modifiable risk factor, use in moderation appears to be a sensible approach.

Radiation to the breast tissue is associated with an increased risk of breast cancer, particularly with exposure at a young age (less than 20 years), again suggesting that a "window of initiation" for breast cancer occurs at a relatively early age. Much of the knowledge about radiation-related breast cancer comes from epidemiologic studies of patients exposed to diagnostic or therapeutic radiation and of Japanese survivors of the atomic bombs.[33] Women treated with chest irradiation for Hodgkin lymphoma in childhood or adolescence and survivors of other childhood cancers (in which radiation is used as a mainstay of therapy) are among the populations at greater risk for secondary breast cancers. The risk increases linearly with radiation dose. Exposure to diagnostic x-rays, including annual screening mammography, does not impart a sufficient dose of radiation for clinical concern in the general population. However, the risk of breast cancer after radiation exposure even in low levels in those with genetic risk factors is unclear and is an ongoing area of research.

Tobacco smoke exposure has not been associated with an increased risk of breast cancer in the past. In recent years, some studies have found that heavy smoking in certain groups is linked to a higher risk, such as in women who started smoking before having their first child.[34] The 2014 US Surgeon

General's report on smoking concluded that there is "suggestive but not sufficient" evidence that smoking increases the risk of breast cancer.[35]

In conclusion, numerous studies have been performed to investigate potential causative factors in the etiology of breast cancer. Several endocrine, genetic, environmental, and lifestyle factors are associated with the development of breast cancer to varying degrees. Some factors are modifiable, but others are not. Additionally, the impact of individual risk factors may vary depending on other confounding variables such as age, family history, estrogen use, and menopausal status. Although epidemiologic studies provide a large body of the current evidence, they have their limitations, and results are varied. Meta-analyses summarize numerous study results, but heterogeneity of studies may limit the applicability of the evidence. Additional prospective, randomized controlled trials are needed to confirm the importance of factors that are associated with the risk of developing breast cancer.

PREVENTION AND EARLY DETECTION

Current efforts at breast cancer prevention are directed toward the identification and removal of risk factors often referred to as risk reduction strategies. Unfortunately, a number of risk factors associated with development of breast cancer, such as family history of breast cancer or personal history of breast or other gynecologic malignancies, cannot be modified. Isolation and cloning of breast cancer susceptibility genes now allow screening of women with histories suggestive of "breast cancer families" and identification of appropriate candidates for prophylactic bilateral mastectomies or bilateral salpingo-oophorectomy. These surgeries are considered for women who are at very high risk for the development of breast or ovarian cancer, particularly if the women's breasts are difficult to evaluate by both physical examination and mammography and if the women have persistent disabling fears that they will be diagnosed with cancer. Guidelines for the incorporation of surgical risk reduction strategies are largely based on genetics and other known risk factors for the development of breast (or ovarian) cancer.

In the last 20 years, there has been increasing interest in pharmacologic risk reduction for breast cancer. The drugs with the most clinical information as risk reduction agents for breast cancer are the selective estrogen receptor modulators (SERMs), tamoxifen and raloxifene. Tamoxifen is useful as an adjunct after treatment of primary breast cancer (see Adjuvant Endocrine Therapy section for details). In randomized trials of tamoxifen as an adjuvant treatment for breast cancer, women who received tamoxifen were also found to have a reduced incidence of contralateral primary breast carcinomas.[36] In a large, randomized, placebo-controlled study, the National Surgical Adjuvant Breast and Bowel Project (NSABP) demonstrated significant reductions in risk of invasive and noninvasive breast cancers with 5 years of tamoxifen therapy (20 mg/day) in women at high risk for developing the disease.[37] Although this study (also known as P-1) is controversial, other studies from around the world also have been reported that investigated the role of tamoxifen as a risk reduction strategy. A meta-analysis of these trials indicates a consistent benefit with tamoxifen in reducing the incidence of ER-positive breast cancers (48% reduction; 95% CI, 36%-58%; $P<0.0001$).[38] Tamoxifen has been repeatedly shown to be a relatively safe drug with an acceptable toxicity profile when used to treat patients with breast cancer. However, its estrogenic effects on the uterus and the coagulation system

increase the risk of serious adverse effects that may be critical for patients taking this agent as a risk reduction strategy. Toxicities associated with tamoxifen are described in the Adjuvant Endocrine Therapy section. Any decision to use tamoxifen for risk reduction should be made after a thorough discussion of the woman's risk of breast cancer, the potential benefits of tamoxifen, and the potential serious adverse events associated with tamoxifen.

A second trial has been reported that compared tamoxifen with raloxifene in high-risk postmenopausal women. The STAR (or P2) trial was published in 2006 and demonstrated a similar rate of invasive breast cancers with the two drugs.[39] However, the rates of noninvasive breast cancer were numerically higher in the raloxifene arm of the trial, although this difference did not reach statistical significance. In 2010, an updated analysis was published, reporting that raloxifene retained 76% of tamoxifen's effectiveness in preventing invasive breast cancer.[40] Rates of endometrial cancer and deep-vein thrombosis (DVT) were more frequent in the tamoxifen arm, but overall quality of life was similar between the two agents.[39] Based on these results, the Food and Drug Administration (FDA) approved raloxifene for breast cancer risk reduction in women at high risk of the disease.

After the STAR update, there has since been an update reviewing SERMs in the prevention of breast cancer. In this meta-analysis, all SERMs reduced the incidence of invasive ER-positive breast cancer not only during treatment but also for at least 5 years after completing therapy.[41] As with all preventive interventions, the risks and benefits need to be carefully considered for each woman.

A similar reduction in the incidence of contralateral primary breast cancers was demonstrated in the adjuvant clinical trials with the aromatase inhibitors (AIs), leading to the premise that AIs may also play a role in risk reduction of breast cancer.[42] Goss et al. published the first results of a randomized, placebo-controlled, phase III trial comparing exemestane with placebo for 5 years in high-risk postmenopausal women.[43] Eligibility criteria were similar to the P-1 and STAR trials, and this report represented a median follow-up period of only 35 months. Nonetheless, significant reductions were seen in the rates of invasive breast cancers with exemestane (HR, 0.35; 95% CI, 0.18-0.70; P=0.002). A second randomized, placebo-controlled, phase III trial by Cuzick et al. compared the AI anastrozole to placebo for5 years in high-risk postmenopausal women.[44] After a median follow up of 5 years, the anastrozole arm showed significant reductions in the rates of invasive breast cancers (HR, 0.50; 95% CI, 0.32-0.76; P=0.001). In both the Goss et al. and Cuzick et al. studies, adverse events were tolerable. Based on this data, AIs appear to be a reasonable option for breast cancer risk reduction. In this setting, AIs were not compared to SERMs although both classes of agents are options. The National Comprehensive Cancer Network (NCCN) has established guidelines for risk reduction strategies, including mastectomy, oophorectomy, and pharmacologic agents.[45] These guidelines are based on risk assessment tools such as the Gail, BRCAPRO, or Claus models as well as other established risk factors. Much of the guideline depends on a woman's preferences for intervention. The American Society of Clinical Oncology (ASCO) also has published recommendations guiding the use of pharmacologic agents for breast cancer risk reduction.[46] These guidelines are similar to the NCCN guidelines in that they recommend the use of tamoxifen, raloxifene, or exemestane for postmenopausal women at high risk (as defined by the Gail or other models) and tamoxifen for premenopausal women at high risk based on the woman's wishes. Although neither exemestane nor anastrozole is FDA approved for breast cancer risk reduction, ASCO and NCCN included AIs as

acceptable options for use in postmenopausal women.[45,46]

The rationale for early detection of breast cancer is based on the relationship between stage of breast cancer at diagnosis and the probability for cure. If all breast cancer cases could be detected at a very early stage of the disease (ie, small primary tumor and negative lymph nodes), then more patients theoretically could be cured of their disease. Screening guidelines for early detection of breast cancer in women at average risk have been developed by several organizations, including but not limited to the American Cancer Society (ACS), the United States Preventive Services Task Force (USPSTF), and the NCCN (See **Table 128-2**).[47,48,49] The ACS guidelines are most commonly cited. However, it is important to note that the expert panels developing these guidelines often differ in their approach and analysis of the available data, as is evident in the controversies that currently exist.

TABLE 128-2 Breast Cancer Screening Guidelines

Risk Category	ACS[1]	USPTF[2]	NCCN[3]
Average Risk			
BSE	Age ≥20 y: optional (discuss benefits and limitations)	Not recommended	Age ≥25 y: breast awareness
CBE	Evidence does not support	Insufficient evidence	Age ≥25-39 y: every 1-3 y Age ≥40 y: annually
Mammography	Age 40-44 y: opportunity annually Age 45-54 y: annually Age ≥55 y: biennially or opportunity annually (as long as in good health and at least 10 years life expectancy)	Age 40-50 y: individualized decision Age 50-74 y: biennial Age >75 y: insufficient evidence	Age ≥40 y: annually
High Risk[a,b]			
BSE	NA	NA	All ages: breast awareness
CBE	NA	NA	All ages: every 6-12 months
Mammography	Age ≥30 y: annually with MRI	NA	Prior RT or strong family history or genetic predisposition, age ≥25 y: annually (+ CBE)

Risk Category	ACS[1]	USPTF[2]	NCCN[3]
			All other categories: annually (+ CBE)
Breast MRI	Age ≥30 y: annually with mammogram	NA	Annually with mammogram + CBE for (a) prior RT, age ≥25 y; (b) lifetime risk >20%; (c) strong family history or genetic predisposition, age ≥25 y; (d) history of LCIS

ACS, American Cancer Society; BSE, breast self-examination; CBE, clinical breast examination by a healthcare professional; LCIS, lobular carcinoma in situ; MRI, magnetic resonance imaging; NA, not addressed; NCCN, National Comprehensive Cancer Network; RT, thoracic radiation therapy; USPTF, United States Preventive Task Force.

[a]High risk is defined by the ACS as women with (a) a known *BRCA1/2* gene mutation; (b) untested woman with first-degree relative with a known *BRCA1/2* gene mutation; (c) lifetime risk of breast cancer of 20%-25% or greater using a risk assessment tool based largely on family history; (d) radiation therapy to the chest between the ages of 10 and 30 years; (e) LiFraumeni syndrome, Cowden syndrome, or Bannayan-Riley-Ruvalcaba syndrome or have first-degree relatives with one of these syndromes. [b]High risk is defined by the NCCN as women with (a) prior thoracic radiation therapy before age 30 years, (b) 5-year risk of ≥1.7% of invasive breast cancer in women ≥35 years old, lifetime risk of >20% as defined by models that are largely based on family history, (d) strong family history or genetic predisposition, (e) LCIS, (f) prior history of breast cancer.

The ACS currently recommends that all women be informed of the benefits and limitations of breast cancer screening.[47] In the 2015 guidelines, ACS did not recommend breast self-examinations (BSEs) but noted that they did not change from their 2003 guidelines which states that beginning at age 20 years women should be told about the benefits and limitations of BSE.[47,50] Several studies have investigated the benefits of BSE. These trials were primarily conducted before the routine use of mammographic screening and demonstrated an inferential benefit in diagnosis of earlier stages of breast cancer. The Shanghai trial appeared to indicate no benefit, but there was a higher rate of biopsies in women who were taught BSE than in women who were not taught BSE.[51] The investigators from this trial caution that this was a study of BSE instruction and not BSE performance. Compliance and competency with the BSE were neither guaranteed nor evaluated in this trial. Because of the lack of direct evidence to support or refute a benefit with BSE and the apparent

associated increase in biopsy rates, the ACS has taken the position that it is optional.[47] Other organizations have taken a similar approach to their recommendations regarding BSE or simply state that there are insufficient evidence to recommend this practice.[48,49]

Recommendations for breast examination by a healthcare professional (clinical breast examination [CBE]) vary among the screening guidelines most often cited. The rate of breast cancer detection using CBE alone is low, with even lower rates in younger women.[52] Randomized clinical trials have reported inconsistent results and often evaluated CBE in conjunction with mammograms. The ACS does not recommend CBE for women of average risk.[47] The USPSTF concluded that there is insufficient evidence to assess the benefits and risks of CBE beyond screening mammography in women older than the age of 40 years.[48]

2 The most controversial screening recommendation for breast cancer is related to annual mammography. It is clear that screening mammography decreases mortality from breast cancer. The controversies surround the balance of benefits and harms associated with a less than perfect screening test in women at average risk of developing breast cancer but of differing ages. Multiple clinical trials have been completed over the years, and multiple meta-analyses of these trials have been conducted as well. Most of the trials included women 50 to 74 years of age, and the interval between testing ranged from 12 to 33 months. The most recent meta-analysis of these data estimated an number needed to invite (NNI) for screening as 1,339 for women aged 50 to 59 years.[53] Some trials also included women aged 40 to 49 years, albeit significantly fewer women in this age group were included in the meta-analyses. The estimated NNI for women aged 39 to 49 years was reported as 1,904. The largest benefit was found in women ages 60 to 69 years with an estimated NNI of 377. None of the trials included women 75 years of age or older; therefore, there are no data to support or refute the benefit of screening mammography in this population.[53]

Incorporation of this new information into national guidelines differs with each organization. The ACS recommends annual screening mammography for women ages 45 to 54 years, biennial screening mammography for women greater than or equal to 55 years and older (as long as they are in good health and have at least a 10 year life expectancy), and the opportunity for annual screening mammography for women 40 to 44 years. Women greater than or equal to 55 years and older should have the opportunity to continue with annual screening rather than changing over to biennial screening.[47] This recommendation allows for individualized decisions to be made based on the overall health of the woman but does not limit access to younger or older women who may benefit from screening. The USPSTF took a different approach, stating that "the decision to start regular, biennial screening mammography before the age of 50 years should be an individualized one and take patient context into account, including the patient's values regarding specific benefits and harms."[48] For women 50 to 74 years of age, the USPSTF recommends biennial screening mammography. This interval recommendation was based on assumptions of risks and benefits based on the available studies. Although the upper limit for screening varies among guidelines, most experts agree that mammograms in women older than the age of 74 are not supported by the current body of evidence, but some women may benefit if they are otherwise in good health and have a life expectancy of 10 years or more. There are also many other debates within this

controversial area, and readers are referred to these references for further details.[47,48,49,53]

Other radiologic methods of breast imaging are also being investigated (eg, digital mammography, ultrasonography, and magnetic resonance imaging [MRI]), and minimal data exist to support these methods in some high-risk populations. Recommendations for women with a high risk of breast cancer are not fully established, and definitions of "high risk" vary among different guidelines. See Table 128-2 for appropriate patients for breast screening MRI as an adjunct to mammography according to the ACS.[54,55] The NCCN also has adopted consensus guidelines for women at high risk of breast cancer, incorporating breast MRI with other established screening tools for women as young as 25 years old.[22]

It should also be noted that there are risks associated with any screening procedure, and they should be discussed with all patients so they are able to make an informed decision regarding these procedures. The risks involved with screening mammograms include false-negative results, false-positive results, overdiagnosis (true positives that will not become clinically significant), and radiation risk. The rate of false-negative results with the current technology is about 20%, which explains why CBE is an important adjunct to screening for many women. Although the specificity of mammography is quite high (90%), most abnormal examinations are false–positive results, leading to additional biopsies and psychological distress. The issue of overdiagnosis refers primarily to the growth in detection of DCIS from screening mammography. (See Noninvasive Carcinoma section for a detailed discussion of DCIS.) The biologic significance of these tumors is unknown because only some of them would become invasive if left in place. So the question remains: Are we treating women who do not require treatment? Experts in the field continue to debate this issue. Radiation exposure also has been discussed in the context of screening mammography, but the small doses of radiation exposure with mammograms (2-4 mGy [0.2-0.4 Rad] per standard two-view examination) appears to be overshadowed by other benefits in terms of reduction in mortality as a consequence of early cancer detection.[48]

CLINICAL PRESENTATION General

- The patient may not have any symptoms because breast cancer may be detected in asymptomatic patients through routine screening mammography.

Local Signs and Symptoms

- A painless, palpable lump is most common.
- Less common: pain; nipple discharge, retraction, or dimpling; skin edema, redness, or warmth.
- Palpable local–regional lymph nodes may also be present.

Signs and Symptoms of Systemic Metastases

- Depends on the site of metastases, but may include bone pain, difficulty breathing, abdominal pain or enlargement, jaundice, or mental status changes.

Laboratory Tests

- Tumor markers such as cancer antigen (CA 27.29) or carcinoembryonic antigen (CEA) may be elevated.
- Alkaline phosphatase or liver function test results may be elevated in patients with metastatic disease.

Other Diagnostic Tests

- Mammography (with or without ultrasonography, breast MRI, or both).
- Biopsy for pathology review and determination of tumor ER or PR status and human epidermal growth factor receptor-2 (*HER2*) status.
- Systemic staging tests may include chest radiography, chest computed tomography (CT), bone scan, abdominal CT or ultrasonography, or MRI.

Significant advances in the safety and efficacy of screening mammography have occurred during the last 2 decades. These advances have enabled superior visualization of breast and breast tissue with a lower dose of radiation being delivered. Despite these advances, about 10% of all palpable masses are not detected by mammography. This is most commonly observed in premenopausal women and may be directly related to the increased density of breast tissue in this estrogen-rich environment. In addition, differences exist between breast imaging quality and interpretation, and it is best to have imaging conducted at the same facility over time if possible.

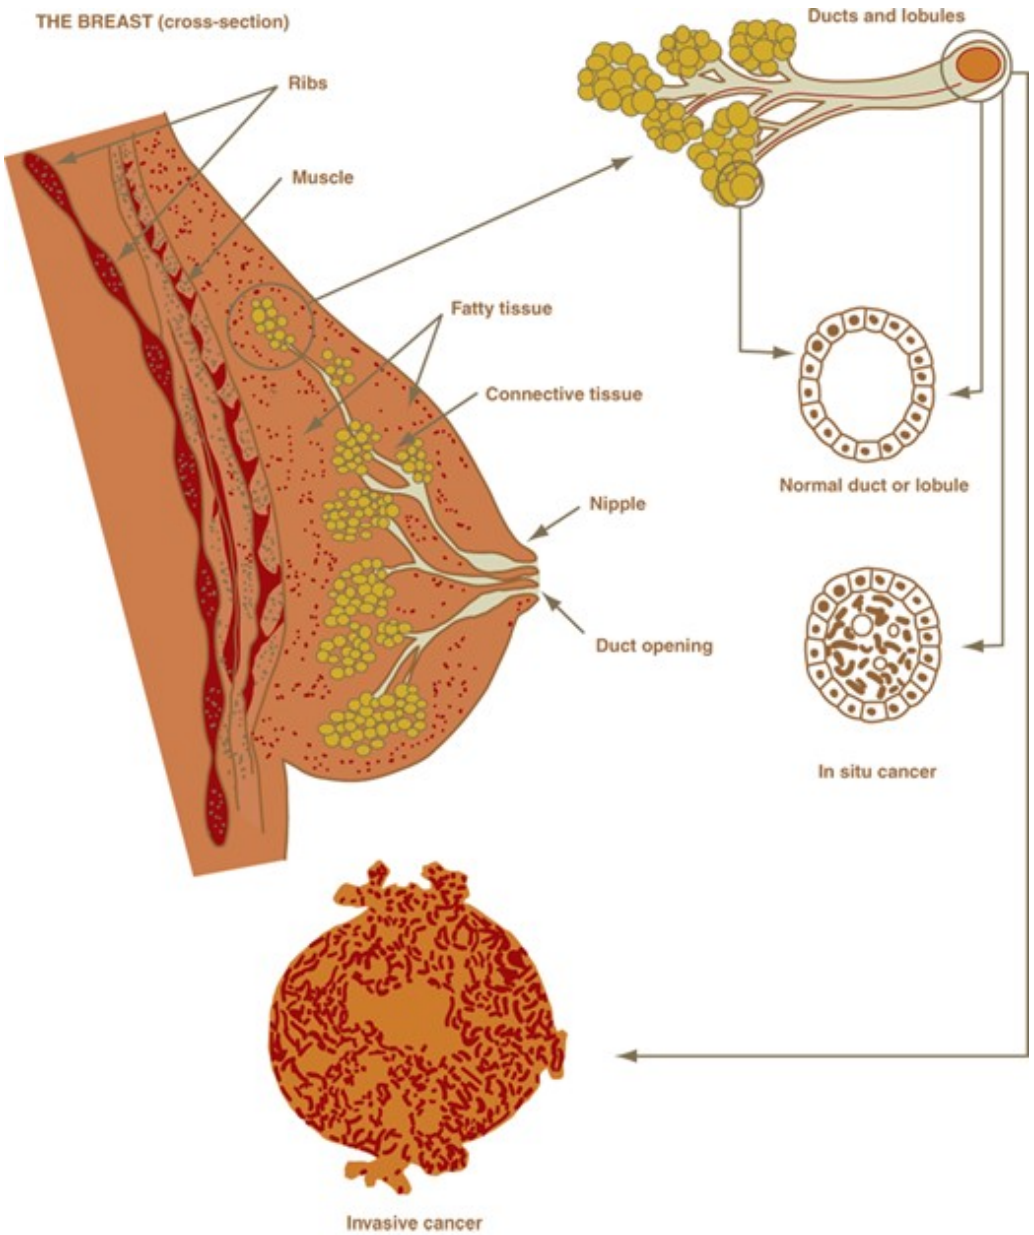
CLINICAL PRESENTATION

A painless lump is the initial sign of breast cancer in most women. The typical malignant mass is solitary, unilateral, solid, hard, irregular, and nonmobile. In small numbers of cases, stabbing or aching pain is the first symptom. Less commonly, nipple discharge, retraction, or dimpling may herald the onset of the disease. In more advanced cases, prominent skin edema, redness, warmth, and induration of the underlying tissue may be observed.

The breast is a complex organ composed of skin, subcutaneous tissue, fatty tissue, and branching ductal and glandular structures (**Fig. 128-2**). Various diseases that affect these structures can produce a palpable mass. In addition, the physiologic changes associated with the menstrual cycle can cause normal breast changes. Common causes of breast masses in young women are fibroadenoma, fibrocystic disease, carcinoma, and fat necrosis.

FIGURE 128-2

Breast anatomy.



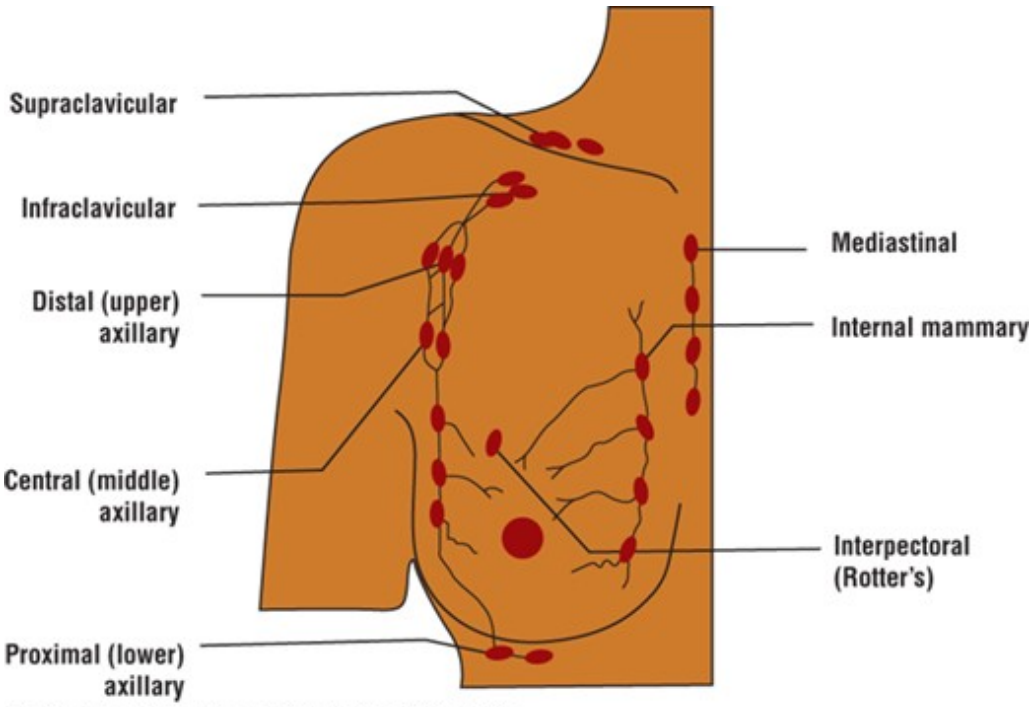
Many women detect some breast abnormality themselves, but in the United States, it is increasingly common for breast cancer to be detected during routine screening mammography in asymptomatic women. It is widely accepted that the smaller the mass, the higher the likelihood of cure. Thus, the routine use of screening mammography has contributed to the recent decline in mortality rate. However, this decreasing mortality rate is also related to improved systemic therapy.

Breast cancer that is confined to a localized breast lesion is often referred to as *early*, *primary*, *localized*, or *curable*. Breast cancer that has spread to local–regional lymph nodes is still considered early stage (**Fig. 128-3**). Unfortunately, breast cancer cells often spread by contiguity, through lymph channels, and through the blood to distant sites. This often occurs early in breast cancer growth, and deposits of tumor cells form in distant sites that are undetected with current diagnostic methods and equipment (micrometastases). When breast cancer cells can be detected clinically or radiologically in sites distant from the breast, the disease is referred to as *advanced* or *metastatic* breast cancer (MBC).

Tissues most commonly involved with distant metastases are lymph nodes (other than local–regional lymph nodes), skin, bone, liver, lungs, and brain. Symptoms of bone pain, difficulty breathing, abdominal enlargement, jaundice, and mental status changes may herald the clinical presentation of MBC. A small percentage of women have signs and symptoms of distant metastases when they first seek treatment. In virtually all of them, a neglected breast mass has been present for several months to years. In addition, 10% to 50% of all patients who initially are treated for localized disease eventually develop signs and symptoms of MBC.[56]

FIGURE 128-3

Lymph node anatomy.



DIAGNOSIS

The initial workup for a woman presenting with a breast mass or symptoms suggestive of breast cancer should include a careful history, physical examination of the breast, three-dimensional mammography, and possibly other breast imaging techniques such as ultrasonography or MRI. Most breast cancers can be visualized on a mammogram as a mass, a cluster of calcifications, or a combination of these findings. Specific mammographic features associated with the highest risk of malignancy include masses with spiculated margins or an irregular shape and calcifications with a linear or segmental distribution.[57] One major factor that affects the ability of mammography to detect cancer includes breast density (the fat-to-glandular tissue ratio of the breast), which may be affected by age, menopausal status, and HRT use. Ultrasonography, MRI, and digital mammography are alternate breast imaging methods that are being investigated for women with dense breasts or

other specific subsets of patients with breast cancer (eg, MRI in patients with inflammatory breast cancer [IBC]).[49] The technical quality of the examination and the expertise of the radiologist are also important factors.

Breast biopsy is indicated for a mammographic abnormality that suggests malignancy or for a palpable mass on physical examination. Three techniques are available: fine-needle aspiration, core-needle biopsy, and excisional biopsy.[58] Excisional biopsy completely removes the abnormal tissue. Needle biopsies are performed percutaneously and include both core-needle biopsy (which removes a core of tissue) and fine-needle aspiration (which removes cells from the suspicious site). Core-needle biopsy is the preferred biopsy method for mammographically detected, nonpalpable abnormalities.[49] Core-needle biopsy offers a more definitive histologic diagnosis, avoids inadequate samples, and can distinguish invasive from in situ breast cancer (which fine needle biopsy cannot). After confirmation of malignancy via core-needle biopsy, subsequent surgical procedures are performed (either before or after systemic therapy) to assure complete removal of the abnormal tissue.

STAGING AND PROGNOSIS

Breast cancer stage is defined on the basis of the primary tumor extent and size (T_{1-4}), presence and extent of lymph node involvement (N_{1-3}), and presence or absence of distant metastases (M_{0-1}) (**Table 128-3** and **Fig. 128-4**). Although many possible combinations of T and N are possible within a given stage, simplistically, stage 0 represents carcinoma in situ (T_{is}) or disease that has not invaded the basement membrane of the breast tissue. Stage I represents a small primary invasive tumor without lymph node involvement or with micrometastatic nodal involvement, and stage II disease usually involves regional lymph nodes. Stages I and II are often referred to as *early breast cancer*. It is in these early stages that the disease is highly curable (99% 5-year survival in patients with disease confined to the breast, node negative).[2] Stage III, also referred to as *locally advanced disease*, usually represents a large tumor with extensive nodal involvement in which either node or tumor is fixed to the chest wall. Stage IV disease is characterized by the presence of metastases to organs distant from the primary tumor and is often referred to as *advanced or metastatic disease* as described earlier (26% 5-year survival rate in patients with distant metastases).[3] Most breast cancer today presents in early stages where the prognosis is favorable (93% of newly diagnosed patients have disease confined to the breast or local lymph nodes).[3]

TABLE 128-3 Tumor, Node, Metastasis Stage Grouping for Breast Cancer

Stage Grouping			
0	T_{is}	N_0	M_0
IA	T_1[a]	N_0	M_0

TNM, tumor, node, metastasis.

[a]T_1 includes T_1mi.

[b]T_0 and T_1 tumors with nodal micrometastasis only are excluded from stage IIa and are classified as stage IB.

FIGURE 128-4

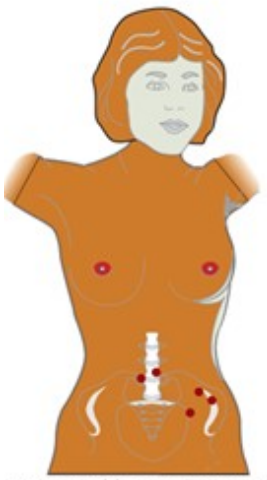
TNM (tumor, node, metastasis) staging system for breast cancer.

Tumor (T)

- T_x Primary tumor cannot be assessed
- T_0 No evidence of tumor
- T_{is} Carcinoma in situ
- T_1 ≤2 cm
  - T_1 mic ≤0.1 cm
  - T_{1a} >0.1-0.5 cm
  - T_{1b} >0.5-1 cm
  - T_{1c} >1-2 cm
- T_2 >2-5 cm
- T_3 >5 cm
- T_4 Any size; with direct extension to chest wall or skin
- T_{4a} Extension to chest wall (not including pectoralis muscle)
- T_{4b} Edema (including peau d'orange) or ulceration of skin or satellite skin nodules
- T_{4c} Both T_{4a} and T_{4b}
- T_{4d} Inflammatory carcinoma

Clinical Nodes (N)

- N_x Regional lymph nodes cannot be assessed (eg, previously removed)
- N_0 No regional lymph node metastasis
- N_1 Metastasis in movable ipsilateral axillary lymph node(s)
- N_2 Metastases in ipsilateral axillary lymph nodes fixed or matted or in clinically detected ipsilateral internal mammary nodes in the absence of clinically evident axillary lymph node metastasis
  - N_{2a} Metastasis in ipsilateral axillary lymph nodes fixed to one another (matted) or to other structures
  - N_{2b} Metastasis only in clinically detected ipsilateral internal mammary nodes and in the absence of clinically evident axillary lymph node metastasis
- N_3 Metastasis in ipsilateral infraclavicular lymph node(s) or in clinically detected ipsilateral internal mammary lymph node(s) and in the presence of clinically evident axillary lymph node metastasis or metastasis in ipsilateral supraclavicular lymph node(s) with or without axillary or internal mammary lymph node involvement
  - N_{3a} Metastasis in ipsilateral infraclavicular lymph node(s) and axillary lymph node(s)
  - N_{3b} Metastasis in ipsilateral internal mammary lymph node(s) and axillary lymph node(s)
  - N_{3c} Metastasis in ipsilateral supraclavicular lymph node(s)



Pathologic Nodes (pN)*

- pN0 No regional lymph node metastasis histologically
- pN1mi Micrometastasis (>0.2 mm but none >2.0 mm)
- pN1 Metastasis in one to three axillary lymph nodes and/or internal mammary nodes with microscopic disease detected by sentinel lymph node dissection but not clinically detected
- pN2 Metastasis in four to nine axillary lymph nodes or in clinically detected internal mammary lymph nodes in the absence of axillary lymph node metastasis
- pN3 Metastasis in 10 or more axillary lymph nodes, in infraclavicular lymph nodes, or in clinically detected ipsilateral internal mammary lymph nodes in the presence of one or more positive axillary lymph nodes; in more than three axillary lymph nodes with clinically negative microscopic metastasis in internal mammary lymph nodes; or in ipsilateral supraclavicular lymph nodes

*Based on axillary lymph node dissection with or without sentinel lymph node dissection

Metastasis (M)

- M_x Distant metastasis cannot be assessed
- M_0 No distant metastases
- M_1 Distant metastasis

Staging for breast cancer is separated into two groups, clinical and pathologic. Clinical staging is assigned before surgery and is based on physical examination (assessment of tumor size and presence of axillary lymph nodes), imaging (mammography, ultrasonography, and so on), and pathologic examination of tissues (eg, biopsy results). Pathologic staging occurs after surgery and uses information from clinical staging but adds data from surgical exploration and resection, such as tumor size at surgery and the involvement of micro- or macro-invasive tumor in the lymph nodes or other metastatic sites. Because of the advent of sentinel lymph node biopsy (SLNB), the assessment

of lymph node status has become more complex (see the Treatment of Early Breast Cancer section). The American Joint Committee for Cancer (AJCC) publishes staging criteria for cancers, and the breast cancer criteria were most recently updated in January 2010.[59] This staging system is widely accepted and used in all breast cancer patients to determine prognosis and assist with treatment decisions. It is also used to report and track breast cancer diagnoses in tumor registries and databases.

PATHOLOGY

The pathologic evaluation of breast tissue serves to establish the histologic diagnosis and to confirm the presence or absence of other factors believed to influence prognosis.

Invasive Carcinoma

Invasive breast cancers are a histologically heterogeneous group of lesions. Most breast cancers are adenocarcinomas and are classified on the basis of their microscopic appearance as ductal or lobular, corresponding to the ducts and lobules of the normal breast (Fig. 128-2). The various histologic types of breast cancer have different prognoses, but it is unknown whether their response to therapy differs because patients in therapeutic trials are not typically stratified according to histologic type. The five most common types of invasive breast cancer are briefly described.[60]

Invasive or *infiltrating ductal carcinoma* is the most common histology, accounting for about 75% of all invasive breast cancers. These tumors commonly spread to the axillary lymph nodes, and their prognosis is poorer than for some other histologic types. *Invasive or infiltrating lobular carcinoma* accounts for 5% to 10% of breast tumors. Both clinical and radiologic findings for these tumors may be quite subtle. The typical presentation is an area of ill-defined thickening in the breast in contrast to a prominent lump characteristic of infiltrating ductal carcinoma. *Infiltrating lobular carcinoma* can also be more difficult to detect by mammography. Overall, *infiltrating lobular carcinoma* and *infiltrating ductal carcinoma* have similar likelihoods of axillary node involvement and disease recurrence and death, yet the sites of metastases may differ. Whereas *infiltrating ductal carcinoma* more frequently metastasizes to the bone or to the liver, lung, or brain, *infiltrating lobular carcinoma* tends to metastasize to the leptomeninges, peritoneal surfaces, retroperitoneum, gastrointestinal tract, reproductive organs, and other unusual sites.

The three most common special types of invasive cancer are *medullary*, *mucinous*, and *tubular*. The prognosis may be more favorable with these unusual histologies. *Medullary carcinoma* accounts for fewer than 7% of all breast carcinomas, *mucinous (or colloid) carcinoma* constitutes about 3%, *and tubular carcinoma* accounts for about 2% of all breast cancers. Histologies rarely reported include adenocystic carcinoma, carcinosarcomas, metaplastic, cribriform, and papillary carcinoma.

Special situations seen clinically and histologically include Paget's disease of the breast, phyllodes tumors, and IBC. Paget's disease of the breast occurs in 1% to 4% of all patients with breast cancer and is characterized by neoplastic cells in the nipple areolar complex. The patient presents clinically with eczematous changes in the nipple with itching, burning, oozing, bleeding, or some combination of these. In most cases, the nipple changes are associated with an underlying carcinoma in the breast

that is usually palpable.

Phyllodes tumors of the breast (also known as cystosarcoma phyllodes) are rare tumors with subtypes that range from benign to malignant. These tumors often enlarge rapidly, are painless, and can appear as fibroadenomas.[61]

IBC is characterized clinically by prominent skin edema, redness and warmth, and induration of the underlying tissue. Biopsies of the involved skin reveal cancer cells in the dermal lymphatics. IBC typically has a very rapid onset and is often mistaken for an infectious cellulitis or mastitis. Although it may look somewhat similar to a neglected mass, its presentation with rapid onset and progression of local symptoms distinguishes it from other cases of locally advanced breast cancer. The prognosis of patients with IBC is poor even if the disease is apparently localized.[62]

Noninvasive Carcinoma

As with invasive carcinoma, the noninvasive lesions may be divided broadly into ductal and lobular categories. Evidence supports that the development of malignancy is a multistep process and that invasive breast cancer has a preinvasive, in situ phase. During the carcinoma in situ phase, normal epithelial cells undergo genetic alterations that result in malignant transformation. Transformed epithelial cells proliferate and pile up within lobules or ducts but lack the required genetic alterations that enable the cells to penetrate the basement membrane. Therefore, carcinoma in situ is diagnosed when malignant transformation of cells has occurred but the basement membrane is intact.

The widespread use of screening mammography with subsequent biopsy and greater recognition of noninvasive breast carcinoma by pathologists has resulted in a significant increase in the diagnosis of in situ breast cancer over the past decade. An estimated 61,000 new cases of female noninvasive (in situ) breast cancer is expected to be diagnosed in 2016.[1] The natural history of these disorders is not well described, and thus the debate continues regarding carcinoma in situ: Is carcinoma in situ preinvasive cancer or simply a marker of unstable epithelium that represents an increased risk for the development of subsequent aggressive cancer?[63,64] Answering this question may change the way noninvasive breast cancers are treated.

Ductal carcinoma in situ (DCIS) is more frequently diagnosed than lobular carcinoma in situ (LCIS). Most cases of DCIS today are found by biopsies performed for clustered microcalcifications seen on screening mammography, a hallmark of this disorder.

The ultimate goal of treatment for noninvasive carcinomas is to prevent the development of invasive disease. If left untreated, it is estimated that 14% to 50% of DCIS lesions will progress to invasive breast cancer.[63] Therefore, up to 50% of these tumors do not progress to invasive disease, but identifying this group of patients is not yet feasible, and all diagnoses should be treated. Locoregional treatment of DCIS depends on its location, size, and pathology.[61] Treatment options include (a) local excision alone with negative margins, (b) local excision (with negative margins) followed by breast irradiation, and (c) traditional total mastectomy with or without reconstruction. Whole-breast irradiation is recommended after excision to significantly decrease the risk of local recurrence, although there is no evidence that survival differs between the previously mentioned

options.[61] Excision with negative margins alone without radiation may be considered in patients with small and low-grade DCIS. Mastectomy had been the standard treatment of DCIS for several decades, but long-term survival appears to be equivalent with mastectomy versus local excision and irradiation, and the latter option allows for breast conservation. If more than one area of the breast is involved with DCIS, a mastectomy is the preferred option. Axillary lymph node dissection (ALND) is generally not indicated, although SLNB (see the Early Breast Cancer section) may be considered in selected patients.[61] Cytotoxic chemotherapy has no role in the treatment of patients with pure DCIS. It is important to determine hormone receptor status on the cancer cells. Tamoxifen treatment for 5 years may be considered in some women with hormone receptor–positive DCIS. The NSABP B-24 trial, which randomized women with DCIS to lumpectomy with radiation plus either tamoxifen or placebo, showed a benefit with tamoxifen in reducing ipsilateral breast cancer recurrence (32% reduction; p=0.025).[65] Further subgroup analyses of this trial showed a benefit for patients with ER-positive DCIS.[66] The NSABP B-35 trial evaluated the role of the AI anastrozole compared to tamoxifen each given for 5 years in the treatment of postmenopausal hormone receptor–positive DCIS in patients who had lumpectomy with radiation therapy. Significant improvement in 10 year point estimates for the breast cancer-free interval was seen with anastrozole (89.1% for tamoxifen and 96.3% for anastrozole, HR, 0.73; p=0.02). Further subgroup analyses of this trial showed the benefit to be primarily in women less than 60 years of age.[67] These decisions are often difficult to discuss with patients because these treatments have toxicities that are worrisome. Nonetheless, an open and honest conversation regarding the risks and benefits is warranted.

LCIS is a microscopic diagnosis. In these cases, there is generally no palpable mass, and no specific clinical abnormality is noted. Unlike DCIS, LCIS does not generally demonstrate calcifications on mammography and in fact is usually undetectable by mammography. Consequently, the diagnosis of LCIS is usually an incidental finding in biopsy specimens obtained because of symptoms or mammography findings consistent with benign lesions. It is unclear whether LCIS is a precursor lesion to invasive carcinoma or serves as a marker of risk for invasive carcinoma developing somewhere in the breast. The risk for developing invasive carcinoma is about 0.5% to 1% per year, and both invasive ductal carcinoma and invasive lobular carcinoma can occur. In about 50% to 70% of patients, there are multiple foci of LCIS in the ipsilateral breast, and the contralateral breast is also affected. Thus, the risk for the development of breast cancer is equally high in either breast, which makes the management of LCIS very controversial.[64] Some experts favor a program of observation, with semiannual physical examination and annual mammography.[61] In selected patients with high-risk genetic mutations or strong family history and in women who are particularly anxious about the development of cancer, bilateral mastectomies with or without reconstruction may be considered.[45] Radiation and systemic chemotherapy have no role in the management of LCIS. The use of chemoprevention with tamoxifen in premenopausal women or tamoxifen, raloxifene, or exemestane in postmenopausal women may also be considered for risk reduction in these patients.[45] See the Prevention and Early Detection section for details.

PROGNOSTIC FACTORS

The natural history of breast cancer varies among patients, with some having extremely aggressive

disease that progresses rapidly and others following a more indolent course. The ability to predict prognosis is extremely important in designing treatment recommendations to maximize quantity and quality of life. A number of pathologic prognostic and predictive factors have been identified. Prognostic factors are characteristics or measurements available at diagnosis or time of surgery that in the absence of adjuvant systemic therapy are associated with recurrence rate, death rate, or other clinical outcomes. Predictive factors are measurements available at diagnosis that are associated with response to a specific therapy. Prognostic and predictive factors fall into three general categories: (a) patient characteristics that are independent of the disease such as age; (b) cancer characteristics such as tumor size or histologic type; and (c) other biomarkers that are measurable parameters in tissues, cells, or fluids, such as hormone receptor status. Ideally, the use of prognostic and predictive factors can limit a specific treatment to patients who are most likely to derive benefit, thus sparing unwanted toxicities in those who are unlikely to benefit.

Age at diagnosis and ethnicity are patient characteristics that may affect prognosis. Some younger patients, particularly those younger than 35 years of age, have more aggressive forms of breast cancer and a worse prognosis. Younger patients are more likely to present with poor prognostic features, such as affected lymph nodes, large tumor size, and tumors negative for hormone receptors. Race and ethnicity may also play a role in breast cancer prognosis. African American women have decreased survival periods compared with white women. The cause of this racial disparity is widely debated, with possible explanations including access to care, socioeconomic status, cultural differences, higher stage at diagnosis, and more aggressive biologic features.

Potentially modifiable prognostic factors include alcohol use, dietary factors, weight, and exercise. The association between breast cancer prognosis and alcohol consumption is not as strong as with alcohol and breast cancer risk. A review of seven observational studies showed that postdiagnosis alcohol consumption was not associated with breast cancer outcomes.[68] Two randomized controlled studies examined the effects of diet on the risk of breast cancer with conflicting results, primarily focusing on lowering dietary fat.[69,70] One study found an improvement in disease-free survival (DFS) with incorporation of a low-fat diet (less than 15% dietary fat per day vs no intervention),[70] but another study found no difference in recurrence rates between two dietary intervention approaches (both incorporating a low-fat, high-fiber approach).[69] Although these studies asked different questions and had many confounding variables that potentially affected the results, most clinicians recommend that breast cancer survivors eat a low-fat, high-fiber diet and maintain a healthy weight. Obesity at the time of a breast cancer diagnosis has been shown to increase the risk of breast cancer–specific and overall mortality compared with nonobese breast cancer patients, although the impact of weight loss in this population is unclear.[68] Observational studies have reported that exercise in women after a diagnosis of breast cancer may also decrease the likelihood of breast cancer recurrence and breast cancer–related death.[68] Based on these data, agencies such as the ACS have recognized that physical activity, weight control, and diet are potentially modifiable risk factors for reducing the risk of recurrent breast cancer and other comorbidities (eg, heart disease, diabetes).[71]

Disease characteristics that have been shown to provide important prognostic information include lymph node status, tumor size, histologic subtype, nuclear or histologic grade, lymphatic and vascular invasion (LVI), and proliferation indices.

Tumor size and the presence and number of involved lymph nodes are established primary factors in assessing the risk for breast cancer recurrence and subsequent metastatic disease. **Table 128-4** shows 5-year survival rates according to size of the primary tumor and axillary node involvement. The major factor that influences the likelihood of recurrence is the presence of positive lymph nodes. However, regardless of lymph node status, the size of the primary tumor remains an independent prognostic factor for disease recurrence.

TABLE 128-4 Five-Year Survival Rates (%) According to Tumor Size and Axillary Lymph Node Status

Lymph Node Status	Tumor Size		
	<2 cm	2-5 cm	>5 cm
Negative	96	89	82
1-3 positive	87	80	73
≥4 positive	66	59	46

Data from Dillon DA, Guidi AJ, Schnitt SJ. Pathology of invasive breast cancer. In: Harris JR, Lippman ME, Morrow M, Osborne CK, eds. Diseases of the Breast, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010:374-407.

The number of affected lymph nodes is directly related to the risk of disease recurrence. The revised staging system for breast cancer recognizes the absolute number of positive nodes as a prognostic factor: N_1 represents one to three positive nodes, N_2 represents four to nine positive nodes, and N_3 represents 10 or more positive nodes in its pathologic staging system.[59] The relationship between tumor size and lymph node status is complex and not a simple grouping (see discussion below).

Certain histologic subtypes and clinical presentation of breast cancer have prognostic importance. As mentioned earlier, because women with pure *tubular* or *mucinous* tumors have more favorable outcomes than those with *invasive ductal carcinomas*, treatment recommendations may differ.[61] IBC, although a clinical designation and not a distinct histologic subtype, is associated with a poor prognosis.[62]

Nuclear grade and tumor (histologic) differentiation are known independent prognostic indicators. Several histologic grading systems have been developed, most of which grade tumors with a score from 1 to 3: grade 1, well differentiated; grade 2, moderately differentiated; and grade 3, poorly differentiated. Higher grade tumors are associated with higher rates of distant metastasis and poorer survival. This factor aids in making treatment decisions, particularly for patients with small tumors and negative lymph nodes.

Lymphatic and vascular invasion (LVI), defined as evidence of tumor emboli in lymphatic or vascular spaces, is a poor prognostic factor likely representing ability of the cancer to spread via hematogenous routes. However, the utility of this as a prognostic factor is largely unknown and is not currently included in either staging or treatment guidelines.[59,61]

The rate of tumor cell proliferation also is associated with risk of breast cancer recurrence. Rate of cell proliferation can be evaluated with various techniques, including (1) mitotic index, which counts the

number of mitotic bodies; (2) thymidine-labeling index or S-phase fraction with DNA flow cytometry, which determines the percentage of tumor cells actively dividing; or (3) the use of monoclonal antibodies (MoABs) to antigens present on proliferating cells, such as Ki-67. In a meta-analysis of 85 studies and nearly 33,000 patients, proliferation markers (including Ki-67, mitotic index, proliferating cell nuclear antigen, and thymidine or bromodeoxyuridine labeling index) were associated with significantly shorter disease-free and OS periods.[72] These proliferation indices are additional factors that may be useful in decision making and may predict for responsiveness to chemotherapy, although this is still controversial.

Hormone receptors are not strong prognostic markers but are used clinically to predict response to endocrine therapy. Hormone receptors are nuclear transcription factors that, upon ligand binding, activate a variety of signal transduction pathways that result in cell growth and proliferation. Determination of both ER and PR status is an established procedure that is important in the management of breast cancer. Immunohistochemistry is used to determine the level (ie, quantity) of hormone receptors, which is important for predictive ability. Other methods of determining ER and PR status, such as mRNA expression, are under investigation but have not been validated as predictive markers. Hormone receptors are most valuable in predicting response to endocrine therapy. About 60% to 70% of patients with ER-positive and PR-positive tumors will respond to hormonal manipulation. More recently, the importance of PR has come under question because response to tamoxifen has been shown to be related to ER status independent of PR status.[36] Guidelines for testing of ER and PR status are available and recommend standards for what tumors to test and methodologic guidelines for pathologists.[73] The majority of patients with primary or MBC have hormone receptor–positive tumors. Hormone receptor positivity, more common in postmenopausal women, is associated with a higher response to endocrine therapy and a longer DFS.

The *HER2/neu* gene is located on chromosome 17q21 and encodes a 185-kilodaton transmembrane tyrosine kinase growth factor receptor. The *HER2* protein is normally expressed at low levels in the epithelial cells of normal breast tissue. *HER2* is a member of the HER growth factor receptor family, and its overexpression is associated with transmission of growth signals that control aspects of normal cell growth and division. *HER2* overexpression occurs in about 20% to 30% of breast cancers and is associated with increased tumor aggressiveness, increased rates of recurrence, and increased mortality rates. In some studies, *HER2* gene amplification and protein overexpression, measured by fluorescence in situ hybridization (FISH) and immunohistochemistry (IHC), respectively, correlates with factors associated with a poor prognosis. *HER2*-positive status clearly predicts response to anti-*HER2* therapy. Tumors that are either IHC 3+ or FISH positive for gene amplification are considered to be positive for *HER2*.[74] For equivocal results of IHC (2+) or FISH, confirmatory testing with the alternate test is recommended. *HER2* gene amplification or protein overexpression has traditionally been considered a poor prognostic factor. However, more recent data suggest that patients with *HER2*-positive MBC treated with trastuzumab, a MoAB directed against the extracellular domain of the *HER2* receptor, have improved survival rates compared with patients with *HER2*-negative MBC or patients with *HER2*-positive MBC who do not receive trastuzumab.[75] These results demonstrate the powerful impact trastuzumab therapy has made on improving patient outcomes.

Although there is a growing understanding of the prognostic significance of individual factors, it is not clear how each factor contributes to the overall prognosis for an individual patient. Computer-aided models, including Adjuvant! (*www.adjuvantonline.com*), are available that combine patient- and tumor-related variables to estimate overall prognosis for individual patients with early stage breast cancer (ESBC) and aid in decisions regarding adjuvant systemic therapy.[76] (See Systemic Adjuvant Therapy later).

Genetic profiling is also being used to provide prognostic and predictive information on clinical outcomes of breast cancer.[77] Commercially available multiparameter gene expression assays include Oncotype DX, MammaPrint and Prosigna. Further details on these assays are available in the Systemic Adjuvant Therapy section later.

Novel molecular markers that have shown prognostic and predictive significance include urokinase-type plasminogen activator and its inhibitor, plasminogen activator inhibitor type 1, cyclin E, and the presence of tumor cells in bone marrow or circulating blood.[78] Prospective validation studies will determine whether these tests can be used to assist decision making in individual patients.

In summary, lymph node status and tumor size are two significant prognostic factors that assist clinicians in estimating prognosis and making treatment recommendations for most breast cancer patients (see Systemic Adjuvant Therapy later). Although the risk of recurrence is clearly high in patients with large primary tumors or lymph node–positive disease, many patients with small primary tumors and lymph node–negative disease will still develop metastases, yet our ability to accurately identify these individual patients is limited. Evaluation of additional prognostic factors can help identify which patients will have a good outcome with local therapy alone and which patients with aggressive features who would benefit from more aggressive, multimodality treatment. Despite these markers, a large proportion of patients will likely be treated unnecessarily with systemic adjuvant therapy, and better prognostic and predictive tools are needed to better select patients to undergo these toxic and costly treatments and procedures.

TREATMENT

Early Breast Cancer (Stage I and II)

Desired Outcomes

The desired therapeutic outcome of adjuvant therapy of breast cancer differs significantly from that of metastatic disease. Adjuvant therapy—chemotherapy, biologic therapy, and hormonal therapy—is administered with curative intent. The rationale for adjuvant therapy is that breast cancer, even when diagnosed in early stages when clinical evidence of distant spread is not apparent, is a systemic disease that spreads early to distant sites. Adjuvant therapy is intended to eradicate micrometastases and thus cure the patient of breast cancer. A predetermined number of cycles of adjuvant therapy or years of biologic or hormonal therapy (or both) are administered. The goals of neoadjuvant therapy are to eradicate micrometastatic disease, determine prognosis, and potentially conserve the breast tissue for a better cosmetic result. Adjuvant and neoadjuvant chemotherapy is often associated with

significant toxicity. Clinicians and patients must weigh the short- and long-term risks of chemotherapy, biological therapy, and endocrine therapy with the benefits of lowering the risk of breast cancer recurrence.

Locoregional Therapy

3 Most patients presenting with breast cancer today have an in situ tumor, a small invasive tumor with negative lymph nodes (stage I),or a small invasive tumor with axillary lymph node involvement (stage II). Surgery alone can cure most, if not all, patients with in situ cancers; 70% to 80% of patients with stage I; and about half of all patients with stage II cancers. The choice of surgical procedures has changed drastically over the past 50 years. This is partly a result of changes in our understanding of the biology of breast cancer and is partly a result of a series of well-conducted clinical trials performed over this time period.

Over the years, many trials have investigated reducing the amount of surgery required to maintain acceptable cosmetic results and rates of local and distant recurrence and mortality. Breast-conserving therapy (BCT) includes removal of part of the breast, surgical evaluation of the axillary lymph node basin, and radiation therapy to the breast. The amount of breast tissue removed as a part of BCT varies from just removing the cancerous "lump" (a lumpectomy) with a small margin of adjacent normal-appearing tissue to removing the "lump" with a wider excision of adjacent normal-appearing tissue (a wide local excision) to removing the entire quadrant of the breast that includes the cancerous "lump" (a quadrantectomy). All of these techniques are referred to as a *segmental or partial mastectomy*. A meta-analysis of 18 clinical trials in almost 10,000 women found no difference in OS for patients who received BCT compared with mastectomy.[79] However, this and other meta-analyses have suggested the potential for a small increase in the risk of locoregional recurrence with BCT.[79,80]

Most patients diagnosed today with breast cancer can be treated with BCT. Several factors should be considered in selecting patients for BCT, including any additional risk the remaining breast tissue poses despite the local effects of radiation therapy. The NCCN recommends that women who carry a known *BRCA1* or *BRCA2* mutation undergo mastectomy and consider additional risk reduction strategies (eg, bilateral mastectomies).[61] Bilateral total mastectomy and oophorectomy reduce the risk of breast cancer occurrence in patients with *BRCA1* or *BRCA2* mutations, but both breast and ovarian cancers have been reported in patients who have had prophylactic removal of these organs. Multiple sites of cancer within the breast and the inability to attain negative pathologic margins on the excised breast specimen are predictive for an increased risk of recurrence with BCT and are indications for mastectomy. Some preexisting collagen vascular diseases (eg, scleroderma, systemic lupus erythematosus) are relative contraindications for the use of BCT because of an increased risk of radiation-related adverse effects. Although local recurrence after BCT has not been consistently associated with an increased mortality rate, it is distressing to the patient and requires surgical removal of the breast. In addition, reconstructive therapy is often not feasible in a breast that has previously received irradiation. Another major consideration in selecting patients for BCT is the expected cosmetic result. For some patients, preservation of a limited amount of breast tissue may not justify the inconvenience of radiation therapy. Another approach to therapy for these patients is

primary (neoadjuvant) systemic therapy to potentially shrink the tumor and minimize surgery (see Systemic Adjuvant Therapy and Locally Advanced Breast Cancer sections for further details). Aside from the probability of local recurrence and the ability to achieve a satisfactory cosmetic result, consideration must be given to the availability of an external-beam radiation facility and the patient's willingness to comply with the prescribed course of radiotherapy. A meta-analysis of 10,801 patients in 17 randomized controlled trials of radiotherapy compared to no radiotherapy after breast conserving surgery demonstrated a reduction in the 10-year risk of first recurrence by 15.7% and the 15-year risk of breast cancer death by 3.8% favoring radiation.[81] In most instances, external-beam radiation therapy used in conjunction with BCT involves 3 to 5 weeks of radiation therapy directed to the entire breast tissue (typically a total of 40-50 Gy administered in 15-25 daily doses Mondays through Fridays with an optional boost of radiation to the tumor bed) to eradicate residual disease. Local tumor control is similar with shorter courses of radiation compared to longer courses, and toxicities such as breast shrinkage, telangiectasias and breast edema is less common with shorter regimens. The preferred radiation course by the NCCN is 40 to 42.5 Gy in 15 to 16 fractions.[61] Complications associated with radiation therapy to the breast are generally minor and include reddening and erythema of the breast tissue and subsequent shrinkage of the total breast mass beyond that predicted on the basis of breast tissue removal.

Clinical trials are investigating the use of accelerated partial breast irradiation, intraoperative radiotherapy, or no radiation after segmental mastectomy for certain patient populations with a very low risk of recurrence.[82] Until the results of these studies are available, the standard approach to BCT includes whole-breast radiation therapy for the majority of patients.

Postmastectomy radiation therapy to the chest wall and regional lymph nodes (if indicated) may also be required in certain situations when tumors are large or the number of positive axillary lymph nodes is high (see the Locally Advanced Breast Cancer section). However, these criteria are also widely debated and are the subject of several meta-analyses. Despite the controversy, it is clear that some women may benefit from local radiation therapy even after removal of the entire breast (ie, total mastectomy). The NCCN Guidelines state that women with four or more positive axillary lymph nodes should undergo postmastectomy radiation therapy. Patients with one to three positive ipsilateral axillary lymph nodes should strongly consider postmastectomy radiation, although conflicting data exist in this patient population. Patients with (a) positive surgical margins, (b) a tumor larger than 5 cm, or (c) tumors less than 5 cm with close margins (less than 1 mm of normal adjacent tissue) should consider postmastectomy chest wall radiation therapy. Finally, patients with surgical margins of at least 1 mm, tumor size of 5 cm or less, and negative axillary lymph nodes do not require postmastectomy chest wall radiation therapy. The optimal sequence of radiation therapy and chemotherapy is somewhat controversial. Concurrent administration of chemotherapy and radiation therapy is usually avoided because of an increase in local adverse effects. Most clinicians administer systemic chemotherapy immediately after surgery (if chemotherapy was not administered before surgery) given the hypothetical presence of systemic micrometastases that cannot be eradicated by local radiation therapy. Radiation therapy is then administered after chemotherapy, leaving hormone therapy (which is given for many years) for the end (see the Adjuvant Biologic Therapy section for a discussion of sequencing trastuzumab).

Accurate assessment of the spread of breast cancer cells to the axillary lymph nodes is critical for prognosis and the determination of the utility of both local and systemic treatments. ALND with histopathologic study of the full axillary specimen, including level I and II lymph nodes, was the gold standard for detecting axillary nodal involvement and determining the number of lymph nodes containing tumor. The number of positive axillary lymph nodes remains the most powerful predictor of breast cancer recurrence and survival, but other benefits may include a therapeutic effect of removing the lymph nodes and obtaining information to guide treatment selection. However, axillary dissection is associated with significant morbidity, including lymphedema (10%-20%), arm pain or numbness (30%), and reduction in quality of life (35%).[83] Recent studies indicate that about 60% of patients with ESBC present with lymph node–negative disease, which indicates that many women would derive no therapeutic benefit but would be exposed to the complications from the procedure.

For these reasons, a procedure involving lymphatic mapping and SLNB is recommended for patients with clinically negative lymph nodes, and guidelines regarding recommendations for this procedure are available.[84] The sentinel lymph node(s) is the first lymph node(s) that receives lymph drainage from the primary tumor. Injection of a vital blue dye, a radiocolloid, or both around the primary breast tumor identifies the sentinel lymph node(s) in most patients, and the status of this lymph node(s) may predict the status of the remaining nodes in the nodal basin. Patients with lymph nodes that are suspicious for cancer involvement either by physical examination or imaging should have a biopsy performed to exclude lymph node involvement. SLNB has become the standard of care for patients with clinically negative axillary lymph nodes.[61] Historically, patients with positive sentinel nodes should proceed to a level I and II ALND, although this has recently been called into question. Data from a single randomized trial suggest that ALND after SLNB in women with clinically node negative tumors smaller than 5 cm, fewer than three involved sentinel lymph nodes, and undergoing BCT with subsequent breast irradiation resulted in higher morbidity, no improvement in local recurrence, and no difference in DFS or OS with SLNB alone.[85] Therefore, the ASCO guidelines currently recommend that clinicians should not recommend ALND for women with ESBC with one or two positive sentinel lymph nodes who will receive BCT followed by radiation.[84] Women undergoing mastectomy with positive sentinel lymph nodes should be offered ALND.

In studies that incorporated completion axillary dissections for comparison, the SLNB procedure accurately predicted the status of the remaining axillary nodes in more than 90% of patients.[83] Greater surgeon experience improves the sensitivity of the procedure. Women with large tumors (greater than 5 cm) or locally advanced disease, IBC, or DCIS when BCT is planned should not receive SLNB.[84] Patients with multifocal or multicentric breast tumors, DCIS when mastectomy is planned, prior neoadjuvant (preoperative) chemotherapy, or prior surgery involving the breast or axilla may be offered SLNB.[84] Patients who are pregnant or lactating are not considered candidates for this procedure because of concerns regarding the effects of the blue dye or the radiocolloid on the fetus. The decision of whether to use the sentinel lymph node procedure or a full axillary dissection is complex, and readers are referred to an excellent review for further information.[83]

The early trials investigating less extensive surgical approaches to breast cancer are widely credited with the finding that BCT is an appropriate primary therapy for most women with stages I and II disease and is preferable because it arguably provides survival rates equivalent to those of modified

radical mastectomy. These historical trials provided valuable information regarding the natural history of the disease and identified pathologic prognostic factors associated with early cancer spread. The preponderance of information available regarding selection of women most likely to benefit from systemic adjuvant therapy was derived from pathologic evaluation of tissues archived from these early trials. It is hoped that further investigation into less extensive local therapy (now focused on the surgical approach to the axilla and radiation therapy) will continue to provide valuable information for the future.

Systemic Adjuvant Therapy

4 *Systemic adjuvant therapy* is defined as the administration of systemic therapy after definitive local therapy (surgery, radiation, or a combination of these) when there is no evidence of metastatic disease but a high likelihood of disease recurrence. By the time breast cancers become clinically detectable, they have likely been present for a number of years and have had ample opportunity to establish distant micrometastases. Micrometastatic disease can travel from the primary breast tumor and spread to distant organs through several different routes (eg, hematogenous spread through blood vessels, lymphangitic spread through lymph channels, local extension to surrounding structures). Because local therapies such as breast surgery and irradiation do not address distant micrometastases, systemic therapy may be required to target these tumor cells that have escaped the local area of the breast. The likelihood of micrometastatic disease presence is used to attempt to identify patients with a high risk of recurrence who would require systemic adjuvant therapy. Many collaborative research groups have conducted stepwise series of studies designed to identify appropriate candidates for systemic adjuvant therapy and the optimal regimens and duration of therapy. Several hundred randomized clinical trials evaluating various systemic adjuvant modalities have been reported. Most published results confirm that administration of chemotherapy, endocrine therapy, targeted therapy, or some combination of these agents, results in improved DFS or OS for all treated patients or more commonly for patients in specific prognostic subgroups (eg, nodal involvement, menopausal status, hormone receptor status, or *HER2* status). The huge amounts of data generated by these trials have resulted in a great deal of controversy, with different conclusions being reached by various experts.

5 Interpretation of results of systemic adjuvant therapy is difficult because of differences in the patient populations studied, the variation in natural history of breast cancer, the absence of information regarding pathologic prognostic factors in many studies, and differences in treatment approach and methods of analysis. Several groups around the world have conducted meta-analyses of similar breast cancer trials in hopes of gaining more insight regarding adjuvant systemic therapy than a single study can provide. One such effort, organized by the EBCTCG, is based on a worldwide collaboration involving multiple randomized trials and is continually updated with results from new clinical trials. The EBCTCG's overview analyses are updated periodically as new data become available. The most recent updates reflect the long-term effects on breast cancer recurrence and survival for adjuvant endocrine therapy and chemotherapy.[36,56,86] Many important questions regarding the optimal way to administer adjuvant chemotherapy and endocrine therapy and the magnitude of benefit as measured by DFS or OS in clinically relevant subsets of patients have been answered by these overview analyses. Simply stated, the results of these analyses support the use of adjuvant

endocrine therapy in all patients with positive hormone receptor status regardless of age, menopausal status, involvement of axillary lymph nodes, or tumor size.[36] The results of these overview analyses also support the use of adjuvant chemotherapy in most women with lymph node metastases or with primary breast cancers larger than 1 cm in diameter (both node negative and node positive).[56] It is important to note that data from clinical trials incorporating anti-*HER2* therapy into adjuvant regimens are not included in these analyses because sufficient long-term follow-up has not been reached. Results from these more recent clinical trials are discussed later.

Table 128-5 uses data from the overview analyses to show the absolute benefits of adjuvant chemotherapy in terms of age and nodal status. In the highest risk group, node-positive women younger than 50 years of age, only 44.8% were alive and disease free at 5 years with no polychemotherapy compared with 59.4% with polychemotherapy, which translates into an absolute DFS benefit of 14.6%. However, in the node-negative group, patients younger than 50 years old in whom DFS with no polychemotherapy was highest (ie, 72.6%), the addition of polychemotherapy produced an absolute benefit of only 9.9%. It should be pointed out that all of these differences in DFS are clearly statistically significant and form the basis for national and international guidelines that recommend offering cytotoxic chemotherapy to most women with ESBC.[61,87,88] However, the absolute survival benefit in node-positive women 50 to 69 years old is quite small (3%), and depending on other disease characteristics and comorbid conditions, patients may elect not to pursue treatment. Although a 3% absolute reduction in death attributable to polychemotherapy may appear small, many patients with breast cancer may accept severe toxicity from treatment to achieve as little as a 1% to 5% absolute improvement in survival.

TABLE 128-5 Absolute Benefits of Adjuvant Chemotherapy by Age and Nodal Status

	With Polychemotherapy (%)	With No Polychemotherapy (%)	Absolute Benefit (%)
Disease-Free Survival			
Age <50 years			
Node negative	82.5	72.6	9.9
Node positive	59.4	44.8	14.6
Age 50-69 years			
Node negative	85.7	80.4	5.3
Node positive	63.3	57.4	5.9
Survival[a]			
Age <50 years	67.6	57.6	10
Age 50-69 years	52.6	49.6	3

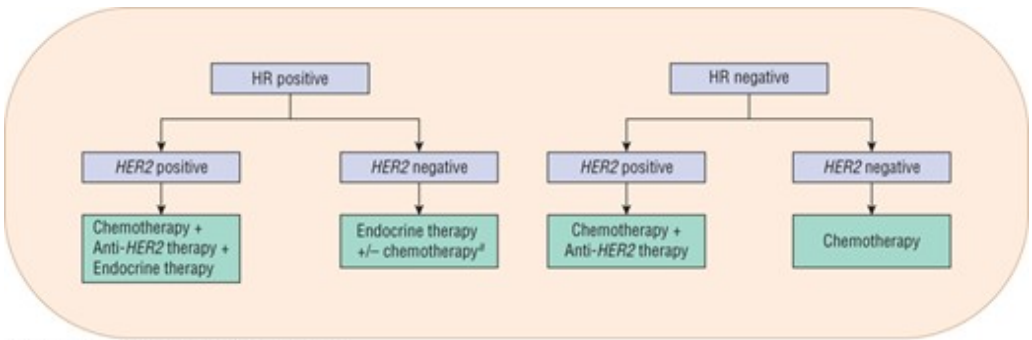
[a]Younger women, 35% node positive; older women, 70% node positive.

Data from reference 86.

Several international and national groups have developed guidelines for treatment of ESBC based on specific patient and disease characteristics and the results of the overview analyses. The three most commonly referenced guidelines are the St. Gallen International Expert Consensus Conference, European Society of Medical Oncology (ESMO), and the NCCN guidelines.[61,87,88] The St. Gallen guidelines are updated every 2 years by an international group of researchers that meets in St. Gallen, Switzerland to review available evidence and create consensus recommendations for selection of adjuvant systemic therapies in specific patient populations outside of the framework of clinical trials. The NCCN and ESMO have also developed practice guidelines for the treatment of breast cancer that are updated annually or more often based on the available evidence. Recommendations from the NCCN for patients with tumors 1 cm or larger or positive lymph nodes are summarized in **Fig. 128-5**. For patients with tumors smaller than 1 cm, micrometastatic lymph node involvement, or negative lymph nodes, treatment is highly individualized and based on multiple patient- and tumor-related factors, including hormone receptor status, *HER2* status, comorbidities, and patient preferences. Specific treatment recommendations are complex, and readers are referred to the guidelines for further details.

FIGURE 128-5

Treatment of patients with breast cancers larger than 1 cm or with positive lymph nodes. Refer to the text for definitions of HR and *HER2* positivity. Refer to the text for management of patients with tumors smaller than 1 cm, micrometastatic lymph node involvement, or negative lymph nodes. [a]Oncotype DX may identify patients who derive little benefit from chemotherapy (lymph node–negative patients only) (see Systemic Adjuvant Therapy section for details). (HR, hormone receptor; *HER2*, human epidermal growth factor receptor-2.)



6 The use of preoperative systemic therapy is the standard of care for patients with locally advanced breast cancer and represents an important treatment option for patients with ESBC. This approach to therapy, referred to as *neoadjuvant* or *primary systemic therapy*, usually consists of chemotherapy but in special circumstances may also include endocrine therapy (eg, in inoperable patients with significant comorbidities or in patients with high sensitivity to endocrine therapy). Advantages of preoperative systemic therapy include (a) a decrease in the size of the tumor to minimize surgery, (b) determination of the response to chemotherapy or hormone therapy in vivo (an important prognostic indicator), and (c) other theoretical advantages (eg, delivery of chemotherapy through an intact vascular system). In a pivotal study conducted by the NSABP (Trial B18),

preoperative chemotherapy was compared with traditional chemotherapy given after surgery (the same chemotherapy and the same number of cycles).[89,90] Although no difference was found in DFS or OS, rates of BCT were higher in the group receiving preoperative chemotherapy (67.8% vs 59.8%).[90] This study also identified a small subset of patients (13%) who had a pathologic complete response (pCR) (no tumor left at surgery) after chemotherapy. These patients went on to have a significantly longer DFS compared with patients who did not achieve a pCR ($p<0.0001$).[90] Importantly, even after 16 years of follow-up, patients who achieved a pCR continued to have superior DFS and OS compared with patients who did not achieve a pCR.[91] Although this approach to therapy was historically reserved for patients with inoperable tumors (locally advanced), the use of preoperative systemic therapy in patients with ESBC is increasing in popularity because of the ability to assess the response to therapy in vivo as well as the potential to decrease the size of the tumor, allowing for less radical surgery and better cosmetic results.

Intensive research efforts are directed toward identifying characteristics of the primary tumor (eg, pathologic or molecular prognostic factors) that may predict for a higher or lower likelihood of distant metastases and death in node-negative patients. Although many prognostic factors are being investigated, no single factor or combination of factors sufficiently identifies those at risk of metastases or is sufficiently standardized to be reproducibly applicable to all patients. Several multiparameter gene expression assays are commercially available as decision-support tools for adjuvant chemotherapy.[77] Oncotype DX® is one of these tests that screens for expression of 21 genes using RT-PCR and results in a recurrence score that can be used to determine the risk of distant recurrence or death from breast cancer in women with ER-positive, node-negative, invasive breast cancer. A low recurrence score (less than 18) indicates a low risk of recurrence with endocrine therapy alone indicating that perhaps adjuvant chemotherapy could be avoided. A high recurrence score (greater than or equal to 31) indicates a high risk of recurrence despite endocrine therapy, suggesting a need for adjuvant chemotherapy followed by endocrine therapy. The utility of chemotherapy in patients with an intermediate score (18-30) is unclear, and is the subject of the prospective TAILORx clinical trial. Retrospective data have suggested that Oncotype DX testing may also be beneficial in selecting patients with positive lymph nodes that may derive little benefit from chemotherapy, and an ongoing clinical trial is underway to further elucidate the role of Oncotype DX in patients with one to three positive lymph nodes after surgery. Other multiparameter gene expression assays include MammaPrint and Prosigna. MammaPrint screens the tumor for 70 genes using microarray technology in breast cancer patients with ESBC, regardless of hormone receptor status. The assay reports the predicted rates of recurrence as high or low. The Microarray In Node-negative Disease may Avoid ChemoTherapy (MINDACT) trial, ongoing in Europe, will compare the predictive capabilities of MammaPrint against the standard prognostic factors to assess which patients with node-negative, ER-positive breast cancer will benefit from adjuvant chemotherapy. PAM50 (Prosigna) is a commercially available multigene test that screens the tumor for 50 genes (plus 5 control genes) to predict distant relapse-free survival and likelihood of recurrence at 10 years in postmenopausal women with ER-positive breast cancer treated with endocrine therapy regardless of nodal status.[77] Prospective data with PAM50 in this patient population is eagerly awaited. Although many clinicians use these tools for individual patients, we await further information to guide the appropriate use of these novel pharmacogenomic tools.

A clinical tool that has been widely adopted for clinical use is an Internet-based tool called Adjuvant! (*www.adjuvantonline.com*), which helps clinicians and patients make informed decisions regarding adjuvant therapy for breast, colon, and lung cancers. The tool allows healthcare professionals to estimate the risks of negative outcomes (eg, cancer recurrence, death), and the potential benefits of therapy (eg, reductions in risks of recurrence and death). This is a validated, evidence-based tool that incorporates multiple prognostic and predictive factors into a mathematical model in which each factor is weighted based on established evidence from clinical trials and is placed in the background of the SEER database for patients living in the United States.[76] By entering the patient's age, comorbidities, ER status, tumor grade, tumor size, and nodal status, the clinician can use the tool to estimate the breast cancer mortality and recurrence risk at 10 years and determine the impact of chemotherapy, hormone therapy, or both on these risks. The results are then projected in a graphic format that is easy to understand and explain to patients, although this tool should not be used directly by patients because of the importance of accurate data entry, selection of different treatment options, and appropriate interpretation of results. Some of the limitations of Adjuvant! include the limited information regarding outcome in patients with tumors that are smaller than 1 cm and no axillary lymph node involvement; it does not incorporate proliferation markers or *HER2* status of the primary tumor; and it does not consider potential adverse effects of therapy for individual patients. Estimates of outcome with the Adjuvant! program may also vary in specific subgroups of patients, such as women who are diagnosed with breast cancer at a younger age.

The most common cytotoxic drugs that have been used alone and in combination as adjuvant therapy for breast cancer include doxorubicin, epirubicin, cyclophosphamide, methotrexate, fluorouracil, carboplatin, paclitaxel, and docetaxel. **Table 128-6** lists some of the most common combination chemotherapy regimens used in the adjuvant setting.

TABLE 128-6 Selected Adjuvant Chemotherapy Regimens for Breast Cancer

AC[b]	**TC**[a,c]
Doxorubicin 60 mg/m^2 IV, day 1	Docetaxel 75 mg/m^2 IV, day 1
Cyclophosphamide 600 mg/m^2 IV, day 1	Cyclophosphamide 600 mg/m^2 IV, day 1
Repeat cycles every 21 days for 4 cycles	Repeat cycles every 21 days for 4 cycles
FAC[d,m]	**TAC**[a,e]
Fluorouracil 500 mg/m^2 IV, days 1 and 4	Docetaxel 75 mg/m^2 IV, day 1
Doxorubicin 50 mg/m^2 IV continuous infusion over 72 hours	Doxorubicin 50 mg/m^2 IV bolus, day 1
Cyclophosphamide 500 mg/m^2 IV, day 1	Cyclophosphamide 500 mg/m^2 IV, day 1 (doxorubicin should be given first)
Repeat cycles every 21-28 days for 6 cycles	Repeat cycles every 21 days for 6 cycles (must be given with growth factor support)
AC → Paclitaxel[a,f]	**Paclitaxel → FAC**[g,m]

AC[b]	TC[a,c]
Doxorubicin 60 mg/m^2 IV, day 1	Paclitaxel 80 mg/m^2 per week IV over 1 hour every week for 12 weeks
Cyclophosphamide 600 mg/m^2 IV, day 1	Followed by:
Repeat cycles every 21 days for 4 cycles	Fluorouracil 500 mg/m^2 IV, days 1 and 4
Followed by:	Doxorubicin 50 mg/m^2 IV continuous infusion over 72 hours
Paclitaxel 80 mg/m^2 IV weekly	Cyclophosphamide 500 mg/m^2 IV, day 1
Repeat cycles every 7 days for 12 cycles	Repeat cycles every 21-28 days for 4 cycles[g]
FEC[h]	**CEF[i]**
Fluorouracil 500 mg/m^2 IV, day 1	Cyclophosphamide 75 mg/m^2 per day orally on days 1-14
Epirubicin 100 mg/m^2 IV bolus, day 1	Epirubicin 60 mg/m^2 IV, days 1 and 8
Cyclophosphamide 500 mg/m^2 IV, day 1	Fluorouracil 600 mg/m^2 IV, days 1 and 8
Repeat cycle every 21 days for 6 cycles	Repeat cycles every 21 days for 6 cycles (requires prophylactic antibiotics or growth factor support)
CMF [j,k]	**Dose-Dense AC → Paclitaxel[a,l,n]**
Cyclophosphamide 100 mg/m^2 per day orally, days 1-14	Doxorubicin 60 mg/m^2 IV bolus, day 1
Methotrexate 40 mg/m^2 IV, days 1 and 8	Cyclophosphamide 600 mg/m^2 IV, day 1
Fluorouracil 600 mg/m^2 IV, days 1 and 8	Repeat cycles every 14 days for 4 cycles (must be given with growth factor support)
Repeat cycles every 28 days for 6 cycles	Followed by:
Or	Paclitaxel 175 mg/m^2 IV over 3 hours
Cyclophosphamide 600 mg/m^2 IV, day 1	Repeat cycles every 14 days for 4 cycles (must be given with growth factor support)
Methotrexate 40 mg/m^2 IV, day 1	
Fluorouracil 600 mg/m^2 IV, days 1 and 8	
Repeat cycles every 21 days for 6 cycles	

AC, Adriamycin (doxorubicin), Cytoxan (cyclophosphamide); CAF, Cytoxan (cyclophosphamide), Adriamycin (doxorubicin), 5-fluorouracil; CEF, cyclophosphamide, epirubicin, 5-fluorouracil; CMF, cyclophosphamide, methotrexate, 5-flourouracil; FAC, 5-fluorouracil, Adriamycin (doxorubicin), cyclophosphamide; FEC, 5-fluorouracil, epirubicin, cyclophosphamide; TAC, Taxotere (docetaxel), Adriamycin (doxorubicin), cyclophosphamide; TC, Taxotere (docetaxel), cyclophosphamide.

[m]FAC may also be given with bolus doxorubicin administration, and the fluorouracil dose is then given on days 1 and 8.

[n]Another way to give these agents in a dose-dense manner is A → P → C as sequential single agents, in the same doses indicated above, every 14 days for 4 cycles each with growth factor support.

The basic principle of adjuvant therapy for any cancer type is that the regimen with the highest response rate in advanced disease should be the optimal regimen for use in the adjuvant setting. However, results from individual clinical trials investigating specific regimens in the adjuvant setting are required to identify the benefits and risks in a specific patient population. Early administration of effective combination chemotherapy at a time when the tumor burden is low should increase the likelihood of cure and minimize the emergence of drug-resistant tumor cell clones. Historically, combination chemotherapy regimens (polychemotherapy) have been more effective than single-agent chemotherapy. Anthracyclines (doxorubicin and epirubicin) and more recently taxanes (paclitaxel and docetaxel) have become the cornerstones of modern chemotherapy for the adjuvant treatment of breast cancer. The overview analysis of adjuvant chemotherapy (discussed previously) analyzed the use of CMF- or anthracycline-based chemotherapy regimens (polychemotherapy) compared with no chemotherapy. Patients who received polychemotherapy had a 23% ± 2% reduction in annual odds of recurrence and a 14% ± 2% reduction in annual odds of death compared with patients who did not receive chemotherapy, establishing adjuvant chemotherapy as a powerful option for reducing breast cancer recurrence. The authors also analyzed results from 20 trials that directly compared an anthracycline-containing regimen with a CMF-type regimen and demonstrated a significant advantage with the anthracycline regimens.[56] In that meta-analysis, anthracycline-containing regimens were modestly superior in reducing recurrence and death compared with regimens without anthracyclines. A 7% ± 3% reduction in annual odds of recurrence and a 9% ± 3% reduction in annual odds of death were reported in the 2012 update with the anthracycline-containing regimens. It should be noted that regimens with higher cumulative doses of anthracycline (at least 240 mg/m^2 of doxorubicin and at least 360 mg/m^2 of epirubicin) were associated with improvements in the RR of recurrence (11% ± 4%) and OS (16% ± 4%) compared with standard CMF regimens. The 2012 update of the meta-analysis also reported data from an additional 33 clinical trials and discovered that incorporation of a taxane reduced the risk of distant recurrence (13% ± 3%), any recurrence (14% ± 2%), and overall mortality (11% ± 3%) compared with a nontaxane regimen.[56] These trials included both sequential and concurrent taxane therapy (paclitaxel or docetaxel) in conjunction with anthracyclines (with or without cyclophosphamide, fluorouracil, or methotrexate). Proportional reductions in recurrence and breast cancer mortality were largely independent of age, nodal status, tumor size, tumor differentiation, or ER status. Most of these trials enrolled node-positive patients only, but some high-risk node-negative patients were also included. There is no apparent biologic reason why patients with node-negative disease should respond differently to the taxanes than those with node-positive disease. However, the absolute benefits for this population may not be large enough to require that all patients with node-negative disease receive an anthracycline- and taxane-based chemotherapy regimen. Because the addition of a taxane may predispose patients to peripheral neuropathy, myelosuppression, and alopecia, adverse events should also be considered. Taxane-containing, non-anthracycline regimens were not included in the meta-analysis but may be appropriate for some patients with a low risk of disease recurrence based

on the results from a single randomized clinical trial.[76] However, this subject remains widely debated, and no single adjuvant chemotherapy regimen is preferred.

Cytotoxic chemotherapy is a particularly important treatment modality for patients with tumors that do not express ER or PR and do not overexpress *HER2* (so called triple negative breast cancer [TNBC]).[92] Patients with TNBC treated with anthracycline- and taxane-based chemotherapy have significantly decreased survival compared with patients with other breast cancer subtypes. Ironically, this subgroup of patients is more likely to respond to neoadjuvant chemotherapy. Therefore, patients with TNBC who achieve a pCR have an excellent long-term survival, but those who have residual disease at the time of surgery have a worse prognosis than non-TNBC patients. The optimal type and duration of chemotherapy for patients with TNBC is unknown. More recently, the addition of carboplatin to a neoadjuvant anthracycline- and taxane-based chemotherapy regimen resulted in a higher pCR rate compared to chemotherapy without carboplatin, but at the cost of increased toxicity.[92] Identification of meaningful molecular targets for this aggressive breast cancer subtype is much needed and research is ongoing. Molecular targets of interest include EGFR, mammalian target of rapamycin (mTOR), and poly-ADP ribose polymerase (PARP).

Although the optimal duration of adjuvant chemotherapy administration is unknown, it appears to be on the order of 12 to 24 weeks and depends on the regimen being used. Optimally, chemotherapy should be initiated within 12 weeks of surgical removal of the primary tumor.[93] "Dose intensity" and "dose density" appear to be critical factors in achieving optimal outcomes in adjuvant breast cancer therapy. *Dose intensity* is defined as the amount of drug administered per unit of time and is typically reported in milligrams per square meter of body surface area per week ($mg/m^2/wk$). Increasing dose, decreasing time between doses, or both can increase dose intensity. *Dose density* is one way of achieving dose intensity but not by increasing the amount of drug given, as occurs with dose escalation, but instead by decreasing the time between treatment cycles. The importance of dose intensity first received wide attention in 1981 when the Milan group reported in a retrospective analysis of their original CMF adjuvant study that only patients who received at least 85% of their planned CMF dose benefited significantly from adjuvant therapy, and those receiving less than 65% of the planned dose had the same DFS and OS as the group of control patients treated with surgery alone.[94] Therefore, dose reductions for standard treatment regimens should be avoided unless necessitated by severe toxicity. But increasing doses beyond those contained in standard treatment regimens does not appear to be beneficial and may be harmful.

Several studies investigating the impact of *dose density* have now been reported. Interest in this approach to adjuvant therapy was stimulated when the Cancer and Leukemia Group B (CALGB) reported results from their trial 9741, which tested not only dose density but also the question of using sequential versus combination chemotherapy regimens. Using a 2 × 2 factorial design, investigators randomized node-positive breast cancer patients after surgery to compare sequential versus concurrent chemotherapy and standard dose versus dose density.[95] The arms of the study were group 1, sequential doxorubicin (A) for 4 cycles followed by paclitaxel (P) for 4 cycles followed by cyclophosphamide (C) for 4 cycles, with all cycles given every 3 weeks; group 2, sequential A for 4 cycles followed by P for 4 cycles followed by C for cycles with all cycles given every 2 weeks with filgrastim; group 3, concurrent AC for 4 cycles followed by P for 4 cycles with all cycles given every 3

weeks; and group 4, concurrent AC for 4 cycles followed by P for 4 cycles with all cycles given every 2 weeks with filgrastim. After a median follow-up period of 36 months, the patients receiving chemotherapy every 2 weeks had a significantly prolonged DFS (at 3 years: 85% vs 81%; RR, 0.74; p=0.01) and OS (92% vs 90%; RR, 0.69; p=0.013) compared with chemotherapy every 3 weeks.[95] The use of sequential versus concurrent chemotherapy did not show a benefit for one over the other in terms of DFS or OS, but sequential therapy did appear to be less toxic. Patients in the concurrent every 2 week group (group 4) had significantly more regimen-related toxicity, including a very high rate of red blood cell transfusions for anemia (13% of cycles).[95] Red blood cell transfusions are rarely required with most other standard adjuvant chemotherapy regimens used for breast cancer.

Dose intensity appears to be important for some drugs but not for others. Many studies with anthracyclines (without taxanes) appear to indicate no benefit from a dose-dense approach to drug administration. These data seem to contradict the CALGB 9741 data. However, data with the taxanes, especially paclitaxel, appear to support a dose-dense (not intense) approach, with weekly therapy producing optimal outcomes.[96] Data with paclitaxel given weekly versus every 3 weeks indicate that this drug is more effective when given weekly in the adjuvant, neoadjuvant, and metastatic settings.[96,97,98] Thus, some speculate that the different paclitaxel schedule is the primary reason for the success with this approach to therapy. A direct comparison between taxane dosing intervals was evaluated in the North American Breast Cancer Intergroup Trial E1199, which randomized patients to receive doxorubicin and cyclophosphamide for 4 cycles every 3 weeks followed by either weekly or every 3 week paclitaxel or docetaxel.[96]

Although this study does not directly address the question of dose density because of the lower doses given in the weekly arms, it appears to support the pharmacologic advantage of a taxane given more frequently as the essential factor driving the beneficial outcomes seen with “dose density” in the CALGB 9741 trial. Although no differences in DFS or OS were observed between the weekly or every 3 week schedule or the different taxanes in the E1199 trial, a subgroup analysis indicated that the weekly paclitaxel arm resulted in improved DFS (HR, 0.84; 95% CI, 0.73-0.96; p=0.011), but not OS (HR, 0.87; 95% CI, 0.75-1.02; p=0.09) compared with paclitaxel administered every 3 weeks. Docetaxel, when administered every 3 weeks, resulted in improved DFS (HR, 0.79; 95% CI, 0.68-0.90; p= 0.001), but not OS (HR, 0.86; 95% CI, 0.73-1.00; p=0.54) compared with paclitaxel administered every 3 weeks. DFS and OS with weekly docetaxel were not significantly different from paclitaxel administered every 3 weeks. Interestingly, a subgroup analysis of patients with TNBC demonstrated a significant benefit in DFS and OS from weekly paclitaxel compared to paclitaxel administered every 3 weeks. This benefit was not seen in patients who received every 3 week docetaxel or weekly docetaxel.[96] This remains an active area of investigation. Although other trials have attempted to investigate dose-dense regimens, they also have other variables that were altered that could potentially impact the outcomes. A meta-analysis by Bonilla et al. evaluated four trials of chemotherapy given in a dose-dense fashion compared with conventional administration.[99] In these studies, patients who received dose-dense chemotherapy had statistically improved DFS and OS compared with patients who received conventionally administered chemotherapy. Unfortunately, none of the trials, with the exception of the CALGB 9741 study, adequately evaluated the true impact of dose density. This remains an area of continued research.

The short-term toxic effects of chemotherapy used in the adjuvant setting are generally well tolerated. Although a number of investigators have demonstrated a reduction in quality of life, most patients are able to maintain a reasonable level of function and emotional and social well-being during treatment.[100] Supportive therapy of patients receiving systemic adjuvant chemotherapy has improved over the past decades. Increased attention to the impact of symptoms on quality of life may account for some of this improvement. In addition, more effective antiemetics have become available to assist in managing chemotherapy-induced nausea and vomiting, and myeloid growth factors are often helpful in preventing febrile neutropenia, particularly in elderly patients and patients receiving dose-dense chemotherapy regimens. Standard anti-nausea medications for anthracycline-based chemotherapy include serotonin receptor antagonists, dexamethasone, and neurokinin-1 antagonists.[101] The use of myeloid growth factors to support some adjuvant chemotherapy regimens may be required (eg, with dose-dense regimens), but these are not routinely used for all adjuvant chemotherapy regimens. Because erythropoiesis-stimulating agents have potential effects on cancer cells and the cellular environment that may negatively impact the antitumor effects of chemotherapy or enhance adverse effects related to the chemotherapy, they should be avoided in patients receiving chemotherapy with a curative intent.[102]

Many other side effects are common with the chemotherapy regimens used for the treatment of ESBC, and patients should be appropriately counseled regarding the likelihood of alopecia, weight gain, and fatigue. Patients who are menstruating often experience a cessation of menses that may not return; cessation of menses may be accompanied by signs and symptoms of menopause. DVT has been reported in women receiving combination chemotherapy regimens.[103] Leukemia and other hematologic disorders have long been associated with the alkylating agents (eg, cyclophosphamide) and the topoisomerase II inhibitors (eg, doxorubicin and epirubicin). Several studies have estimated a 0% to 1.5% cumulative incidence of leukemia or myelodysplasia after adjuvant chemotherapy with median follow-up period of 3 to 11 years.[104] To date, the dose-dense regimens have not been associated with an excess rate of leukemias, but the follow-up period for these trials is relatively short.

Cardiomyopathy induced by doxorubicin occurs in fewer than 1% of women whose total dose of doxorubicin is less than 320 mg/m^2.[105] This risk may be further decreased by use of continuous infusion or weekly doxorubicin. It should be noted that epirubicin in the adjuvant setting is usually given at a dose of 100 to 120 mg/m^2.[61] At this dose, epirubicin has an equal chance of causing cardiomyopathy as standard doxorubicin doses when both agents are given as bolus or short infusions. Taxanes are often associated with hypersensitivity reactions, peripheral neuropathy, or myalgias and arthralgias for a few days after the infusion.

It is important to note that the magnitude of survival benefit for adjuvant chemotherapy in stages I and II breast cancer is modest, with an absolute reduction in mortality rate of only 5% at 10 years for patients with negative axillary lymph nodes and 10% for patients with positive axillary lymph nodes. In addition, it is currently not possible to accurately predict who will attain this survival benefit. The advent of genetic prognostic tools, such as Oncotype DX, can help to identify patients who may derive little or no benefit from chemotherapy. However, these tests are only appropriate in specific subsets of patients. Many patients with breast cancer may accept toxicity from treatment to achieve

as little as a 1% to 5% absolute improvement in survival. Thus, in the absence of the ability to predict who will benefit, it is likely that most patients with stage I and stage II breast cancer would choose adjuvant chemotherapy.

The optimal chemotherapy regimen for use in the adjuvant setting has yet to be identified, and the choice of chemotherapy regimen for a specific patient is complex. Many adjuvant chemotherapy regimens are available, and most of these regimens have not been directly compared in randomized clinical trials. In some cases, the choice of chemotherapy regimen may be geographic, particularly if a regimen has been developed and studied by a particular institution. Based on data from clinical trials and the previously mentioned pooled analysis, the concomitant or sequential addition of a taxane to an anthracycline-based chemotherapy regimen has become the standard of care for women with node-positive breast cancer. Data from meta-analyses and randomized trials specifically in patients with high-risk node negative disease support the use of anthracycline- and taxane-based chemotherapy regimens in this patient population.[56,76] Results from a single trial that evaluated a taxane-containing (non-anthracycline) regimen are available, and this regimen may be an appropriate treatment in a subset of patients at low risk of disease recurrence. NCCN recommendations are purposefully vague, and they do not differentiate between patients with node-positive or negative breast cancer. The NCCN has designated preferred chemotherapy regimens, as listed in Table 128-6, although detailed information is not provided regarding the rationale behind these designations.

Adjuvant Biologic Therapy

As biologic agents continue to demonstrate significant activity against MBC, they are subsequently tested in the adjuvant or neoadjuvant setting. Trastuzumab is a MoAB targeted against the *HER2*-receptor protein. It has demonstrated significant survival benefits when administered with chemotherapy in women with metastatic, *HER2*-positive breast cancer. Several published trials support the use of trastuzumab in combination with or sequentially after adjuvant chemotherapy for patients with early stage, *HER2*-positive breast cancer (**Table 128-7**).[106] Results from these trials report up to a 50% reduction in the risk of recurrence with the addition of trastuzumab to an adjuvant chemotherapy regimen. A meta-analysis of the six available clinical trials investigating the addition of trastuzumab to chemotherapy involving almost 14,000 women revealed superior DFS (OR, 0.69; 95% CI,0.59-0.80; $P<0.001$) and OS (OR, 0.78; 95% CI, 0.69-0.88; $P<0.001$) in patients with *HER2*-positive breast cancer who received trastuzumab with chemotherapy compared with those that received chemotherapy alone.[107] This difference in DFS translated into a 31% overall lower RR for disease progression or death from any cause for patients who received trastuzumab. Although the benefit of adding trastuzumab to these regimens is obvious, the type of chemotherapy, sequence of administration, and duration of trastuzumab differed among the trials, making the optimal trastuzumab-based regimen less obvious.

TABLE 128-7 Selected Regimens for *HER2*-Positive Early-Stage Breast Cancer

Regimen	Drugs	Doses	Frequency	Cycles
Adjuvant				
AC → PH →	Doxorubicin	60 mg/m^2 IV	Every 21 days	4

Regimen	Drugs	Doses	Frequency	Cycles
Adjuvant				
	Cyclophosphamide	600 mg/m^2 IV	Every 21 days	4
	followed by			
	Paclitaxel	175 mg/m^2 IV over 3 hours	Every 21 days	4
	or			
H[a]	Paclitaxel	80 mg/m^2 IV over 1 hours	Every 7 days	12 weeks
	with Trastuzumab	4 mg/kg IV → 2 mg/kg IV	Every 7 days	12 weeks
	followed by			
	Trastuzumab	2 mg/kg IV or 6 mg/kg IV	Every 7 days or every 21 days	Complete 1 year
	Docetaxel	75 mg/m^2 IV	Every 21 days	6
	Carboplatin	AUC 6 IV	Every 21 days	6
TCH[b]	Trastuzumab	4 mg/kg IV → 2 mg/kg IV	Every 7 days	18 weeks
	followed by			
	Trastuzumab	6 mg/kg IV	Every 21 days	Complete 1 year
	Chemotherapy	See reference for details		At least 4
Chemo → H[c]	*followed by*			
	Trastuzumab	8 mg/kg IV→ 6 mg/kg IV	Every 21 days	1 year
	Doxorubicin	60 mg/m^2 IV	Every 21 days	4
	Cyclophosphamide	600 mg/m^2 IV	Every 21 days	4
	followed by			
AC → TH[b]	Docetaxel	100 mg/m^2 IV	Every 21 days	4
	Trastuzumab	4 mg/kg IV → 2 mg/kg IV	Every 7 days	12 weeks
	followed by			
	Trastuzumab	6 mg/kg IV	Every 21 days	Complete 1 year
TCHP[d]	Docetaxel	75 mg/m^2 IV	Every 21 days	6
	Carboplatin	AUC 6 IV	Every 21 days	6

Regimen	Drugs	Doses	Frequency	Cycles
Adjuvant				
	Trastuzumab	8 mg/kg IV → 6 mg/kg IV	Every 21 days	6
	Pertuzumab	840 mg IV → 420 mg IV	Every 21 days	6
	followed by			
	Trastuzumab	6 mg/kg IV	Every 21 days	Complete 1 year
THP → FEC[e]	Neoadjuvant Docetaxel[f]	75 mg/m^2 IV	Every 21 days	4
	Trastuzumab	8 mg/kg IV → 6 mg/kg IV	Every 21 days	4
	Pertuzumab	840 mg IV → 420 mg IV	Every 21 days	4
	followed by adjuvant			
	5-Fluorouracil	600 mg/m^2 IV	Every 21 days	3
	Epirubicin	90 mg/m^2 IV	Every 21 days	3
	Cyclophosphamide	600 mg/m^2 IV	Every 21 days	3

AC, Adriamycin (doxorubicin), Cytoxan (cyclophosphamide); FEC, fluorouracil, epirubicin, cyclophosphamide; H, Herceptin (trastuzumab); PH, paclitaxel, Herceptin (trastuzumab); TCH, Taxotere (docetaxel), carboplatin, Herceptin (trastuzumab); TCHP, Taxotere (docetaxel), carboplatin, Herceptin (trastuzumab), pertuzumab; TH, Taxotere (docetaxel), Herceptin (trastuzumab); THP, Taxotere (docetaxel), Herceptin (trastuzumab), pertuzumab.

[f]Some guidelines allow the substitution of paclitaxel for docetaxel.

Most of the regimens investigated in these adjuvant trials included an anthracycline and a taxane given concurrently with trastuzumab or sequentially before trastuzumab. From the available evidence, it appears that administration of a taxane with trastuzumab may be more effective than trastuzumab administered after chemotherapy. In the previously mentioned meta-analysis, sequential and concomitant use of trastuzumab with chemotherapy both prolonged DFS compared with chemotherapy alone; whereas concomitant trastuzumab also improved OS, sequential trastuzumab did not.[107] The adjuvant use of trastuzumab without an anthracycline has been reported in one trial (Breast Cancer International Research Group 006) and appears to provide similar benefit with diminished cardiac adverse effects as compared with traditional anthracycline-containing adjuvant trastuzumab regimens.[108] The duration of trastuzumab therapy in these adjuvant trials ranges from 9 to 104 weeks in the published studies. The optimal duration of trastuzumab therapy is unknown, although the most current data support the use of trastuzumab for a total of 52 weeks. The most commonly used trastuzumab-based adjuvant chemotherapy regimens are listed in Table 128-7.

The incidence of adverse cardiac effects associated with the addition of trastuzumab appears to increase when an anthracycline is included in the regimen before administration of trastuzumab. The incidence of symptomatic heart failure with adjuvant trastuzumab ranges from 0.5% to 4% in highly selected patients who participated in the clinical trials.[108,109] The higher risk of cardiac complications may be acceptable in many patients given the significant reductions in breast cancer recurrence and death rates. Sequential administration of trastuzumab after chemotherapy (as in the HERA trial) appears to produce a lower incidence of cardiac toxicity (symptomatic congestive heart failure = 2% with trastuzumab). Also, the use of a non–anthracycline-based regimen in the BCIRG 006 trial (Table 128-7) was associated with a low incidence (0.4%) of symptomatic heart failure compared with other regimens.[108] However, cross-trial comparisons are challenging because the definition of cardiac events in each trial was different. Therefore, application of these results to individual patients is fraught with difficulties, and many different regimens may be appropriate for a given patient. Concurrent administration of trastuzumab with an anthracycline is very controversial because of potentially higher rates of cardiac dysfunction (see the Anti-*HER2* Agents of MBC section). Similar to many MoABs, trastuzumab is associated with infusion-related reactions such as fever, chills, and rigors temporally associated with trastuzumab infusions.[110] Postmarketing surveillance data have identified "pulmonary toxicity" and "anaphylaxis" as rare but potentially life-threatening reactions associated with trastuzumab. Chemotherapy-related adverse effects, including neutropenia, infection, and diarrhea, are slightly more frequent with the addition of concurrent trastuzumab therapy, but these toxicities are easily managed and do not preclude the use of trastuzumab in patients with ESBC.

All of these adjuvant trials continued trastuzumab administration during adjuvant radiation therapy and endocrine therapy. The administration of trastuzumab during radiation therapy was evaluated in patients that participated in the N9831 clinical trial. Patients that received concurrent radiation therapy with adjuvant trastuzumab did not experience a significant increase in cardiac events or acute radiation-related adverse events with the exception of transient leukopenia.[111] Therefore, if radiation

therapy is clinically indicated, trastuzumab is typically administered concomitantly with radiation.

Many questions remain regarding the optimal use of trastuzumab in the adjuvant or neoadjuvant therapy of ESBC. The use of trastuzumab with chemotherapy in the adjuvant or neoadjuvant setting is now considered to be the standard of care for patients with node-positive and high-risk node-negative *HER2*-positive breast cancer.[61] Controversy exists regarding the use of anti-*HER2* therapy in patients with small, *HER2*-positive, node-negative tumors. Several retrospective analyses of patients with *HER2*-positive tumors smaller than 1 cm who did not receive trastuzumab appear to indicate a poor prognosis, suggesting that these patients may also benefit from trastuzumab-based adjuvant chemotherapy.[112] A single arm, nonrandomized clinical trial demonstrated an excellent 3-year disease-free survival (98.7%) in patients who received weekly paclitaxel and trastuzumab for 12 weeks, followed by trastuzumab every 3 weeks for a total of one year in patients with lymph-node negative, *HER2*-positive, breast cancers smaller than 3 cm.[113] The MoAB pertuzumab has become an important treatment option for patients with *HER2*-positive breast cancer in the neoadjuvant setting.[114] Two clinical trials have shown high rates of pCR at the time of surgery following chemotherapy in combination with trastuzumab and pertuzumab. Patients included in these trials were required to have tumors larger than 2 cm or positive lymph nodes. See Table 128-7 for details regarding the most commonly used regimens. A large clinical trial with pertuzumab in combination with trastuzumab and chemotherapy in the adjuvant setting for *HER2*-positive breast cancer is ongoing and results are eagerly awaited.

Clinical Controversy…

Trastuzumab clearly has improved the outcomes for women with lymph node–positive and high-risk lymph node–negative early-stage, *HER2*-positive breast cancer. However, patients with small (less than 1 cm) tumors with negative lymph nodes were not included in prospective clinical trials with trastuzumab. Retrospective data suggest that patients with small *HER2*-positive tumors who did not receive trastuzumab-based chemotherapy have a poor prognosis. A single arm, nonrandomized clinical trial with weekly paclitaxel and trastuzumab for 12 weeks, followed by trastuzumab every 3 weeks for a total of one year has been conducted in this patient population. Questions remain regarding optimal use of trastuzumab in this patient population, and each patient must weigh the risks versus benefits for his or her individual circumstance.

Adjuvant Endocrine Therapy

Endocrine therapies that have been studied in the treatment of primary or early-stage breast cancer include tamoxifen, toremifene, oophorectomy, ovarian irradiation, luteinizing hormone–releasing hormone (LHRH) agonists, and AIs. The choice of agent(s) depends on menopausal status and is based on a multitude of clinical trials completed in this setting that establish different roles for different therapies.

Tamoxifen was traditionally the gold standard adjuvant endocrine therapy and has been used in the adjuvant setting for more than 3 decades. Tamoxifen is antiestrogenic in breast cancer cells, but it appears to have estrogenic properties in other tissues and organs.[115,116] More recent studies show

that tamoxifen and other similar drugs have many estrogenic and antiestrogenic effects that depend on the tissue and the gene in question, and they are more appropriately called SERMs. Women receiving adjuvant tamoxifen therapy have reduced risk of recurrence and mortality compared with women not receiving adjuvant tamoxifen therapy.[36] In the United States, tamoxifen is generally considered the adjuvant endocrine therapy of choice for premenopausal women, although newer data also support the use of LHRH agonists or oophorectomy in combination with AIs in this group of women.

If chemotherapy and radiation therapy are not required, adjuvant endocrine therapy is generally initiated shortly after surgery or as soon as pathology results are known. When adjuvant chemotherapy is also required, endocrine therapy should be administered after chemotherapy is completed. This recommendation is based on evidence from a phase III trial suggesting tamoxifen administered concurrently with chemotherapy may antagonize the beneficial effect of chemotherapy.[117] In the phase III clinical trial, administration of sequential tamoxifen resulted in a marginally superior DFS compared with concurrent use of tamoxifen with chemotherapy (HR, 0.84; 95% CI, 0.70-1.01; P=0.061).[117] Some clinicians also advocate the initiation of endocrine therapy after completion of radiation therapy, but this subject is very controversial, and few trials have addressed the issue of concurrent versus sequential endocrine therapy and radiation therapy.

Historically, the duration of tamoxifen therapy in the adjuvant setting has been 5 years. However, the results of two recent studies have suggested that a longer duration of tamoxifen may be more effective. In the ATLAS trial, patients with ER-positive breast cancer who had 10 years of tamoxifen had improved DFS and OS compared with those with 5 years of treatment.[118] In the aTTom trial, patients with ER-positive breast cancer who received 10 years of tamoxifen had improved DFS, but not breast cancer mortality, compared with those who received 5 years of treatment.[119] Previous randomized trials comparing 5 years of tamoxifen treatment with longer than 5 years of tamoxifen treatment have shown opposite results and, in fact, were stopped early because of these detrimental outcomes.[120] Patients in the ATLAS and aTTom trials who received 10 years of tamoxifen had increased toxicities, including an increased risk of developing endometrial cancer (ATLAS and aTTom trials) and pulmonary embolism (ATLAS trial only) compared with those receiving tamoxifen for 5 years.[118,119] With this new information, administration of tamoxifen for 10 years can be considered in women with a higher risk of breast cancer recurrence, although the clinician must weigh the risk of toxicity associated with prolonged therapy.

Clinical Controversy…

For premenopausal women with early-stage or locally advanced hormone-receptor-positive breast cancer, tamoxifen administered for 5 years has historically been the gold standard. However, two recent clinical trials have suggested a decreased risk of breast cancer recurrence in premenopausal women with ovarian suppression and AI compared to tamoxifen and ovarian suppression for 5 years. Confounding factors include the use of ovarian suppression with tamoxifen in these trials and newer data with tamoxifen given for 10 years. Providers should discuss the risks and benefits of endocrine therapy options individually in each premenopausal patient.

The most reliable information regarding the side effects of tamoxifen comes from the NSABP Breast Cancer Prevention Trial (P-1).[37] This trial randomized 13,388 women 35 years of age or older who were at increased risk for breast cancer to placebo (*n* = 6,707) or to 20 mg/day of tamoxifen (*n* = 6,681) for 5 years. Although the primary finding of this study is that tamoxifen reduces the risk of invasive breast cancer by 49%, this study also provides an excellent opportunity to determine the risk of side effects associated with tamoxifen. Information was prospectively collected with regard to the occurrence of hot flashes, vaginal discharge, irregular menses, fluid retention, nausea, skin changes, diarrhea, and weight gain or loss. The self-administered depression scale and a global quality-of-life and a sexual function scale were administered at each follow-up visit. The only symptomatic differences noted between the placebo and tamoxifen group were related to hot flashes and vaginal discharge, both of which occurred more often in the tamoxifen group. No important differences between the two groups were observed in the various self-reporting instruments. Tamoxifen did not increase the risk of ischemic heart disease but did reduce the risk of hip radius and spine fractures. Of note, the rates of stroke, pulmonary embolism, and DVT were elevated in the tamoxifen group (stroke: RR, 1.59; pulmonary embolism: RR, 3.01; and DVT: RR, 1.60), particularly in women age 50 years or older. The rate of endometrial cancer was increased in the tamoxifen group (RR, 2.53), and this increased risk occurred predominantly in women age 50 years or older. The increased risk of endometrial carcinoma is similar in magnitude to that associated with postmenopausal estrogen replacement therapy and is likely a consequence of an estrogenic effect of tamoxifen on the endometrium. Some experts argue that this risk is acceptable because the endometrial cancer induced by tamoxifen is low stage, low grade, and easily treated with surgery or other means and does not pose a life-threatening risk to women. Tamoxifen was also associated with an increased risk of uterine sarcomas (a more aggressive form of endometrial cancer), but this risk appears to be lower than the more common endometrial cancers identified in the NSABP P-1 study. Routine endometrial biopsy is not currently recommended for women receiving tamoxifen therapy. However, women receiving tamoxifen therapy should be counseled to have regular gynecologic examinations and immediately report unusual vaginal bleeding to their primary clinicians for further evaluation.[121]

In premenopausal women, the use of LHRH agonists (ovarian suppression) or ovarian ablation provides benefit in the adjuvant setting. In the EBCTCG overview analysis published in 2005, the overall benefit of ovarian ablation or suppression was significant compared with no treatment (reduction in annual odds of recurrence = 25% ± 12% in women younger than 40 years old and 29% ± 6% in women 40-49 years old).[122] Many of the ongoing trials with the LHRH agonists were not yet included in this analysis, and most of the clinical trials analyzed included patients with hormone receptor–positive, –negative, and unknown tumor status. In an update of this analysis, study inclusion was restricted to patients treated with ovarian suppression with LHRH agonists (not ovarian oblation or oophorectomy) and patients with tumors known to be hormone receptor positive.[123] The addition of a LHRH agonist reduced the rates of recurrence by 25%, deaths after recurrence by 28%, and all deaths by 27% in women younger than 40 years; no significant reductions in recurrence or death were noted in patients older than 40 years. Also, a similar benefit was observed with goserelin as compared with CMF chemotherapy in hormone-sensitive premenopausal breast cancer patients but not in patients with hormone receptor–negative tumors.[123] It is not clear whether the benefit of chemotherapy in this population is a result of the actual effects of chemotherapy or a result of the

endocrine effects of chemotherapy-induced amenorrhea. Consequently, some studies have investigated the benefits of adding ovarian ablation or suppression to chemotherapy either with or without tamoxifen. Results from these studies clearly indicate a benefit from ceasing menses regardless of whether this is caused by chemotherapy or ovarian ablation or suppression.[123] It is not clear whether the addition of an LHRH agonist to tamoxifen is advantageous in women with hormone receptor–positive tumors who continue to menstruate after chemotherapy. The optimal duration of adjuvant LHRH agonist use is unknown, with trials ranging from 18 months to 5 years of treatment. Two recently published clinical trials evaluated the benefit of combining an LHRH agonist with tamoxifen or with an AI in premenopausal women. In the TEXT trial, premenopausal patients with hormone receptor–positive early-stage breast cancer were randomized to receive 5 years of tamoxifen or exemestane, both concomitantly with triptorelin for ovarian suppression. In the SOFT trial, premenopausal patients with hormone receptor–positive early-stage breast cancer were randomized to receive 5 years of tamoxifen alone, tamoxifen with triptorelin or exemestane with triptorelin. Combined results of the tamoxifen/triptorelin arms and exemestane/triptorelin arms from the SOFT and TEXT studies demonstrated prolonged 5-year DFS with exemestane compared to tamoxifen (91% vs 87%, $P<0.001$).[124] Results from the tamoxifen only arm of the SOFT trial were not reported in this analysis. Subsequently, results from the SOFT trial were published. In this trial, the estimated 5-year DFS rate did not significantly differ with tamoxifen alone compared to tamoxifen with ovarian suppression (HR 0.78; 95% CI 0.66-1.04).[125] Not unexpectedly, patients who received tamoxifen with ovarian suppression more frequently experienced menopausal symptoms such as hot flushes, sweating, and vaginal dryness compared to patients who received tamoxifen alone. Based on this data, the combination of ovarian suppression and an AI could be considered in premenopausal women with hormone receptor-positive ESBC.

In postmenopausal women, incorporation of AIs is the standard of care in the adjuvant setting. Four different approaches to therapy have been undertaken with these agents: (a) direct comparison with tamoxifen for adjuvant endocrine therapy; (b) sequential use after 5 years of adjuvant tamoxifen therapy; (c) sequential use after 2 to 3 years of adjuvant tamoxifen; and (d) 2 years of treatment with an AI followed by 3 years of adjuvant tamoxifen. In an analysis of two trials that compared 5 years of adjuvant tamoxifen to 5 years of an AI (n = 9885), the risk of recurrence at 10 years was significantly reduced in women who received an AI compared to tamoxifen (RR 0.80; 95% CI 0.73-0.88).[86] In a separate analysis of trials investigating a switch to an AI, 12,799 patients who had completed 2 to 3 years of adjuvant tamoxifen therapy were randomized to continue tamoxifen or crossover to an AI for the remainder of 5 years.[86] The results of this analysis show a decreased risk of recurrence at 7 years after randomization in patients who switched to an AI compared with those who continued with tamoxifen alone (RR 0.90; 95% CI 0.81-0.99). The Breast International Group (BIG) 1-98 trial, which compared letrozole with tamoxifen, also included two separate arms that investigated the value of switching from tamoxifen to an AI or vice versa. With 71 months of follow-up period, the sequential arms did not improve estimated 5-year DFS compared with letrozole alone in either comparison.[61] Clinical trials are also investigating longer durations of AI use to assess the benefits and harms of continued estrogen deprivation, the results of which are greatly anticipated.

Most national and international guidelines currently recommend incorporation of an AI into the adjuvant endocrine therapy regimen for all postmenopausal, hormone-sensitive breast cancers.[61] The

current NCCN guidelines for breast cancer management state that any of the following are acceptable endocrine therapy regimens for these women: (a) an AI for 5 years (or longer based on expert opinion); (b) tamoxifen for 2 to 3 years followed by an AI for a total of 5 years of endocrine therapy; or (c) tamoxifen for 5 years followed by an AI for another 5 years (total of 10 years of endocrine therapy).[61] The NCCN panel believes that the three available AIs (anastrozole, letrozole, and exemestane) have similar antitumor efficacy and toxicity profiles, and many other clinicians agree. Therefore, the optimal endocrine therapy regimen in the adjuvant setting has yet to be determined, and incorporation of biologic therapies into these regimens is also being examined. Results from ongoing trials are eagerly awaited to more clearly define a treatment strategy for women facing this clinical dilemma.

Aromatase inhibitors (AIs) are generally well tolerated. Adverse effects include bone loss or osteoporosis, hot flashes, myalgias or arthralgias, vaginal dryness or atrophy, mild headaches, and diarrhea. Although concerns surrounding loss of bone density and an increased risk of osteoporosis are evident in these adjuvant trials, the overall impact on quality of life and long-term survival are still being evaluated. Bone modifying agents are coadministered with the AI in many patients in the metastatic setting and may also be beneficial in the adjuvant setting. Other adverse events that are worrisome include questionable effects on the cardiovascular system (eg, hypercholesterolemia), cognitive functioning, and joint health. Longer follow-up from these trials will continue to provide valuable information to guide treatment decisions and management of adverse effects.

In summary, tamoxifen has been used in the adjuvant setting for nearly 30 years and has a very well-defined safety and efficacy profile in this setting. The roles of other agents such as AIs in postmenopausal women and LHRH agonists in premenopausal women have changed the landscape of adjuvant endocrine therapy, and incorporation of other biologic therapies may further impact outcomes.

The pharmacologic disposition of tamoxifen in humans is very complex and has only recently been elucidated (**Fig. 128-6**). Tamoxifen is now considered to be a prodrug. Although the parent compound has significant clinical activity, tamoxifen is metabolized through multiple enzymes, including CYP3A4, CYP2C19, CYP2D6, and others, to metabolites that appear to be more active than the parent compound.[126] The active metabolites 4-hydroxytamoxifen (4OH-TAM) and 4-hydroxy-*N*-desmethyltamoxifen (endoxifen) have nearly a 100-fold higher affinity for the ER compared with tamoxifen. Endoxifen is present in the serum at a 6 to 12-fold higher concentrations compared with 4OH-TAM; hence, endoxifen is thought to be the most important metabolite for the clinical activity of tamoxifen. The formation of endoxifen is highly dependent on the enzymatic activity of CYP2D6. However, multiple other pathways may also be important for determining activity, including deactivation pathways (eg, SULT-1-A1, UGT). Polymorphisms in CYP2D6 can lead to increased or decreased formation of endoxifen and may be related to improved or diminished clinical outcomes, respectively. Although clinical data suggest that certain polymorphisms in CYP2D6 may result in poorer DFS or relapse-free survival in patients receiving tamoxifen, other studies show either no relationship or the opposite effect between clinical outcomes and CYP2D6 polymorphisms. Multiple commercially available assays for CYP2D6 are available, but widespread testing for patients receiving tamoxifen is not currently recommended based on available evidence.[61,87] Excellent reviews on this

subject are available.[126] Potent inhibitors of CYP2D6, such as paroxetine and fluoxetine, may decrease levels of endoxifen in patients receiving tamoxifen.[126] The clinical outcomes related to such drug–drug interactions in an individual patient are largely unknown and may depend on their underlying CYP2D6 genetic status (eg, poor metabolizer, extensive metabolizer). In one population-based cohort study, concomitant use of tamoxifen and paroxetine (but not other antidepressants) resulted in increased risk of breast cancer death.[127] Even though high-quality data on strong CYP2D6 inhibitors and breast cancer outcomes in patients receiving tamoxifen are limited, common sense would dictate avoiding known strong inhibitors of CYP2D6, if possible, in patients receiving tamoxifen.

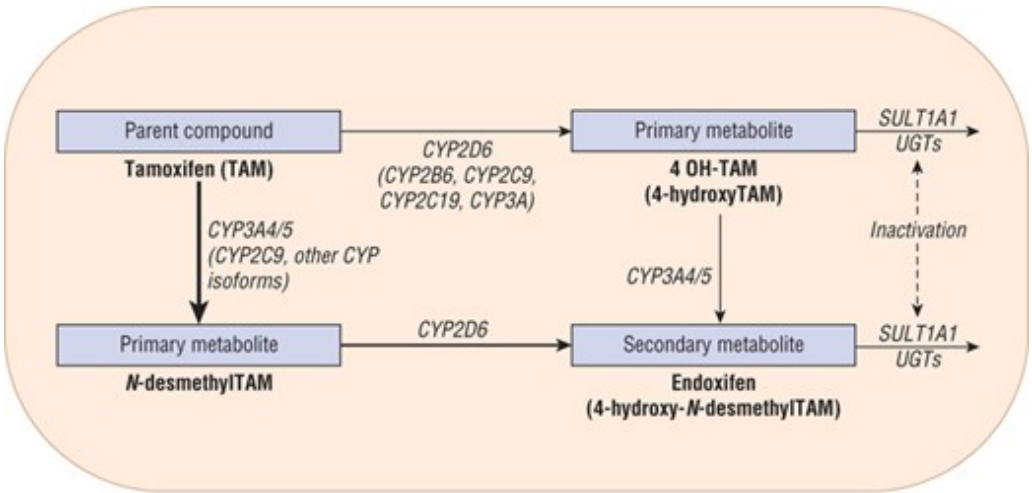
Tamoxifen metabolism. Widths of the arrows approximate allocation of parent compound to various metabolites.



Locally Advanced Breast Cancer (Stage III)

6 *Locally advanced breast cancer* generally refers to breast carcinomas with significant primary tumor and nodal disease but in which distant metastases cannot be documented. A wide variety of clinical scenarios can be seen within this group of patients, including neglected tumors that have spread locally, to IBCs that are a unique clinical entity. IBC is associated with similar clinical findings compared with neglected, locally advanced breast tumors (eg, erythema representing skin involvement). The distinction between the two diagnoses lies in the rapidity of onset of symptoms. Many locally advanced breast cancers are diagnosed in patients who have had symptoms for months to years and have neglected to seek medical attention. Although these women have a poor prognosis because of the delay in diagnosis, they are not classified as IBC. The hallmark of IBCs is the rapid onset of symptoms within weeks to months, including erythema of the skin with or without a detectable underlying breast mass. These patients are often inappropriately treated for cellulitis with antibiotics for several weeks to months. Because of the aggressive nature of this disease, a delay in diagnosis can be fatal for some of these women.

The natural history of locally advanced breast cancer shows that even when local–regional control is accomplished, systemic relapse and death from breast cancer eventually occur in most patients if systemic therapy is not used.[128] That observation led to interest in the use of neoadjuvant or primary chemotherapy in locally advanced breast cancer, which renders inoperable tumors resectable and can increase rates of BCT. Other potential benefits related to early initiation of systemic therapy include delivery of drugs through an intact vasculature, in vivo assessment of response to therapy, and the opportunity to study the biologic effects of the systemic treatment. For patients with inoperable breast cancer, including IBC, the initial approach to therapy should be chemotherapy with the goal of achieving resectability. The NCCN guidelines addressing the management of locally advanced disease recommend primary chemotherapy with an anthracycline- and taxane-containing regimen.[61]

After neoadjuvant chemotherapy, most tumors respond with more than a 50% decrease in tumor size; about 70% of patients experience a reduction in their stage of disease. The chemotherapy regimens used in this setting are similar to those used in the adjuvant setting, but generally include an anthracycline and incorporate a taxane in some manner. For patients with *HER2*-positive tumors, the incorporation of trastuzumab and pertuzumab with chemotherapy is appropriate.[114] Neoadjuvant endocrine therapy may be an option for patients who have unresectable hormone receptor–positive tumors who are unable to receive chemotherapy (eg, multiple comorbid conditions).[129] However, this approach to therapy is not common.

Local therapy usually follows chemotherapy, and the extent of surgery is determined by response to chemotherapy, the wishes of the patient, and the cosmetic results likely to be achieved. However, many patients may be able to have BCT if an acceptable response to chemotherapy is accomplished. Adjuvant radiation therapy should be administered to all locally advanced breast cancer patients to minimize local recurrences regardless of the type of surgery used for that individual patient (eg, mastectomy or segmental mastectomy). Inoperable tumors that are unresponsive to systemic chemotherapy may require radiation therapy for local management and may not be eligible for surgical resection after radiation. These patients are not commonly encountered but have a very poor prognosis. For most patients with locally advanced breast cancer, cure is still the primary goal of therapy and can be achieved in a large number of patients when all treatment modalities are used.

Metastatic Breast Cancer (Stage IV)

7 Treatment of MBC with cytotoxic, biologic, or endocrine therapy often results in regression of disease and improvements in quality of life. The choice of therapy for metastatic disease is based on the presence or absence of certain tumor or patient characteristics and extent of disease involvement. The most important factors predicting response to therapy are the presence of *HER2*, estrogen, and progesterone receptors in the primary tumor tissue. Tumors overexpressing *HER2* receptor protein are more likely to benefit from *HER2*-targeted therapy. Tumors expressing high levels of ER, PR, or both are more likely to respond to endocrine therapy. For TNBC, investigators and clinicians are diligently searching for biologic targets that may be predictive of response to a number of agents (eg, BRCA1 mutations with the platinum agents). The extent of metastases is also an important factor to consider. Endocrine therapy is the treatment of choice for patients with hormone receptor–positive tumors who exhibit mild to no symptoms of disease, regardless of *HER2* status. For

cases where hormone receptors and *HER2* receptors are over-expressed, an endocrine agent in combination with a *HER2*-targeting agent (eg, trastuzumab or lapatinib), should be considered. Data with biologic, targeted therapies (eg, everolimus, palbociclib) which appear to target endocrine resistance, have changed the approach in patients with *HER2*-negative, HR-positive MBC, favoring combination endocrine/biologic therapy as first- or second-line therapy compared to single agent endocrine therapy for some patients. Patients with symptomatic visceral or central nervous system (CNS) involvement generally have more rapidly growing cancers that require up-front chemotherapy, either alone or with *HER2*-targeted therapy. In this clinical setting, for tumors that over-express *HER2*, regimens that combine *HER2*-targeted therapy with chemotherapy are preferred.[130]

Patients who respond to initial endocrine therapy alone often respond to a second (or even third) hormonal manipulation. But the response rate is lower, and the duration of response is shorter with second (and third) hormonal manipulations. Patients who respond initially to an endocrine/biologic combination are generally treated with a second combination with varying results. Little information is known about subsequent response to therapy after biologic combinations in this setting and this is the subject of much research. Patients typically are sequentially treated with endocrine therapy (alone or with a biologic agent) until their tumors cease to respond or the patient ceases to benefit from endocrine therapy, at which time cytotoxic chemotherapy can be administered. Subsequent response to chemotherapy after endocrine/biologic therapy combinations is also currently unknown, but is frequently recommended for patients who can tolerate chemotherapy. Concurrent administration of more than one endocrine therapy or combining chemotherapy plus endocrine therapy is generally avoided in the setting of MBC because of increased toxicity and no substantial improvement in OS. Women with hormone receptor–negative tumors; with rapidly progressive or symptomatic lung, liver, or bone marrow involvement (a visceral crisis); and with progressive disease while on initial endocrine therapy (with or without a biologic agent) are usually treated with cytotoxic chemotherapy.[61]

All breast cancer patients with metastases to the bone should be considered for treatment with a bone-modifying agent (eg, pamidronate, zoledronic acid, or denosumab) because these agents have been shown to decrease the rates of skeletal-related events, such as fractures, spinal cord compression, and pain, and the need for radiation to the bones or surgery.[131] These agents do not act as anticancer agents and should be coadministered with other therapies targeting the cancer cells specifically.

Desired Outcomes

After advancing beyond local–regional disease, breast cancer is currently incurable. However, some patients live for many years with metastatic disease, making this a chronic disease requiring long-term management strategies that incorporate improvements or maintenance of quality of life. Palliation is the desired therapeutic outcome in the treatment of MBC. Optimizing benefits and minimizing toxicity are general therapeutic goals of any therapy administered in this setting. Therefore, sequential single-agent chemotherapy is often chosen over combination regimens, but individual circumstances may call for more rapid responses in which combination therapy may be indicated. Endocrine therapy is generally less toxic than chemotherapy and may be a more appropriate option for patients with hormone receptor–positive breast cancer with or without a

biologic, targeted therapy. Tumor response to a particular treatment regimen may be measured by changes in laboratory tests, diagnostic imaging, and physical signs and symptoms. If a patient is tolerating therapy well, clear evidence of disease progression on imaging or physical examination is required to warrant changing therapy. Unless the patient clearly cannot tolerate the regimen or the cancer is clearly progressing at a rate that will quickly cause symptoms (or is causing symptoms already), there is not a sound reason to change therapy. Optimizing quality of life is an important therapeutic end point in the treatment of patients with MBC and eventually requires discontinuation of active cancer therapy and a shift to supportive care with hospice services. Balancing between quantity and quality of life is a frequent battle waged by many oncology clinicians in close collaboration with their patients, and difficult decisions are faced during this time.

Biologic or Targeted Therapy

Therapies that focus on molecular targets through novel mechanisms are often referred to as biologic or targeted therapy. These agents, while using the biologic knowledge gained from decades of research, are designed to specifically target cancer cells while generally sparing normal tissues. For breast cancer, several agents are available that focus on a myriad of targets that are differentially expressed in breast cancer cells and play a critical role in their proliferation and survival.

HER2-Targeted Agents

HER2, in selected breast cancers, is a very important protein for maintenance of breast cancer cell proliferation and survival. Currently, four anti-*HER2* agents are available in the United States, trastuzumab, lapatinib, pertuzumab and ado-trastuzumab emtansine.

As mentioned previously, trastuzumab is a MoAB targeted against the *HER2*-receptor protein. Pertuzumab is also a MoAB but binds to a different epitope on *HER2* and prevents protein dimerization and subsequent cell signaling. Ado-trastuzumab emtansine (also called T-DM1) is a MoAB-drug conjugate with a trastuzumab backbone linked to a potent tubulin inhibitor, emtansine (DM1). Lapatinib is a small-molecule TKI targeted against the *HER2* protein and the *HER1* (EGFR) protein, leading to dual signaling blockade.

Evidence supporting the use of *HER2*-targeted therapy is found in two systematic reviews: 1) ASCO clinical practice guideline for systemic therapy for patients with advanced *HER2*-positive breast cancer published in 2014 and 2) systematic review by Cancer Care Ontario (CCO) published in 2011.[130] These systematic reviews found evidence of progression-free (PFS), time-to-progression (TTP) and overall response rate benefits with the addition of trastuzumab to chemotherapy. Additionally, the combination of trastuzumab and chemotherapy increased OS, an endpoint that had historically been stagnant for this disease. The addition of trastuzumab to endocrine therapy in the CCO review was found to increase PFS and TTP, but not OS. Based on this information, the ASCO guidelines clearly recommend the use of first-line *HER2*-directed therapy with chemotherapy for patients with *HER2*-positive MBC. Combination endocrine therapy plus *HER2*-directed therapy (either trastuzumab or lapatinib) is appropriate as first-line therapy in selected cases where the tolerability of chemotherapy may be problematic or after a patient has achieved maximal response with a

chemotherapy-*HER2* therapy approach. First-line endocrine therapy alone may be considered in selected cases where disease burden is low, there is a presence of comorbidities and/or there has been a long disease-free interval.[130]

First-line therapy with a pertuzumab-trastuzumab-taxane combination is now the standard for *HER2*-overexpressing MBC. Two regimens predominate in this setting. The use of docetaxel administered every 3 weeks in combination with trastuzumab and pertuzumab (both administered every 3 weeks) has the most evidence to support its use in this setting. Substitution of docetaxel with weekly paclitaxel may be utilized if tolerability with docetaxel is problematic.[130]

Second-line *HER2*-targeted therapy for MBC that has progressed during or after first-line *HER2*-targeted therapy should include ado-trastuzumab emtansine (T-DM1). Use of this agent is largely based on a single, randomized phase III trial comparing the antibody-drug conjugate (T-DM1) to lapatinib plus capecitabine, which was previously the standard of care after progression on a trastuzumab-containing regimen. Patients on this trial had received zero to 3 prior regimens for metastatic disease. T-DM1 was associated with increased OS and PFS and fewer adverse events overall. In this trial, there were a small number of patients who had no prior therapy for metastatic disease, but the numbers were considered insufficient to draw any sound conclusions in this subset of patients. Several ongoing clinical trials are underway to explore the use of T-DM1 compared with trastuzumab-chemotherapy combination regimens and pertuzumab-trastuzumab combinations as first-line therapy and these results are eagerly awaited.[130]

Subsequent therapy (third-line) for *HER2*-positive, MBC is somewhat controversial. If a patient has not yet received pertuzumab and/or T-DM1, then these agents can be used as stated earlier. If a patient has been treated with pertuzumab and T-DM1, then use of another *HER2*-targeted regimen may be considered. This could include lapatinib plus capecitabine, a chemotherapy-trastuzumab combination, or trastuzumab plus lapatinib. For patients with tumors that are ER/PR positive, the option of endocrine therapy, alone or with trastuzumab or lapatinib, is also available. See **Table 128-8** for details on *HER2*-targeted regimens.[130]

TABLE 128-8 Selected Regimens for *HER2*-Positive Metastatic Breast Cancer

Selected Chemotherapy/Biologic Regimens	
Docetaxel + Trastuzumab + Pertuzumab	
Docetaxel 75 mg/m^2 IV day 1 Trastuzumab 8 mg/kg IV day 1 followed by 6 mg/kg IV Pertuzumab 840 mg IV day 1 followed by 420 mg IV Repeat cycle every 21 days	**Ado-Trastuzumab Emtansine (T-DM1)** Ado-Trastuzumab Emtansine 3.6 mg/kg IV day 1 Repeat cycle every 21 days

Paclitaxel + Trastuzumab + Pertuzumab	**Trastuzumab + chemotherapy**
	Trastuzumab 8 mg/kg IV day 1 followed by 6 mg/kg IV day 1
Paclitaxel 80 mg/m^2 IV days 1, 8, 15	Repeat cycle every 21 days (for Q 21 day chemotherapy) **OR**
Trastuzumab 8 mg/kg IV day 1 followed by 6 mg/kg IV	Trastuzumab 4 mg/kg IV day 1 followed by 2 mg/kg IV day 1
Pertuzumab 840 mg IV day 1 followed by 420 mg IV	Repeat cycle weekly (for weekly chemotherapy)
Repeat cycle every 21 days	Chemotherapy may include any one of the following:
	Paclitaxel, docetaxel, protein-bound paclitaxel, capecitabine, vinorelbine, gemcitabine
Selected Endocrine Therapy/Biologic Therapy Regimens	
Trastuzumab + Lapatinib	Trastuzumab + Anastrozole
Lapatinib 1,000 mg orally daily continuously	Anastrozole 1 mg orally daily continuously
Trastuzumab 8 mg/kg IV day 1 followed by 6 mg/kg IV day 1	Trastuzumab 8 mg/kg IV day 1 followed by 6 mg/kg IV day 1
Repeat cycle every 21 days **OR**	Repeat cycle every 21 days **OR**
Trastuzumab 4 mg/kg IV day 1 followed by 2 mg/kg IV day 1	Trastuzumab 4 mg/kg IV day 1 followed by 2 mg/kg IV day 1
Repeat cycle weekly	Repeat cycle weekly
Lapatinib + Capecitabine	
Lapatinib 1,250 mg orally daily continuously	Lapatinib + Letrozole
	Lapatinib 1,500 mg orally daily continuously
Capecitabine 1,000 mg/m^2 twice daily × 14 days	Letrozole 2.5 mg orally daily continuously
Repeat cycle every 21 days

Data from references 1,2,3,4.

Brain metastases are very common in patients with *HER2*-positive MBC with over 50% of patients experiencing brain metastases over their lifetime. This statistic is somewhat misleading in that the rate of brain as a site of first recurrence in patients with ESBC is still very low (1%-3%), negating the need for routine screening for brain metastases. However, a very low threshold for diagnostic testing exists if any neurologic signs or symptoms occur. Local therapy including surgery, whole-brain radiation, stereotactic radiosurgery or some combination of these approaches are considered as initial therapy. Systemic therapy will continue if the remainder of metastatic sites are stable. If extracranial metastases are progressing, changing the *HER2*-targeted therapy according to guidelines is appropriate.[132]

Clinical Controversy…

This phenomenon is thought to be due to the overall success of *HER2*-targeted therapy at extracranial sites and the presence of the blood-brain-barrier (BBB) which prevents *HER2*-targeted MoAB from accessing these tissues, creating a sanctuary site for breast cancer cells to flourish. There is some evidence that responses in the brain may be possible even with the large, *HER2*-targeted antibodies due to disruptions in the BBB from disease or prior local therapy (surgery or radiation). While there are anecdotal reports of responses in the brain, the likelihood is low that the patient's disease will respond in the brain. There is some evidence that the small molecule TKI, lapatinib, maybe effective in this scenario, but overall local therapies tend to offer the best approach in conjunction with systemic therapy. If local therapy fails to control disease in the brain, best supportive or palliative care may be prudent, depending on the status of their extracranial sites of disease and their overall performance status.[132]

Adverse effects of the *HER2*-targeted therapies have been identified and are primarily related to the heart. Therefore, all therapies in this class, regardless of their exact mechanism of receptor blockade, have some degree of cardiotoxicity that should be acknowledged and monitored for. The type of cardiotoxicity differs depending on the agent in question. Trastuzumab and likely pertuzumab are associated with myocardial damage leading to heart failure clinically similar to anthracycline-associated cardiomyopathy. The incidence of heart failure is approximately 5% with single-agent trastuzumab and the risk is unacceptably high when trastuzumab is given concurrently with an anthracycline.[133] Fortunately, heart failure seen with trastuzumab is somewhat reversible with pharmacologic management, and some patients have continued therapy with trastuzumab after their left ventricular ejection fraction has returned to normal with medical management. Close monitoring

for clinical signs and symptoms of heart failure as well as routine echocardiography is recommended in order to intervene with appropriate cardiac treatments. The incidence of cardiotoxicity with pertuzumab administered in combination with trastuzumab is largely unknown. One early study with pertuzumab was stopped early because of cardiotoxicity that surpassed 50% at the time of study discontinuation. Subsequent studies have not demonstrated an increased rate of cardiotoxicity beyond that seen with trastuzumab alone.[114] This discrepancy is likely to be better characterized as further clinical evidence and experience is gained with this agent. Nonetheless, careful clinical monitoring is required. Cardiotoxicity with T-DM1 is largely similar to that seen with trastuzumab.

Because of concerns regarding the role of *HER2* in normal cardiac functioning, lapatinib may also increase the risk for cardiac dysfunction. However, in a review of more than 3,689 patients who received lapatinib in phase I to III trials, cardiotoxicity occurred in only 1.6% of patients.[134] Although these data are reassuring, it does not rule out the possibility of expanded toxicity when this agent is used in patients not included in the clinical trials such as those with underlying cardiac risks. Rare QT prolongation has also been reported with lapatinib, but the exact clinical significance of this effect is widely debated. Drug interactions that increase systemic exposure to lapatinib may predispose patients to this rare complication.

Adverse events associated with MoABs are seen with trastuzumab, pertuzumab and T-DM1 and include infusion-related reactions (primarily fever and chills). These occur in about 40% of patients receiving trastuzumab during the initial infusion and generally go unrecognized by patients. Other infusion-related reactions with trastuzumab include mild nausea, pain at tumor sites, rigors, headaches, dizziness, hypotension, rash, and asthenia, which are much less common.[133] A rare but more severe reaction consisting of severe hypersensitivity or pulmonary reactions has been reported in postmarketing surveillance with trastuzumab. It is important to educate patients regarding the pulmonary reactions because these may occur up to 24 hours after the infusion and can be fatal if not promptly treated. Trastuzumab may increase the incidence of infection, diarrhea, and other adverse events slightly when given with chemotherapy, but most of these increases are not clinically significant for an individual patient. The adverse effects of pertuzumab appear to be similar, with increases in febrile neutropenia and grade 3 diarrhea evident in the phase III trial with docetaxel.[114] As clinicians gain more experience with this agent outside the context of clinical trials, the true incidence and severity of these adverse events will become more evident.

Other adverse events associated with lapatinib include primarily rash and diarrhea. These adverse effects appear to be more significant when combined with chemotherapy (eg, capecitabine, paclitaxel) but are generally manageable with aggressive antidiarrheal therapy or dose reductions. Other rare effects have been reported (QT prolongation, hepatotoxicity, and interstitial lung disease), and patients should be counseled regarding these effects. Drug–drug and drug–food interactions are particularly important with lapatinib because of its metabolism through CYP 3A4 and other pharmacokinetic and pharmacodynamic issues.[135] Many of the adverse effects listed previously may be exacerbated by drug or food interactions, and careful review of patients' medication lists and education regarding these issues are extremely important.

It should be noted that only 15% to 20% of patients with MBC overexpress *HER2*. To date, there is no

benefit associated with the administration of trastuzumab to patients with *HER2*-negative tumors (IHC score of 0-1+, or FISH negative) and a very questionable benefit associated with administration of trastuzumab to women with tumors that are 2+ for *HER2* by IHC staining alone. Further analyses investigating what other predictive markers may be clinically useful are currently ongoing.[136]

Other Targeted Agents

As previously mentioned, treatments for MBC rarely eliminate all cancer cells, and cures are seldom seen after the cancer has spread beyond the local area of the breast and axilla. Acquired drug resistance develops in nearly all patients. Alterations in cell signaling, cell cycle control, and apoptotic signaling are among the common mechanisms of resistance with chemotherapy, endocrine therapy, and anti-*HER2* therapy. The PI3K/protein kinase-B (also called Akt) pathway includes many different proteins, one of the most important being the mTOR tyrosine kinase. mTOR is an important mediator for cell proliferation and regulation of apoptosis, angiogenesis, and cellular metabolism. Use of mTOR inhibitors to treat MBC has resulted in conflicting results. Temsirolimus, an intravenous mTOR inhibitor, was administered with letrozole as first-line therapy for MBC in a large randomized phase III trial, resulting in no improvement in PFS.[137] Everolimus, an oral mTOR inhibitor, was administered with exemestane as second-line therapy for MBC after an AI and produced significant improvements in PFS.[138] In combination with tamoxifen, everolimus demonstrated superior clinical benefit rate and TTP in a small, randomized phase II trial.[139]

Targeting mTOR also appears to be important for *HER2*-positive MBC patients progressing on trastuzumab. Limited data have explored the use of everolimus with trastuzumab–taxane combinations that appear to be promising, but added toxicities and cost are important factors to consider when adding an mTOR inhibitor to a patient's regimen.[139] The most common adverse events experienced in the everolimus–exemestane trial were mucositis, fatigue or asthenia, cough, pyrexia, and hyperglycemia.[138] As more patients receive this combination outside the context of a clinical trial, adverse effects related to metabolic effects (hypercholesterolemia, hypertriglyceridemia, hyperglycemia) and pneumonitis may become more prevalent because these are evident in patients receiving everolimus for other cancer types (eg, renal cell carcinoma).

Cell cycle regulators play an important role in drug resistance and a great deal of investigation has occurred to elucidate specific pathways at work in breast cancers. Cyclin-dependent kinases (CDK), in coordination with their regulatory cyclin partners, form CDK-cyclin heterodimer complexes that control cell cycling. CDK-4 and -6 are critical components of this process. In some breast cancer cell lines, these complexes are responsible for phosphorylating the retinoblastoma tumor suppressor gene product (RB), thus inactivating the suppression of cell division and allowing unregulated progression through the cell cycle. Palbociclib, a potent, selective inhibitor of CDK-4 and -6, effectively prevents phosphorylation of RB, leaving it in an active state that is able to appropriately regulate cell division. This action reverses some acquired resistance to tamoxifen and AIs and appears to be synergistic with trastuzumab in *HER2*-amplified cell lines. While this is encouraging and hopeful, combining these agents with DNA-damaging techniques (eg, chemotherapy, radiation) is very complex and sequencing and timing are very important.[140] To date, palbociclib has shown improved PFS in combination with letrozole (as first-line therapy) and fulvestrant (as second-line

therapy). Further explanation of palbociclib's role in therapy can be found below in the Endocrine Therapy section. Preclinical data with other palbociclib combinations is promising, but remains investigational until further information on optimal timing and sequencing with specific agents is elucidated.

Targeting tumor blood vessels is another strategy to fight breast cancer and potentially reverse drug resistance. One of the most important growth factors that regulates the development of new blood vessels (angiogenesis) is VEGF. Bevacizumab is a MoAB targeted against VEGF and is FDA approved for use with chemotherapy for the management of a variety of malignancies. Bevacizumab has also been tested in clinical trials with capecitabine and paclitaxel in patients with MBC. Conflicting results have been reported with the use of bevacizumab in combination with chemotherapy in patients with MBC, and in 2012, the FDA withdrew the approval for bevacizumab in combination with paclitaxel for management of newly diagnosed MBC. Nonetheless, NCCN guidelines for management of breast cancer continue to list bevacizumab–paclitaxel as one option for the management of *HER2*-negative MBC. Continuing controversy exists regarding this agent in the management of MBC.[141,142] Many other biologic or targeted agents are being investigated and may change the overall management of breast cancer for both early and metastatic disease.

Endocrine Therapy

9 The pharmacologic goal of endocrine therapy for breast cancer is to either (a) decrease circulating levels of estrogen or (b) prevent the effects of estrogen at the breast cancer cell by blocking the hormone receptors or downregulating the presence of these receptors. Achievement of the first goal depends on the menopausal status of the patient, but achievement of the second goal is independent of menopausal status. Many endocrine therapies are available to target either pathway, and combinations of drugs with differing mechanisms of action have also been investigated. Unfortunately, most combinations of endocrine therapy with a second endocrine therapy have not demonstrated significant benefits over single-agent hormone therapy but have increased toxicity. Therefore, combinations of endocrine agents for MBC are generally not recommended outside the context of a clinical trial. With the approval of lapatinib, everolimus and palbociclib for MBC, we now have combination endocrine regimens that are quite effective, although they introduce an increased risk of adverse events that require supportive management strategies and may limit the utility of these combinations in some patients. These combinations address de novo or acquired resistance with endocrine therapy and have demonstrated efficacy over single agents in specific patient populations. Sequential use of single endocrine agents is common in the metastatic setting when a patient is progressing on one agent after experiencing an initial response. Responsive patients are often treated with a series of endocrine agents, usually over several years, before chemotherapy is considered. In conjunction with biologic therapies, such sequential approaches are currently untested, but are being investigated and make logical sense given the indolent nature of these hormone-sensitive metastases.

Data with lapatinib, everolimus, and palbociclib put these regimens squarely in the forefront in the battle against this disease. For patients with *HER2*-positive metastases, lapatinib or trastuzumab has been administered with letrozole or anastrozole, respectively, with substantial benefits seen

compared to endocrine therapy alone. Newly diagnosed patients with *HER2*-negative, HR-positive MBC should be considered for treatment with palbociclib and letrozole therapy. In this patient population, the palbociclib/letrozole regimen provided nearly double the duration of PFS compared to letrozole alone in one small, randomized phase 2 trial which was the basis for the FDA-approval of palbociclib (PALOMA-1).[143] Subsequent publication of interim results of the PALOMA-3 trial indicates a benefit is also seen with the addition of palbociclib to fulvestrant in patients who had relapsed or progressed during previous endocrine therapy (second-line therapy).[144] Limitations with these combinations include small numbers of patients, limited follow-up, and a toxicity profile that is not typical of endocrine therapy regimens. Myelosuppression, mainly neutropenia, is the dose-limiting toxicity seen with palbociclib and occurs in 50% to 80% of patients. Interestingly, the consequences of this appear to be minimal at least in the short-term data currently available. Rates of neutropenic fever are very low (less than 1%) and other infections have included only mild upper respiratory infections. Pulmonary embolism was seen in 1% to 4% of patients and other common side effects include mild fatigue and nausea. Other, confirmatory trials with palbociclib plus letrozole or exemestane are currently underway.[140]

As mentioned earlier, everolimus is now approved for use with exemestane as second-line therapy in HR-positive, *HER2*-negative MBC in patients who have progressed on a non-steroidal AI (eg, anastrozole, letrozole). Adverse events associated with this combination are more prominent than that seen with palbociclib and include metabolic syndrome, mucositis, fatigue and pneumonitis to name a few. The use of this combination after palbociclib/letrozole has not yet been reported, but concerns regarding changes in resistance patterns exist and future trials addressing sequencing these regimens are needed to determine the optimal order of administration.

Outside of these regimens that include novel targeted agents, there is little evidence that the survival benefit from one endocrine therapy is clearly superior to that achieved with other therapies in women with MBC. Prior to the availability of biologic agents, randomized controlled trials demonstrated similar OS in patients with MBC comparing antiestrogens, AIs, progestins, estrogens, and androgens as well as surgical procedures, including oophorectomy, adrenalectomy, and hypophysectomy. Consequently, the choice of a particular endocrine therapy is based primarily on the mechanism of action, toxicity, and patient preference (**Tables 128-9** and **128-10**). Based on these criteria, tamoxifen is the preferred initial agent when metastases are present in a premenopausal woman except when the patient's cancer recurs at the same time or within 1 year of adjuvant tamoxifen therapy. In these cases, other agents are generally used. For postmenopausal women, the AIs are generally used first followed by other endocrine therapies upon progression.[61,145]

TABLE 128-9 Therapies Used for HR-Positive Metastatic Breast Cancer

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Comments
Aromatase Inhibitors: Nonsteroidal					
Anastrozole	Arimidex, generic	1 mg orally daily			

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Comments
Letrozole	Femara, generic	2.5 mg orally daily		Caution in severe liver impairment[a]	
Aromatase Inhibitor: Steroidal					
Exemestane	Aromasin, generic	25 mg orally daily			Take after meals
Antiestrogens: SERMs					
Tamoxifen	Nolvadex, generic	20 mg orally daily		See text regarding *CYP2D6*	See text regarding *CYP2D6*
Toremifene	Fareston	60 mg orally daily			
Antiestrogen: SERD					
Fulvestrant	Faslodex	500 mg IM every 28 days (after loading days 1, 15, 29)	250-500 mg (see text for details)	Moderate liver impairment[a] administer 250 mg IM every 28 days (after loading days 1, 15, 29)	
LHRH Agonists					
Goserelin	Zoladex	3.6 mg SC every 28 days		Premenopausal women only	
Leuprolide	Lupron (IM), generic	3.75 mg IM every 28 days	Other formulations and doses are not used for breast cancer	Premenopausal women only	Not FDA approved for breast cancer; other formulations are administered differently
Triptorelin	Trelstar	3.75 mg IM every 28 days		Premenopausal women only	Not FDA-approved for breast cancer
Progestins					

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Comments
Megestrol acetate	Megace, generic	40 mg orally 4 times a day	80 mg twice daily also appropriate		Absorption maybe increased when taken with food
Medroxyprogesterone	DepoProvera, generic	400 mg IM every week	400-1,000 mg IM every week	May need to decrease dose in severe liver impairment[a]	
Androgens					
Fluoxymesterone	Androxy, generic	10 mg orally twice a day	10-20/day in divided doses	Avoid in severe renal or liver impairment[a]	
Estrogens					
Ethinyl estradiol	Multiple generics	1 mg orally 3 times a day	Lower doses not effective	Avoid in jaundice or "marked" liver disease	Take with food
Conjugated estrogens	Premarin	2.5 mg orally 3 times a day	Lower doses not effective	Avoid in jaundice or "marked" liver disease	Take with food
Biologic/Targeted Therapies					
Everolimus (+ Exemestane)	Afinitor	10 mg orally daily	2.5-10 mg daily	Adjust dose in mild, moderate and severe liver impairment; also monitor for myelosuppression, hyperglycemia, dyslipidemia, renal dysfunction. May need to adjust dose with concomitant CYP3A4 inhibitors/inducers	Do not split tablets
Palbociclib (+ Letrozole or Fulvestrant)	Ibrance	125 mg orally daily × 21 days, followed by 7 days	75-125 mg daily	Adjust dose for myelosuppression. Avoid concomitant strong inhibitors of *CYP3A4* and moderate/severe	Do not split tablets

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Comments
		off, repeated every 28 days		inducers of *CYP3A4*	

IM, intramuscular; LHRH, luteinizing hormone-releasing hormone; SC, subcutaneous; SERD, selective estrogen receptor downregulator SERM, selective estrogen receptor modulator.

[a]Severe liver impairment: Child-Pugh class C; moderate liver impairment: Child-Pugh class B; minor liver impairment: Child-Pugh class A.

TABLE 128-10 Drug Monitoring for Endocrine Therapies

Drug	Adverse Drug Reaction	Monitoring Parameters	Comments
Aromatase inhibitors	Hot flashes Arthralgias or myalgias Osteoporosis Hypercholesterolemia	Patient assessment BMD Lipid panel	Interval of monitoring controversial
Antiestrogens: SERMs[a]	Hot flashes Endometrial hyperplasia or cancer Venous thromboembolism Osteopenia (premenopausal women only)	Patient assessment Annual gynecologic assessment Consider BMD for premenopausal women	Routine transvaginal ultrasonography and endometrial biopsies are not recommended in the absence of symptoms
Antiestrogens: SERDs[a]	Hot flashes Injection-site reactions	Patient assessment	
LHRH agonists	Hot flashes Injection-site reactions Osteoporosis	Patient assessment BMD	
Progestins[a]	Weight gain Vaginal bleeding or spotting	Patient assessment Periodic weights	

Drug	Adverse Drug Reaction	Monitoring Parameters	Comments
Androgens[a]	Nausea Venous thromboembolism Hirsutism Acne Masculinization Increased hemoglobin Nausea	Patient assessment Complete blood counts	
Estrogens[a]	Venous thromboembolism Nausea or vomiting Venous and arterial thromboembolism Fluid retention Breast tenderness Endometrial hyperplasia or cancer	Patient assessment Annual gynecologic assessment	Routine transvaginal ultrasonography and endometrial biopsies are not recommended in the absence of symptoms

BMD, bone mineral density; LHRH, luteinizing hormone-releasing hormone; SERD, selective estrogen receptor downregulator; SERM, selective estrogen receptor modulator.

[a]Liver function tests obtained periodically to screen for changes in hepatic elimination, hepatotoxicity, and the presence of hepatic metastases.

In postmenopausal and castrated women, the main source of estrogen is derived from the peripheral conversion of androstenedione, produced by the adrenal gland, into estrone and estradiol. This conversion requires the enzyme aromatase. Aromatase also catalyzes the conversion of androgens to estrogens in the ovary in premenopausal women and in extraglandular tissue, including the breast and breast cancer cells, in postmenopausal women. Therefore, AIs effectively reduce the levels of estrogens in circulation and in the target organ. Third-generation AIs available in the United States include anastrozole, letrozole, and exemestane. A major advantage of these specific compounds is their preferable toxicity profile, which consists mainly of bone loss and/or osteoporosis, mild nausea, hot flashes, arthralgias and/or myalgias, and mild fatigue. Anastrozole and letrozole are nonsteroidal compounds that exhibit reversible, competitive inhibition of aromatase. These are triazole

compounds and have no intrinsic hormonal activity. Exemestane is a steroidal compound that binds irreversibly to aromatase, forming a covalent bond. Although this mechanism may have theoretical advantages to the reversible binding seen with the nonsteroidal agents, there is no clinical evidence that this drug is superior to other agents in this class. Exemestane does possess some androgenic properties at doses that are much higher than those used clinically and may have unique toxicities in some patients.[145]

Third-generation AIs have been compared with several other endocrine therapies since their approval. Although results are somewhat mixed, there appears to be at least equivalent activity seen with all three of the AIs compared with tamoxifen as first-line therapy and megestrol acetate as second-line therapy after progression on tamoxifen in postmenopausal women with positive or unknown hormone receptor status.[145] Compared with tamoxifen, there appears to be a lower incidence of thromboembolic events and vaginal bleeding in patients who received selective AIs. As second-line therapy after tamoxifen, more nausea, vomiting, and hot flashes are seen with the AIs and more weight gain, fluid retention, and thromboembolism with megestrol acetate. Although generally considered therapeutically equivalent, the use of a steroidal AI (exemestane) after a patient progresses on a nonsteroidal inhibitor (anastrozole or letrozole) may provide some benefit and is a common practice based on limited data. The opposite sequence also has shown some benefit; thus, patients may receive two AIs (first-line and second-line) sequentially, especially patients who progress while on adjuvant tamoxifen therapy.[61]

The AIs should only be used in postmenopausal women. Based on the available evidence, pre- or premenopausal women, whose ovaries are functioning, are inappropriate candidates for these therapies. Use of the AIs in addition to ovarian ablation (eg, oophorectomy or LHRH agonists) is appropriate and acceptable after progression on tamoxifen. Interestingly, the use of AIs in men with advanced breast cancer is controversial due to concerns that the pituitary feedback loop may be activated, increasing the levels of follicle-stimulating hormone, LH, and possibly testosterone. Therefore, although objective responses are seen with single-agent AI therapy in men with breast cancer, consensus has yet to be reached regarding the clinical utility of these agents in men, and some clinicians are investigating the combination of an LHRH agonist with an AI in this population.[146] Conducting clinical trials in this patient population is fraught with limitations, making evidence-based decisions very difficult.

Antiestrogens bind to ERs, which inhibit receptor-mediated gene transcription and therefore block the effect of estrogen on the end target. This class of agents is subdivided into two pharmacologic categories, SERMs and pure antiestrogens. SERMs include tamoxifen and toremifene (and raloxifene for breast cancer risk reduction in high-risk women) and demonstrate tissue-specific activity, both estrogenic and antiestrogenic, as described previously. The agonistic activity is thought to be responsible for many of the adverse reactions seen with these agents, including the increased risk of endometrial cancer, and has led to the development of pure ER antagonists that lack estrogen agonist activity. Pure antiestrogens are also referred to as selective estrogen receptor downregulators (SERDs). These molecules bind to ER, inhibit estrogen binding, and degrade the drug–ER complex, thus decreasing the amount of ER expressed. Fulvestrant is currently the only pure antiestrogen commercially available in the United States.

Tamoxifen is generally considered to be the antiestrogen of choice in premenopausal women with MBC who have hormone receptor–positive tumors. The toxicities of tamoxifen are described in the Adjuvant Endocrine Therapy section earlier. The only additional toxicity that may be observed in the setting of MBC (specifically bone metastases) is a tumor flare or hypercalcemia, which occurs in about 5% of patients after the initiation of any SERM therapy and is not an indication to discontinue the drug. It is generally accepted that this reaction is associated with response to endocrine therapy, but patients who do not experience such a reaction may still respond. This reaction is seen less frequently with the concurrent use of bisphosphonates as a result of their inhibition of osteoclasts, subsequently preventing the release of calcium from the bone.

Toremifene is another commercially available SERM for the treatment of breast cancer. It exhibits similar efficacy and tolerability compared with tamoxifen in the metastatic setting. Cross-resistance to toremifene has been demonstrated in patients with tamoxifen-refractory disease.[147] Thus, at the current time, toremifene appears to be an alternative to tamoxifen in postmenopausal patients with positive or unknown hormone receptor status with MBC. Details regarding its metabolism are becoming available, but a lack of robust clinical data to suggest it as an alternative to tamoxifen in settings where there are concerns regarding drug interactions leaves its role in therapy unclear at this time. Raloxifene, another SERM, was originally approved for prevention of osteoporosis in postmenopausal women. Available data with raloxifene as a treatment for breast cancer show very low response rates and no significant clinical benefit. Consequently, use of this agent for breast cancer treatment should be discouraged. The use of raloxifene for breast cancer risk reduction in high-risk postmenopausal women has been reported (see Prevention and Early Detection).

Fulvestrant is approved for the second-line therapy of postmenopausal MBC patients with hormone receptor–positive tumors. Biologically, fulvestrant should produce similar outcomes in premenopausal women, but no data exist to confirm the safety or efficacy in premenopausal women in the presence of active ovarian function. In conjunction with ovarian suppression or ablation, fulvestrant is an appropriate therapy in young women. It is unique in that it is given as an intramuscular injection and the dosing of fulvestrant has been controversial. Many comparative studies used what is now thought to be an insufficient dose; therefore, its place in therapy is not clearly defined.

Studies have compared fulvestrant with anastrozole, exemestane, and tamoxifen in the treatment of postmenopausal women with MBC with varying results. Initially, comparative trials with fulvestrant and an AI (anastrozole or exemestane) demonstrated similar efficacy and safety when given after patients progressed on tamoxifen therapy.[145] When compared directly with tamoxifen as first-line therapy, fulvestrant appeared to be less effective than tamoxifen. Subsequent data confirm that the appropriate dose of fulvestrant for MBC should be 500 mg intramuscularly administered every 2 weeks for 3 doses (days 1, 15, and 29) followed by administration every 28 days. This loading approach to dosing facilitates reaching steady-state plasma levels more rapidly, allowing for a response to be seen within a clinically relevant time frame. A randomized, phase II study comparing this fulvestrant dosing strategy with anastrozole in postmenopausal women with hormone receptor–positive MBC demonstrated superior TTP and OS with fulvestrant with similar objective responses seen with subsequent hormone therapy administered to both groups.[148] Although the power of this

phase II study is limited, it is encouraging to better understand how dosing may impact response with this novel endocrine agent. To accomplish this dosing, two intramuscular injections of 5 mL each are administered simultaneously. Although cumbersome and slightly more uncomfortable, patients appear to tolerate this higher dose relatively well, exhibiting similar toxicity profiles regardless of the dose administered.

Combining therapy with anastrozole and fulvestrant has been investigated in three randomized phase III trials with conflicting results. Although the combination does appear to be well tolerated, the overall benefits (if any) appear to be modest, and sequential single agents are most commonly administered in the palliative setting of metastatic disease. Adverse events related to fulvestrant include injection-site reactions, hot flashes, asthenia, and headaches.[61]

Another goal of endocrine therapy in premenopausal women is to reduce estrogen production with surgery, radiation, or medication. Ovarian ablation (surgically or chemically) is still commonly used in some parts of the United States and is considered by many specialists to be the endocrine therapy of choice in premenopausal women. The mortality rate with surgical oophorectomy is low, usually less than 3% in appropriately selected patients. While radiotherapeutic ablation of the ovaries is effective, this approach is typically not used in the United States. Chemical castration with LHRH analogs is increasingly used instead of oophorectomy in premenopausal women. Because effects with the LHRH analogs are reversible, use of these agents may also be used to determine how a patient will tolerate estrogen deprivation. If the patient tolerates this therapy, then an oophorectomy may be proposed as a permanent therapeutic intervention.

Medical castration with LHRH analogs induces responses in about one third of unselected premenopausal MBC cases. This is accomplished through downregulation of LHRH receptors in the pituitary, decreasing levels of LH, which subsequently lead to a decrease in circulating estrogen to castrated levels. Thus, the effect of LHRH analogs on circulating estrogen levels in premenopausal breast cancer simulates an oophorectomy. The three agents available and used in the United States are leuprolide, goserelin, and triptorelin, but only goserelin is FDA-approved for the treatment of MBC. These agents are administered as an injection every 4 weeks (all products have extended formulations, lasting 3 months to 1 year, but they are not recommended for the treatment of breast cancer) and are associated with minimal side effects, including amenorrhea, bone loss or osteoporosis, hot flashes, and occasional nausea (Table 128-10). LHRH analogs may also produce a flare response because of an initial surge in luteinizing hormone (LH) and estrogen production lasting 2 to 4 weeks. This flare response is similar to that seen with tamoxifen, and patients with high-volume, bulky disease should be monitored for increasing pain and hypercalcemia during the initiation period. Combining LHRH analogs with tamoxifen or an AI has been investigated with varying results. In order to safely administer AIs to premenopausal women, the ovarian function must be suppressed or ablated. The question remains as to whether the combination of an LHRH analog and an AI is superior to tamoxifen alone. Both approaches to therapy are appropriate to consider. Combining an LHRH analog with tamoxifen remains controversial, although some data in ESBC indicate a benefit may exist. This also would be an appropriate consideration in a young, premenopausal woman.[61]

Other endocrine therapies that have data to support their use in MBC include the progestins (such as

megestrol acetate and medroxyprogesterone acetate), high-dose estrogens (such as ethinyl estradiol) and high-dose androgens (fluoxymesterone). Typically, these agents are less well tolerated than more contemporary agents discussed previously. The most common side effect of megestrol acetate is weight gain, occurring in 20% to 50% of patients. Other side effects associated with progestins include vaginal bleeding in 5% to 10% of patients, either while taking the progestational agent or when it is discontinued, and less than a 10% incidence of hot flashes. Thromboembolic complications are also associated with these agents.[149] About one-third of patients placed on high-dose estrogens will discontinue them because of side effects, the most important of which are thromboembolic events, vomiting, and fluid retention. Less common side effects include areolar hyperpigmentation, breast tenderness and engorgement, vaginal discharge, incontinence, hot flashes, and phlebitis. All of the effective androgens cause masculinizing effects, including hirsutism and acne, in more than 50% of patients. The mechanism by which these agents exert a therapeutic effect in breast cancer is unknown. However, these agents may inhibit aromatase, among other pharmacologic effects that antagonize estrogen.

Cytotoxic Therapy

10 The vast majority of MBC are devoid of *HER2*-overexpression and represent one of the most prevalent cancer problems facing the developing world. Investigators continue to look for acceptable targets and innovative approaches to treating this group of cancers. For hormone receptor-positive MBC, endocrine therapy should be considered first-line as stated previously. Hormone-receptor-positive tumors that fail to respond to initial endocrine therapy or become refractory to endocrine therapy, require chemotherapy. Patients with triple negative tumors require chemotherapy as initial therapy of metastases. Overall, this group of patients represents a minority population, but has a relatively poor prognosis. Therefore, cytotoxic chemotherapy is eventually required in most patients with MBC and this is an area of much needed innovation.[92]

Combination chemotherapy results in an objective response in approximately 50% to 60% of unselected, chemotherapy-naive patients. The clinical use of biomarkers and genetic panels as a means to make clinical cancer treatment decisions is relative new. In MBC the large body of evidence superseding these types of data remains informative. In the absence of a clear predictive marker, the choice of chemotherapy is chosen based on overall efficacy, but also on the prevalence of toxicity, performance status and presence of comorbidities in the patient, pace of disease (eg, indolent vs visceral crisis), and patient preferences in terms of schedules, dosing route (eg, oral versus intravenous), and frequency (eg, weekly vs every 3 weeks) of the chemotherapy. Therefore, an optimal first-line or later-line chemotherapy choice varies between patients.

While response rates are high with combination chemotherapy, sequential use of single-agent therapies utilized in succession is also an effective strategy that may be preferred due to decreased rates of adverse events. In the palliative setting, when efficacy is similar, the least toxic approach is preferred. In clinical practice, patients who require a rapid response (eg, those with symptomatic bulky metastases or a visceral crisis) may benefit from combination chemotherapy despite the added toxicity. This decision is complex and should be made on an individual patient basis.

Most patients experience partial responses to chemotherapy, but complete disappearance of disease occurs in fewer than 10% of patients treated. The median duration of response is highly variable, ranging from 5 to 18 months. Some patients with small volume metastatic disease will have an excellent response to an initial course of chemotherapy and may live 5 to 10 years or longer without evidence of disease. The median OS for patients after commonly used chemotherapy combinations ranges between 14 and 33 months. The median time to response ranges from 2 to 3 months in most studies, but this period depends on the site of measurable disease and can range from 3 weeks (skin and lymph node metastases) to 18 weeks (bone metastases). After a chemotherapy regimen has been initiated, it is usually continued until there is unequivocal evidence of progressive disease or intolerable side effects. **Table 128-11** lists some selected chemotherapy agents used in the metastatic setting.[150]

TABLE 128-11 Selected Chemotherapy Regimens for *HER2*-Negative Metastatic Breast Cancer

Single-Agent Chemotherapy

Paclitaxel[a,b]

Paclitaxel 175 mg/m^2 IV over 3 hours

Repeat cycles every 21 days

or

Paclitaxel 80 mg/m^2/wk IV over 1 hour

Repeat dose every 7 days

Docetaxel[d,e]

Docetaxel 60-100 mg/m^2 IV over 1 hour

Repeat cycles every 21 days

or

Docetaxel 30-35 mg/m^2/wk IV over 30 minutes

Repeat dose every 7 days

Protein-Bound Paclitaxel[g,h]

Vinorelbine[c]

Vinorelbine 30 mg/m^2 IV, days 1 and 8

Repeat cycles every 21 days

or

Vinorelbine 25-30 mg/m^2/wk IV

Repeat cycles every 7 days (adjust dose based on absolute neutrophil count; see product information)

Gemcitabine[f]

Gemcitabine 600-1,000 mg/m^2/wk IV, days 1, 8, and 15

Repeat cycles every 28 days (may need to hold day 15 dose based on blood counts)[q]

Ixabepilone[i]

Ixabepilone 40 mg/m^2 IV over 3 hours

Repeat cycles every 21 days

Single-Agent Chemotherapy

Protein-bound Paclitaxel 260 mg/m^2 IV over 30 minutes

Repeat cycles every 21 days

or

Protein-bound paclitaxel 100-150 mg/m^2 IV over 30 minutes on days 1, 8, and 15

Repeat cycle every 28 days

Eribulin[k]

Eribulin 1.4 mg/m^2/dose IV over 2-5 minutes on days 1 and 8

Repeat dose every 21 days

Liposomal Doxorubicin[l]

Liposomal doxorubicin 30-50 mg/m^2 IV over variable duration

Repeat cycles every 28 days

Capecitabine[j]

Capecitabine 2,000-2,500 mg/m^2 per day orally, divided twice daily for 14 days

Repeat cycles every 21 days

Combination Chemotherapy Regimens

Gemcitabine + Carboplatin[m]

Gemcitabine 1,000 mg/m^2 IV, days 1 & 8

Carboplatin AUC 2 IV, day 1 & 8

Repeat cycles every 21 days

Ixabepilone + Capecitabine[i]

Ixabepilone 40 mg/m^2 IV over 3 hours, day 1

Capecitabine 1,750-2,000 mg/m^2/day orally divided twice daily for 14 days

Paclitaxel + Gemcitabine[n]

Paclitaxel 175 mg/m^2 IV over 3 hours, day 1

Gemcitabine 1,250 mg/m^2 IV days 1 and 8

Repeat cycles every 21 days

Paclitaxel + Bevacizumab[o]

Paclitaxel 90 mg/m^2 IV over 1 hour, days 1, 8, and 15

Bevacizumab 10 mg/kg IV over 30-90 minutes, days 1 and 15

Single-Agent Chemotherapy

Repeat cycles every 21 days Repeat cycles every 28 days

Factors associated with an increased likelihood of response to chemotherapy include a good performance status, a limited number (one to two) of disease sites (or involved organ systems), and a prolonged previous response to chemotherapy or hormonal therapy (ie, long disease-free interval). Patients who have progressive disease during chemotherapy have a lower likelihood of response to a subsequent chemotherapy. However, this is not necessarily true for patients who are given chemotherapy after a treatment-free interval of substantial duration (eg, more than 1 year). Treatments may be repeated if some time has passed between therapies, but this is rarely done because of the large number of agents now available to treat breast cancer. Hormone receptor–positive tumors that are resistant to endocrine therapy are as likely to respond to chemotherapy as patients who receive upfront chemotherapy. Age, menopausal status, and receptor status do not appear to be directly associated with response to chemotherapy. However, there continues to be much debate surrounding the potential association between hormone receptor status and response to chemotherapy (eg, ER status and anthracyclines). Most clinical decisions regarding chemotherapy are not currently influenced by hormone-receptor status. Molecular tumor subtypes (eg, luminal A, luminal B, etc.) have not been extremely helpful in selecting an optimal chemotherapy regimen. TNBC is an aggressive phenotype associated with a poor prognosis. These cancers have variable responses to chemotherapy, although many of them have high chemosensitivity. Unfortunately, TNBCs have a high chance of brain metastases and shorter survival after a first metastatic event compared with other subtypes. TNBC is strongly associated with germline mutations in the BRCA-1 gene and this potentially leads to increased sensitivity to platinum agents due to lack of intact DNA repair mechanisms. Clinical implications of this mutation are being tested now, but many clinicians may add a platinum agent to the chemotherapy regimen in some patients with a BRCA-1 germline mutation.[92]

A number of chemotherapeutic agents have demonstrated activity in the treatment of breast cancer, including doxorubicin (conventional and liposomal), epirubicin, paclitaxel (conventional and protein bound), docetaxel, capecitabine, fluorouracil, cyclophosphamide, methotrexate, vinblastine, vinorelbine, gemcitabine, ixabepilone, eribulin, carboplatin, cisplatin, mitoxantrone, mitomycin C, thiotepa, and melphalan. The most active classes of chemotherapy in MBC are the anthracyclines and the taxanes, producing response rates as high as 50% to 60% in patients who have not received prior chemotherapy for metastatic disease.[150] Doxorubicin (conventional and liposomal) and epirubicin have demonstrated significant efficacy in the metastatic setting and are generally considered therapeutically equivalent when dosed appropriately. Administration of these agents is limited by their cumulative cardiotoxicity. Paclitaxel, docetaxel, and protein-bound paclitaxel are also FDA-approved for the treatment of MBC and are generally considered therapeutically equivalent, yet lack complete cross-resistance. Taxane administration is limited by cumulative peripheral neuropathy. Most patients will likely receive each of these agents at some point in the course of their MBC.

An increasing number of patients diagnosed with MBC have been exposed to adjuvant chemotherapy consisting of an anthracycline and a taxane. If metastases are found within 6 to 12 months of completing treatment with these agents, many clinicians will choose treatment from a different chemotherapy class. If it has been longer since their adjuvant therapy, then retreating with the same agents may be considered. However, given the cardiotoxicity associated with the anthracyclines, the use of these agents in the metastatic setting has been generally avoided until the availability of liposomal anthracyclines. Pegylated liposomal doxorubicin is associated with less

cardiotoxicity and similar efficacy compared with conventional doxorubicin and is a viable option for women who recur more than 1 year after their adjuvant anthracycline regimen.[150]

Weekly administration of paclitaxel and protein-bound paclitaxel results in higher response rates, TTP, and survival in addition to a more favorable side effect profile compared with administration every 3 weeks.[150] The most useful weekly dose of conventional paclitaxel in the metastatic setting appears to be 80 mg/m^2/wk with no breaks in therapy. With this approach, the toxicity profile of paclitaxel changes with less myelosuppression and delayed onset of peripheral neuropathy but slightly more fluid retention and skin and nail changes. Although the incidence of hypersensitivity reactions is also slightly less at these lower doses (requiring fewer premedications), it remains at about 3% despite incorporation of all available preventive measures. There is currently debate regarding the most appropriate weekly dose of protein-bound paclitaxel in the metastatic setting. Doses of 100 to 150 mg/m^2/wk administered on days 1, 8, and 15 of a 28-day cycle have been investigated, demonstrating some evidence of a dose–response relationship. In the metastatic palliative setting, a lower dose is generally chosen, minimizing toxicity while not significantly compromising efficacy. Docetaxel is most appropriately dosed on an every-3-week schedule for MBC. Weekly dosing did not produce improvements in disease response and was associated with significantly more toxicities than the every-3-week dosing strategy.

After patients have been treated with an anthracycline and a taxane, single-agent capecitabine, vinorelbine, or gemcitabine have resulted in response rates of 20% to 25%.[150] Of these agents, only capecitabine is FDA approved as a single agent for MBC. Gemcitabine is only FDA-approved in combination with paclitaxel for MBC. However, all of these are included in most national and international guidelines as appropriate therapy for MBC. Decisions regarding which agent to choose are based on patient characteristics, expected toxicities, and previous exposure to chemotherapy.

Other antimicrotubule agents have also been approved for the management of MBC, demonstrating significant benefits in patients who have had prior exposure to multiple other chemotherapy agents. Ixabepilone is an epothilone compound with a similar but distinct mechanism of action from the taxanes, binding to β-microtubulin in a unique manner but ultimately leading to microtubule stabilization and cell death in a similar manner compared with the taxanes. It is approved for use in combination with capecitabine and as a single agent for the management of MBC. Eribulin is another antimicrotubule agent with a unique mechanism of action. The first synthetic analogue of halochondrin B, eribulin effectively inhibits polymerization of tubulin into microtubules and suppresses the microtubule growth phase similar to the vinca alkaloids. The mechanism of eribulin's antitumor efficacy differs from the vinca alkaloids in that eribulin does not appear to have any effect on the microtubule shortening phase. These subtle differences are thought to be important for eribulin's efficacy in patients who have been exposed to multiple therapies, including other antimicrotubule agents. It is approved for use as a single agent for the management of MBC patients who have received at least two prior chemotherapies for their metastatic disease.[150]

Both of these agents are associated with similar toxicities compared with the taxanes and vinca alkaloids, respectively (eg, myelosuppression, neuropathy, myalgias or arthralgias, alopecia, and skin and nail changes with ixabepilone and myelosuppression and neuropathy with eribulin).

Hypersensitivity is occasionally seen with ixabepilone because it is also solubilized in Cremophor-EL, the likely causative agent in paclitaxel-associated hypersensitivity. However, eribulin has not been associated with hypersensitivity reactions and is not formulated in a complex solvent system that may predispose patients to allergic-type reactions. Neuropathy may become problematic in patients who have received numerous sequential neurotoxic chemotherapy agents; therefore, careful monitoring of the impact on quality of life is imperative because these therapies are administered in a palliative setting. Ongoing clinical trials are investigating these agents in other combinations and in earlier stages of the disease, and these results are eagerly awaited.[150]

Radiation Therapy

Radiation is an important modality in the treatment of symptomatic metastatic disease. The most common indication for treatment with radiation therapy is painful bone metastases or other localized sites of disease refractory to systemic therapy. Radiation therapy provides significant pain relief to about 90% of patients who are treated for painful bone metastases. Radiation is also an important modality in the palliative treatment of metastatic brain lesions and spinal cord lesions, which respond poorly to systemic therapy, as well as eye or orbit lesions and other sites where significant accumulation of tumor cells occurs. Skin and lymph node metastases confined to the chest wall area may also be treated with radiation therapy for palliation (eg, open wounds or painful lesions). Chemotherapy may also be added to radiation for sensitization purposes.

PERSONALIZED PHARMACOTHERAPY

Personalized pharmacotherapy is a very broad term that includes many old and new scientific approaches to predict which patients should be treated, how they should be treated, and their likelihood of response or toxicity to treatment. These approaches may be focused on the tumor(s) itself or on patient or host factors. Breast cancer clinicians have been using these approaches to therapeutic decisions for decades and continue to search for novel characteristics to further individualize the choice of therapies.

Most scientific studies in breast cancer focus on tumor-specific markers either individually or as a panel of markers. Since the mid-1970s, clinicians have been using biomarkers to individualize therapy for patients with breast cancer. Initially, the tumor's ER or PR status was used to determine whether endocrine therapy (starting with tamoxifen) would benefit patients with MBC. Although these data have been widely available for many years, ER and PR testing in all breast cancers worldwide has been a relatively new phenomenon. Other biomarkers have been developed over the decades, with *HER2* being the most widely accepted alternate marker for breast cancer. *HER2* was initially studied as a prognostic biomarker in an attempt to ascertain an individual patient's risk of breast cancer recurrence and chemotherapy sensitivity or resistance. Although these applications of *HER2* testing remain controversial, the use of *HER2* testing to establish the likelihood of response or benefit to anti-*HER2* therapies is well established and required for all breast tumors at diagnosis. (See the Adjuvant Systemic Therapy section.)

It is clear from these individual biomarker studies that breast cancers are very heterogeneous, and

interaction among markers is also important. Incorporation of multiple markers into biomathematical formulas that predict the likelihood of recurrence of cancer have been developed and are used across the United States to assist clinicians and patients in making informed decisions regarding adjuvant systemic therapy (eg, Adjuvant! Online). These predictive formulas are useful but do not incorporate several markers that have since been validated individually (eg, *HER2*, Ki-67, LVI). Genetic panels such as Oncotype DX, Mammaprint, and PAM50 were developed to screen for and quantify multiple genetic markers in tumor cells and are used as prognostic biomarkers to determine the risk of recurrence in early-stage breast cancer patients. The exact role these genetic panels will play in treatment decisions in the future is uncertain, but scientists and clinicians have embraced the technology, and the copious amounts of data collected from these analyses are being analyzed and incorporated into clinical trials and new standards every day.

Although these are all examples of tools that are used to individualize or personalize pharmacotherapy, very few markers are currently used clinically to represent host or patient differences. One promising area of research is in pharmacogenomics related to drug pharmacokinetics or pharmacodynamics. Results from studies with tamoxifen and CYP2D6 genotyping have been mixed, which is probably related to the complex metabolism of tamoxifen and large number of other prognostic factors (see the Adjuvant Endocrine Therapy section). Throughout this chapter are examples of characteristics that are used to individualize therapy. As more research is done in this field, the amount of tools available to clinicians to assist with treatment decisions will expand greatly.

EVALUATION OF THERAPEUTIC OUTCOMES

The desired therapeutic outcome of adjuvant therapy of breast cancer differs significantly from that of metastatic disease. Adjuvant therapy—chemotherapy, biologic therapy, and hormonal therapy—is administered with curative intent. The rationale for adjuvant therapy is that breast cancer, even when diagnosed in early stages when clinical evidence of distant spread is not apparent, is a systemic disease that spreads early to distant sites. Adjuvant therapy is intended to eradicate micrometastases and thus cure the patient of breast cancer. Therefore, the overall goal of adjuvant therapy is to cure the disease, which is something that cannot be fully evaluated for years after initial diagnosis and treatment. In addition, because disease cannot be detected at the time adjuvant therapy is started, assessment of disease response is not possible. Instead, a predetermined number of cycles of adjuvant therapy or years of biologic or hormonal therapy are administered. Adjuvant chemotherapy is often associated with significant toxicity. Maintaining dose intensity has been demonstrated to be important in the cure of disease, and therefore optimizing supportive care measures such as antiemetics and growth factors is highly recommended. The concept of dose density, using growth factors to maintain blood counts while decreasing the interval between chemotherapy administrations, is very controversial in the management of early-stage breast cancer. Multiple studies investigating this approach to adjuvant chemotherapy have been conducted with conflicting results and many more trials continue to be analyzed in hopes of determining the long-term outcomes related to this approach to therapy. The goals of therapy with neoadjuvant chemotherapy are slightly different. These goals focus on earlier end points of tumor response so as to minimize surgery, determine prognosis, and potentially conserve the breast tissue for a better cosmetic result.

The other outcomes discussed with adjuvant therapy also apply to this scenario in terms of improving survival and decreasing recurrences compared with no systemic therapy.

Palliation is the therapeutic outcome in treatment of MBC. Optimizing benefits and minimizing toxicity are general therapeutic goals of any therapy administered in this setting. Therefore, sequential single agents are often chosen over combination regimens, but individual circumstances may call for more rapid responses in which combination therapy may be indicated. Tumor response to a particular treatment regimen may be measured by changes in laboratory tests, diagnostic imaging, or physical signs or symptoms. Periodic testing is clinically useful in some circumstances, but careful interpretation of results is required. If a patient is tolerating therapy well, clear evidence of disease progression on imaging or physical examination is required to warrant changing therapy. Unless the patient clearly cannot tolerate the regimen or the cancer is clearly progressing at a rate that will quickly cause symptoms (or is causing symptoms already), there is not a sound reason to change therapy. Optimizing quality of life is an important therapeutic end point in the treatment of patients with MBC. A number of valid and reliable tools are available for objective assessment of quality of life in patients with breast cancer.

ACS	American Cancer Society
AI	aromatase inhibitor
AJCC	American Joint Committee for Cancer
ALND	axillary lymph node dissection
ASCO	American Society of Clinical Oncology
BCT	breast-conserving therapy
BIG	Breast International Group
BMI	body mass index
BSE	breast self-examination
CALGB	Cancer and Leukemia Group B
CBE	clinical breast examination
CDK	cyclin-dependent kinases
CI	confidence interval
CMF	cyclophosphamide, methotrexate, fluorouracil (regimen)
CNS	central nervous system
CYP	cytochrome P450 enzyme
DCIS	ductal carcinoma in situ
DFS	disease-free survival
DVT	deep-vein thrombosis
EBCTCG	Early Breast Cancer Trialists' Collaborative Group

EGFR	epidermal growth factor receptor; also known as HER1
ER	estrogen receptor
ESBC	early stage breast cancer
ESMO	European Society of Medical Oncology
FDA	Food and Drug Administration
FISH	fluorescence in situ hybridization
HER2	human epidermal growth factor receptor-2
HR	hazard ratio
HRT	hormone replacement therapy
IBC	inflammatory breast cancer
IHC	immunohistochemistry
LCIS	lobular carcinoma in situ
LH	luteinizing hormone
LHRH	luteinizing hormone–releasing hormone
LVI	lymphatic and vascular invasion
MBC	metastatic breast cancer
MINDACT	Microarray In Node-negative Disease may Avoid ChemoTherapy
MoAB	Monoclonal antibody
MRI	magnetic resonance imaging
mTOR	mammalian target of rapamycin
NCCN	National Comprehensive Cancer Network
NCI	National Cancer Institute
NNI	number needed to invite for screening to extend one woman's life
NSABP	National Surgical Adjuvant Breast and Bowel Project
OR	odds ratio
OS	overall survival
PARP	poly-ADP ribose polymerase
pCR	pathologic complete response
PFS	progression-free survival
PI3K	phosphatidylinositol 3-kinase
PR	progesterone receptor
RR	relative risk
SEER	Surveillance, Epidemiology, and End Results
SERD	selective estrogen receptor downregulator
SERM	selective estrogen receptor modulators
SLNB	sentinel lymph node biopsy
STAR	Study of Tamoxifen and Raloxifene

TTP	Time to progression
TKI	tyrosine kinase inhibitor
TNBC	triple negative breast cancer
USPSTF	United States Preventive Services Task Force
VEGF	vascular endothelial growth factor
WHI	Women's Health Initiative

Chapter 129: Lung Cancer

Val R. Adams; Sarah Scarpace Peters

INTRODUCTION

KEY CONCEPTS

- 1 Lung cancer is the leading cause of cancer deaths in both men and women in the United States. The overall 5-year survival rate for all types of lung cancer is about 15%.
- 2 Cigarette smoking is responsible for most lung cancers. Smoking cessation should be encouraged, particularly in those receiving curative treatment (ie, Stages I to IIIA non-small cell lung cancer [NSCLC] and limited-stage small cell lung cancer [SCLC]).
- 3 NSCLC is the most commonly diagnosed type of lung cancer (about 80%). NSCLC typically has a slower growth rate and doubling time than SCLC.
- 4 Annual screening with low-dose computed tomography imaging (LDCT) is currently recommended to identify lung cancer in high-risk individuals. However, several studies are evaluating the optimal frequency and duration, as well as the impact of false-positive tests.
- 5 Treatment decisions are guided by the stage of disease (which is characterized by tumor size and spread), histology (squamous or non-squamous), and molecular features (epidermal growth factor receptor [EGFR] mutations or anaplastic lymphoma kinase [ALK] positivity) of the tumor. Patient-specific factors (ie, performance status, comorbid conditions, etc.) must also be considered when developing a treatment plan.
- 6 The treatment goals in lung cancer are cure (early stage disease), prolongation of survival, and maintenance or improvement of quality of life through alleviation of symptoms.
- 7 Early stage lung cancer has the highest cure rates when surgical resection of the tumor is used with or without chemotherapy for NSCLC and chemoradiotherapy for SCLC.
- 8 Advanced-stage lung cancer is primarily treated with systemic therapy. Doublet platinum-based chemotherapy regimens are superior in response to single-agent regimens and should be used when the patient can tolerate the associated toxicity. Platinum-containing doublets are first-line treatment in most cases of NSCLC and SCLC.
- 9 Targeted therapies for advanced-stage NSCLC are preferred over platinum-based doublets as first-line therapy in those patients whose tumors express certain genetic mutations such as EGFR exon 19 deletions or exon 21 (L858R) substitution mutations or ALK-positive.
- 10 Immunotherapy with anti-programmed-death receptor-1 (PD1) monoclonal antibody is currently approved for the second-line treatment of NSCLC and is a novel therapeutic class of treatment available for these patients.
- 11 Optimal patient care needs to include prevention and treatment of adverse events from drug therapy. Adverse events may cause delays in treatment administration, increase morbidity, and contribute to treatment failure.

Lung cancer is a major cause of morbidity and mortality. It has reached epidemic proportions in many industrialized countries and is the most frequently fatal malignancy in the world. It is estimated that 224,390 new cases of lung cancer were diagnosed in the United States in 2016.[1]

Despite major advances in the understanding and management of lung cancer, the overall 5-year survival rate for all types of lung cancer remains a dismal 18%.[1] In the United States, lung cancer accounts for about 13% of all newly diagnosed cancer in adults.[1] 1 It remains the leading cause of cancer death in both adult men and women, with about 158,080 deaths in 2016.[1] The incidence and death rate caused by lung cancer are declining, which has been attributed to decreased tobacco use over the last 50 years. In comparison to whites, the incidence and mortality of lung cancer is greater in African American men and slightly lower in African American women.[1]

The incidence of lung cancer increases with age, with about 58% of deaths occurring between 60 and 79 years.[1] Early lung cancer screening studies failed to demonstrate a survival advantage, but in November 2010, the largest trial of its kind, the National Lung Screening Trial, demonstrated a 20% reduction in the relative risk of death from lung cancer in moderate-to-high risk individuals (95% confidence interval [CI], 6.8 to 26.7; P=0.004). Among subjects enrolled in lung cancer screening trials, the rate of malignancy in the pulmonary nodule detected on low-dose computed tomography (LDCT) scan is low, and surgical procedures are not without risk. Consequently, patients who receive scans as part of lung cancer screening or for another purpose should have other criteria or tests done before considering a biopsy to evaluate for malignant pathology.[2]

Patients with lung cancer may undergo surgery, chemotherapy, radiation, or multimodality therapy, depending on the histologic type of the tumor, presence of genetic mutations, its size and location, and the presence of metastases at diagnosis.[3,4] Two leading oncology groups representing leading clinicians in the United States have published clinical practice guidelines for the treatment of lung cancer. The National Comprehensive Cancer Network (NCCN) has developed consensus-based guidelines that provide recommendations regarding the screening, staging, and treatment of both non-small cell lung cancer (NSCLC) and small cell lung cancer (SCLC).[3,4] The American Society of Clinical Oncology (ASCO) published evidence-based guidelines that were updated in 2015.[5] ASCO also endorsed the guidelines of other organizations related to the treatment of SCLC,[6] the use of radiotherapy for locally advanced NSCLC,[7] and the use of molecular testing for NSCLC.[8]

ETIOLOGY

Lung carcinomas arise from normal bronchial epithelial cells that have acquired multiple genetic lesions and are capable of expressing a variety of phenotypes.[9] Significant advances have been made recently in understanding the molecular genetic changes involved in lung cancer pathogenesis.[9] A large variety of molecular lesions result in abrogation of key cellular regulatory and growth control pathways. Activation of a proto-oncogene, inhibition or mutation of tumor suppressor genes, and production of autocrine (self-stimulatory) growth factors contribute to cellular proliferation and malignant transformation.[9] Many of these molecular alterations are common to both SCLC and NSCLC, but certain mutations are found more frequently in specific subtypes of lung cancer and offer more targeted interventions to prevent or treat lung cancer. In autocrine loop abnormalities, SCLC frequently overexpresses C-KIT (a protein tyrosine kinase receptor that is specific for stem cell factor [CD117]), while NSCLC frequently overexpresses epidermal growth factor receptor (EGFR). EGFR inhibitors, such as erlotinib, gefitinib, afatinib, and osimertinib, are used clinically to treat NSCLC and theoretically offer a potential method of lung cancer chemoprevention.[9-,10,11] Crizotinib, ceritinib, and alectinib, drugs that target the EML4-ALK gene rearrangement protein, demonstrates the importance of this pathway in a subset of adenocarcinoma lung cancer patients.[12]

2 Smoking is a major cause of lung cancer, with about 80% of lung cancer deaths in the United States directly attributed to tobacco use. Tobacco smoke contains many substances,

including tumor promoters, carcinogens, and cocarcinogens.[13] The association between environmental tobacco smoke (ETS; also referred to as passive smoking) and lung cancer risk in nonsmokers is not as clear. Most studies have consistently found that spouses of smokers have higher rates of lung cancer than spouses of nonsmokers (about 25% higher risk). In addition, workplace exposure to environmental smoke increases the risk of lung cancer by about 17%. It is currently estimated that ETS contributes to about 3,000 lung cancers annually. Although many of these studies have methodologic flaws, the data consistently show dose-risk relationship, with no safe level of exposure.[13] Smoking cessation is associated with a gradual decrease in the risk, but more than 5 years is necessary before an appreciable decline in risk occurs and the risk never returns to that of a nonsmoker.[13] Because of the public health implications, the United States has several, mainly state-led, tobacco control efforts, including antismoking campaigns, increased tobacco taxes, and smoke-free areas in many public areas. Although the prevalence of cigarette smoking has slowly decreased, it remains at about 19% in 2010 and 2011.[13]

Although most cases of lung cancer are attributable to cigarette smoking, less than 20% of smokers develop lung cancer, which suggests that other risk factors are relevant. An increased risk of lung cancer has been associated with exposure to other environmental respiratory carcinogens (eg, asbestos, benzene, and arsenic). Genetic risk factors are also important, with an increased risk of lung cancer observed in those with first-degree relatives diagnosed with the disease. Lung cancer risk is associated with polymorphisms that affect the expression and/or function of enzymes regulating metabolism of tobacco carcinogens, DNA repair, or inflammation. Patients with a history of chronic obstructive airway disease and adults with asthma are at an increased risk for lung cancer.[9,10] Further studies to better identify which patients are at highest risk of developing lung cancer will be key for new lung cancer screening trials and in chemoprevention trials.

HISTOLOGIC CLASSIFICATION

Before treatment begins, it is critical that an experienced lung cancer pathologist reviews the pathologic material because of the different treatment regimens for NSCLC and SCLC.

3 NSCLC is diagnosed in most (80%) lung cancer patients. NSCLC typically has a slower growth rate and doubling time than SCLC. The histologic classification of NSCLC is well defined and widely accepted (**Table 129-1**).[14] In the most recent classification, the histologic types, subtypes, and identifiable variants convey information about tumors' natural behavior and in some cases influence therapeutic decisions.[14,15]

TABLE 129-1 Histologic Classification of Non-Small Cell Lung Carcinomas

1. Squamous cell carcinoma
    - Papillary
    - Clear cell
    - Small cell (probably should be discontinued)
    - Basaloid
2. Adenocarcinoma
    - Minimally invasive adenocarcinoma (MIA)
    - Invasive adenocarcinoma
    - Lepidic predominant (previously classified as bronchioalveolar carcinoma [BAC])
    - Acinar predominant
    - Papillary predominant
    - Micropapillary predominant
    - Solid predominant with mucin
    - Variants of invasive adenocarcinoma
    - Invasive mucinous adenocarcinoma (previously classified as BAC)
    - Colloid
    - Fetal (low and high grade)
    - Enteric
3. Large cell carcinoma
    - Variants
    - Large cell neuroendocrine carcinoma
    - Combined large cell neuroendocrine carcinoma
    - Basaloid carcinoma
    - Lymphoepithelioma-like carcinoma
    - Clear cell carcinoma
    - Large cell carcinoma with rhabdoid phenotype
4. Adenosquamous carcinoma
5. Sarcomatoid carcinomas
    - Pleomorphic carcinoma
    - Spindle cell carcinoma
    - Giant cell carcinoma
    - Carcinosarcoma

- Pulmonary blastoma
- Other

6. Carcinoid tumor
    - Typical carcinoid (TC)
    - Atypical carcinoid (AC)
7. Carcinomas of salivary gland type
    - Mucoepidermoid carcinoma
    - Adenoid cystic carcinoma
    - Epimyoepithelial carcinoma

Adapted from 2004 WHO classification and the 2011 IASCL/ATS/ERS classification as described in reference 16.

Four major cell types of carcinomas (squamous cell, adenocarcinoma, large cell, and small cell) account for more than 90% of all lung tumors. Early studies with localized disease demonstrated that radiation could cure small cell histology, while surgery did not. Studies with the other histologic types demonstrated better outcomes with surgery than with radiation, which provided the basis for the general classification of SCLC and NSCLC. Historically, systemic treatment for NSCLC histologies was the same and resulted in a similar overall prognosis, which again supported a general classification of SCLC and NSCLC. Translation of histology and genetics in NSCLC has led to personalized medicine. Trials have clearly shown that optimal therapeutic selection requires knowledge of the histology and genetic mutational status.[8,9] For metastatic NSCLC, there are four pathways: (1) squamous cell histology, (2) non-squamous histology with an EGFR mutation (EGFR+), (3) non-squamous histology with and ALK-EML4 rearrangement (ALK+), and (4) non-squamous histology with wild type EGFR and ALK.

Squamous cell carcinoma was once the most common histology, but it now represents less than 30% of all lung cancers. Squamous cell carcinomas have a much higher incidence in smokers and among males and appear to have a strong dose-response relationship to tobacco exposure. Most of these tumors occur centrally, but the incidence of peripheral presentation is increasing. Studies describing the natural history of lung cancer in the era of screening with LDCT scans have revealed a relatively constant tumor volume doubling time (104-122 days), while the other histologies indicate that smaller tumors found with a CT scan are more indolent (eg, doubling times three to four times longer with CT-discovered tumors).[2] Squamous cell tumors are slower to metastasize, but they eventually spread to the hilar and mediastinal lymph nodes, liver, adrenal glands, kidneys, bone, and GI tract. Since it is rare that tumors of squamous histology harbor an EGFR or ALK-EML4 mutation, patients are not routinely tested for genetic mutations unless the patient is a nonsmoker or there are concerns about the adequacy of the sample.[4,9,10] Adenocarcinoma accounts for about one-half of lung cancers and is increasing in frequency. It is the most common histology in nonsmoking lung cancer patients. The natural history of adenocarcinoma in the lung shows that small tumors discovered with CT screening are relatively slow growing and the tumor doubling time increases as they get larger; volume doubling time of tumors discovered with CT screening is about 576 days, while those found with routine care double every 169 days.[2] This information is most important when considering screening programs and the potential for lead time bias. Patients with adenocarcinoma can present with a single nodule, multifocal nodules, or rapidly progressing, bilateral, diffuse processes. This histology is likely to metastasize from a relatively small tumor (often before the diagnosis of the primary tumor) and spread widely to distant sites, including the contralateral lung, liver, bone, adrenal glands, kidneys, and CNS. As a result, adenocarcinoma has a worse prognosis than squamous cell carcinoma, but the prognosis is similar when controlled for stage.[4,10]

Table 129-1 shows several sub-classifications and variants of adenocarcinoma. These tumors should undergo genetic testing for EGFR mutations and EML4-ALK rearrangements, which can influence prognosis and guide therapy for advanced tumors.

Large cell carcinomas are undifferentiated epithelial tumors, which tend to be large and bulky tumors arising in the periphery of the lung, have a propensity to metastasize in a pattern quite similar to adenocarcinomas, and are associated with a similar poor prognosis.[4,10] They also should be tested for EGFR and ELM4-ALK genetic aberrations, which provide prognostic information and guide therapy. SCLCs account for about 15% of all lung tumors. They are distinguished by their appearance as small neoplastic cells with round to oval nuclei. These tumors occur in both the major bronchi and the periphery of the lung. SCLC is a very aggressive and rapidly growing tumor, with about 60% to 70% of patients initially presenting with disseminated disease outside of the hemithorax. These tumors commonly express neuroendocrine differentiation, which may account for some of the paraneoplastic syndromes frequently associated with this disease. SCLC secretes gastrin-releasing peptide that acts as an autocrine growth factor. Secretion of other peptide hormones, cytogenetic abnormalities, and amplification and increased expression of oncogenes are also common. This disease has a propensity to metastasize to the lymph nodes, opposite lung, liver, adrenal glands and other endocrine organs, bone, bone marrow, and CNS.[3,11] They do not contain EGFR or EML4-ALK mutations and consequently are not tested for those. Current research is attempting to identify targetable genetic mutations for these tumors. Lung tumors can exhibit more than one histologic cell type (eg, adenosquamous) and mixed histology tumors should also undergo genetic testing for EGFR and EML4-ALK alterations.[8,9] Patients can also occasionally have multiple lung nodules arising in different lobes or the contralateral lung. They can be the same or different histology. This is referred to as synchronous tumors, and the nodules may be of similar or different cell types. If one tumor is pure squamous histology, then genetic testing can be omitted. Synchronous tumors worsen the patient's overall prognosis.[4]

CLINICAL PRESENTATION

At the time of diagnosis, 16% of lung cancers are localized, 22% have regional spread, and 57% have distant metastases (the remaining were not staged).[1] Location and extent of the tumor determine the presenting signs and symptoms. A lesion in the central portion of the bronchial tree is more likely to cause symptoms at an earlier stage as compared with a lesion in the periphery of the lung, which may remain asymptomatic until the lesion is large or has spread to other areas. The most common initial signs and symptoms include cough, dyspnea, and chest pain or discomfort, with or without hemoptysis.[10] Unfortunately, many patients with lung cancer also have chronic pulmonary and/or cardiovascular diseases (usually related to smoking), and such symptoms may go unnoticed or be attributed to the concomitant disease. Many patients also exhibit systemic symptoms of malignancy such as anorexia, weight loss, and fatigue. Disseminated disease can cause extrapulmonary signs and symptoms such as neurologic deficits resulting from CNS metastases, bone pain or pathological fractures secondary to bone metastases, or liver dysfunction resulting from tumor involvement in the liver.[10]

CLINICAL PRESENTATION Lung Cancer

Local Signs and Symptoms Associated with Primary Tumor or Regional Spread within the Thorax

- Cough
- Hemoptysis
- Dyspnea
- Rust-streaked or purulent sputum
- Chest, shoulder, or arm pain
- Wheeze and stridor

- Superior vena cava obstruction
- Pleural effusion or pneumonitis
- Dysphagia (secondary to esophageal compression)
- Hoarseness (secondary to laryngeal nerve paralysis)
- Horner's syndrome
- Phrenic nerve paralysis
- Pericardial effusion/tamponade
- Tracheal obstruction

Extrapulmonary Signs and Symptoms Associated with Metastatic Involvement

- Bone pain and/or pathologic fractures
- Liver dysfunction
- Neurologic deficits
- Spinal cord compression

Paraneoplastic Syndromes

- Weight loss
- Cushing's syndrome
- Hypercalcemia (most commonly in squamous cell lung cancer)
- Syndrome of inappropriate secretion of antidiuretic hormone (most commonly in SCLC)
- Pulmonary hypertrophic osteoarthropathy
- Clubbing
- Anemia
- Eaton-Lambert's myasthenic syndrome
- Hypercoagulable state

Paraneoplastic syndromes are signs and symptoms that occur at sites away from the primary tumor or its metastases and are not associated with direct tumor involvement. They may be caused by the production of biologically active substances (eg, peptide hormones) or antibodies, or by other undefined mechanisms. Paraneoplastic syndromes occur more frequently with lung cancer than with any other tumor, and more frequently with SCLC than with NSCLC. These syndromes may be the first signs of a tumor and may prompt the search for an underlying malignancy.[11]

SCREENING AND PREVENTION

4 Most lung cancer patients are diagnosed with advanced disease, which is a key factor in the poor prognosis associated with this disease. Surgery and radiation are the most effective treatment modalities in NSCLC and SCLC, respectively, which generally limit curative intent to patients diagnosed at an early clinical stage.[3,4,6,7] Therefore, it is important to diagnose lung cancer earlier, which implies a potential improvement with screening. Several screening techniques, including chest x-ray, CT, and positron emission tomography (PET), scanning have been investigated to detect lung cancer at an earlier stage. The mortality results from screening with a chest x-ray have been negative, but positive results for LDCT scans to screen for lung cancer have been reported. A recent systematic review of the potential benefit and harm from LDCT screening was reported with accompanying recommendations.[17] The largest and only positive study was known as the National Lung Cancer Screening trial that enrolled more than 54,000 high-risk smokers. The study reported a decrease in overall (7% vs 7.5%) and lung cancer-specific (1.3% vs 1.7%) mortality with LDCT versus control, respectively. The resulting recommendation is to offer annual LDCT screening to individuals aged 55 to 74 years with a 30-pack-year history who are still smoking or have quit for less than 15 years. These recommendations come with a few caveats, including the fact that the most important step is for current smokers to quit. The optimal frequency and duration of screening is unknown and the harm from screening, including frequent false-positive findings, is unknown.[17] Consequently, patients interested in screening should be enrolled in a clinical trial so answers to these important questions can be answered.

The term *chemoprevention* refers to the use of prophylactic medications to prevent the development of cancer. Many studies of potential chemopreventive agents, including nonsteroidal anti-inflammatory drugs (NSAIDs), retinoids, inhaled glucocorticoids, vitamin E, selenium, and green tea extracts, have been conducted, but none have been successful.[18] Large randomized clinical trials have evaluated β-carotene as a lung cancer chemopreventive agent in high-risk patients (older smokers). Rather than prevent lung cancer, the trials clearly show that older people who smoke have a higher risk of developing and dying of lung cancer if they take a β-carotene supplement. Nonsmokers do not appear to have an altered risk of lung cancer with β-carotene consumption.[18] The impact of selenium and/or vitamin E supplementation was evaluated in older men as part of a large prostate cancer prevention study (Selenium and Vitamin E Cancer Prevention Trial [SELECT]). Unfortunately, no benefit was seen with selenium or vitamin E supplementation on lung cancer incidence or mortality.[18]

Because the net benefit of screening is still being defined and chemoprevention trials have not proven to provide a survival benefit, the current recommendation is to avoid smoking and maintain a healthy diet with high amounts of fruits and vegetables.[19]

DIAGNOSIS

A patient suspected of having lung cancer should undergo a diagnostic evaluation. Diagnosis of lung cancer requires both visualization of the cancerous lesion and tissue sampling for pathologic assessment. All patients must have a thorough history and physical examination with emphasis on detecting signs and symptoms of the primary tumor, regional spread of the tumor, distant metastases, and paraneoplastic syndromes. The patient's performance status should be assessed to determine whether or not a patient may be able to tolerate surgery or chemotherapy.[3,4,10,11]

Visualization of the suspected tumor provides the clinician with the information necessary to choose the most appropriate sampling technique. Chest radiographs, endobronchial ultrasound, CT scans, and PET scans are among the most valuable diagnostic tests.[10,11] Chest radiography is the primary method of lung cancer detection and may also be used to measure tumor size, establish gross lymph node enlargement, and detect other tumor-related findings, such as pleural effusion, lobar collapse, and metastatic bone involvement of ribs, spine, and shoulders. In addition, CT scans may be helpful in the evaluation of parenchymal lung abnormalities, detection of masses only suspected on the chest radiography, and

assessment of mediastinal and hilar lymph nodes. PET scans are more accurate than CT scans to distinguish malignant from benign lesions, detect mediastinal lymph node metastases, and identify metastatic spread. Most recently, the use of integrated CT-PET technology has been reported to improve the diagnostic accuracy in the staging of NSCLC over either CT or PET technology alone.[10]

Once the tumor has been located, pathologic examination of tumor tissue is necessary to establish the diagnosis of lung cancer. Tissue is typically obtained through the least invasive method likely to result in an adequate sample; methods include sputum cytology, tumor biopsy by bronchoscopy, mediastinoscopy, percutaneous needle biopsy, or open-lung biopsy. The tissue sample not only confirms malignancy but is also necessary to determine the histology (ie, squamous cell, adenocarcinoma, large cell, or small cell) and to provide adequate tissue for molecular analysis. Once the diagnosis is established, additional radiologic tests may be required to evaluate lymph nodes and potential metastatic sites for accurate staging. Surgical candidates will have additional sampling of their mediastinal nodes to determine those with Stage IIIB (N_3) disease (**Table 129-2**).[3,4,10,11]

TABLE 129-2 Tumor (T), Node (N), Metastasis (M) Staging for Non-Small Cell Lung Cancer

Primary Tumor		Description
T_1		Tumor ≤3 cm in diameter, surrounded by lung or visceral pleura, without invasion more proximal than lobar bronchus
	T_{1a}	Tumor ≤2 cm in diameter
	T_{1b}	Tumor >2 cm but ≤3 cm in diameter
T_2		Tumor >3 cm but ≤7 cm, or tumor with any of the following features: • –Involves main bronchus, ≥2 cm distal to carina • –Invades visceral pleura • –Associated with atelectasis or obstructive pneumonitis that extends to the hilar region but does not involve the entire lung
	T_{2a}	Tumor >3 cm but ≤5 cm
	T_{2b}	Tumor >5 cm but ≤7 cm
T_3		Tumor >7 cm or any of the following: • –Directly invades any of the following: chest wall, diaphragm, phrenic nerve, mediastinal pleura, parietal pericardium, main bronchus <2 cm from carina (without involvement of carina) • –Atelectasis or obstructive pneumonitis of the entire lung • –Separate tumor nodules in the same lobe
T_4		Tumor of any size that invades the mediastinum, heart, great vessels, trachea, recurrent laryngeal nerve, esophagus, vertebral body, carina, or with separate tumor nodules in a different ipsilateral lobe
Regional Lymph Nodes (N)		
N_0		No regional lymph node metastases
N_1		Metastasis in ipsilateral peribronchial and/or ipsilateral hilar lymph nodes and intrapulmonary nodes, including involvement by direct extension
N_2		Metastasis in ipsilateral mediastinal and/or subcarinal lymph node(s)
N_3		Metastasis in contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph node(s)
Distant Metastasis (M)		
M_0		No distant metastasis
M_1		Distant metastasis
	M_{1a}	Separate tumor nodule(s) in a contralateral lobe; tumor with pleural nodules or malignant pleural or pericardial effusion
	M_{1b}	Distant metastasis

Stage	T	N	M	5-Year Survival (%)
IA	T_{1a}-T_{1b}	N_0	M_0	73
IB	T_{2a}	N_0	M_0	58
IIA	T_{1a}, T_{1b}, T_{2a}	N_1	M_0	46
	T_{2b}	N_0	M_0	
IIB	T_{2b}	N_1	M_0	36
	T_3	N_0	M_0	
IIIA	T_{1a}, T_{1b}, T_{2a}, T_{2b}	N_2	M_0	
	T_3	N_1, N_2	M_0	24
	T_4	N_0, N_1	M_0	
IIIB	T_4	N_2	M_0	9
	Any T	N_3	M_0	
IV	Any T	Any N	M_{1a} or M_{1b}	13

Data from references 4 and 20.

STAGING

5 Once the diagnosis of lung cancer is confirmed, the extent of disease must be determined to estimate prognosis and guide therapy. For NSCLC, tumor growth and spread are staged with the American Joint Committee on Cancer (AJCC) tumor, node, and metastasis (TNM) staging system. SCLC is typically staged with the Veterans Administration Lung Cancer Study Group method.[14,21]

Non-Small Cell Lung Cancer

Clinical staging of NSCLC with the TNM system evaluates the size of the tumor, extent of nodal involvement, and presence of metastatic sites. The TNM criteria were last updated in January 2010.[14] The combination of these three evaluations determines the stage. Clinical stages and associated survival rates are described in Table 129-2. For comparison of various therapeutic modalities, a simpler stage grouping system is used in which Stage I refers to tumors confined to the lung without lymphatic spread, Stage II refers to large tumors with

ipsilateral peribronchial or hilar lymph node involvement, Stage III includes other lymph node and regional involvement, and Stage IV includes tumor with distant metastases. Local disease is associated with the highest cure and survival rates, while those with advanced disease have a 5-year survival rate of less than 10%.

Small Cell Lung Cancer

The most commonly used system of staging SCLC was developed originally by the Veterans Administration Lung Cancer Study Group.[2,1] This system categorizes SCLC into two stages: limited and extensive disease. When evidence of the tumor is confined to a single hemithorax and can be encompassed by a single radiation port, the disease is considered limited. Any progression beyond this point is extensive disease. About 60% to 70% of patients initially present with extensive-stage disease. The initial pretreatment evaluation of an SCLC patient should include a medical history, a clinical examination, and laboratory survey, as well as a CT scan of the chest, abdomen, and head. Typically the approach is to identify tumor spread that would demonstrate extensive stage, at which time the workup can stop. For patients without extrathoracic disease identified by these tests, a bone scan and bone marrow biopsy should be performed to confirm limited-stage disease.[3,11]

TREATMENT

Desired Outcomes

6 The desired outcomes of lung cancer treatment depend on tumor histology, stage of disease, and patient characteristics such as age, history, and performance status.[4] These aspects must be assessed before appropriate treatment can be recommended. In the development of a patient care plan, the ultimate goals of therapy should be considered. In patients with early stage disease who can tolerate aggressive treatment, a definitive cure is the desired outcome of treatment. With advanced stage disease, the desired outcomes of treating lung cancer patients who can tolerate aggressive therapy include prolongation of survival. Regardless of treatment based on survival, all therapies should ultimately improve quality of life through alleviation of symptoms. Patients should carefully consider whether to receive aggressive treatment that may prolong survival by a few months but includes a high potential for toxicity that could significantly decrease quality of life. Treatment decisions must include both the healthcare team and an informed and well-counseled patient.

Non-Small Cell Lung Cancer

If left untreated, patients with advanced NSCLC will die within 3 to 5 months and those with early stage disease treated with routine care will die within 10 to 11 months.[10] Surgery, radiation therapy, and systemic therapy with cytotoxic chemotherapy or targeted therapies are all used in the management of NSCLC patients. The applications of these treatment modalities are determined by stage and other patient-specific factors (eg, age and performance status).[4,10] **Table 129-3** lists commonly used chemotherapy regimens including doses and schedules.[4,10]

TABLE 129-3 Common Chemotherapy Regimens Used to Treat Advanced Stage Lung Cancer

	Small Cell Lung Cancer		Non-Squamous EGFR and ALK WT		Squamous Cell		EGFR Mutation Positive		ALK Rearrangement Positive	
Place in Therapy	**Regimen**	**Dosage Schedule**	**Regimen**	**Drugs, Doses, Frequency**	**Regimen**	**Drugs, Doses, Frequency**	**Regimen**	**Drugs, Doses, Frequency**	**Regimen**	**Drugs, Doses, Frequency**
First Line	Etoposide/cisplatin (EP)[4,11]	Cisplatin 80 mg/m^2 IV on day 1 Etoposide 100 mg/m^2 IV on days 1-3; repeat cycle every 3 weeks[83,92] or Cisplatin 60 mg/m^2 IV on day 1 Etoposide 120 mg/m^2 IV on days 1-3; repeat cycle every 3 weeks	Carboplatin/paclitaxel /bevacizumab[3,5,10]	Carboplatin AUC 6 IV mg/mL/min on day 1 Paclitaxel 200 mg/m^2 IV on day 1 Bevacizumab 15 mg/kg IV on day 1 Repeat cycle every 3 weeks × 6 cycles—continue bevacizumab until progression	Gemcitabine/cisplatin (GC)[3,5,10]	Gemcitabine 1,000 mg/m^2 IV on days 1, 8, and 15 Cisplatin 100 mg/m^2 IV on day 1 repeat cycle every 28 days	Erlotinib[3,5,10]	Erlotinib 150 mg (one 150 mg capsule) po daily on an empty stomach	Crizotinib[3,5,12]	Crizotinib 250 mg (one 250 mg capsule) po bid without regard to meals
	Cisplatin/irinotecan (IP)[4,11]	Cisplatin 60 mg/m^2 IV on day 1 Irinotecan 60 mg/m^2 IV on days 1, 8, and 15; repeat cycle every 4 weeks Or Cisplatin 30 mg/m^2 IV on day 1 Irinotecan 65 mg/m^2	Carboplatin/pemetrexed[3,5,10,26]	Carboplatin AUC 5 mg/mL/min IV on day 1 Pemetrexed 500 mg/m^2 IV on day 1 Repeat cycle every 3 weeks	Gemcitabine/cisplatin /Necitumumab[3,10]	Gemcitabine 1,250 mg/m^2 IV on days 1 and 8 Cisplatin 75 mg/m^2 IV on day 1 Necitumumab 800 mg IV on day 1 and 8 Repeat cycle every 21 days	Afatinib[3,5,10]	Afatinib 40 mg (one 40 mg tablet) po daily on an empty stomach		

	Small Cell Lung Cancer		Non-Squamous EGFR and ALK WT		Squamous Cell		EGFR Mutation Positive		ALK Rearrangement Positive	
Place in Therapy	**Regimen**	**Dosage Schedule**	**Regimen**	**Drugs, Doses, Frequency**	**Regimen**	**Drugs, Doses, Frequency**	**Regimen**	**Drugs, Doses, Frequency**	**Regimen**	**Drugs, Doses, Frequency**
Second Line	Topotecan[4,11]	IV on days 1 and 8; repeat cycle every 3 weeks Topotecan 1.5 mg/m^2/day IV days 1-5 Repeat every 21 days	Docetaxel/Ramucirumab[3]	Docetaxel 75 mg/m^2 IV day 1 Ramucirumab 10 mg/kg IV day 1 Repeat every 21 days	Docetaxel/Ramucirumab[3]	Docetaxel 75 mg/m^2 IV day 1 Ramucirumab 10 mg/kg IV day 1 Repeat every 21 days	Osimertinib[3]	Osimertinib 80 mg (one 80 mg tablet) po daily without regard to meals	Ceritinib[3,12]	Ceritinib 750 mg (five 150 mg capsules) po daily on an empty stomach
			Nivolumab[3]	Nivolumab 3 mg/kg IV day 1 Repeat every 2 weeks	Nivolumab[3]	Nivolumab 3 mg/kg IV day 1 Repeat every 2 weeks			Alectinib[12]	Alectinib 600 mg (four 150 mg capsules) po twice daily with food

Local Disease (Stage I-II)

Local disease is associated with a favorable prognosis, and the goal of therapy is cure. Surgery is the mainstay of treatment and may be used alone or in some situations with radiation and/or chemotherapy. Patients who have comorbid conditions preventing them from being surgical candidates can be treated with radiation in place of surgery with curative intent, although the cure rates are lower. Stage IA and IB tumors are treated with surgery alone; when complete resection is achieved, adjuvant therapy is not routinely recommended.[4,7] If surgical margins are positive, re-resection is recommended. Alternatively, patients may receive radiotherapy with or without chemotherapy. Although controversial, patients with IB tumors and high-risk features (poorly differentiated tumors, vascular invasion, wedge resection, minimal margins, tumors more than 4 cm, or visceral pleural involvement) may also receive adjuvant chemotherapy.[4,7] Postoperative radiation therapy with older techniques may be detrimental and is not recommended.[4,7]

Stage IIA and IIB disease is primarily treated with surgery, which should be followed by adjuvant chemotherapy. The adjuvant treatment regimen of choice is not clear, but the positive clinical trials used platinum-based regimens, with arguably the best clinical trial data coming from cisplatin–vinorelbine (**Table 129-4**).[15] The absolute benefit in terms of 5-year overall survival in large randomized trials ranges from no benefit to 15%, with a recent systematic review reporting an absolute difference of 4%. The analysis suggested little effect of the chemotherapy regimen.[15] Although genetics and histology influence systemic treatment and outcomes in advanced disease, this approach has not been tested in large randomized adjuvant therapy trials.

TABLE 129-4 Common Chemotherapy Regimens used in the Adjuvant Treatment of Non-Small Cell Lung Cancer

Regimen[4]	Drugs and Doses	Frequency and Number of Cycles
Cisplatin/etoposide	Cisplatin 100 mg/m^2 IV day 1 Etoposide 100 mg/m^2 IV daily on days 1, 2, and 3	Every 28 days for 4 cycles
Cisplatin/vinorelbine	Cisplatin 50 mg/m^2 IV days 1 and 8 Vinorelbine 25 mg/m^2 IV days 1, 8, 15, and 22	Every 28 days for 4 cycles
	Cisplatin 100 mg/m^2 IV day 1 Vinorelbine 30 mg/m^2 IV days 1, 8, 15, and 22	Every 28 days for 4 cycles
Carboplatin/paclitaxel	Carboplatin AUC 6 IV day 1 Paclitaxel 200 mg/m^2 IV day 1	Every 21 days for 4 cycles
Cisplatin/pemetrexed	Cisplatin 75 mg/m^2 IV day 1 Pemetrexed 500 mg/m^2 IV day 1	Every 21 days for 4 cycles (for non-squamous histology only)

Adjuvant radiation should be avoided in patients who have complete resection and clean margins because it has not demonstrated to be beneficial and can be detrimental. In those with resected lung cancer and N_2 nodal disease, radiation is recommended followed by adjuvant chemotherapy. Radiation, or more commonly chemoradiotherapy, is the treatment of choice for Stage II patients who are medically inoperable. Concurrent rather than sequential administration of chemotherapy and radiation therapy is preferred. Platinum-based chemotherapy is usually given when concurrent chemoradiotherapy is given; recommended regimens include cisplatin with either etoposide or pemetrexed (only for non-squamous histology) or carboplatin with either paclitaxel or pemetrexed (only for non-squamous histology).[4] Neoadjuvant chemotherapy can be used in patients with early stage disease. The trials and meta-analysis include Stages I-III and is discussed in Stage III.

Locally Advanced Disease (Stage III)

Patients with more advanced local disease have large tumors, multiple tumors, and/or nodal involvement—particularly mediastinal nodal involvement (N_2). Collectively this group of

patients is heterogeneous and few large clinical trials are available to guide treatment. Consequently, treatment is best planned by a multimodality team where individual features and patient input are considered. Optimal outcomes are achieved with multimodality therapy that typically includes systemic chemotherapy. Patients with operable disease should be considered for surgery preceded or followed by systemic chemotherapy. Adjuvant chemotherapy after surgery in selected patients improves overall survival (see Table 129-4).[4,15] The primary adjuvant trials included patients with Stage IIIA disease as well as early stage disease; 5-year survival in these studies improved by about 5%. Chemotherapy administration prior to surgery (ie, neoadjuvant) should also be considered. It will treat micrometastatic disease (if present) prior to surgery and reduce tumor size, making surgery easier and better tolerated. However, it is possible that the tumor will grow and become inoperable during therapy. Two meta-analyses have reported that neoadjuvant chemotherapy improves 5-year survival by about 5% compared with surgery alone.[36,37] The analysis did not analyze what stage is most likely to benefit, what regimen is best, or how it would compare to surgery followed by adjuvant therapy. It is discussed here because the potential benefit of reducing the tumor size to make the surgery easier and, in some cases, feasible is most attractive for patients with larger tumors. Although a randomized trial comparing neoadjuvant and adjuvant therapy has not been reported, it appears that both approaches are roughly equivalent and better than surgery alone.

Radiation may be given in place of surgery as the local treatment modality combined with chemotherapy. Although a large definitive trial has not been performed, this research question has been evaluated in small randomized trials. The largest trial randomized 333 Stage IIIA (N_2) patients who responded to three cycles of induction chemotherapy to radiation or surgery. No significant difference in median overall survival (17.5 vs 16.3 months for radiation and surgery, respectively) or overall 5-year survival was observed.[38] This study suggests that surgery could be avoided by administering chemoradiotherapy, but it does not improve survival. Based on the knowledge that dual-modality therapy was better than a single modality, researchers tested trimodal therapy in small studies. The results of the only phase III randomized trial (SAKK-16/00) compared neoadjuvant chemotherapy followed by surgery with sequential neoadjuvant chemoradiotherapy followed by surgery.[39] The event-free survival, overall survival, and local failure did not differ between groups. It is currently recommended that patients with resectable Stage IIIA NSCLC be treated with chemotherapy followed by surgery or radiation, depending on individual patient and tumor features.[4,7]

Patients with Stage IIIA disease who are not surgical candidates or have a tumor that cannot reasonably be resected and nearly all Stage IIIB patients are usually treated with both an active platinum-containing regimen and concurrent radiotherapy. Patients with tumors that cannot fit safely in a radiation port may receive induction chemotherapy followed by chemoradiotherapy. Responding patients may then become surgical candidates. Patients who are not surgical candidates should continue treatment with concurrent chemotherapy and radiation. Patients who are not candidates for radiation are treated like Stage IV disease as discussed further.[4,5,7]

Clinical Controversy...

Multimodality therapy improves outcomes for patients with Stage III disease, but the sequence and use of surgery or radiation remains to be defined.

Advanced-Stage Disease (Stage IIIB and IV)

8 About two-thirds of NSCLC patients present with advanced disease (unresectable Stage IIIB or IV) at the time of diagnosis.[1,4,10] These advanced tumors are generally not surgically resectable. A few patients with single metastatic sites may undergo surgical resection of both the primary tumor and the metastatic site.[4,5] For patients who have a tumor that will fit in a tolerable radiation port, chemoradiotherapy should be considered, but systemic therapy is the primary treatment modality for most of these patients.

The intent of first-line therapy is to palliate symptoms, improve quality of life, and increase the duration of survival. The benefits of cytotoxic chemotherapy—as measured by overall survival and quality of life—were not clearly established until the 1990s. The Non-Small Cell Lung Cancer Collaborative Group reported in 1995 the pivotal results of a large meta-analysis of 52 clinical trials of chemotherapy in the management of NSCLC with follow-up of an additional 16 trials in 2010.[40] The results of this updated meta-analysis showed that chemotherapy, either alone or combined with surgery or radiotherapy, improves median survival for patients with advanced-stage NSCLC by 2 to 4 months and increases the 1-year absolute survival rate from 10% to 20%; this rate did not change between the years 1995-2010.[40] Since chemotherapy became the standard treatment, new agents and targeted therapies have extended these modest gains in survival, while in some cases decreasing toxicity profiles. Current guidelines and experts agree that most patients with advanced-stage disease should receive at least one antitumor regimen.[4,5]

Patient selection for treatment of advanced-stage NSCLC depends on patient-specific factors that include age, performance status, and comorbid conditions. The patient's current performance status (Eastern Cooperative Oncology Group [ECOG] performance status of 0 to 2) appears to be the most consistent predictor of a better response and improved survival after chemotherapy. All patients with a good performance status without significant comorbidities, including elderly patients, should receive first-line therapy. Patients with an ECOG performance status 2 or significant comorbidities should be considered for less intensive therapy (eg, single-agent chemotherapy). Patients with poor ECOG performance status (more than or equal to 3) do not respond well to chemotherapy. Patients with an unfavorable prognosis (poor performance status or significant concomitant diseases) should receive best supportive care and palliative radiation when necessary.[4,5]

Historically a platinum doublet has been used as first-line therapy regardless of histology and in the absence of tumor genetic markers. In many cases these regimens are still appropriate (see Table 129-3). However, translating tumor genetics to practice has led to personalized medicine for advanced NSCLC. Instead of treating all patients the same, clinicians now categorize patients in one of four groups: (1) squamous histology, (2) EGFR mutated, (3) ALK positive (EML4-ALK rearrangement), or (4) non-squamous with wild type EGFR and ALK. 9 The four groups have been defined by varied response to drug therapy and/or toxicity to therapy. Select treatments for each group are outlined in Table 129-3.

Squamous Cell Histology

First-line therapy for advanced-stage squamous cell lung cancer has not changed much since the mid-1990s. The standard of care continues to be a platinum doublet, with arguably the best doublet being either carboplatin plus paclitaxel[57] or cisplatin and gemcitabine.[41] Necitumumab, in combination with cisplatin and gemcitabine, was recently approved for first-line treatment of advanced squamous cell histology patients. The international trial randomized 1,093 patients to receive cisplatin and gemcitabine with or without necitumumab. The necitumumab arm had a similar response rate (31% vs 29%), median progression-free survival (5.7 vs 5.5 months), but longer median survival (11.5 vs 9.9 months, P=0.01).[23] At this point it is too early to see if this incremental improvement is enough to change the standard of care. Although platinum-based combination regimens remain the preferred treatment, nonplatinum-based combinations are acceptable and recommended in patients with a contraindication to a platinum agent. Nonplatinum doublets (eg, gemcitabine plus paclitaxel or docetaxel) have been evaluated in the setting of first-line therapy of advanced NSCLC. The results of a meta-analysis comparing platinum-based regimens with either the same regimen without the platinum or the platinum replaced by another agent demonstrated that platinum provides a modest benefit.[42,43] One meta-analysis evaluated 17 trials with a total of 4,792 patients and found a small but significant 1-year survival benefit with a platinum-based combination regimen compared with nonplatinum combination regimens (relative risk = 1.08, 95% CI 1.01-1.16).[43] A number of trials and meta-analyses have been performed to determine if carboplatin and cisplatin are equally effective or if one is more effective in NSCLC.[44,45,46,47] Individual clinical trials have produced equivocal data and meta-analyses report conflicting results.[44,46,47] One meta-analysis of doublet regimens reported that cisplatin was slightly superior when combined with a "newer" agent; cisplatin improved survival by 11% (P=0.039).[45] Clinical trials comparing the two agents have also demonstrated a different toxicity profile. Cisplatin is associated with more GI (severe nausea and vomiting) and renal toxicity than carboplatin. However, carboplatin is associated with more hematologic toxicity (thrombocytopenia) than cisplatin.[46] Although neither is clearly superior to the other, many clinicians have historically used carboplatin because of its more tolerable renal and GI toxicity, but over the past few years the trend has reversed toward increased use of cisplatin, which could be attributed to improved antiemetics (ie, the combination of a neurokinin-1 receptor antagonist, 5-HT3 receptor antagonist, and a corticosteroid). The lack of progress for first-line treatment represents the slow translation of targeted therapies to be safe and effective in this histology.

The duration of first-line therapy has also been studied. The optimal number of cycles remains controversial.[48] Response rates and quality of life were not improved with administration of six as compared with three cycles of mitomycin, cisplatin, and vinblastine.[49] For those receiving paclitaxel–carboplatin, administration of chemotherapy until disease progression had no clinically significant benefit in survival, response rate, or quality of life, but increased toxicity as compared with administration of four cycles.[50] Many large randomized trials have used six cycles as a standard. Current guidelines recommend four to six cycles of first-line platinum-based doublet chemotherapy for advanced squamous cell lung cancer that is stable or responding to chemotherapy.[4] The one exception to this recommendation is when necitumumab is added to cisplatin plus gemcitabine, where the chemotherapy stops after six cycles,

but the necitumumab continues until progression (continuation maintenance).[23]

Significant advances with targeted therapy have been made for second-line treatment. After failure of first-line therapy, second-line monotherapy with docetaxel has been the standard. Pemetrexed, erlotinib, and afatinib can be used as second-line treatment. Pemetrexed appears to lack efficacy in squamous histology and is not recommended in this histology group.[4,41] Erlotinib and afatinib (EGFR tyrosine kinase inhibitors) provide most of their benefit to patients with an EGFR mutation (rarely seen in squamous histology) and therefore are not often used.[16,51] Afatinib and erlotinib have been compared in a large randomized trial for second-line treatment of squamous cell NSCLC. The progression-free and overall survival favored the afatinib arm (2.6 vs 1.9 months, P=0.01; and 7.9 vs 6.8 months, P=0.0077, respectively) making it the EGFR tyrosine kinase inhibitor of choice for this situation.[52] The efficacy of docetaxel has recently been improved with the addition of ramucirumab, a monoclonal antibody against VEGFR2. A large randomized trial comparing docetaxel with or without ramucirumab reported an increase in progression-free survival and overall survival (4.5 vs 3 months, P<0.0001, and 10.5 vs 9.1 months, P=0.023) favoring the ramucirumab arm.[29] This trial included all NSCLC histologies and about 26% of tumors were squamous histology. Response by histology was not compared, but ramucirumab appeared to be active in all histologies. In patients with squamous cell histology, median overall survival was 9.5 months in the ramucirumab-docetaxel arm compared to 8.2 months in the docetaxel alone arm. More importantly, no safety concerns (serious and fatal bleeding) like those seem with bevacizumab and chemotherapy in squamous histology were reported.[29]

10 Perhaps the most exciting new breakthrough has been the immune checkpoint inhibitors, nivolumab and pembrolizumab (PD1 inhibitors). Nivolumab was approved as second-line therapy for advanced stage squamous histology based on a phase III trial that randomized patients to receive nivolumab or docetaxel.[33] Nivolumab increased progression-free and overall survival (3.5 vs 2.8 months, P<0.001, and 9.2 vs 6.0 months, P<0.001).[33] This data has generated significant interest because historically immune responses can be durable; in this study the 1-year survival was 42%, which is remarkable for second-line therapy.[33] Pembrolizumab was approved as second-line therapy for all NSCLC histologies. The KEYNOTE-001 study compared three different pembrolizumab arms and was designed to identify and validate tumor PD-L1 expression to identify responders.[53] The primary endpoint of the study verified that patients who have a tumor where 50% of the cells express PD-L1 are most likely to benefit (PD-L1+). The progression-free survival was 3.7 months, overall survival was 12 months, and response rate was 19% for the entire population. The outcomes for PD-L1+ patients were significantly better; progression-free survival was 6.3 months, overall survival not reached (lower boundary of the CI was 13.7 months), and response rate was 45%.[53] These numbers were impressive enough for the FDA to approve the drug and the assay to determine PD-L1 positivity. More recently, a large trial randomized 1,034 patients to pembrolizumab 2 mg/kg, pembrolizumab 10 mg/kg, or docetaxel 75 mg/m^2 as second-line therapy for NSCLC. The median progression-free survival did not differ between arms, but overall survival with pembrolizumab (both arms) was superior to docetaxel (overall survival 10.4, 12.7, and 8.5 months for pembrolizumab 2 mg/kg, 10 mg/kg, and docetaxel arms, respectively). The overall survival difference was even greater in the patients with PD-L1+ tumors. The subgroup analysis showed that pembrolizumab was better in PD-L1 negative tumors patients as compared to docetaxel. Therefore, the value of knowing PD-L1 status is likely more important for prognosis than drug selection.[35] Due to the lack of comparative trials between PD1 inhibitors, the best second-line option is yet to be defined.[4]

Third-line therapy and beyond can be considered for patients who desire treatment and have a good performance status. The best agent(s) has not been determined in clinical trials. Therapeutic decisions are based on patient specific factors including prior therapies and potential contraindications to specific agents. Most commonly the treatment selection should be monotherapy with an agent known to have activity in clinical trials.[4]

Non-Squamous Histology

Patients with advanced non-squamous histology have new treatment options based on tumor genetic findings. This group needs to be considered as three separate subgroups: (1) EGFR mutation positive, (2) ALK+, and (3) non-squamous with wild type EGFR and ALK. Determining which treatment path (subgroup) to put them in begins at the time of diagnosis where tumor tissue samples should undergo genetic testing. More specifically, tumor tissue needs to be tested for mutations in the kinase domain of EGFR, exon 19 and mutation of exon 21 (del746-750 and L858R), as well as for the EML4-ALK rearrangement. Tumors that harbor one of these genetic mutations (positive findings) will have a different treatment pathway.[4]

Patients who have a tumor that harbors a *mutation in the EGFR receptor* should receive first-line EGFR tyrosine kinase inhibitor: afatinib, erlotinib, or gefitinib.[5] In prospective randomized trials, EGFR inhibitors are superior to traditional chemotherapy regimens. They result in progression-free survival times of about 11 months, which is about 4 to 5 months longer than chemotherapy.[5,27] All three agents have been approved by the FDA for first-line treatment in EGFR mutation positive patients. There are no randomized head-to-head comparisons of these agents in this group of patients so the most effective agent is unclear. A recent meta-analysis comparing the three agents to chemotherapy for progression-free survival and overall survival by the two most common mutation types (exon 19 deletion and exon 21 L858R mutation) and subgroup comparisons by EGFR inhibitor type (reversible binding versus irreversible binding) was published.[54] The analysis found that all agents were associated with a significantly longer progression-free survival in exon 19 deletion (hazard ratio [HR] 0.27, 95% CI: 0.20-0.36) and L858R (HR 0.44, 95% CI: 0.33-0.58). Interestingly, the subgroup analysis suggests that the irreversible inhibitor (afatinib) is less effective in L858R mutated tumors than the reversible inhibitors (erlotinib and gefitnib). The overall survival analysis found that patients with an exon 19 deletion had improved survival (HR 0.72, 95% CI: 0.60-0.88). The analysis was not able to account for cross over from chemotherapy to an EGFR tyrosine kinase inhibitor, which was common.[54] Although this study did not identify which type of agent was best, it clearly supports the guidelines that recommend patients with an activating EGFR mutation should receive first-line EGFR tyrosine kinase inhibitor therapy instead of chemotherapy. They also show that prognosis with exon 19 deletion is better than exon 21 L858R mutation.[54]

After failing first-line EGFR tyrosine kinase inhibitor treatment, patients may be treated with a second-line EGFR tyrosine kinase inhibitor. If erlotinib or gefitinib (reversible EGFR binding inhibitors) was given as first-line therapy, then afatinib can be used as second-line treatment. A placebo controlled randomized trial showed that afatinib generated a 7% response (all partial responses) and improved progression-free survival (3.3 vs 1.1 months, P<0.0001).[55] This lack of cross resistance can be attributable to the activity of afatinib in tumors that harbor an EGFR T790M mutation. This acquired mutation occurs in about half of patients treated with erlotinib and gefitinib, and impairs binding of the drug to the receptor.[56] Osimertinib, an irreversible EGFR binding TKI, was designed to bind to this mutation and recently received accelerated FDA approval for patients with a T790M mutation. The approval was based on overall response in two single arm trials where 57% and 61% of patients responded to treatment. Although complete responses were rare, the median duration of response was reported to be 12.5 months.[30] Ongoing studies will determine the true benefit of this agent and its ultimate role in therapy. Based on the current data, osimertinib is an attractive second-line therapy for patients with a T790M mutation.

Second-line chemotherapy after failing a first-line EGFR tyrosine kinase inhibitor has been the standard and is still reasonable given the lack of trials comparing second-line regimens. For those who start chemotherapy, it is not clear whether patients should start with a platinum doublet or a single agent. For patients who can tolerate aggressive treatment, most will start treatment with a platinum doublet in the same path as non-squamous advanced disease without an EGFR mutation or ALK rearrangement.[4,5]

Third-line treatment is a likely option for those patients who still have a good performance status, desire for treatment, and can tolerate chemotherapy. For patients who have received two EGFR tyrosine kinase inhibitors, they could then be treated with a platinum doublet with or without bevacizumab, similar to non-squamous patients with wild type EGFR and ALK. For patients who received second-line chemotherapy, they would also follow the treatment path for non-squamous histology second-line therapy.[4,5]

The NCCN guidelines recommend that patients whose tumors have *an ALK rearrangement* should be treated with first-line crizotinib, an ALK tyrosine kinase inhibitor.[4] A phase III trial comparing first-line crizotinib to chemotherapy in patients with ALK+ disease found crizotinib to be superior. The median progression-free survival was 10.9 months versus 7 months (P<0.001) favoring crizotinib. The response rate was also higher in the crizotinib group, 74% versus 45% (P<0.001) and the median duration of response was longer, 11.3 versus 5.3 months. Overall survival was not different at the time of analysis, which is likely due to the relatively low number of deaths and high rate of cross over from chemotherapy to crizotinib.[25]

Second-line therapy with another ALK tyrosine kinase inhibitor appears to be a viable option after failing first-line crizotinib. Ceritinib was approved based on a non-comparative trial that reported a 56% response rate in crizotinib treated patients.[31] The median progression-free survival in the NSCLC population was 7 months. Based on these findings the FDA approved ceritinib as second-line therapy for this patient population. Alectinib is another recently approved option. It was approved based on two non-comparative trials that enrolled patients who had failed first-line crizotinib. The response rate was 38% to 48% and the duration of response from 7.2 to 11.2+ months depending upon the analysis. The attractive outcome with this study occurred in patients with brain metastases; the CNS response rate was 61%, which includes an 18% complete response rate. It is unclear at this point how ceritinib and alectinib compare, but patients with brain metastases have a proven option with alectinib.[34] Second-line chemotherapy is another reasonable option given the lack of

comparative data between ceritinib or alectinib and chemotherapy. Similar to the EGFR mutated process, most patients would then begin the non-squamous wild type EGFR and ALK pathway with doublet chemotherapy and continue future treatment options along that pathway.[4]

Third-line therapy and beyond for those who have failed crizotinib and ceritinib or alectinib is reasonable and would involve chemotherapy. Although we do not have any data evaluating this process, most patients would start treatment with a platinum doublet similar to the EGFR and ALK wild type pathway.[4]

Most NSCLC patients have advanced-stage disease whose tumor is *non-squamous histology and does not have an EGFR or ALK aberration*. First-line treatment options for this subgroup of patients consist of four to six cycles of a platinum doublet and with some regimens the addition of bevacizumab. Patients who have benefit will continue with maintenance therapy. Historically, platinum-based doublets consisting of cisplatin or carboplatin combined with a "newer agent" paclitaxel (nab paclitaxel), docetaxel, gemcitabine, pemetrexed, or vinorelbine are considered the standard and equally effective in this population.[4,5] Based on an intergroup study comparing four regimens, carboplatin and paclitaxel had slightly less toxicity and was considered by ECOG to be the standard of care.[57] When evaluating the addition of a targeted agent, ECOG performed a prospective randomized trial comparing carboplatin and paclitaxel for six cycles with or without bevacizumab 15 mg/kg every 3 weeks.[22] The bevacizumab was continued until progression or unacceptable toxicity. As a result of bleeding complications seen in the phase II trial, patients with squamous cell carcinoma or brain metastases were excluded. The addition of bevacizumab led to longer progression-free survival from 4.5 to 6.2 months (P<0.001), median overall survival from 10.3 to 12.3 months (P=0.003), and 1-year survival from 44% to 51%.[22] NCCN guidelines recommend the addition of bevacizumab to chemotherapy for patients with advanced NSCLC of non-squamous cell histology, no history of recent significant hemoptysis, no CNS metastasis, and not receiving therapeutic anticoagulation.[4] Interestingly, a study that randomized patients to cisplatin and gemcitabine with or without bevacizumab did not find any survival benefit with the addition of bevacizumab.[58] This trial indicates that bevacizumab may not be equally synergistic with all chemotherapy regimens and the best evidence supports its use in combination with carboplatin and paclitaxel for lung cancer.

Another attractive option, particularly for patients with a contraindication to bevacizumab is cisplatin and pemetrexed. A phase III trial comparing six cycles of cisplatin and either gemcitabine or pemetrexed included all NSCLC patients, but was analyzed for this treatment subgroup. The overall survival with cisplatin and pemetrexed was noninferior to cisplatin and gemcitabine in all patients and in those with non-squamous histology. The cisplatin and pemetrexed had less neutropenia, anemia, and thrombocytopenia but more nausea than cisplatin and gemcitabine.[41] This study supports the concept that pemetrexed has limited activity in squamous cell histology, but is as good as other new agents when combined with a platinum agent and perhaps better in non-squamous histologies. Table 129-3 lists selected regimens for non-squamous NSCLC.

Therapy beyond four to six cycles is typically a single agent and is described as maintenance therapy.[4] Several studies demonstrate that continuation or switch maintenance therapy improves survival of NSCLC patients with non-squamous histology.[5] Continuation maintenance therapy is continuing at least one of the agents used in a combination for four to six cycles until progression. Alternatively, switch maintenance therapy is starting a new agent in responding patients after four to six cycles. Pemetrexed, bevacizumab, and erlotinib are the agents that have a proven survival benefit as monotherapy maintenance (switch or continuation), although the combination of pemetrexed and bevacizumab has also been shown to be a benefit.[5] Two large trials have evaluated pemetrexed as maintenance therapy.[59,60] In the largest phase III trial, 663 patients who responded to platinum-doublet therapy were randomized to pemetrexed maintenance (switch maintenance) or no further therapy until relapse. The results show that pemetrexed maintenance therapy prolonged median overall survival (13.4 vs 10.6 months, P=0.012). Interestingly, the benefit was only seen in patients with non-squamous histology, and the best results occurred in patients with adenocarcinoma (median survival 16.8 vs 11.5 months, HR 0.73, 95% CI 0.56-0.96). This histologic-specific benefit of pemetrexed is consistent in both the first (in combination with cisplatin)- and second (as a single agent)-line settings.[59] A second large study enrolled 939 non-squamous histology patients and treated them with four cycles of cisplatin and pemetrexed. The 539 patients who showed benefit from treatment (responders and stable disease) were randomized to continuation maintenance with pemetrexed or placebo. Continuation maintenance with pemetrexed resulted in a longer median overall survival (13.9 vs 11 months) and 1-year survival (58% vs 45%).[60] These two studies clearly established maintenance therapy as standard therapy, but for patients who start a doublet with bevacizumab, it is unclear if both bevacizumab and pemetrexed should be used as continuation maintenance. Initial results from the Alimta/Avastin versus Avastin Alone (AVAPERL) study show that bevacizumab and pemetrexed are superior to bevacizumab alone based on progression-free survival.[61] However, a larger study that compared carboplatin, paclitaxel, and bevacizumab with bevacizumab continued maintenance to carboplatin, pemetrexed, and bevacizumab with bevacizumab and pemetrexed continuation maintenance found no difference in overall survival.[26] Ongoing studies will address the effectiveness of maintenance therapy in specific situations.

Another recently reported randomized phase III trial shows that maintenance therapy with erlotinib prolongs disease-free survival versus placebo (Sequential Tarceva in Unresectable NSCLC [SATURN] study).[63] A total of 1,949 patients received four cycles of a platinum doublet; the 889 patients without progressive disease were then randomized to erlotinib or placebo. Erlotinib maintenance prolonged survival by 1 month (11 vs 12 months), which included all patients (11% with EGFR mutation and 89% EGFR wild type). Erlotinib maintenance appeared to be most effective in patients with adenocarcinoma histology and in those with an EGFR mutation. Although this study is compelling, pemetrexed is more commonly used because those with an EGFR mutation should receive first-line EGFR tyrosine kinase inhibitor therapy and continue it until progression.[4,5]

Studies evaluating gemcitabine[64] and docetaxel[65] maintenance therapy have been reported with some positive data. Both studies demonstrate that maintenance therapy improved progression-free survival, with a nonsignificant trend for improved overall survival. These agents should be considered in patients with a contraindication to pemetrexed and erlotinib.

Clinical Controversy…

The benefit of maintenance pemetrexed and bevacizumab for patients with non-squamous cell Stage IV NSCLC is proven. However, the benefit of bevacizumab and pemetrexed versus pemetrexed alone as maintenance is unknown. Additional clinical trial results to clarify optimal maintenance therapy for patients with non-squamous Stage IV NSCLC are needed.

Monotherapy with nivolumab, pembrolizumab, docetaxel, pemetrexed, or erlotinib are options for second-line therapy in patients with a good performance status who progress during or after first-line chemotherapy.[4,5] Docetaxel was the first to receive FDA approval for the treatment of advanced NSCLC after failure of a platinum-based chemotherapy regimen. The initial docetaxel dose of 100 mg/m^2 IV over 1 hour every 21 days was decreased to 75 mg/m^2 after an interim analysis showed a greater risk of severe neutropenia with the higher dose. Docetaxel, at the 75 mg/m^2 dose, was superior to best supportive care in terms of time-to-disease progression (10.6 vs 6.7 weeks, P=0.001), median survival (7.5 vs 4.6 months; P=0.047), and 1-year survival (37% vs 11%; P=0.003).[66] Both doses had a statistically significant improvement in 1-year survival when compared with a control regimen of vinorelbine or ifosfamide (32%, 21%, and 19%, respectively).[67] The efficacy of docetaxel has recently been improved with the addition of ramucirumab. A large randomized trial comparing docetaxel with or without ramucirumab found an increase in progression-free survival and overall survival (4.5 vs 3 months, P<0.0001, and 10.5 vs 9.1 months, P=0.023) favoring the ramucirumab arm.[29] This trial included all NSCLC histologies and about 73% had non-squamous histology. Overall survival in the non-squamous histology patients was 11.1 months with ramucirumab versus 9.7 months with docetaxel alone.[29]

The second chemotherapy agent approved as second-line treatment is pemetrexed. The approval was based on results of a phase III trial that randomized 571 patients to receive either pemetrexed 500 mg/m^2 with folate and cyanocobalamin supplementation or docetaxel 75 mg/m^2. No significant differences in overall response rate, stable disease, or median survival between the pemetrexed and docetaxel arms were observed. Docetaxel had significantly more hematologic toxicities as compared with pemetrexed, leading to more hospitalizations and use of hematopoietic growth factors and erythropoiesis-stimulating agents. Patients receiving docetaxel had a significantly higher incidence of alopecia, while patients receiving pemetrexed had a significantly higher elevation of alanine aminotransferase.[68] Pemetrexed appears to be a preferred option based on this study, but it is not appropriate as second-line therapy when it is used as maintenance therapy.

Erlotinib, a relatively nontoxic agent that targets the EGFR, was approved in November 2004 as a single agent for patients with advanced NSCLC whose disease progressed after at least one prior chemotherapy regimen. Its approval was based on an international, multicenter, randomized, double-blind phase III trial (BR.21) in 731 patients with locally advanced or metastatic NSCLC who had failed at least one prior chemotherapy regimen.[69] Patients were randomized to receive either erlotinib 150 mg or placebo orally once daily. Patients in the erlotinib group had a significantly higher objective response rate (9% vs 1%, P<0.001) and longer median progression-free and overall survival (9.9 vs 7.9 weeks, P<0.001 and 6.7 vs 4.7 months, HR 0.73, P<0.001, respectively) than those in the placebo group. Patients in the erlotinib group also had significantly improved symptom control, specifically time-to-deterioration of cough, dyspnea, and pain.[69] Although these benefits are relatively modest, some individual patients show a profound response. Analysis of predictive biomarkers led to EGFR mutational testing and to the recommendation that patients who have EGFR mutation-positive tumors should receive first-line erlotinib, afatinib, or gefitinib.[4,5,24]

As described above in the section on squamous cell histologies, the PD-1 inhibitors nivolumab and pembrolizumab are options in the second-line setting. Although currently only pembrolizumab is FDA-approved for all histologies and nivolumab is only FDA-approved for squamous cell histology, data from the CHECKMATE-057 study suggests that nivolumab is also active in non-squamous histologies and improves overall survival compared to docetaxel.[32] More recently, a large trial comparing second-line pembrolizumab to docetaxel found overall survival to be better with pembrolizumab regardless of PD-L1 expression, although the survival advantage was most impressive in patients with PD-L1 positive tumors.[35] The comparative trials indicate that pemetrexed and docetaxel are equally effective,[68] and docetaxel plus ramucirumab are superior to docetaxel alone.[29] Similarly nivolumab and pembrolizumab are superior to docetaxel alone.[32] All five monotherapies and ramucirumab-docetaxel are acceptable regimens, but the NCCN guidelines list nivolumab or pembrolizumab as preferred.[4] Their recommendation is likely attributed to the impressive durability of response.

Third-line therapy and beyond is reasonable for patients who have a good performance status and can tolerate another agent. Typically monotherapy with an active agent would be used in this setting. Erlotinib was tested in all histologies in the second- or third-line setting and is an appropriate option.[69] For patients who received an immune check point inhibitor (nivolumab or pembrolizumab), docetaxel would be an option with or without ramucirumab. For those who received second-line docetaxel with or without ramucirumab, an immune checkpoint inhibitor would be an option. For patients who want treatment beyond third-line, a single agent with activity could be used.[4,5]

In summary, patients with advanced-stage NSCLC should have their tumor tested for histology and those with a non-squamous histology should be tested for an EGFR mutation or ALK rearrangement. Based on these findings there are four distinct groups that have different treatment pathways and prognosis. The good news is that better understanding of tumor biology has resulted in better drugs and drug selection, which will hopefully improve prognosis for most patients.

Elderly and Poor-Performance Status Patients

Single-agent chemotherapy is an alternative in elderly patients or those with an ECOG performance status of 2.[69] First-line, single-agent chemotherapy has objective response rates of 5% to 25% with no significant effect on overall survival. Complete responses are rare and responses that do occur are of brief duration (ie, 2-4 months).[70,71] Among the most active cytotoxic chemotherapy agents in NSCLC are cisplatin, carboplatin, docetaxel, paclitaxel, etoposide, gemcitabine, ifosfamide, irinotecan, topotecan, mitomycin, vinblastine, vinorelbine, and pemetrexed.[4] Erlotinib, afatinib, and crizotinib are also active as a single agent and should be considered in patients with a mutation-positive tumor.

Historically, patients with an ECOG performance status 2 were excluded from NSCLC trials because of excessive toxicity with minimal benefit from combination cytotoxic therapy. A recent randomized phase III trial comparing single-agent weekly docetaxel with docetaxel and gemcitabine in elderly or poor performance status (35% of patients) had disappointing results.[72] No survival differences were observed between the two treatment arms in the 122 poor-performance status patients (3.8 vs 2.9 months, respectively) and the median survival is short compared with patients with good performance status.[72] Another randomized phase III trial compared single-agent gemcitabine with gemcitabine/carboplatin in patients with ECOP performance status 2.[80] The median overall survival was not different between gemcitabine and gemcitabine/carboplatin (5.1 vs 6.7 months, respectively). The authors concluded that single-agent therapy is still the standard in this setting.[72] The updated ASCO guidelines state that available data support the use of single-agent and combination chemotherapy, but are relatively weak and incorporate elderly and poor performance status patients. They emphasize the need to individualize this decision.[5] A recent meta-analysis shows that patients with performance status 2 benefit from treatment.[73] The NCCN guidelines list both single agents and combinations for patients with a performance status of 2, and best supportive care for patient with a performance status of 3 or 4 unless they have an EGFR mutation or ALK rearrangement where they can receive a tyrosine kinase inhibitor.[4]

Personalized Pharmacotherapy

The translation of basic science to the clinic has resulted in personalized pharmacotherapy plans. Treatment decisions are influenced by tumor biology as described above, but must also consider patient characteristics (eg, comorbidities and performance status). Treatment guidelines generally apply to patients who are fit and desire aggressive therapy. Patient-specific factors that can alter these recommendations include age and comorbid conditions that serve as a relative or absolute contraindication to aggressive platinum-based doublet therapy and even some targeted therapies such that the risk of toxicity outweighs the benefit.[5] For example, elderly patients or those with an ECOG performance status of 2 have a modest benefit to aggressive platinum-doublet therapy; patients with an ECOG performance status of 3 have little to no benefit and a high risk of toxicity. Other considerations include renal dysfunction and the use of a platinum agent, and history of hemoptysis and the use of bevacizumab. Although these examples appear to provide clear guidance, risk is often a continuum and it is sometimes not clear how to treat individual patients (eg, a fully functioning 50-year-old with angina and a serum creatinine of 1.7 mg/dL (150 µmol/L) and Stage IIIB squamous cell lung cancer).

Evaluation of Therapeutic Outcomes

For patients who have undergone surgical resection with or without chemotherapy, radiation, or both, a physical examination and chest radiography are recommended every 3 to 4 months for the first 2 years, then every 6 months for 3 years, and then annually. In addition, a low-dose spiral chest CT scan is recommended annually to monitor for evidence of local recurrence. Suspicious symptoms or physical findings (eg, bone pain, visual abnormalities, headache, or elevated liver function tests) should prompt an evaluation to rule out distant metastases.[4,5]

Tumor response to chemotherapy is generally evaluated at the end of the second or third cycle and at the end of every second cycle thereafter. Patients with stable disease, with objective response, or with measurable decrease in tumor size (complete or partial response) should continue until four to six cycles have been administered. Patients with non-squamous histology tumors who respond (ie, nonprogressive disease) should be considered for maintenance therapy with pemetrexed. Following initial therapy for NSCLC, patients must be monitored for evidence of disease progression.[4,5] Second-line therapy and beyond is traditionally given until progression. The immune checkpoint inhibitors can display a different response pattern than traditional chemotherapy or targeted therapy. It can take some time for the immune system to become activated and then the tumor will initially be infiltrated with cytotoxic lymphocytes that radiographically can appear as progression prior to a response.[74] Although the registry trials continue to assess response based on RECIST criteria, an immune response criterion has been proposed where essentially progression needs to be documented on two consecutive assessments at least 4 weeks apart.[75] The median time-to-response for immune checkpoint inhibitors is 10 to 12 weeks.

Small Cell Lung Cancer

Small cell lung cancer is a rapidly dividing malignancy that spreads early in the disease course. Consequently, most patients present with extensive-stage disease (about 60%-70% of new cases). When patients with SCLC are not treated, the disease quickly becomes fatal. Fortunately, SCLCs are very responsive to chemotherapy and radiation. Chemotherapy with or without radiotherapy is the treatment of choice for most patients. Even after a complete response to therapy, the cancer usually recurs within 6 to 8 months, and survival time following recurrence is typically short (about 4 months). With treatment, median survival rates for patients with limited and extensive disease are 14 to 20 and 9 to 11 months, respectively. Treatment planning starts with stage of disease (ie, limited vs extensive stage), but must also take into account other factors, including performance status (treatment usually restricted to performance status 0 or 1), patient age, comorbid conditions (eg, renal failure), and patient desire to receive treatment.[3,6]

Limited Disease

7 When a single SCLC mass is found, local therapy with radiation or surgery is considered, although the use of surgery in SCLC is limited to solitary nodules, without evidence of metastasis to lymph nodes. One of the factors differentiating SCLC and NSCLC is the fact that radiation is favored for treatment of local disease over surgery. Radiation is always combined with chemotherapy in limited-stage SCLC, and the regimen of choice is etoposide and cisplatin (the EP regimen). Carboplatin may be substituted for cisplatin to reduce nausea and vomiting, nephrotoxicity, or neurotoxicity,[76] although increased myelosuppression in the form of thrombocytopenia may result. In European countries, a three-drug combination containing an anthracycline has been the mainstay of therapy, but mounting clinical evidence shows that these regimens are inferior to EP plus concurrent radiation and have more toxicity.[77] Consequently, the guidelines recommend that the EP regimen be used with concurrent radiotherapy.[3,6] Because patients with SCLC commonly have a recurrence in the CNS,

trials have been performed to evaluate the benefit of prophylactic cranial irradiation (PCI). A pivotal study showed that PCI reduces the incidence of brain metastasis and increases 3-year survival from 15% to 21%.[78,79] Therefore, patients who achieve a complete response with treatment should be offered PCI.

Extensive Disease

8 Platinum regimens are also the treatment of choice in extensive disease, and many studies have failed to show superiority to the EP regimen as first-line treatment. A combination of irinotecan and cisplatin in one Japanese study demonstrated an increased median survival time by about 3 months over the EP regimen. This regimen showed a lower incidence of severe neutropenia but exhibited higher rates of moderate-to-high grade diarrhea in an Asian population.[80] However, irinotecan and cisplatin failed to improve survival as compared with EP in a study conducted in the United States.[81] Therefore, EP remains the regimen of choice for treating extensive-stage SCLC in the United States, with irinotecan and cisplatin reserved as an acceptable alternative. Concurrent radiotherapy is not used routinely in extensive disease. However, a recent study that randomized extensive-stage patients responding to chemotherapy to observation or PCI reported that PCI decreased the 1-year risk of brain metastasis (14.6% vs 40.4%), and prolonged survival (13.3% vs 27.1% at 1 year).[82] A more recent Japanese study reported that PCI reduced the risk of brain metastases, but did not improve overall survival. The results of these studies led to guideline revisions recommending PCI for patients with limited disease responding to chemotherapy.[3,6]

Recurrent Disease

Small cell lung cancer patients who relapse or progress after first-line chemotherapy have a median survival of 4 to 5 months. Unfortunately, when disease recurs, it is usually less sensitive to chemotherapy. The decision of whether or not to use second-line chemotherapy is often based on the length of time between completion of the induction chemotherapy regimen and relapse. If this interval is less than 3 months, the patient has refractory SCLC and is unlikely to respond to second-line therapy; hence, they should receive best supportive care or be enrolled in a clinical trial. For those with greater than a 3-month time interval between first-line chemotherapy and relapse, the expected response rate to treatment is about 25%, and second-line therapy should be considered.[3,6] Topotecan (IV and oral) is the only FDA-approved second-line therapy for SCLC. The pivotal trial leading to the approval randomized patients to IV topotecan or to cyclophosphamide, doxorubicin, and vincristine (CAV) regimen.[83] The response rates, time-to-disease progression, and overall survival were not different between groups. Interestingly, the proportion of patients experiencing symptom improvement was higher in the topotecan arm. The hematologic toxicity was similar between arms, but there was slightly more neutropenia in the CAV arm and more anemia and thrombocytopenia in the topotecan arm. Nonhematologic toxicity appears to be higher in the CAV arm; 11% of patients required a dose reduction compared with 1% in the topotecan arm.[83] Oral topotecan appears to be equally effective and similar in terms of dosing, toxicity, and effectiveness as IV topotecan.[28] Based on these studies, topotecan should be considered as the second-line treatment of choice, but because of its modest efficacy other agents warrant consideration. Agents that are recommended in national guidelines include single-agent topotecan (oral or IV), irinotecan, gemcitabine, paclitaxel, docetaxel, oral etoposide, temozolomide, and vinorelbine; CAV regimen; and participation in a clinical trial.[3,6]

Personalized Pharmacotherapy

Personalized pharmacotherapy based on tumor biology has not become a standard for SCLC. However, there is significant interest to identify targeted drug therapy that will improve the outcomes of all or subpopulations of patients with SCLC. Genotyping studies to identify targetable mutations are currently being employed. If a drug inhibiting a specific pathway proves to be beneficial, then optimal treatment may be individualized based on the tumor biology. Until then, we will continue to choose treatment primarily based on stage, comorbid conditions, and performance status. Similar to NSCLC, patients without comorbid conditions and good performance status will typically receive a platinum doublet (cisplatin and etoposide), but elderly patients, those with significant comorbid conditions, or those with an ECOG performance status of 2 may receive less aggressive treatment (a single agent), and those with extensive-stage disease who are bedridden will not be given cytotoxic therapy because of a lack of benefit.

Evaluation of Therapeutic Outcomes

The effectiveness of first-line therapy is evaluated after two to three cycles of treatment. At this point, therapy is continued for four to six cycles of therapy in patients with a complete or partial response or stable disease, and discontinued or changed to a non–cross-resistant regimen in patients demonstrating evidence of progressive disease. In the case of SCLC, those with response benefit from the addition of PCI following initial therapy. After recovery from first-line therapy, follow-up visits should occur every 3 months for years 1, 2, and 3, then every 4 to 6 months for years 4 and 5, and then annually for patients with either a partial or complete response.[3,6]

Complications and Supportive Care

Patients with lung cancer frequently have numerous concurrent medical problems. Such problems may be related to invasion of the primary tumor and its metastases, paraneoplastic syndromes (see Clinical Presentation earlier), chemotherapy and radiotherapy toxicity, or concomitant disease states (eg, cardiac disease, renal dysfunction, chronic obstructive pulmonary disease, asthma, or diabetes). Depression is also common and sometimes persistent in patients with SCLC and NSCLC and should be treated. Identification, diagnosis, and treatment of the patient as a whole may improve the patient's overall quality of life and tolerance to cancer treatments.

11 The chemotherapy regimens used in the management of lung cancer are intensive and are associated with a wide variety of toxic effects. Nausea and vomiting may be severe. Cisplatin-containing regimens require the use of aggressive acute and delayed antiemetic regimens containing a serotonin antagonist, dexamethasone, and neurokinin-1 receptor antagonist.[84] Patients experiencing protracted nausea and vomiting may require IV hydration and nutritional support. Myelosuppression is often the dose-limiting toxicity associated with chemotherapy. Granulocytopenia places patients at a high risk for serious infections. Other toxic effects associated with these chemotherapy regimens include mucositis, anemia, nephrotoxicity, peripheral neuropathies, and ototoxicity.

About 30% to 65% of advanced-stage NSCLC patients will develop bone metastases, which may lead to significant bone pain, pathologic fractures, spinal cord compression, and hypercalcemia.[85] Zoledronic acid, an IV administered bisphosphonate, has been shown to reduce skeletal-related events in patients with bone metastases at a dose of 4 mg over 15 minutes infused every 3 weeks. Although the data do not show a significant reduction in skeletal-related events, time-to-first event is significantly increased (230 vs 163 days, P=0.023), thereby making zoledronic acid a viable therapy for patients with bone metastases. Denosumab has been compared to zoledronic acid in solid tumor patients including lung cancer and found to be noninferior in preventing or delaying first on-study skeletal-related event.[86] A subgroup exploratory analysis of lung cancer patients suggests that denosumab may prolong survival by just over a month.[87] Since they are equally effective for the primary endpoint, the potential benefit in survival might be considered when selecting therapy.

Patients receiving radiation therapy may experience complications including severe esophagitis, fatigue, radiation pneumonitis, and cardiac toxicity. These toxicities are usually more common and severe when radiation is combined with chemotherapy. The patient's baseline performance status and the degree of pulmonary dysfunction (eg, chronic obstructive pulmonary disease from years of tobacco use) must be considered in decisions concerning radiation dosage and fractionation.[88]

Patients who receive an immune checkpoint inhibitor can develop immune-related adverse events. Most commonly they include the GI tract where they present as diarrhea, the skin where they present as a rash, and pneumonitis where patients present with dyspnea. Holding therapy and intervening with steroids can blunt the progression of these toxicities. The other key point is that responses to immune checkpoint inhibitors can be delayed in onset.[88] A new response criterion has been developed for immunotherapies, which differs from RECIST criteria by requiring documentation of significant tumor grown on two occasions at least 4 weeks apart to be defined as progression. However, the registry trials for pembrolizumab and nivolumab both used the traditional RECIST criteria, indicating that the immune response criteria will not become the standard.

It is readily apparent that many lung cancer patients receive complex pharmacologic regimens that may include chemotherapeutic agents, immune checkpoint inhibitors, antiemetics, antibiotics, analgesics, anticoagulants, bronchodilators, corticosteroids, anticonvulsants, and cardiovascular agents. Such regimens necessitate intensive therapeutic monitoring in order to avoid drug-related and radiotherapy-related toxic effects and to optimize therapeutic outcomes for individual patients.

Chapter 130: Colorectal Cancer

Lisa M. Holle; Jessica M. Clement; Lisa E. Davis

INTRODUCTION

KEY CONCEPTS

- 1 Advancing age, inherited and acquired genetic susceptibilities, lifestyle factors, inflammatory bowel disease, type 2 diabetes mellitus, and environmental factors are associated with colorectal cancer risk.
- 2 Regular use of aspirin and other nonsteroidal anti-inflammatory drugs, calcium intake, and higher blood vitamin D levels may reduce risk of colorectal cancer, but they are not currently recommended for routine cancer prevention.
- 3 Effective colorectal cancer detection programs incorporate routine screening starting at age 50 years for average-risk individuals. Colorectal adenomas can progress to cancer and should be removed.
- 4 The histologic stage of colorectal cancer upon diagnosis—determined by depth of bowel invasion, lymph node involvement, and presence of metastases—is the most important prognostic factor for disease recurrence and survival.
- 5 The treatment goal for stages I, II, and III colon cancer is cure; surgery should be offered to all eligible patients for this purpose. Six months of fluoropyrimidine-based adjuvant systemic therapy reduces the risk of cancer recurrence and overall mortality in patients with stage III and select populations with stage II colon cancer. An oxaliplatin-containing regimen further reduces risk as compared with fluoropyrimidine alone.
- 6 Combined modality neoadjuvant therapy consists of fluoropyrimidine-based chemosensitized radiation therapy and surgery for patients with stage II or III cancer of the rectum and is considered standard of care to decrease risk of local and distant disease recurrence.
- 7 Preoperative chemotherapy may reduce tumor size and convert unresectable disease to

resectable disease in selected patients with metastatic colorectal cancer. This strategy offers the potential for prolonging overall survival and cure for metastatic disease.

- 8 Chemotherapy is palliative for metastatic disease. A fluoropyrimidine with oxaliplatin or irinotecan improves survival compared to fluoropyrimidine monotherapy and should be offered to patients who are candidates for aggressive treatment. The ability for patients to receive all active cytotoxic agents (eg, fluoropyrimidine, oxaliplatin, and irinotecan) during the course of their disease improves their overall survival.

- 9 Bevacizumab plus fluoropyrimidine-based chemotherapy as initial therapy for metastatic disease is considered standard of care and provides a survival benefit as compared with combination chemotherapy alone.

- 10 The addition of an epidermal growth factor receptor (EGFR) inhibitor (cetuximab or panitumumab) to initial treatment for RAS wild-type advanced or metastatic disease may improve tumor response rates and survival. Individuals who have disease progression after initial therapy not containing an EGFR inhibitor may benefit from cetuximab or panitumumab, either alone as a single agent or combined with other drugs. However, patients with RAS gene mutations should not receive cetuximab or panitumumab as these tumor mutations predict lack of treatment response.

Colorectal cancer involves the colon, rectum, and anal canal. It is one of the three most common cancers in adult men and women in the United States.[1] In 2016, an estimated 134,490 new cases will be diagnosed, of which 95,270 will involve the colon and 39,220 the rectum. An additional 8,080 new cases of cancer involve the anus, anal canal, or anorectum. For both adult men and women, colorectal cancer is the third leading cause of cancer-related deaths in the United States. An estimated 49,190 deaths will occur during 2016.

Mortality and incidence rates associated with colorectal cancer in the United States have decreased steadily over the past two decades. Incidence rates vary worldwide, with the highest incidence rates in economically developed countries.[2] Colorectal cancer mortality rates have been decreasing likely due to increased screening and/or improved treatments; however, mortality rates continue to increase in less developed countries in eastern Europe and South America.[2]

Multiple factors are associated with the development of colorectal cancer, including inherited susceptibility, environmental and lifestyle factors, and certain disease states. Overall, about 40% of affected individuals undergo a surgical procedure alone intended for cure. An additional 37% of individuals can potentially be cured with surgery followed by adjuvant radiation therapy (XRT), chemotherapy, or both. Curability is influenced primarily by the depth of tumor penetration, involvement of lymph nodes, and presence of metastatic disease. Five-year survival rates are about 90% for persons with early stages of colon and rectal cancer.[3] After the tumor has spread regionally to adjacent lymph nodes or tissues, 5-year survival rates drop to about 70% for both colon and rectal cancer. Five-year survival for individuals with metastatic disease is about 13%.

Treatment modalities for colorectal cancer include surgery, XRT, chemotherapy, and targeted

molecular therapies (eg, angiogenesis inhibitors and epidermal growth factor receptor inhibitors). Surgery is the important and definitive procedure associated with cure. XRT can improve curability following surgical resection in rectal cancer and may reduce symptoms and complications associated with advanced disease. Chemotherapy is used in the adjuvant setting to increase cure rates and in treatment for advanced stages of disease to prolong survival. Selected patients with metastatic disease who receive aggressive preoperative chemotherapy and targeted therapies experience higher resection rates and can be potentially cured. Much progress has been made in the treatment of advanced disease, the ability to identify candidates for potentially curative surgical procedures, and the availability of active drug regimens that improve patients' survival.

EPIDEMIOLOGY

Colorectal cancer is the third most common malignancy worldwide in men and second most common malignancy in women, accounting for more than 1.4 million new cases annually.[2] The variation in colorectal cancer occurrence worldwide is at least 20-fold.[2] The highest incidence rates are found in Australia and New Zealand, Europe, North America, and South Korea. The lowest incidence rates are seen in less-developed areas such as Africa and South Central Asia. Most recently, incidence rates have rapidly increased in newer economically developed countries where rates were historically low, such as in eastern Europe and in Japan, Kuwait, and Israel.[2] The increases in these countries is thought to be associated with an increased prevalence of risk factors associated with westernization, such as unhealthy diet, obesity, and smoking.

The incidence of invasive colon cancer is greatest among males, who have an age-adjusted incidence rate of 37.4 per 100,000, as compared with females for whom the rate is 29.9 per 100,000.[3] Invasive cancer of the rectum occurs less frequently; the incidence rate is 16.5 and 10.3 per 100,000 for males and females, respectively. Differences in colorectal cancer incidence exist among ethnic groups in the United States, where incidence is highest among African Americans followed by, American Indian/Alaska Native, Whites, Hispanic/Latino, and Asian American/Pacific Islander.[2] Cultural and genetic factors as well as disparities in access to healthcare services, may influence risk among population groups.

The overall incidence of colon and rectal cancers in the United States continues to decline, with an annual percent decrease of more than 4.3% from 2007 to 2011 in adults over the age of 50 years and 1.8% per year in adults younger than 50 years.[1] Cancer incidence rates have declined in every major ethnic group since 1975, although less among American Indian/Alaska Natives. Most recent rapid declines in incidence rates are attributed to screening and polyp removal.[1] **Figure 130-1** displays trends for incidence and mortality rates among White and African American males and females in the United States.[4]

FIGURE 130–1

National Cancer Institute, Surveillance Epidemiology, and End Results (SEER) incidence and mortality rates for invasive colon and rectum cancer, 1975-2012. SEER 9 areas and US Mortality Files (National

Center for Health Statistics, CDC). Rates are age adjusted to the 2000 US standard population (19 age groups—Census P25-1130). *(From reference 4.)*

Cancer of the colon and rectum accounts for about 8% of all cancer deaths in the United States.[1] The median age for death from cancer of the colon or rectum is 74 years.[4] It is estimated that 49,190 individuals will die of colorectal cancer in the United States in 2016, which represents a continued decline in overall combined mortality for both colon and rectal cancer.[1] Overall mortality rates are highest among African American males and females, although a steep rate of decline began in the late 1990s.[3] Colorectal cancer death rates are decreasing among all ethnic groups, but mortality rates are not statistically lower in American Indian/Alaska Natives.[3] Factors contributing to the overall decline in colorectal cancer mortality include decreasing incidence rates, screening programs with early polyp removal, and more effective and better tolerated treatments. Differences among different world geographic regions, and in population groups in the United States, may also reflect variations in underlying tumor biology, stage at diagnosis, access to screening programs, and availability of effective treatments.[2]

ETIOLOGY AND RISK FACTORS

Numerous studies suggest that the development of colorectal cancer is related to both uncontrollable and modifiable risk factors. Age, family history, clinical and genetic susceptibilities cannot be controlled by individuals. However, lifestyle factors, dietary, and environmental factors that

affect the bowel may influence an individual's risk of developing colorectal cancer.

Personal Medical History

Age

An individual's risk of developing cancer of the colon or rectum increases with advancing age, rising progressively after age 50.[3] The median age at colon cancer diagnosis is 69 years in men and 73 years in women and 63 years in men and 65 years in women for rectal cancer.[3] Although about 10% of patients are less than 50 years of age at the time of diagnosis, the incidence of colorectal cancer is increasing in this age group, in contrast to overall rates of decline among adults age 50 years and older. The reasons for this pattern are unclear, but may reflect increasing trends in obesity and detrimental dietary factors among younger people.[3]

Adenomatous Polyps or Colorectal Cancer

A prior history of high-risk adenomatous polyps, particularly multiple adenomas or size 10 mm or more, is associated with increased risk of colorectal cancer.[5] Individuals with a prior diagnosis of colon or rectal cancer have a greater risk of developing a new malignancy at another area in their colon or rectum as compared to individuals without a prior history of colorectal cancer.

Inflammatory Bowel Disease

Individuals with chronic inflammatory bowel disease, such as ulcerative colitis or Crohn's disease, have about a two-fold greater risk of developing colorectal cancer than the average individual.[3,6] This risk increases with the extent and duration of disease, a familial history of colorectal cancer, coexistent primary sclerosing cholangitis, and the degree of inflammation. The risk is even greater for young individuals and increases for all affected individuals with increasing extent of bowel involvement and disease duration. Recent data suggest that the overall incidence is staying steady or diminishing in Western countries. The cumulative risk of colorectal cancer is low early in life, but increases over time. The reported incidence ranges from 2% to 3% at 10 years after diagnosis to 5% to 8% at 20 years and 8% to 18% at 30 years.[6] Recent evidence suggests that the risk may be lower in these patients in more recent years because of improved screening and disease management.[3] Chronic underlying inflammation, oxidative stress, genetic instability, and release of various cytokines, including nuclear factor-kappa B and tumor necrosis factor-alpha, and intestinal microbiota appear to promote tumorigenesis.[6] The progressive dysplastic changes that bowel mucosa undergo are similar to those observed in adenomatous polyps. Overall, persons diagnosed with either disease constitute about 1% to 2% of all new cases of colorectal cancer each year.

Type 2 Diabetes Mellitus

Type 2 diabetes mellitus, independent of body mass size and physical activity level, is associated with increased colorectal cancer risk, although glycosylated hemoglobin (HbA_{1c}) alone as an indicator

of hyperglycemia and association with colorectal cancer is inconsistent.[7] Metabolic syndrome is associated with an elevated risk of colorectal cancer. In a meta-analysis of 24 studies, diabetes was associated with a 37% increase in risk of colorectal cancer and increased risk of colorectal cancer mortality.[8] Features associated with type 2 diabetes, such as hyperinsulinemia and elevated levels of free insulin-like growth factor-1 (IGF-1), promote tumor cell proliferation.[7,9] Individuals diagnosed with colorectal cancer and type 2 diabetes have a higher risk of all-cause mortality compared to individuals without diabetes.[9] Risk of death from cardiovascular disease was higher among patients receiving insulin whereas colorectal cancer related mortality was lower with insulin use. Individuals with type 2 diabetes mellitus treated for colorectal cancer also have decreased disease-free survival (DFS) and overall survival (OS) and experience a higher incidence of treatment-related diarrhea and risk of death.

Family History and Inherited Genetic Risk

Colorectal Cancer or Adenomatous Polyps

1 Three specific patterns of colon cancer occurrence are generally observed: sporadic, familial, and recognized hereditary syndromes. Although most cases of colon cancer are sporadic in nature, about 30% of patients who develop colorectal cancer will have a family history of colorectal cancer.[10] In these families, the frequency of colorectal cancer is too high to be considered sporadic, but the pattern is not consistent with an inherited syndrome. First-degree relatives of patients diagnosed with colorectal cancer have an increased risk of the disease (2 times the risk), which is higher if the relative was diagnosed at age 45 or younger (3-6 times higher). Similarly, parents and siblings of relatives diagnosed with adenomatous polyps are at increased risk for developing colorectal cancer. The reasons for these associations are not established, but may be related to a combination of inherited genes and environmental factors.

Hereditary Syndromes

1 Colorectal cancer is a consequence of several well-defined genetic syndromes.[10] The two most common forms of hereditary colon cancer are familial adenomatous polyposis (FAP) and Lynch syndrome, historically known as *hereditary nonpolyposis colorectal cancer* (HNPCC). Both forms result from a specific germline mutation. FAP is a rare autosomal dominant trait caused by inactivating mutations of the adenomatous polyposis coli (*APC*) gene and accounts for about 1% of all colorectal cancers. The disease is manifested by hundreds to thousands of tiny sessile adenomatous polyps that carpet the colon and rectum, typically arising during adolescence. The polyps continue to proliferate throughout the colon, with eventual transformation to malignancy and have a propensity for occurring in the proximal colon. The risk of developing colorectal cancer for individuals with untreated FAP is virtually 100%; most will develop colorectal cancer by the fourth and fifth decades of life. Several variants of FAP exist and are associated with different extracolonic manifestations.

Lynch syndrome is an autosomal dominant inherited syndrome and is the most common hereditary predisposition for colorectal cancer.[10] Patients with Lynch syndrome are predisposed to many types

of cancer (eg, endometrial, stomach, and ovarian), but the risk of colorectal cancer is the highest.[3] Germline mutations in one of the DNA mismatch-repair (MMR) genes, most commonly *MLH1*, *MSH2*, *MSH6*, or *PMS2*, are responsible for Lynch syndrome, which accounts for 2% to 4% of overall colorectal cancer cases.[10] A fifth germline cause of Lynch syndrome has been recently described, whereby a deletion occurs in the epithelial cell adhesion gene, but this cause is rare. The estimated lifetime risk of developing colorectal cancer is about 50% and 80% for carriers of germline MMR mutations. Multiple generations within a family are affected, and colorectal cancer develops early in life, with a mean age at time of diagnosis of about 45 years of age.[3] If Lynch syndrome is suspected in a patient diagnosed with colorectal cancer, typically due to early age at diagnosis or family cancer history, the tumor is examined for evidence of deficient MMR to distinguish between sporadic or germline genetic mutations. Criteria for diagnosis of Lynch syndrome have been established, and it is important to identify carriers of these MMR mutations so that they can be counseled and followed appropriately.[10]

Enzyme Polymorphisms

1 Increasing evidence suggests that genetic polymorphisms in drug-metabolizing enzymes, such as *N*-acetyltransferases (NAT1 and NAT2), cytochrome P450 (CYP) isoenzymes, glutathione-*S*-transferase enzymes, methylenetetrahydrofolate reductase (MTHFR), and hemochromatosis gene mutations, may confer genetic susceptibility to colorectal cancer.[11] Individuals with certain variations in NAT1, NAT2, CYP1A2, CYP1A1, and CYP2E1 enzyme genotypes may be particularly susceptible to carcinogenic effects of a high dietary intake of meat, tobacco smoke, or other environmental factors.

Lifestyle Factors

Nonsteroidal Antiinflammatory Drug and Aspirin Use

2 Several lifestyle factors are known to affect colorectal cancer risk (**Table 130-1**). Observational studies have reported that regular (at least 2 doses per week) nonsteroidal antiinflammatory drug (NSAID) and aspirin use is associated with a reduced risk of colorectal cancer. In an average-risk individual, regular aspirin use is associated with a 20% to 40% reduction in the risk of colorectal adenoma and colorectal cancer.[12] In patients with prior adenomas or diagnosis of colorectal cancer, regular daily aspirin use reduces colorectal adenoma recurrence, and colorectal cancer incidence and mortality.[7,13,14]

TABLE 130-1 Lifestyle Factors Associated with Colorectal Cancer Risk

Factor	Comments
Elevated Risk	
Sedentary lifestyle	Inverse relationship between physical activity and colon cancer risk; colon cancer risk 40% lower for physically active individuals compared to less active individuals

Factor	Comments
Overweight and obesity	Elevated BMI, waist circumference, and waist-to-hip ratio directly associated with increased cancer risk
Alcohol intake	Risk of colorectal cancer 23% higher with 2-4 alcohol drinks/day compared to <1 drink/day; risk association strongest for males
Cigarette smoking	Prolonged cigarette smoking increases risk of large adenomas and carcinoma; higher colorectal cancer mortality in current smokers; risk may be higher for rectal cancer than for colon cancer and persists after smoking cessation for up to 25 years
Western diet	High caloric, saturated fat diet, processed meat and red meat (especially fried and barbecued) consumption increases cancer risk; influence of low dietary fiber intake not established
Reduced Risk	
Aspirin and nonaspirin NSAID use	Regular aspirin or NSAID use associated with 20% to 45% reduction in adenoma recurrence and colorectal cancer risk. Benefit in risk reduction requires at least 5-10 years of use
Postmenopausal hormone use	Exogenous hormone intake decreases risk of adenomas, colon, and rectal cancer by about 35%
Calcium and vitamin D intake	Vitamin D 400 international units and calcium intake of 1,000 mg/day (adults <50 years) or 1,200 mg/day (adults >50 years) may help reduce colorectal cancer risk but data remains unclear

BMI, body mass index; NSAID, nonsteroidal antiinflammatory drug.

Benefit has also been seen with NSAID and cyclooxygenase-2 inhibitor (COX-2) use. NSAID use over a 10- to 15-year period is associated with protection against adenomas and colorectal cancer, with a 30% to 45% reduction in the risk of colorectal cancer.[12] The protective effects of these agents appear to be related to their inhibition of COX-2 and free radical formation. COX-2 overexpression is seen in precancerous and cancerous lesions in the colon and is associated with decreased colon cancer cell apoptosis and increased production of angiogenesis-promoting factors.[13,14] Up to 50% of colorectal adenomas and 85% of sporadic colon carcinomas have elevated levels of COX-2, and COX-2 overexpression in colorectal cancer is associated with a worse survival. COX-2 appears to play a role in polyp formation, and COX-2 inhibition suppresses polyp growth, restores apoptosis, and decreases expression of proangiogenic factors. Inhibition of COX-2 also downregulates the phosphatidylinositol 3-kinase (PI3K) signaling pathway, which plays an important role in carcinogenesis and cancer cell resistance to apoptosis.[15]

Postmenopausal Hormone-Replacement Therapy

Exogenous postmenopausal oral hormone-replacement therapy is associated with a significant reduction in colorectal cancer risk.[16] Risk reduction is seen in postmenopausal women receiving both estrogen only and combined estrogen and progestin therapy, and persists for about 10 years after

therapy is discontinued.

Several mechanisms for a protective effect of estrogens on the bowel have been identified.[7] Age-related declines in estrogen levels are associated with estrogen receptor hypermethylation, which is associated with reduced expression of the estrogen receptor gene and dysregulated colonic mucosal cell growth. Estrogen may also interact with bile acids, or alter levels of insulin and IGF-1, an important mitogen that influences cell-cycle progression in certain cells. However, because postmenopausal hormone replacement therapy increases breast cancer risk and harmful cardiovascular effects, its use is not recommended to prevent colorectal cancer.

Obesity and Physical Inactivity

1 Physical inactivity and elevated body mass index (BMI), independent of level of physical activity, are associated with an elevated risk of colon adenoma, colon cancer, and rectal cancer.[7,17,18,19] Individuals with a higher level of activity throughout life have the lowest risk, which may be up to 50% lower than that of physically inactive individuals. Possible hypotheses are that physical activity stimulates bowel peristalsis, resulting in decreased bowel transit time; or that exercise-induced alterations in body glucose, insulin resistance, hyperinsulinemia, and possibly other hormones reduce tumor cell growth.[18]

In most studies, a 5-unit increase above a healthy BMI was associated with increased risk of colorectal cancer in men, but the relationship is weaker and less consistent for women, possibly because of interactions with age or hormone replacement therapy.[18,19] Differences in body composition and distribution of fat weight among men and women could contribute to this discrepancy.[7,16] Several mechanisms have been proposed to explain the association between body size and colorectal cancer risk, including insulin resistance, chronic inflammation, and alterations in growth factors or steroid hormones.[7]

Alcohol and Tobacco Use

1 Alcohol consumption increases the risk of colorectal cancer, but stronger associations have been observed for men than for women, possibly because alcohol consumption is generally greater in men than in women.[7] Lifetime and baseline alcohol consumption increase risk of cancer of the colon and rectum, and an alcohol intake of about 2 to 4 alcoholic beverages per day have a 23% higher risk of colorectal cancer than those who consume less than 1 each day.[3] Proposed mechanisms include impaired folate metabolism, abnormal DNA methylation, suppressed tumor immune surveillance, and other procarcinogenic effects related to alcohol intake.[7]

Cigarette smoking is associated with an increased risk of colorectal cancer (about 18% higher) and mortality, with a stronger association for cancer of the rectum than for cancer of the colon than in nonsmokers.[20,21] The risk of colorectal cancer development persists after smoking cessation for as many as 25 years.[21] Early tobacco use may also influence risk of cancer recurrence and mortality among colon cancer survivors, possibly due to an increase in genetic alterations that influence tumor

behavior.[22]

Dietary Intake and Nutrients

1 Epidemiologic studies of worldwide incidence of colorectal cancer suggest that economic development and dietary habits strongly influence its development. However, findings based on epidemiologic data are subject to potential biases and inconsistencies in how dietary factors are categorized and measured, and numerous studies have been able to clearly establish only a few specific dietary habits as independent risk factors for colorectal cancer development.

Fiber, Fruit, and Vegetables

1 Worldwide, high-fiber dietary patterns have been associated with a low incidence of colorectal cancer.[7,23,24] Dietary fiber is composed of both water-soluble and insoluble remnants of plant cells that are not processed by normal human digestive enzymes. Foods that are high in fiber include vegetables, fruits, grains, and cereals. Dietary fiber is postulated to reduce colonic mucosal cell exposure to carcinogens through the dilution or reduced absorption of carcinogens in the bowel, reduced fecal pH, reduced bowel transit time, alterations in bile acid metabolism, or increased production of short-chain fatty acids.[7] At present, the role of dietary fiber with regard to amount, source, and type and colorectal cancer risk requires further study.

Red Meat, Processed Meat, and Fat

1 Studies suggest that dietary fat intake may be associated with colorectal cancer risk.[7,23] This may have resulted from the use of dietary evaluations that focused on the quantity, origin, or type (saturated, monounsaturated, and polyunsaturated) of fat rather than on the source of dietary fat ingested. Dietary fat may promote cancer development as a result of its effect on fecal bile acid concentrations. Dietary fat ingestion stimulates the release of bile acids that are converted by colonic flora to secondary bile acids, which are associated with bowel mucosal irritation and cell proliferation responses and may promote tumor growth.[23]

The association between red, but not white, meat consumption and colorectal cancer is strongest, which may be related to the heterocyclic amines and polycyclic aromatic hydrocarbons formed during the cooking process, or the presence of specific fatty acids in red meat, such as arachidonic acid.[7,23] Processed meat products containing certain preservatives may increase exogenous exposure to carcinogenic *N*-nitroso compounds.[23] Although red and processed meat and high saturated fat intake has been associated with increased risk of colorectal cancer, the exact nature and magnitude of these risks have not been determined.

Calcium and Vitamin D

2 Inverse associations between dietary calcium, vitamin D intake, and serum 25-hydroxyvitamin D_3 levels, and colorectal cancer risk have been reported in several observational studies.[7,23,25] Calcium

may exert antiproliferative effects by binding to bile and fatty acids in the small intestine, thereby reducing colonic epithelial cell exposure to mutagens.[12] In addition, calcium induces differentiating, proapoptotic, and direct growth-restraining activities on both normal and tumor cells in the gastrointestinal tract. Vitamin D also has antiproliferative and differentiation and proapoptotic effects in addition to immune response modulation on colonic epithelial cells and on a variety of tumor cells.[7,12,25] Most of its actions are mediated through a high-affinity nuclear vitamin D receptor, and the expression of this receptor is altered during different phases of colon cancer development.[12] Thus, cellular responsiveness to vitamin D and associated cancer risk is unlikely limited to dietary intake alone. Vitamin D and calcium appear to interact synergistically to protect against adenoma recurrence and colorectal cancer, but large, long-term controlled trials have yet to confirm that supplementation with calcium and vitamin D reduce colorectal cancer risk.[12]

Folate and Other Micronutrients

Folate intake has been linked to colorectal cancer risk through epidemiologic and experimental studies in cell lines, animals, and humans.[7,26] However, the underlying basis for this is complex, particularly because alcohol use, smoking, genetic variants of the *MTHFR* gene, and other factors can interfere with folate metabolism.[7,26] Cellular folates act to accept and donate methyl groups in cellular processes that influence DNA synthesis and methylation of DNA, RNA, and proteins.[26] Variations in DNA methylation of gene promoter regions influence gene expression and DNA stability. Inappropriate hypermethylation leads to inactivation of tumor suppressor gene function and hypomethylation can result in oncogene activation.[26]

The relationship between the timing of folate exposure to the development of neoplastic foci may influence what appears to be a bimodal impact of folate on tumorigenesis.[7,26] Moderate folate supplementation, if initiated prior to the establishment of neoplastic foci, may be protective, whereas excessive or increased intake might enhance growth of established early neoplastic lesions.[7,26] Thus, an adequate dietary folate intake may be enough to lower the risk of colorectal cancer, and exceeding normal intake may not be beneficial.

Epidemiologic and animal model data suggest that deficiencies in other dietary micronutrients, including vitamin B_6, selenium, vitamin C, vitamin E, and carotenoids, may increase colorectal cancer risk, but there is no convincing evidence that the incidence of colorectal cancer is greater in patients with low serum levels than in patients with adequate levels.[7,27]

PATHOPHYSIOLOGY

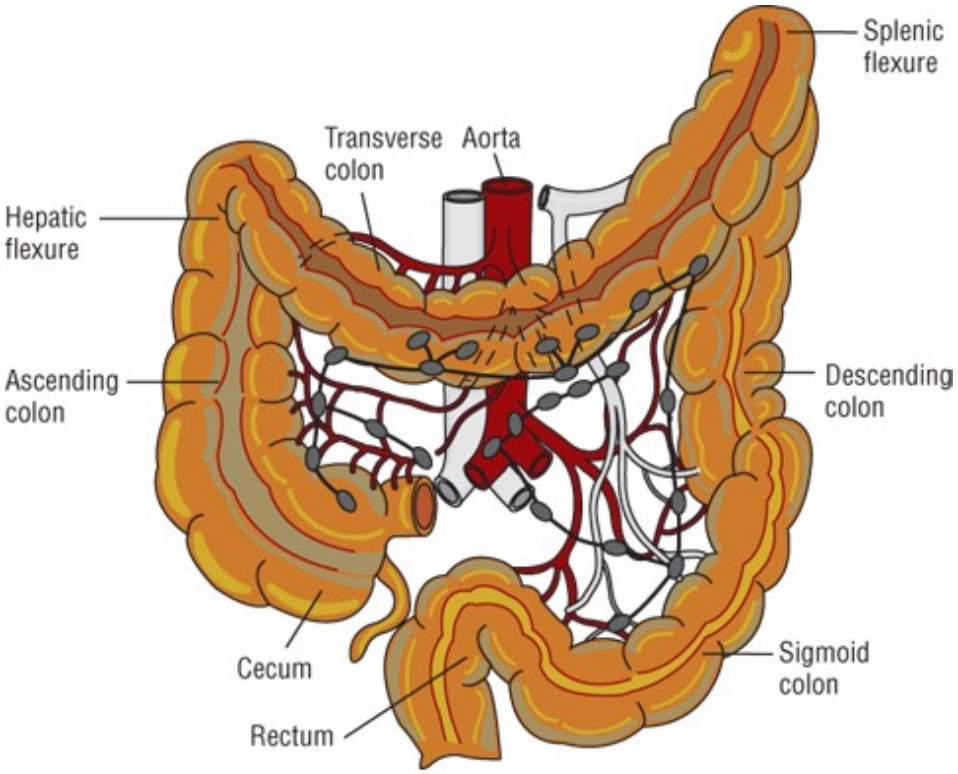
Anatomy and Bowel Function

The large intestine consists of the cecum; the ascending, transverse, descending, and sigmoid colon; and the rectum (**Fig. 130-2**). In adults, it extends about 1.5 m and has a diameter ranging from 8 cm in the cecum to 2 cm in the sigmoid colon. The function of the large intestine is to receive 500 to 2,000 mL of ileal contents per day. Absorption of fluid and solutes occurs in the right colon or the

segments proximal to the middle of the transverse colon, with movement and storage of fecal material in the left colon and distal segments of the colon. Mucus secretion from goblet cells into the intestinal lumen lubricates the mucosal surface and facilitates movement of the dehydrated feces. It also serves to protect the luminal wall from bacteria and colonic irritants such as bile acids.

FIGURE 130-2

Colon and rectum anatomy.



Four major tissue layers, from the lumen outward, form the large intestine: the mucosa, submucosa, muscularis propria, and serosa (**Fig. 130-3**). Embedded in the submucosa and muscularis propria is a rich lymphatic capillary system. Lymphatic channels do not extend into the mucosa. The muscularis propria consists of circular smooth muscle and outer longitudinal smooth muscle bands. Contraction of these muscle groups moves colonic material toward the anal canal. The outermost layer of the colon, the serosa, secretes a fluid that allows the colon to slide easily over nearby structures within the peritoneum. The serosa covers only the anterior and lateral aspects of the upper third of the rectum. The lower third lies completely extraperitoneal and is surrounded by fibrofatty tissue as well as adjacent organs and structures.

FIGURE 130-3

Cross-section of bowel wall.

The surface epithelium of the colonic mucosa undergoes continual renewal, and complete replacement of epithelial cells occurs every 4 to 8 days. Cell replication normally takes place within the lower third of the crypts, the tubular glands located within the intestinal mucosa. The cells then mature and differentiate to either goblet or absorptive cells as they migrate toward the bowel lumen. The total number of epithelial cells remains relatively constant as the number of cells migrating from the crypts is balanced by the rate of exfoliation of cells from the mucosal surface. This 2-phase process is critical to the malignant transformation of the epithelial cells. The number of dysplastic and hyperplastic aberrant crypt foci increases with increasing age; as the mass of abnormal cells accumulates at the top of the crypt and starts to protrude into the stream of fecal matter, their contact with fecal mutagens can lead to further cell mutations and eventual adenoma formation.

Colorectal Tumorigenesis

The development of a colorectal neoplasm is a multistep process involving several genetic and phenotypic alterations of normal bowel epithelium structure and function, leading to dysregulated cell growth, proliferation, and tumor development. Because most colorectal cancers develop sporadically, with no inherited or familial disposition, efforts have been directed toward identifying these alterations and learning whether detection of such changes may lead to improved cancer detection or treatment outcomes.

Features of colorectal tumorigenesis include genomic instability, activation of oncogene pathways, mutational inactivation or silencing of tumor-suppressor genes, DNA mismatch repairs, and

activation of growth factor pathways.[11] A genetic model has been proposed for colorectal tumorigenesis that describes a process of transformation from adenoma to carcinoma (**Fig. 130-4**).[28,29,30,31] The adenoma to carcinoma sequence of tumor development reflects an accumulation of mutations within colonic epithelium that confers a selective growth advantage to the affected cells. Key elements of this process include hyperproliferation of epithelial cells to form a small benign neoplasm or adenoma in conjunction with acquisition of various genetic mutations.[29] These mutations occur early and frequently in sporadic cases of both adenomas and colorectal cancer. Somatic mutations must occur in multiple genes to produce the malignant transformation. **Table 130-2** lists important genetic mutations that are associated with colorectal cancers.[11,30]

FIGURE 130-4

Genetic changes associated with the adenoma–carcinoma sequence in colorectal cancer. The accumulation of genetic changes in the pathogenesis of colorectal cancer includes microsatellite instability (MSI) initiated by aberrant DNA methylation or mismatch repair (MMR) gene mutation with subsequent disruption in transforming growth factor-*β* receptor type II (TGF-*β*2R) and BAX signaling; mutation in the adenomatous polyposis coli (*APC*) gene or abnormalities in *β*-catenin leading to inappropriate activation of the Wnt signaling pathway; mutational activation of cyclooxygenase-2 (COX-2) and impaired prostaglandin degradation from loss of 15-prostaglandin dehydrogenase (15-PGDH); *KRAS*, *PIK3CA*, or *BRAF* oncogene activation; increased epidermal growth factor receptor (EGFR) signaling; and deletions or mutations of tumor suppressor genes *SMAD4*, *PTEN*, *P53*. Chromosomal instability (CIN) is a common feature of sporadic disease, but causative factors are not defined. The sequence of molecular events may differ between somatic and inherited genetic alterations. *(Data from references 28,29,30,31.)*

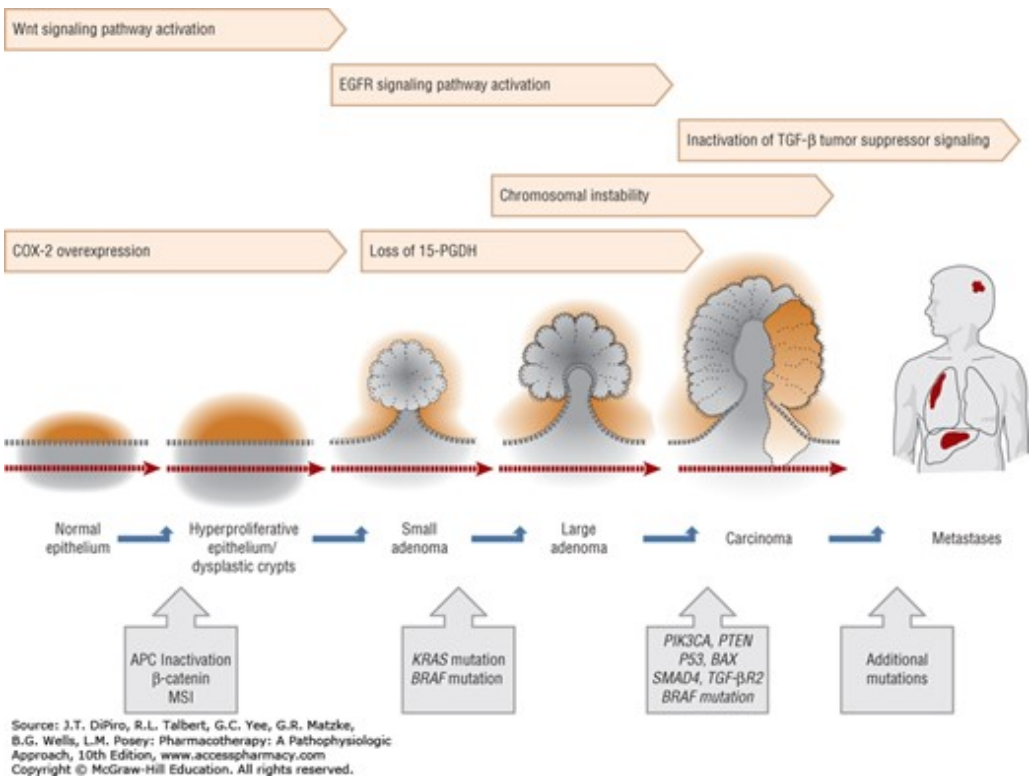

TABLE 130-2 Genetic Mutations Associated with Colorectal Cancer

Type of Mutation	Disease	Genes	Comments
Germline	Familial adenomatous polyposis (FAP)	*APC*	Multiple adenomas and carcinomas in colon and rectum
	MYH-associated polyposis	*MYH*	Autosomal recessive syndrome; wide spectrum of degree of polyposis; frequent *KRAS* mutations
	Lynch syndrome	DNA MMR genes: *MSH2*, *MLH1*, *MSH6*, *PMS2*	Colorectal cancer in absence of extensive polyposis; predisposition for endometrial, ovarian, gastric, hepatobiliary, urothelial, pancreatic, brain, and skin cancers
Somatic	Sporadic colorectal cancer	Oncogenes:	
		KRAS	Mutations found in about 40% of cancers
		NRAS	Mutations found in <5% of cancers
		BRAF	*BRAF* V600E mutation found in 5%-10% of cancers
		PIK3CA	Mutations found in 15%-25% of cancers
		EGFR	Gene amplification in 5%-15% of cancers
		Tumor suppressor genes:	
		P53	Loss or mutation in 60%-70% of cancers
		SMAD4	Mutations in 10%-15% of cancers
		APC	Inactivated in 70%-80% of sporadic cancers
		TGF-βR2	Inactivating mutations present in 10%-15% of cancers; mutations in more than 90% of cancers with MSI
		PTEN	Frequency of inactivating mutations about 10% but loss of PTEN protein expression evident in 15%-20% of cancers

APC, adenomatous polyposis coli; EGFR, epidermal growth factor receptor; MMR, mismatch repair; MSI, microsatellite instability; TGF-*β*R2, transforming growth factor-*β* receptor type II.

Data from references 11 and 30.

Genomic Instability

Genomic instability plays an integral role in normal colonic or rectal mucosal transformation to

carcinoma.[11] Three molecular pathways that lead to genomic instability are the microsatellite instability (MSI), CpG island methylator phenotype (CIMP), and chromosomal instability (CIN) pathways. The most common type is CIN, which leads to alterations in chromosomal structure and copy number. Important consequences of CIN include imbalanced chromosome number (aneuploidy), chromosomal gene amplifications, and loss of a wild-type allele of a tumor-suppressor gene, also referred to as loss of heterozygosity (LOH). More than 50% of sporadic colorectal cancers exhibit CIN and involve tumor suppressor genes *APC* and *P53*, loss of 18q allele, and aneuploid DNA content.

Microsatellites are series of repeat nucleotide sequences that are spread out across the entire genome.[11] Microsatellite replication errors within tumor DNA occur frequently, and mutations of the MMR genes that recognize and regulate DNA MMR errors contribute to MSI and colorectal tumorigenesis. Germline mutation of MMR genes is an important characteristic of Lynch syndrome, but somatic mutations are also present in about 15% of sporadic colorectal cancers.

Alterations in gene expression or function in the absence of DNA sequence alterations are referred to as epigenetic changes, and these are usually due to methylation of DNA gene promotor regions or histone modifications.[11] CIMP is characterized by hypermethylation of a panel of multiple genes that are associated with gene silencing and subsequent loss of tumor suppressor gene function.[31] About 15% of sporadic colorectal cancers arise as a consequence of CIMP.

Oncogene and Tumor Suppressor Gene Alterations

Mutation or loss of the *APC* tumor suppressor gene is a key factor involved in tumor formation through activation of the Wnt signaling pathway, a mediator of cell-cycle progression, cell proliferation, differentiation, and apoptosis.[11] The *APC* gene encodes for APC protein that binds to and degrades cytoplasmic β-catenin, a downstream component of the Wnt signaling pathway. In the absence of functional APC, β-catenin accumulates in the cytoplasm, then enters the nucleus and activates transcription of various genes, leading to constitutive activation of the Wnt signaling pathway. Inactivation of the *APC* gene is the single gene defect responsible for FAP, and is frequently an initiating event in sporadic colorectal cancer.[11]

Mutational inactivation of *P53* represents a frequent and second key step in colorectal tumorigenesis, occurring in about 50% to 75% of colorectal cancers.[11] Normal *P53* gene expression is important for G_1 cell-cycle arrest to facilitate DNA repair during replication and to induce apoptosis. A third step in tumor progression is the mutational inactivation of the transforming growth factor-β (TGF-β) signaling pathway, which facilitates adenoma transition to high-grade dysplasia or carcinoma and also inactivates *SMAD4*. In normal epithelium, TGF-β has an antiproliferative role and induces growth arrest and apoptosis. Alterations in *SMAD4* or TGF-β receptors lead to a loss of the normal growth inhibitory response to TGF-β.

Several oncogene-activating mutations play an important role in promoting colorectal cancer.[11] Mutations in members of the *RAS* gene family—*KRAS*, *HRAS*, and *NRAS*—in addition to *BRAF*, activate the mitogen-activated protein kinase (MAPK) signaling pathway, which stimulates cell proliferation

and other activities that promote carcinogenesis. Mutations of *PIK3CA*, which encodes the catalytic subunit of a PI3K survival pathway, increase production of phosphatidylinositol-3,4,5-triphosphate, which influences cell growth, proliferation, and survival. Mutation or loss of *PTEN*, a tumor suppressor gene that antagonizes PI3K signaling, produces similar effects. Multiple additional genetic alterations contribute to carcinoma formation and metastases by altering cellular growth, metabolism, migration, and invasive capabilities, and angiogenesis.[31]

Growth Factor Signaling Pathways

Aberrant signaling of growth factor pathways plays an important role in colorectal tumorigenesis. Activation of prostaglandin signaling is an early step in the adenoma to carcinoma transformation process and is induced by upregulated expression of COX-2 and inflammation.[29] COX-2 mediates the synthesis of prostaglandin E_2, which stimulates cancer growth.[29] Furthermore, 80% of colorectal cancers have loss of 15-prostaglandin dehydrogenase (15-PGDH), the rate-limiting enzyme responsible for prostaglandin degradation. Gene amplification of the epidermal growth factor receptor (*EGFR*) gene that encodes for a transmembrane glycoprotein involved in signaling pathways which affect cell growth, differentiation, proliferation, and angiogenesis, is present in 5% to 15% of all colorectal cancers.[30] EGFR activation enables downstream signaling of the MAPK, PI3K, and Akt pathways that influence colorectal tumorigenesis. EGFR is overexpressed in up to 75% of colorectal cancers and high tumor EGFR overexpression is associated with worse prognosis.[32] These mechanisms are relevant because of the availability of pharmacologic agents that can influence these signaling pathways and affect cell growth.

Histology

Adenocarcinomas account for about 85% of tumors of the large intestine and 10% to 15% are classified mucinous adenocarcinoma.[33] The other histologic types, such as signet-ring adenocarcinoma, squamous cell carcinoma, and neuroendocrine carcinomas, are rare. Adenocarcinomas are assigned one of three tumor grade designations based on the degree of cellular differentiation, the degree to which the tumor resembles the structure, and function of its cell of origin. The most differentiated adenocarcinomas are low-grade tumors, whereas high-grade tumors are the most undifferentiated, and have frequently lost the characteristics of mature normal cells. Poorly differentiated tumors are associated with a worse prognosis than those that are relatively better differentiated.

Mucinous adenocarcinomas possess the same basic structure as adenocarcinomas but differ in that they secrete an abundant quantity of extracellular mucus. They tend to be frequent in patients with MMR mutations.[33] Signet-ring adenocarcinomas also have a characteristic appearance but are uncommon. Signet-ring histology occurs more frequently in individuals younger than 50 years of age, patients with ulcerative colitis, and tends to present at a more advanced stage of disease at diagnosis. Both mucinous and signet-ring adenocarcinoma histologies confer a poor prognosis. Patients with neuroendocrine tumors and squamous cell carcinoma often present with distant metastases and have a poor prognosis as well.

PREVENTION AND SCREENING

Cancer prevention efforts can be considered as either primary or secondary. Primary prevention strategies aim to prevent the development of colorectal cancer in a population at risk. Secondary prevention approaches are undertaken to prevent malignancy in a population that has already manifested an initial disease process. Several promising primary and secondary prevention strategies are currently undergoing study (**Table 130-3**).[7,24,34,35,36,37,38,39,40]

TABLE 130-3 Prevention Strategies Under Evaluation for Colorectal Cancer

Prevention Strategy	Proposed Mechanism of Protective Effect
Aspirin, NSAIDs, and COX-2 selective inhibitors	Inhibit COX-2; downregulate PI3K signaling pathway; induce apoptosis
Calcium	Direct binding to bile and fatty acids; inhibits epithelial cell proliferation
Curcumin	Antiinflammatory and antioxidant effects; induces p53-independent apoptosis; inhibits NF-κB and PI3K/Akt/mTOR signaling pathways
Difluoromethylornithine (Eflornithine)	Inhibits cellular proliferation through alterations in polyamine metabolism via inhibition of ornithine decarboxylase
Epigallocatechin gallate (EGCG)	Major polyphenolic constituent of green tea. Strong antioxidant; inhibits lipoxygenase and COX activity; inhibits cell proliferation and angiogenesis via inhibition of cell signaling proteins and proangiogenic signaling pathways
High-fiber diet supplementation	Decreases fecal bile acids; decreases bowel transit time; direct binding to fecal mutagens; dilution of fecal material
Genistein	Flavonoid phytoestrogen; modulates cell-cycle progression, induces apoptosis; possesses antioxidant and antiinflammatory activities
HMG-CoA reductase inhibitors	Induce intestinal cell apoptosis and inhibit cell proliferation; suppress angiogenesis; synergistic COX-2 inhibition with NSAIDs
Metformin	Targets IGF pathway to influence cell growth, proliferation, and differentiation. Activation of AMPK inhibits insulin and protein synthesis, and suppresses NF-κB activity
NO-NSAIDs	Nitrous-oxide release mimics effects of prostaglandins on gastrointestinal epithelium; suppress formation of aberrant colonic crypt foci
Omega (ω)-3 polyunsaturated fatty acids (ω-3 PUFAs)	Inhibit COX-2 expression; COX-2 independent mechanisms
Probiotic bacteria	Alter intestinal microflora; inactivate carcinogens; improve host immune response; regulate cell proliferation by altering cell signaling pathways, apoptosis, and cell differentiation
Resveratrol	Antiinflammatory and antioxidant effects; induces apoptosis; influences genes that inhibit cell-cycle progression, cell proliferation,

Prevention Strategy	Proposed Mechanism of Protective Effect
	metastasis, and angiogenesis
Quercetin	Flavonoid antioxidant constituent in fruit, vegetables, tea, and wine; induces apoptosis

AMPK, AMP-activated protein kinase; COX, cyclooxygenase; EGFR, epidermal growth factor receptor; HMG-CoA, β-hydroxy-β-methylglutaryl-coenzyme A; IGF, insulin-like growth factor; MAPK, mitogen-activated protein kinase; mTOR, mammalian target of rapamycin; NF-κB, nuclear factor -kappa B; NO-NSAIDs, nitrous oxide donating nonsteroidal antiinflammatory drugs; NSAIDs, nonsteroidal antiinflammatory drugs; PI3K; phosphatidylinositol 3-kinase.

Data from references 7, 24, and 34,35,36,37,38,39,40.

Diet

1 Although early studies suggest that a substantial increase in daily dietary fiber or decrease in dietary fat intake might significantly reduce colorectal cancer risk, results from prospective, controlled trials show no protective effects of fiber intake on colorectal adenoma or carcinoma risk. However, a recent meta-analysis suggests a 10% reduction in colorectal cancer risk with 10 gram daily intake of total dietary and cereal fiber and up to a 20% risk reduction with 3 servings of whole grains daily.[23,24] There is insufficient evidence to support the use of fiber supplementation as a colorectal cancer prevention strategy at this time.

Chemoprevention

2 The most widely studied agents for the chemoprevention of colorectal cancer are aspirin, nonaspirin NSAIDs, and COX-2 selective inhibitors, but only aspirin is recommended for chemoprevention in some patients.[7,13,24,37,38] The effectiveness of these agents has been studied in high-risk individuals and within the general population.

In individuals with FAP, celecoxib, NSAIDs, and aspirin have been studied to delay development of adenomatous polyps and to reduce polyp recurrence following colectomy with a retained rectum, but they are not viewed as alternatives to surgery.[34] In randomized, controlled trials, celecoxib 400 milligrams (mg) orally twice daily as an adjunct to usual care significantly reduced the mean size and number of colorectal polyps after 6 to 9 months of treatment. However, FDA approval for celecoxib was withdrawn because of lack of data showing long-term benefit. Sulindac has been shown to induce adenoma regression, but does not appear to delay or prevent malignancy. The benefits of these agents are transient, because patients experience an increase in size and number of polyps within a few months after discontinuing treatment. Sulindac is not recommended as chemoprevention for individuals with FAP. These agents may be useful to reduce adenoma recurrence following surgery, but additional data with long-term use are needed.

Nonaspirin NSAIDs and COX-2 inhibitors were associated with reduced risk of sporadic and recurrent colorectal adenomas in cohort and case-control studies, and COX-2 inhibitors were also effective in

controlled trials.[7] Celecoxib was associated with a 34% relative risk reduction in adenoma recurrence and 55% risk reduction in the incidence of advanced adenomas.[34] Optimal dosing, agents, and duration of treatment remain to be determined, and potential cardiovascular events in addition to risk of gastric ulceration and bleeding with these agents are of concern. Although NSAIDs may be appropriate for selected individuals at high risk for colorectal cancer but low risk for cardiovascular disorders, the United States Preventive Services Task Force (USPTF) has concluded that potential harms associated with NSAID use (other than aspirin) outweigh benefits for prevention of colorectal cancer in the general population.[38] However, USPTF guidelines recommend daily low-dose aspirin for at least 10 years in adults ages 50 to 59 years who have a life expectancy of at least 10 years and are not at risk for bleeding for primary to prevent both cardiovascular disease and colorectal cancer. Adults ages 60 to 69 years may also receive low-dose-daily aspirin for at least 10 years if the benefits outweigh the risks.

Clinical Controversy…

Emerging data support the use of aspirin as colorectal cancer chemoprevention for patients with Lynch syndrome and regular long-term aspirin use modestly reduces colorectal cancer risk in individuals without Lynch syndrome. However, because of the small risk of serious bleeding associated with even low doses, aspirin should only be used as chemoprevention in those adults ages 50-69 for a minimum of 10 years if benefits outweigh the risks.

The use of aspirin as both a primary and a secondary chemopreventive agent remains controversial. Aspirin reduces of risk of sporadic and recurrent adenomas by about 17% and advanced adenomas by 28%.[34,39] Higher aspirin doses reduced the incidence of colorectal cancer over a 23-year follow-up period by 26% among the general population, but lower doses (75-300 mg) of daily aspirin for 5 years was also associated with a risk reduction in colorectal cancer incidence and in 20-year mortality from colorectal cancer by 34%.[34,37,39] Individuals with Lynch syndrome who received aspirin 600 mg daily for at least 2 years experienced a 59% reduction in colorectal cancer risk that became evident 5 years after the aspirin was first started and had been discontinued.[39] Although the optimal aspirin dose and treatment durations are unknown, increasing evidence supports a chemoprotective effect of aspirin in select high-risk individuals and in the general population. The extent of risk reduction appears to be inversely related to duration of therapy and the chemopreventive effects of aspirin may be delayed by 5 to 10 years. However, the balance of risks and benefits with long-term aspirin use is currently unclear, and aspirin is only recommended for chemoprevention in some patients. *PIK3CA* mutations, which are present in up to 20% of colorectal cancers, and polymorphisms in genes that regulate proinflammatory processes may serve as biomarkers to identify patients who may benefit from prophylactic or adjuvant aspirin therapy.[41]

Randomized controlled trials of calcium, vitamin D, and folate supplementation as chemoprevention have also been conducted, but findings do not support their use at this time.[7,34] Individuals at high risk of colorectal cancer may experience a moderate reduction in risk of recurrent colorectal adenomas with 5 years of calcium supplementation.[20] However, individuals with adequate vitamin D levels and no known increased risk of colorectal cancer do not appear to benefit from calcium or vitamin D supplementation.[42] In two trials, folate supplementation was associated with a

nonsignificant increase in adenoma recurrence. Based on these results, the use of folate supplementation to reduce colorectal cancer risk is not recommended at this time.[8] Additional intervention trials of various micronutrients, epigenetic modulators, and other chemopreventive agents have been completed or are ongoing.[7,13,24,25,34,35,36,40]

Surgical Resection

Surgical resection remains an option to prevent colon cancer in individuals at extremely high risk for its development.[43] Despite the effects of NSAIDs and COX-2 selective inhibitors on adenoma development and recurrence in individuals with FAP, their effects are incomplete and surgical resection is necessary for cancer prevention for these high-risk individuals. Individuals with FAP who are found to have polyposis on lower endoscopy screening examinations should undergo total proctocolectomy and ileal pouch–anal anastomosis or subtotal colectomy with an ileorectal anastomosis, typically starting around age 20 years. Because of the high incidence of metachronous (ie, consecutive development) cancers (45%) in patients with Lynch syndrome, prophylactic subtotal colectomy with an ileorectal anastomosis is recommended for individuals who are not candidates for routine close follow-up. Colonoscopic polypectomy, removal of polyps detected during screening colonoscopy, is considered the standard of care for all individuals to prevent the progression of premalignant adenomatous polyps to adenocarcinomas.

Screening

3 Colorectal cancer screening decreases mortality by detecting cancers at an early, curable stage, and by detecting and removing adenomatous polyps. Multiple screening recommendations for early detection of colorectal cancer have been established; differences exist in specific screening guidelines published by various organizations.[5,44,45,46,47,48,49] Structural tests detect colorectal polyps and cancer whereas fecal-based tests detect early cancer. This section reviews available screening techniques for colon and rectal cancer.

Colonoscopy

3 Colonoscopy facilitates examination of the entire large bowel to the cecum in most patients, and allows for simultaneous removal of premalignant lesions. Although no randomized trials show that colonoscopy decreases colorectal cancer mortality, observational studies show a 56% to 77% decrease in the incidence in colorectal cancer with colonoscopy and polyp removal and about a 50% reduction in colorectal mortality.[49] Colonoscopy allows for greater visualization of the colon, but it involves sedation, complete bowel preparation, and is associated with greater risk and inconvenience to patients. However, it is the preferred screening method based on its superior ability to detect and remove lesions in the proximal as well as distal colon and colonoscopy is therefore considered the gold standard for colorectal screening.[49] Four large-scale, randomized, prospective trials are evaluating colonoscopy versus no screening or fecal immunochemistry test (FIT).

Flexible Sigmoidoscopy

Flexible sigmoidoscopy (FSIG) uses a 60-cm flexible sigmoidoscope to examine the lower half of the bowel to the splenic flexure for most patients, and is thus capable of detecting 50% to 60% of cancers.[49] Randomized trials show that FSIG decreases colorectal cancer incidence and mortality by 31% and 38%, respectively. The combination of FSIG and a fecal-based test appears to improve sensitivity for lesions that will be missed by sigmoidoscopy alone, but the true benefit of this approach to general practice has not been established.[45] FSIG offers the advantage of not requiring sedation or extensive bowel preparation, but the entire colon cannot be examined with FSIG and suspicious lesions must be evaluated by colonoscopy.

Computed Tomography Colonography

Computed tomography colonography, also referred to as *virtual colonoscopy*, is an imaging procedure that creates 2- or 3-dimensional images of the colon by combining multiple helical computed tomography (CT) scans. Initial tests show high sensitivity and specificity for detecting adenomas at least 6 mm in size and sedation is not required. However, the procedure requires complete bowel preparation, is associated with radiation exposure, and many individuals will still be referred for colonoscopy to remove detected lesions. Individuals who refuse to undergo invasive colonoscopy or FSIG may find this screening method more acceptable.

Double-Contrast Barium Enema

A double-contrast barium enema (DCBE) involves coating the interior bowel with barium and distending it with air to produce an image of the entire colon in most examinations, and the retained barium outlines small polyps and mucosal lesions.[45] This approach is the least expensive method of examining the entire colon, but is considered inferior to colonoscopy for detecting polyps and colorectal cancer. In addition, DCBE requires bowel preparation cleaning, is associated with radiation exposure, and a supplemental colonoscopy is required if suspicious lesions are identified. However, DCBE is considered an alternative for individuals who do not wish to undergo or are not suitable for colonoscopy.

Fecal Occult Blood Tests

Fecal occult blood tests (FOBTs) are used to detect occult blood in the stool that may be associated with bleeding adenomas or cancer. Results from randomized, controlled trials of annual FOBT screening show a reduction in colorectal cancer mortality by 33%.[45,49] Unlike structural tests, FOBTs are noninvasive and do not require bowel preparation. Two main methods are available to detect occult blood in the feces: guaiac-based FOBT (gFOBT) and FITs, also known as immunochemical fecal occult blood test (iFOBT). Several gFOBTs are available that detect peroxidase activity of heme when hemoglobin comes in contact with a guaiac-impregnated paper. When a solution containing hydrogen peroxide is poured over the paper, a blue color appears if the test is positive. The testing process is complex and requires specific patient counseling to avoid inaccurate results (**Table 130-4**).[45]

TABLE 130-4 Patient Counseling Points Prior to Guaiac-Based Stool Tests

To Avoid False Positives	To Avoid False Negatives
Dietary restrictions • Avoid red meat (beef, lamb, liver) and raw vegetables with peroxidase activity (turnips, broccoli, cauliflower, and radishes) for 3 days prior to testing[a]	• Avoid vitamin C in excess of 250 mg supplements and from citrus juices and fruit for 3 days prior to testing • Avoid testing dehydrated samples (rehydrating of samples is not recommended)
Medical restrictions • Avoid rectal enemas, rectal medications, and digital rectal examinations for 3 days prior to testing • Avoid aspirin and nonsteroidal antiinflammatory drugs for up to 7 days prior to testing • Avoid testing if blood from hemorrhoids is evident in stool • Delay testing until 3 days after menstrual bleeding has ended	
Procedure for guaiac-based stool testing Patient uses an applicator stick to apply stool to 2 test cards on 3 separate occasions, usually from different bowel movements on consecutive days (total of 6 test cards or samples). After the sample dries, the card is mailed or returned to the healthcare professional.	

[a] Test instructions for several products no longer contain dietary vegetable or fruit restrictions.

Data from reference 45.

Clinical guidelines have been developed for performing and interpreting results of gFOBT.[45] Several limitations associated with gFOBT screening are of concern. Many early-stage tumors do not bleed, and therefore the false-negative rates can be high and are variable depending on the gFOBT product used. In addition, the test results may not be valid because the test is often poorly performed both in the home and in physician office settings.[45,46] However, these concerns are addressed by testing three successive stool samples. False-positive results can prove to be very expensive and inconvenient for a patient because of the follow-up tests required to confirm a positive result. Annual screening, preferably using a high-sensitivity gFOBT (eg, Hemoccult SENSA), is an acceptable option for individuals at average risk for colorectal cancer. It should be noted that FOBT conducted in conjunction with a digital rectal exam during an office visit is not considered adequate colorectal

screening.

FITs (iFOBTs) were developed to reduce false-positive and false-negative test results associated with the gFOBT. FIT uses antibodies to detect the globin protein portion of human hemoglobin. Globin is degraded by enzymes in the upper gastrointestinal tract; therefore, FIT is more specific for lower gastrointestinal bleeding. Also, immunochemical tests do not produce false-negative results in the presence of vitamin C or meat/vegetables containing peroxidase activity.[45] Moreover, testing involves a single stool sample collection annually. Comparative studies report that FIT is more accurate than gFOBT for detecting cancer and advanced adenomas, although colonoscopy identifies more adenomas.[49]

Stool DNA Screening Tests

Molecular screening strategies analyze stool samples for presence of potential markers of malignancy in cells that are shed from premalignant polyps or adenocarcinomas in the bowel.[45,49] Adenoma and carcinomas can contain certain DNA mutations and markers of MSI that can be detected using a multiple marker panel for stool DNA (sDNA) testing. One FDA-approved sDNA test is currently commercially available, but the appropriate screening interval is not clear.[49] Therefore, it is not routinely recommended as a screening option by all screening guidelines.

Screening Summary

Table 130-5 outlines current US screening guidelines for early detection of colorectal cancer with the goal of cancer prevention.[44,45,46,47,48,49] Men and women who are at average risk for colorectal cancer (their only risk factor is age greater than or equal to 50 years) should begin regular screening starting at age 50 years with a colonoscopy every 10 years, or annually using a sensitive gFOBT or FIT, or undergo FSIG every 5 years, alone or in conjunction with annual FOBT. Several screening methods are available, and because each method is associated with different benefits and potential harms, patient preferences and available resources should be considered for individual patients.[45] More rigorous (usually starting at an earlier age) screening recommendations are given for moderate- to high-risk individuals and colonoscopy is generally preferred for initial screening and surveillance following polyp removal in this population.[5,45,46,49] Most organizations recommend discontinuing screening and surveillance in populations when risk may outweigh benefit.[5] The United States Preventive Services Task Force (USPSTF) and NCCN recommend routine colorectal cancer screening for individuals age 50 to 75 years with different consideration given to adults 76 to 85 years and recommends against screening for adults older than 85 years.[5,49] The American College of Physicians recommends against screening adults older than age 75 years or with a life expectancy of less than 10 years.[44]

DIAGNOSIS

Signs and Symptoms

The signs and symptoms associated with colorectal cancer can be extremely varied and nonspecific. Patients with early-stage colorectal cancer are often asymptomatic, and lesions are usually found as a result of screening studies. Any change in bowel habits (eg, constipation, diarrhea, or alteration in size or shape of stool), abdominal pain, or distension may all be warning signs of a malignant process. Obstructive symptoms and changes in bowel habits frequently develop with tumors located in the transverse and descending colon. Rectal cancer may be associated with tenesmus, though bleeding is the most common symptom of rectal cancer. Bleeding may be acute or chronic and can appear as bright red blood mixed with stool or melena. Iron-deficiency anemia, presenting as weakness and fatigue, can develop as a result of chronic occult blood loss.

About 20% of patients with colorectal cancer present with metastatic disease.[1] Metastatic spread occurs as a result of direct tumor invasion of the peritoneum or by lymphatic or hematogenous spread. The venous drainage of the colon and rectum influences the pattern of metastases most commonly seen. The most common site of metastasis is the liver followed by the lungs and then bones, specifically the sacrum, coccyx, pelvis, and lumbar vertebrae. Liver metastases are present in 25% of patients at presentation, with another 25% to 30% of patients developing liver metastases in the following 2 to 3 years.[50]

Workup

When a patient is suspected of having colorectal carcinoma, a complete history and physical examination should be performed. The patient history should include a past medical history and family history, especially noting the presence of inflammatory bowel disease, colorectal cancer, polyps, and familial clustering of cancers to assess risk for an inherited colorectal cancer syndrome as well as a full medication history, including prescription, over-the-counter and complementary alternative therapies. A complete physical examination includes careful abdominal examination for the presence of masses or ascites, a rectal examination, and an assessment for possible hepatomegaly and lymphadenopathy. A breast and pelvic examination is recommended in all women.

CLINICAL PRESENTATION General

- Patient symptoms are usually nonspecific and can vary drastically among patients.
- Most patients are asymptomatic.

Symptoms

- Change in bowel habits (generally an increase in frequency) or rectal bleeding.

- Constipation, depending on the location of the tumor.
- Nausea, vomiting, and abdominal discomfort.
- Fatigue may be present if anemia is severe.

Signs

- Blood in the stool is the most common sign in symptomatic patients.
- Hepatomegaly and jaundice in advanced disease.
- Leg edema as a consequence of lymph node involvement, thrombophlebitis, fistula formation, weight loss, and pain in the lower back or radiating down the legs may be indicative of widespread disease.

Laboratory Tests

- Positive guaiac stool test and anemia (iron deficiency) from blood loss.
- Elevated carcinoembryonic antigen (more likely in patients with higher stages at presentation).
- Elevated liver enzymes may be present with metastatic disease.

An evaluation of the entire large bowel requires a total colonoscopy and allows for tissue collection for a histologic evaluation to provide a preliminary diagnosis following the procedure. Patients with invasive cancer of the colon or rectum require a complete staging workup with laboratory testing and imaging of the abdomen, pelvis, and chest. Baseline laboratory tests should be obtained and include a complete blood cell count, platelet count, international normalized ratio, prothrombin time, activated partial thromboplastin time, liver chemistries, renal function tests, and carcinoembryonic antigen (CEA) level. Abnormal liver chemistry test results may suggest liver involvement with tumor. However, patients with metastatic disease to the liver may have normal liver chemistries. Iron studies (eg, serum ferritin, serum iron, and total iron-binding capacity) may be useful to identify iron deficiency in patients with anemia.

CEA belongs to a group of cell-surface glycoproteins termed *oncofetal proteins*, which are expressed during embryonic development and reexpressed on the cell surfaces of many carcinomas, particularly those originating from the gastrointestinal tract. CEA concentrations can be measured in the blood and can, therefore, potentially serve as a marker for colorectal cancer. Elevated CEA levels are more frequent in patients with metastatic disease, but not all colorectal cancers produce CEA. It is important to recognize, however, that several concomitant disease states are associated with an elevated CEA: liver diseases, gastritis, peptic ulcer disease, diverticulitis, chronic obstructive pulmonary disease, chronic or acute inflammatory conditions, and diabetes.[51] Most commercially available assays list a value of less than 5 ng/mL (mcg/L) as the upper limit of normal. Although CEA measurement is too insensitive and nonspecific to be used as a screening test for early-stage colorectal cancer, it is the surrogate marker of choice for monitoring colorectal cancer response to treatment, particularly if the pretreatment concentration is elevated.[51] The CEA test may have

preoperative prognostic implications because it has been shown to correlate with the size and degree of differentiation of the carcinoma. Elevated preoperative CEA levels correlate with a poor survival and may predict likelihood of recurrence, regardless of tumor stage at diagnosis. However, it should not be used as an indication for adjuvant therapy. After a potentially curative resection, CEA levels should return to normal within 4 to 6 weeks. Persistently elevated CEA levels may indicate residual disease, while elevations after normalization may indicate relapsed disease.

Radiographic imaging studies are used to evaluate the extent of disease involvement for initial staging and subsequently to monitor disease response to therapy. Contrast dye-enhanced CT scans of the chest, abdomen, and pelvis are performed to evaluate for pulmonary, hepatic, and retroperitoneal involvement as well as occult abdominal and pelvic disease. In certain cases, such as patients with contrast dye allergies, magnetic resonance imaging (MRI) of the abdomen and pelvis may be performed. A glucose analog [^{18}F]-fluorodeoxyglucose-positron emission tomography (PET) scan may also be performed as the primary imaging modality or to confirm metastatic disease if findings from CT or MRI scans are not conclusive. PET imaging may provide functional information to assist in discriminating between benign and malignant disease by detecting tumor-related metabolic alterations in affected tissues. PET scans are commonly used for the detection of recurrent colorectal cancer in patients with rising CEA levels and inconclusive findings on standard imaging studies. A PET scan is often performed in conjunction with a CT scan for anatomical localization of a lesion(s). For initial rectal cancer staging, assessment of the extent of tumor spread into the surrounding mesorectum and depth of invasion within the bowel wall may be performed using MRI or endorectal ultrasound.

Because of the increased likelihood of HNPCC in patients diagnosed with colorectal cancer younger than the age of 50 years, MMR protein testing on the cancer specimen is recommended.[49] The level of MMR protein expression can be determined by immunohistochemistry, which is decreased with MMR gene mutations. Gene sequencing can also be performed to detect MSI. If immunohistochemical analysis of the tumor reveals absence of MLHI protein expression, *BRAF* gene mutation testing is recommended to distinguish between somatic and germline *MLH1* gene mutation.[49] Individuals with abnormal MMR protein expression or MSI should be referred for genetic counseling as additional testing and cancer susceptibility risk assessment may be appropriate for themselves and family members.

STAGING

4 The purpose of staging examinations is to determine the extent of disease, which allows the oncologist to develop treatment plans and estimate overall prognosis. The same TNM classification system is used for both cancers of the colon and rectum since the categories reflect similar survival outcomes.[52,53] This classification assesses three aspects of cancer growth: T (tumor penetration), N (lymph node involvement), and M (presence or absence of metastases) into account. The TNM classification also allows for various subdivisions within each of the three categories, which is then used for determining the disease stage. **Table 130-6** summarizes the staging definitions used in the TNM system and corresponding 5-year survival rates.[52,53,54] **Figure 130-5** shows the various stages

of cancer based on cancer penetration through the bowel wall and extension to regional lymph nodes. Of note, an individual patient's stage is determined at the time of the initial diagnosis and does not change with progression of disease or recurrence. For example, if a patient is diagnosed with stage II colon cancer and later recurs with metastases to the liver, that patient is stage II now with metastatic disease to the liver, not stage IV.

TABLE 130-6 Colon Cancer by TNM Classification and Associated 5-Year Relative Survival

Stage	T	N	M	Survival (%)
0	T_{is}	N_0	M_0	95.6

IVB	Any T	Any N	M_{1b}	

Primary Tumor (T)

T_{is}, Carcinoma in situ: intraepithelial or invasion of lamina propia.[a]

T_1, Tumor invades submucosa.

T_2, Tumor invades muscularis propria.

T_3, Tumor invades through the muscularis propria into pericolorectal tissues.

T_{4a}, Tumor penetrates to the surface of the visceral peritoneum.[b]

T_{4b}, Tumor directly invades or is adherent to other organs or structures.[b,c]

Lymph Nodes (N)

N_0, no regional lymph node metastasis

N_1, metastasis in 1-3 lymph nodes

N_{1a}, metastasis in 1 lymph node

N_{1b}, metastasis in 2-3 lymph nodes

N_{1c}, tissue tumor deposits without lymph node metastasis

N_2, metastasis in more than 4 lymph nodes

N_{2a}, metastasis in 4-6 lymph nodes

N_{2b}, metastasis in more than 7 lymph nodes

Distant Metastasis (M)

M_0, no distant metastasis

M_{1a}, metastasis confined to one site or organ

M_{1b}, metastasis in peritoneum or more than 1 site or organ

[a]T_{is} includes cancer cells confined within the glandular basement membrane (intraepithelial) or mucosal lamina propria (intramucosal) with no extension through the muscularis mucosae into the submucosa.

[b]Direct invasion in T_4 includes invasion of other organs or other segments of the colorectum as a result of direct extension through the serosa, as confirmed on microscopic examination (eg, invasion of the sigmoid colon by a carcinoma of the cecum) or, for cancers in a retroperitoneal or subperitoneal location, direct invasion of other organs or structures by virtue of extension beyond the muscularis propria (ie, respectively, a tumor on the posterior wall of the descending colon invading the left kidney or lateral abdominal wall; or a mid or distal rectal cancer with invasion of prostate, seminal vesicles, cervix, or vagina).

[c]Tumor that is adherent to other organs or structures, grossly, is classified cT_{4b}. However, if no tumor is present in the adhesion, microscopically, the classification should be pT_{1-4a} depending on the anatomical depth of wall invasion. The V and L classifications should be used to identify the presence or absence of vascular or lymphatic invasion whereas the PN site-specific factor should be used for perineural invasion.

PROGNOSIS

4 The stage of colorectal cancer upon diagnosis is the most important independent prognostic factor for survival and disease recurrence. Five-year relative survival is about 90% for individuals who present with a localized tumor stage at diagnosis as compared with about 13% for individuals with metastatic disease at diagnosis.[1]

Clinical factors present at the time of diagnosis that are associated with a poor prognosis and decreased survival include bowel obstruction or perforation, high preoperative CEA level, distant metastases, and location of the primary tumor in the rectum or rectosigmoid area.[55] Along with resection of the primary tumor, a minimum of 12 lymph nodes must be examined to accurately determine regional lymph node involvement and predict lymph node-negative disease.[55] The pathologic assessment also includes determination of TNM stage, tumor type, and histologic grade, presence of venous, and lymphatic invasion, and whether the resected margins are free of tumor.[56] Consideration of these factors plays an important role in determining optimal strategies for treatment and appropriate follow-up.

Additional morphologic tumor features that have negative prognostic value with regard to clinical outcome include infiltrative tumor border configuration, evidence of perineural invasion, extranodal tumor deposits, and presence of tumor budding, characterized by clusters of cells that possess properties of malignant stem cells and are associated with increased risk of local and distant spread.[56] A high density of tumor-infiltrating lymphocytes in the tissue specimen is associated with a favorable outcome.[55,56]

Certain molecular markers, particularly MSI, 18q/*DCC* mutation or LOH, *BRAF* V600E mutation, and

RAS mutations, are also associated with colorectal cancer prognosis, although the pathologic stage of disease remains the primary prognostic assessment.[57]

Colorectal cancers with allelic LOH on chromosome 18q or absent DCC protein are associated with a worse prognosis within stages II and III disease, but data are insufficient to warrant use of this test in practice at this time.[56,57] MSI can be determined through DNA sequencing or by immunohistochemistry staining for protein products of the MMR genes. Colorectal cancers that demonstrate high MSI (MSI-H) appear to be associated with a more favorable outcome and appear to predict the benefit of adjuvant fluoropyrimidines for early-stage disease.[55,56,57] Tumor DNA *BRAF* and *RAS* mutation status appear to be linked to OS but are not used to determine prognosis.

Although multiple prognostic biomarkers for colorectal cancer have been identified, single molecular tests other than MSI are not used routinely in clinical practice. However, several multigene assays have been developed that provide prognostic information to assist in identifying individuals at high risk for cancer recurrence from early-stage disease.[57,58] The Onco*type* DX colon cancer assay is commercially available and has been validated in several trials as a prognostic test for stage II and III colon cancer.[57,58,59] Gene expression profiles classify risk of recurrence of low, intermediate, or high, and these scores are prognostic for recurrence, DFS, and OS. The ColoPrint gene expression assay characterizes risk of recurrence as low or high, and is undergoing further validation in clinical trials.[58] The ability for these and other gene signature assays in development to predict which patients may benefit from adjuvant chemotherapy has not been well established.

TREATMENT

Colorectal Cancer

Desired Outcomes

Treatment goals for cancer of the colon or rectum are based on the stage of disease at presentation. Stages I, II, and III disease are considered potentially curable and the goal of management is to eradicate potential micrometastases after surgical resection. Based on the numbers and site(s) of metastases, about 20% to 30% of patients with metastatic colorectal cancer may be cured, if their metastases are considered resectable.[58] Most patients with stage IV disease are not curable, and treatments for metastatic disease are considered palliative to reduce symptoms, avoid disease-related complications, and prolong survival. However, special attention should be given to those with oligo-lesions in the liver or lung since potential cure is still possible for some of these patients.

General Approach to Treatment

Performance status, concomitant disease states, lifestyle factors, patient preferences, and patient age (although advanced age is not an absolute contraindication for aggressive therapies) must be considered in the treatment planning process. Special or emergent conditions, such as bowel obstruction or perforation, severe pain, anemia, or other symptomatic problems, need to be addressed acutely, after which time a more long-term disease-specific plan can be developed. The

treatment approaches for cancer of the colon or rectum reflect two primary treatment goals: curative therapy for localized disease and palliative therapy for metastatic cancer.

For patients for whom treatment intent is curative, surgical resection of the primary tumor is the most important component of therapy. Depending on the extent of disease and whether the tumor originated in the colon or rectum, further adjuvant chemotherapy or chemotherapy plus XRT (chemoradiation) may be appropriate. For selected patients with resectable metastases, surgical resection may be an option. However, for most patients with metastases, systemic chemotherapy is the mainstay of treatment; XRT may also be useful for disease palliation of localized symptoms. Patients with metastatic disease who are asymptomatic may benefit from initiation of therapy, and continuous treatment should be considered.

Operable Disease

Surgery

5 Individuals with operable—stages I, II, and III—cancer of the colon or rectum should undergo complete surgical resection of the primary tumor mass with regional lymphadenectomy as a curative approach for their disease.[60] The surgical approach for colon cancer generally involves complete resection of the tumor with at least a 5 cm margin of tumor-free bowel and a regional lymphadenectomy.

The preferred surgical procedure for rectal cancer is a total excision of the mesorectum, the surrounding tissue containing perirectal fat and draining lymph nodes.[60,61] If the distal margin clear of tumor is at least 1 cm, sphincter-preserving surgery may be possible for patients with cancers in the middle and lower portion of the rectum. Individuals who are not candidates for sphincter-sparing resections or have extensive local spread of tumor will require an abdominoperineal resection. This involves removal of the distal sigmoid, rectosigmoid, rectum, and anus with the establishment of a permanent sigmoid colostomy.

Colectomies for colon cancer can be performed as open procedures or laparoscopically. Laparoscopic colectomy has become an accepted procedure for colon and rectal cancer.[60] This technique appears to produce similar results to conventional surgery, with the benefits of a smaller surgical incision, shorter hospital stay, shorter duration of ileus, and reduced pain. Complications associated with colorectal surgery include infection, anastomotic leakage, obstruction, adhesion formation, sexual dysfunction, and malabsorption syndromes, depending on the site and extent of resection. Complications affecting bowel function associated with surgery for rectal cancer increase as the level of anastomosis approaches the anus.

Adjuvant Therapy for Colon Cancer

Adjuvant therapy in colorectal cancer is administered to selected individuals after complete tumor resection in an attempt to eliminate residual micrometastatic disease, thereby decreasing tumor recurrence and improving survival rates. Patients should start adjuvant therapy as soon as they are

medically stable following surgery because each 4-week delay results in a 14% decrease in OS.[58] Because more than 90% of patients with stage I colon cancer are cured by surgical resection alone, adjuvant therapy is not indicated.[58,60]

Adjuvant chemotherapy is standard therapy for patients with stage III colon cancer. The presence of lymph node involvement with tumor places patients with stage III colon cancer at high risk for recurrence, and the risk of death within 5 years of surgical resection alone is as high as 70%, depending on the number of lymph nodes involved.[60] In this population of patients, adjuvant chemotherapy significantly decreases risk of cancer recurrence and death and is standard of care. Adjuvant chemotherapy should be initiated as soon as the patient is medically stable, as delays in chemotherapy have been associated with a decrease in OS.

The role of adjuvant chemotherapy for all patients without lymph node involvement (stage II) colon cancer is controversial because early studies that showed improvements in survival included patients with both stage II and III colon cancer. However, the QUASAR trial, which included patients with mostly stage II disease, showed a significant improvement in OS with adjuvant fluorouracil and leucovorin as compared to observation alone.[60]

Patients with stage II disease who are at higher risk for relapse include those with inadequate lymph node sampling, perforation of the bowel at presentation, poorly differentiated tumors, perineural invasion, and T_4 lesions (stage IIB/IIC), and many practitioners offer this therapy to selected patients, with a detailed discussion with patients regarding the potential benefits versus treatment-related toxicities.[58] Individuals with MSI-H tumors have a better prognosis compared to those with MSI-L and may not benefit or even be harmed from adjuvant fluoropyrimidine chemotherapy. In addition, subgroup analysis from the QUASAR trial indicated that individuals greater than 70 years of age did not appear to benefit from adjuvant chemotherapy.[60] Optimal dosing, administration schedule, and duration of therapy have yet to be determined, but most practitioners use the same treatment approach as that used for patients with stage III colon cancer.

Adjuvant Radiation Therapy

Adjuvant XRT has a limited role in colon cancer because most recurrences are extrapelvic and occur in the abdomen. A subset of patients with recurrent disease or with T_4 tumors that have penetrated fixed structures may benefit from adjuvant fluorouracil-based chemoradiation, with consideration of intraoperative radiation.[58] Selected candidates may also be considered for preoperative fluoropyrimidine-based chemoradiation to improve resectability. Adverse effects associated with XRT in colorectal cancer can be acute or chronic. Acute effects primarily include hematologic depression, dysuria, diarrhea, abdominal cramping, and proctitis. Chronic symptoms that sometimes persist for months following discontinuation of XRT include persistent diarrhea, proctitis or enteritis, small bowel obstruction, perineal tenderness, sexual dysfunction, and impaired wound healing.

Adjuvant Systemic Chemotherapy

5 Standard adjuvant chemotherapy regimens include a fluoropyrimidine (fluorouracil [with leucovorin] or capecitabine) as a single agent and in combination with oxaliplatin.[62,63,64,65,66,67,68,69] The addition of leucovorin increases the binding affinity of the active fluorouracil metabolite to thymidylate synthase (TS), thus enhancing its cytotoxic activity. Combinations of fluorouracil plus leucovorin have been studied extensively in the adjuvant setting, based on the observation that fluorouracil plus leucovorin substantially improves response rates as compared with fluorouracil alone for metastatic disease.[58,60] Leucovorin administration prior to fluorouracil is the most effective approach to enable intracellular-reduced folates to accumulate prior to fluorouracil administration. When leucovorin is unavailable, levoleucovorin, the active isomer of racemic leucovorin, can be substituted as an alternative. The recommended levoleucovorin dose is 50% of the leucovorin dose.[70] The addition of oxaliplatin is superior to fluoropyrimidines alone in stage III colon cancer, but this benefit hasn't been observed in stage II colon cancer.[58]

Fluorouracil/Leucovorin Regimens

Schedules of fluorouracil and leucovorin administration vary among the different regimens. Historically in the United States, the Roswell Park regimen and the Mayo Clinic regimen were once commonly used, while in Europe, treatments such as the de Gramont regimen favored a continuous IV schedule of fluorouracil (**Table 130-7**).[62,63,64,65,66,67,68,69]

TABLE 130-7 Chemotherapy Regimens for the Adjuvant Treatment of Colorectal Cancer

Regimen	Agents	Comments
The Historical Standard		
FOLFOX4[62]	Oxaliplatin 85 mg/m^2 IV day 1 Leucovorin 200 mg/m^2 per day IV over 2 hours days 1 and 2 Fluorouracil 400 mg/m^2 IV bolus, after leucovorin, then 600 mg/m^2 CIV over 22 hours days 1 and 2 Repeat every 2 weeks	Improved OS and DFS as compared with infusional fluorouracil-leucovorin–based regimens
The Current Standard		
mFOLFOX6[63]	Oxaliplatin 85 mg/m^2 IV on day 1 Leucovorin 400 mg/m^2 IV on day 1 Fluorouracil 400 mg/m^2 IV bolus, after leucovorin on day 1, then 1,200 mg/m^2/day × 2 days CIV (total 2,400 mg/m^2 over 46-48	Easier administration and better tolerated as compared to FOLFOX4; common toxicities: sensory neuropathy, neutropenia. A preferred regimen for adjuvant colon and rectal therapy

Regimen	Agents	Comments
	hours) Repeat every 2 weeks	
Alternative Regimens		
Capecitabine[64]	Capecitabine 1,250 mg/m^2 PO twice daily on days 1 through 14 Each cycle lasts 14 days and is repeated every 3 weeks × 24 weeks	Equivalent DFS as compared with the Mayo Clinic regimen with improved tolerability; hand-foot syndrome common, useful for patients without vascular access or have difficulties with travel to infusion center
CapOx[65]	Oxaliplatin 130 mg/m^2 IV day 1 Capecitabine 850-1,000 mg/m^2 twice daily orally days 1 through 14 Each cycle lasts 3 weeks × 24 weeks	Improved DFS in patients with stage III colon cancer compared to capecitabine alone; common dose-limiting toxicities: neuropathies and hand–foot syndrome. A preferred regimen for adjuvant rectal therapy.
de Gramont regimen[66]	Leucovorin 200 mg/m^2 per day IV over 2 hours, days 1 and 2 Fluorouracil 400 mg/m^2 per day IV bolus, followed by 600 mg/m^2 CIV over 22 hours, days 1 and 2 for 2 consecutive days after leucovorin Repeat every 2 weeks	Improved safety as compared with the Mayo Clinic regimen; hand–foot syndrome common
FLOX[67]	Oxaliplatin 85 mg/m^2 IV administered on weeks 1, 3, and 5 Fluorouracil 500 mg/m^2 IV bolus weekly × 6 Leucovorin 500 mg/m^2 IV weekly × 6 Each cycle lasts 8 weeks and is repeated for 3 cycles	Improved DFS as compared with bolus fluorouracil-leucovorin–based regimens. Increased toxicity (diarrhea and neuropathies) compared to FOLFOX4
Mayo Clinic regimen[68]	Leucovorin 20 mg/m^2 per day IV, days 1 to 5	Leukopenia common dose-limiting toxicity, diarrhea, and stomatitis common

Regimen	Agents	Comments
	Fluorouracil 425 mg/m^2 per day IV, days 1 to 5 after leucovorin Repeat every 4 to 5 weeks Leucovorin 500 mg/m^2 IV day 1 over 2 hours	
Roswell Park Regimen[69]	Fluorouracil 500 mg/m^2 IV day 1 after leucovorin Repeat weekly for 6 of 8 weeks × 4 cycles Leucovorin 400 mg/m^2 per day IV	Leukopenia common dose-limiting toxicity, diarrhea, and stomatitis common
Simplified Biweekly[63]	Fluorouracil 400 mg IV bolus, after leucovorin, then 1,200 mg/m^2/day days 1 and 2 (total 2,400 mg/m^2 over 46-48 hours) for 2 consecutive days Repeat every 2 weeks	Hand–foot syndrome common

CIV, continuous intravenous infusion; DFS, disease-free survival; OS, overall survival; PO, by mouth.

Clinical studies comparing the efficacy of bolus and continuous infusion schedules generally favor continuous infusion of fluorouracil, which is probably related to its short plasma half-life and S-phase specificity for optimal TS inhibition. Continuous IV infusions also permit increased fluorouracil dose intensity, which may account for the higher response rates observed with prolonged infusions of fluorouracil. In most common combination regimens, fluorouracil is administered by both IV bolus injection and continuous IV infusion. This method of administration is now the most common method of administration in the United States and has replaced the Roswell Park and Mayo Clinic regimens.

Clinically significant differences in toxicity occur based on the dose, route, and schedule of fluorouracil administration. Leukopenia is the primary dose-limiting toxicity of IV bolus fluorouracil, although diarrhea, stomatitis, and nausea and vomiting can also occur.[71] The incidence and severity of stomatitis can be significantly reduced with the use of oral cryotherapy. In this approach, the patient is instructed to chew and hold ice chips in the mouth during the period between 5 minutes prior to and 30 minutes following the bolus injection of fluorouracil. The protective effects of this procedure are probably related to the local vasoconstriction caused by the ice chips, which temporarily reduces blood flow to the oral mucosa, thereby reducing drug exposure to the oral mucosa.

Although continuous IV infusion fluorouracil is generally well tolerated, dose-limiting toxicities can be

substantial. A distinct toxicity, palmar–plantar erythrodysesthesia ("hand–foot syndrome" or PPE), and stomatitis occur most frequently with this route of administration.[71] Hand–foot syndrome occurs in 24% to 40% of patients receiving extended continuous IV infusions and is characterized by painful swelling and erythroderma of the soles of the feet, palms of the hands, and distal fingers. The skin toxicity is fully reversible on interruption of therapy or dose reduction and is not life threatening, but it can be significant and acutely disabling. The incidence of stomatitis, diarrhea, and hematologic toxicity is not substantial at standard doses, but it increases with increasing fluorouracil doses. No significant difference is noted in the incidence of mucositis, diarrhea, nausea and vomiting, or alopecia between continuous and bolus IV fluorouracil administration.[71]

An additional determinant of fluorouracil toxicity, regardless of the method of administration, is related to its catabolism and pharmacogenomic factors. Dihydropyrimidine dehydrogenase (DPD) is the main enzyme responsible for the catabolism of fluorouracil to inactive metabolites. A rare pharmacogenetic disorder characterized by complete or near-complete deficiency of this enzyme has been identified in patients with cancer. Patients with this enzyme deficiency develop severe toxicity, including death, after fluorouracil administration. Molecular studies have identified a relationship between allelic variants in the *DPYD* gene (the gene that encodes DPD) and a deficiency in DPD activity.[57]

In summary, fluorouracil and leucovorin can be administered in a variety of treatment schedules, but none has proven superior with regard to overall patient survival and these regimens tend to be used in patients unable to tolerate an oxaliplatin-containing regimen. Table 130-7 lists examples of some of these regimens. A weekly or bimonthly schedule of leucovorin plus fluorouracil (either bolus or continuous infusion) may be more convenient for the patient in terms of fewer scheduled clinic appointments, less interference with work schedules, and ease of dose adjustments based on toxicity.

Fluorouracil Plus Oxaliplatin Regimens

5 Current National Comprehensive Cancer Network (NCCN) guidelines recommend a FOLFOX (fluorouracil/leucovorin and oxaliplatin) regimen as the preferred treatment for patients with stage III colon cancer who can tolerate combination therapy.[58] These recommendations are based on results from the Multicenter International Study of Oxaliplatin/5-Fluorouracil/Leucovorin in the Adjuvant Treatment of Colon Cancer (MOSAIC) trial, where the addition of oxaliplatin resulted in a 20% risk reduction in disease recurrence and increased 5-year DFS (73% vs 67%) as compared with fluorouracil plus leucovorin alone. With a median follow-up of 82 months, the addition of oxaliplatin resulted in a statistically significant absolute 6-year OS difference of 2.5%.[63] Oxaliplatin was associated with increased risk of paresthesia, neutropenia, and gastrointestinal toxicity (nausea, vomiting, and diarrhea) that were manageable with supportive care. This initial trial was performed with FOLFOX4 dosing schedule, more recent studies have further modified the to improve tolerability and the most current standard is mFOLFOX6 regimen.[58]

Further supporting the role of oxaliplatin in the adjuvant setting are the results of the National Surgical Adjuvant Breast and Bowel Project C-07 trial, which compared bolus fluorouracil and leucovorin, with or without oxaliplatin.[67] A significant risk reduction in disease recurrence by 20% was

seen with oxaliplatin added to the fluorouracil backbone. As expected, neurotoxicity was increased with oxaliplatin. This method of administration, called the FLOX regimen (fluorouracil, leucovorin, and oxaliplatin), is associated with increased diarrhea and neuropathies as compared with the aforementioned regimen used in the MOSAIC trial. Though listed as an option according to current NCCN guidelines, its use is limited by its toxicity.[58]

Oxaliplatin has minimal renal toxicity, myelosuppression, and nausea and vomiting when compared with other platinum-based drugs. Oxaliplatin is associated with both acute and persistent neuropathies.[72] The acute neuropathies occur within 1 to 2 days of dosing and resolve within 2 weeks. The neuropathies usually occur peripherally, but may also occur in the jaw and tongue. A rare acute syndrome of pharyngolaryngeal dysesthesia (1%-2% of patients) is characterized by subjective sensations of difficulty in swallowing and shortness of breath. Overall, acute neuropathies occur in about 90% of patients, and are precipitated or exacerbated by exposure to cold temperatures or cold objects. Thus, patients should be instructed to avoid cold drinks and use of ice, and to cover skin before exposure to cold or cold objects. Several prophylactic and treatment strategies have been studied with varying degrees of success. Persistent neuropathy is typically a cumulative adverse effect, occurring after 8 to 10 cycles. The neuropathy is characterized by paresthesia, dysesthesia, and hypoesthesia, but may also include deficits in proprioception that can interfere with daily activities (eg, writing, buttoning, swallowing, and difficulty walking as a result of impaired proprioception). Persistent neuropathy occurs in about one-half of patients receiving oxaliplatin but usually resolves with dosage reductions or cessation of oxaliplatin therapy.[58,72] Prophylaxis with calcium and magnesium infusions has not been proven effective. A “stop-and-go” approach where oxaliplatin is temporarily discontinued after 3 months of therapy (or sooner with significant neuropathic symptoms) with the other drugs continued, reduces neurotoxicity without compromising OS and has been advocated.[58] Oxaliplatin can be reinitiated at disease progression in those patients that experience near complete resolution of neurotoxicity. Anticonvulsant and antidepressant agents are potentially useful to treat symptoms.

Capecitabine Regimens

5 Capecitabine has been evaluated in adjuvant studies as a replacement for fluorouracil in an attempt to improve the safety and ease of administration of the chemotherapy regimen. Capecitabine is converted to fluorouracil through a three-step activation process, the final step being activation by thymidine phosphorylase, which is present in greatest concentrations at the tumor site. These activation steps lead to about a threefold increase in tumor fluorouracil levels. The use of CapOx (capecitabine plus oxaliplatin) has been demonstrated to prolong 3-year DFS (71% vs 67%) as compared to bolus fluorouracil alone in patients with stage III disease, but no difference in OS was observed. The toxicities differed for the two regimens, with increased risks of neuropathies and hand–foot syndrome with CapOx and increased risk of neutropenia/neutropenic fever with fluorouracil.[65] Capecitabine is FDA approved as a single agent in the adjuvant setting and has been shown to be noninferior to bolus fluorouracil and leucovorin in patients with stage III colon cancer.[64] Both regimens were given for 6 months. DFS between the groups was found to be equivalent. Secondary end points of relapse-free survival (hazard ratio [HR] 0.86; $P = 0.04$) and safety were improved with capecitabine. In particular, the incidence of diarrhea, stomatitis, and neutropenia was

decreased with capecitabine, but the incidence of hand–foot syndrome was increased with capecitabine. Doses may need to be reduced in patients who experience side effects. Patients with renal dysfunction can accumulate drug and often require dose modification. This regimen is recommended when patients are considered unable to tolerate combination therapy.[58]

Selection of an Adjuvant Regimen

Selecting a specific regimen from those listed in Table 130-7 requires an assessment of several patient-specific factors, including the performance status of the patient, comorbid conditions that may exist, and patient preferences for treatment based on lifestyle factors that are important to the patient. If a clinical trial is not an option, most patients with a good performance status will receive mFOLFOX6. Single-agent capecitabine may be the preferred option for patients with preexisting neuropathies, such as diabetic patients, or those patients wishing not to receive IV chemotherapy for any other reason. Fluorouracil and leucovorin has limited use at this time but is an acceptable option for patients who cannot receive oxaliplatin and are unable to tolerate or take oral capecitabine. For example, patients who develop severe hand–foot syndrome may tolerate bolus fluorouracil/leucovorin because this toxicity is minimal with this administration method.

Patient age should also be considered when selecting an appropriate regimen. Subset analysis of the MOSAIC and NSABP-C07 trials have demonstrated no OS benefit from adding oxaliplatin to patients older than the age of 70 years and these patients may be appropriate for fluoropyrimidine-based therapy.[60,67]

Clinical Controversy…

Current guidelines discourage the use of age as a sole determining factor in choosing an adjuvant chemotherapy regimen. However, subset analysis of large clinical trials has shown that patients older than the age of 70 years may not benefit from adjuvant oxaliplatin and may need to be treated differently.

Adjuvant and Neoadjuvant Therapy for Rectal Cancer

6 Rectal cancer involves those tumors found below the peritoneal reflection in the most distal 15 cm of the large bowel, and as such is distinct from colon cancer in that it has a propensity for both local and distant recurrence. The higher incidence of local failure and overall poorer prognosis associated with rectal cancer is a result of anatomic limitations in excising adequate radial margins around the rectal tumor. Most patients with stage II or stage III rectal cancer should receive combined-modality therapy consisting of XRT and fluoropyrimidine-based chemotherapy perioperatively.[60,73]

Neoadjuvant Therapy

6 Neoadjuvant (preoperative) chemoradiation is considered standard of care for most patients with stage II or II rectal cancer because of significant reduction in local recurrence, fewer toxicities, and

improved sphincter-preserving surgeries as compared to postoperative chemoradiation.[61,73] However, some patients are unable to tolerate a typical 5- to 6-week chemoradiation regimen and may be more appropriate candidates for a short course of preoperative radiation therapy alone.[73] Chemotherapy combined with XRT typically involves continuous infusion fluorouracil, oral capecitabine, or bolus fluorouracil and leucovorin; the addition of oxaliplatin to either fluoropyrimidine was associated with increased toxicities without clear improvements in complete remission rates or survival benefit.[60,73] Although oxaliplatin and other agents continue to be evaluated in this setting, the addition of oxaliplatin, irinotecan or biologic agents (eg, cetuximab, panitumumab, and bevacizumab) is currently not recommended.[73]

Adjuvant Therapy

6 Current NCCN guidelines for rectal cancer indicate that preoperative fluoropyrimidine-based chemotherapy plus XRT is the preferred initial treatment for resectable stage IIA (T_3 N_0), stage III (any T, N_{1-2}, or T_4/locally unresectable lesions).[73] This should be followed additional adjuvant chemotherapy after surgery to total 6 months of chemotherapy (combined total from preoperative and postoperative regimens). Postoperative treatment regimens include a fluoropyrimidine-based chemotherapy. FOLFOX or CapeOx are preferred regimens, but FLOX, fluorouracil, and leucovorin, and capecitabine can be used as well. Combined chemoradiation is preferred for patients that do not receive preoperative radiation therapy.[60,61,73]

Metastatic Disease: Initial Therapy

Multiple efficacious treatment options for metastatic colorectal cancer are available. Patients are generally classified as having resectable, potentially resectable, or unresectable metastatic disease. Surgery and XRT are used to manage isolated sites of tumor. Chemotherapy is for disseminated disease and the primary treatment modality for unresectable metastatic colorectal cancer. Patients with resectable or potentially resectable metastases are candidates for multimodality therapy.[74] Tumor *RAS* (*KRAS* exon 2 and nonexon 2 and *NRAS*) and *BRAF* genotyping for mutation status is recommended for patients at the time when metastatic disease is diagnosed to identify appropriate treatment options.[58,73] Testing can also be performed on archived tissue samples obtained when the cancer was initially diagnosed.

Resectable or Potentially Resectable Metastatic Colorectal Cancer

Surgery

7 Up to 25% of patients will present with hepatic metastases at the time of diagnosis, and 60% of patients with colorectal cancer will develop hepatic metastases sometime during the course of their disease.[75] The lung is the second most common site of cancer recurrence. Resection of colorectal cancer metastases (metastasectomy) can achieve 5-year OS rates between 20% and 70%, whereas 5-year OS in patients with unresectable metastatic disease is uncommon.[58] Therefore, a primary goal

is surgical resection of metastases with curative intent in those individuals for whom complete surgical resection is realistically possible. Patients with no significant general medical risk factors, fewer than four hepatic lesions, CEA levels less than 200 ng/mL (mcg/L), small tumor size, lack of extrahepatic tumor, and adequate surgical margins have the best opportunity for an improved long-term outcome.[75] The primary site of tumor should also be completely resected. Complete surgical resection of discrete metastases in extrahepatic sites, such as the lung, peritoneum, abdomen, and brain, has been less studied but appears to benefit patients with small numbers of metastases who are appropriate candidates for surgery. Adjuvant systemic chemotherapy is recommended to reduce the risk of recurrence following resection.[58]

Neoadjuvant (Conversional) and Adjuvant Chemotherapy

7 Patients that present with metastatic disease isolated to the liver or lung and who undergo resection of all metastatic and primary lesions have an increased probability of survival compared with those whose metastatic lesions remain unresected.[74] Therefore, strategies to increase the success rate of these resections (or convert unresectable lesions to resectable) is the primary goal in these patients. Neoadjuvant chemotherapy, also referred to as conversional chemotherapy, is the primary method to increase complete resection rates in both patients with resectable or potentially resectable liver or lung lesions. In some cases, individuals with metastatic disease initially deemed unresectable may achieve significant tumor regression following neoadjuvant chemotherapy to then be considered for surgery.[58]

The optimal sequencing of chemotherapy for patients with initially resectable metastatic disease is controversial, as treatment options include surgery followed by chemotherapy or perioperative (pre- and postoperative) chemotherapy with surgery.[58,73] Because of the high risk of recurrence following resection of metastases, postoperative chemotherapy is always recommended. Administration of both pre- and postoperative chemotherapy is common practice, but hepatotoxicity associated with preoperative chemotherapy should be considered. Steatohepatitis occurs in 4% to 28% of patients who receive irinotecan-containing regimens and vascular sinusoidal obstructive liver injury develops in 10% to 61% of patients receiving oxaliplatin.[76] Therefore, surgery is performed as soon as possible after the disease becomes resectable. Preoperative chemotherapy is limited to a 2- to 3-month time period, and patients undergo close monitoring.

Regimens are the same for neoadjuvant and adjuvant therapy. The choice of agents depends on patient-specific factors but may include regimens such as FOLFOX, FOLFIRI, FOLFOXIRI (infusional fluorouracil and leucovorin, oxaliplatin, and irinotecan), CapOx, and FOLFOX alternating with FOLFIRI. Biologic agents have been added to the aforementioned regimens.[77] If patients receive bevacizumab, surgery should not occur within 6 weeks of the last dose of therapy, and bevacizumab should not be restarted until 6 to 8 weeks after surgery due to the risk of bleeding or wound healing complications. EGFR inhibitors are to be considered only in patients that have tumors with wild-type *RAS*. Postoperative chemotherapy should be administered to patients to complete a total of 6 months of chemotherapy (pre- and postoperative).[58]

Patients with unresectable lesions are eligible for the same chemotherapy regimens (see Table 130-7). However, because the primary goal is surgical resection whenever possible, patients should be evaluated for possible resection after every 2 months of therapy. If resection occurs, adjuvant chemotherapy should be administered to complete a total of 6 months of chemotherapy.

Hepatic-Directed Therapies

7 Individuals with liver-only or liver-predominant metastatic disease may be considered for hepatic-directed therapy in addition to or as an alternative to surgical resection. Hepatic artery infusion (HAI) involves the placement of a permanent access catheter to the hepatic artery through which chemotherapy can be infused directly into the liver.[58] This approach offers the advantage of delivering high drug concentrations to tumors locally, thereby limiting systemic toxicities. Floxuridine with dexamethasone and fluorouracil with or without leucovorin are most commonly used agents. HAI is associated with potential biliary toxicity and the technical expertise required warrants use in selected patients by experienced practitioners.[58] Another option is hepatic transarterial chemoembolization, which delivers high concentrations of cytotoxic agents directly to the tumor and results in the embolization or devascularization of the liver, blocking perfusion of the tumor and eliminating its blood supply. This procedure involves the instillation of a mixture that incorporates chemotherapeutic agents, radioactive contrast dye, and/or an embolic agent directly into the hepatic artery. Agents most commonly used include doxorubicin, mitomycin, and cisplatin, which are usually dissolved in about 10 to 15 mL of a radiographic contrast dye. Addition of an embolic agent to the mixture results in either a temporary or permanent occlusion of the hepatic artery. Alternatively, drug-eluding beads of doxorubicin or irinotecan mixed with an embolic agent have been used. Local tumor response rates with these strategies are high and most patients will experience partial or complete relief of symptoms. Toxicities include postembolization syndrome characterized by nausea, fatigue, and transient elevations in hepatic enzymes and bilirubin, gastrointestinal ulcerations, and biliary toxicity. Although various hepatic-directed therapies offer potential disease palliation in select patients with unresectable, yet limited hepatic metastases, no conclusive survival advantage has been demonstrated. XRT can also be used to sites of hepatic tumor using external beam radiation therapy or percutaneous arterial injection of micron-sized embolic particles loaded with a radioisotope (radioembolization). Other less common methods include tumor ablation procedures using radiofrequency ablation or microwave energy to generate heat that destroys localized tumor cells. Cryoablation can also be used, which includes placement of a cryoprobe into the tumor, either percutaneously or intraoperatively, and then lowering the probe temperature to –20°C to –40°C and rewarming it in cycles, resulting in formation of an ice ball that causes tumor destruction. These strategies may be useful for patients who have very small hepatic lesions and are unable to undergo liver resection surgery, but they are less successful than surgical interventions.[58]

Unresectable Metastatic Colorectal Cancer

Unless the primary tumor is causing an obstruction, surgery in patients with established unresectable disease is rarely indicated. XRT may be useful to control localized symptoms in patients with metastatic colorectal cancer. Systemic chemotherapy palliates symptoms and improves survival in

patients with unresectable disease. Common treatment regimens include combinations of cytotoxic and biologic agents.

Chemotherapy

7 Accepted initial chemotherapy regimens for metastatic colorectal cancer consist of oxaliplatin-containing regimens (FOLFOX, CapOx), irinotecan-containing regimens (FOLFIRI), oxaliplatin plus irinotecan plus fluorouracil plus leucovorin (FOLFOXIRI), infusional fluorouracil plus leucovorin alone, and capecitabine alone.[58] Current guidelines recommend the addition of bevacizumab to FOLFOX, CapOx, FOLFIRI, infusional fluorouracil plus leucovorin, and capecitabine alone, or an EGFR inhibitor added to FOLFOX or FOLFIRI or administered alone, if *RAS* wild type.[58] The goals of therapy, history of prior chemotherapy, tumor *RAS* mutation status, and risk of drug-related toxicities should be considered when an appropriate management strategy is defined for each individual. Treatment regimens are the same for metastatic cancer of the colon and rectum. **Table 130-8** lists common initial chemotherapeutic regimens for metastatic disease.[78,79,80,81,82,83,84,85,86,87]

TABLE 130-8 Initial Chemotherapeutic Regimens for Metastatic Colorectal Cancer

Regimen	Agents	Major-Dose Limiting Toxicities	Comments
Patients Appropriate for Intensive Therapy with *RAS* Mutations			
mFOLFOX4+/– bevacizumab[78]	Oxaliplatin 85 mg/m^2 IV day 1 Leucovorin 400 mg/m^2 IV day 1 Fluorouracil 400 mg/m^2 IV bolus, after leucovorin day 1, then 1,200 mg/m^2/day × 2 days CIV (total 2,400 mg/m^2 over 46-48 hours) Repeat every 2 weeks +/– Bevacizumab 5 mg/kg IV day 1 before mFOLFOX6 **Repeat cycle every 2 weeks**	mFOLFOX4: Sensory neuropathy, neutropenia Bevacizumab: hypertension, thrombosis, proteinuria	Easier administration as compared with original FOLFOX

Regimen	Agents	Major-Dose Limiting Toxicities	Comments
CapeOX +/– bevacizumab[78]	Oxaliplatin 130 mg/m^2 IV day 1 Capecitabine 850 to 1,000 mg/m^2 orally twice a day, days 1 to 14 Repeat cycle every 3 weeks +/– Bevacizumab 7.5 mg/kg IV day 1 Repeat cycle every 3 weeks	CapeOX: Diarrhea, hand–foot syndrome, neuropathies Bevacizumab: hypertension, thrombosis, proteinuria	Reduced capecitabine dose better tolerated; patient must be able to be adherent and report side effects a timely fashion
FOLFIRI+/– bevacizumab[79]	Irinotecan 180 mg/m^2 IV day 1 Leucovorin 400 mg/m^2 IV day 1 Fluorouracil 400 mg/m^2 IV bolus, after leucovorin day 1, then 1,200 mg/m^2/day × 2 days CIV (total 2,400 mg/m^2 over 46-48 hours) +/– Bevacizumab 5 mg/kg IV day prior to FOLFIRI Repeat cycle every 2 weeks	FOLFIRI: Diarrhea, mucositis, neutropenia Bevacizumab: hypertension, thrombosis, proteinuria	May be preferred in patients who have preexisting neuropathy or those in which neuropathy may be debilitating to their line of work (eg, musician)
Fluorouracil/leucovorin +/– bevacizumab[80,81]	See Table 107-X for fluorouracil/leucovorin regimen options +/– Bevacizumab 5 mg/kg IV day prior to fluorouracil and	Fluorouracil/Leucovorin: diarrhea, hand–foot syndrome, mucositis, neutropenia Bevacizumab: hypertension,	Infusional fluorouracil/leucovorin regimen preferred to bolus fluorouracil regimen. Infusional regimens tend to have

Regimen	Agents	Major-Dose Limiting Toxicities	Comments
	leucovorin Repeat cycle every 2 weeks	thrombosis, proteinuria	more hand–foot syndrome and stomatitis and bolus regimens more neutropenia; weekly or bimonthly schedule of leucovorin plus fluorouracil (either bolus or continuous infusion) may be more convenient for the patient in terms of fewer scheduled clinic appointments, less interference with work schedules, and ease of dose adjustments based on toxicity
Capecitabine +/– bevacizumab[82]	Capecitabine 850-1,250 mg/m^2 orally twice a day, days 1 to 14 +/– Bevacizumab 7.5 mg/kg IV day 1 Repeat cycle every 3 weeks	Capecitabine: Hand–foot syndrome, diarrhea, hyperbilirubinemia Bevacizumab: hypertension, thrombosis, proteinuria	May be preferred in those without a port or limited venous access; patient must be able to be adherent and report side effects a timely fashion
FOLFOXIRI +/– bevacizumab[83]	Irinotecan 165 mg/m^2 IV day 1 prior to oxaliplatin Oxaliplatin 85 mg/m^2 IV prior to leucovorin day 1 Leucovorin 400 mg/m^2 IV day 1 prior to fluorouracil Fluorouracil 1,600 mg/m^2/day × 2 days CIV (total 3,200 mg/m^2 over 48 hours)	FOLFOXFIRI: Neutropenia, diarrhea, stomatitis, peripheral neurotoxicity, thrombocytopenia Bevacizumab: hypertension, thrombosis, proteinuria	More neutropenia and peripheral neurotoxicity compared to FOLFIRI; often used in medically fit individuals with diffuse aggressive disease to palliate symptoms and as potential conversion therapy

	Repeat cycle every 2 weeks +/– Bevacizumab 5 mg/kg IV day 1 before FOLFOXIRI Repeat cycle every 2 weeks		
Patients Appropriate for Intensive Therapy with *RAS* Wild Type			
mFOLFOX4 + cetuximab or panitumumab[83,84]	mFOLFOX4 regimen + Cetuximab (400 mg/m^2 IV loading dose, then cetuximab 250 mg/m^2 IV weekly thereafter OR cetuximab 500 mg/m^2 IV every 2 weeks) IV before mFOLFOX 4 OR Panitumumab 6 mg/kg IV day 1 before mFOLFOX6 Repeat cycle every 2 weeks	mFOLFOX4: Sensory neuropathy, neutropenia Cetuximab: Papulopustular and follicular rash, asthenia, constipation, diarrhea, allergic reactions, hypomagnesemia Panitumumab: rash, diarrhea, hypomagnesemia	Only *RAS* wild-type tumor
FOLFIRI + cetuximab or panitumumab[83]	FOLFIRI + Cetuximab (400 mg/m^2 IV loading dose, then cetuximab 250 mg/m^2 IV weekly thereafter OR cetuximab 500 mg/m^2 IV every 2 weeks) IV before FOLFIRI OR Panitumumab 6 mg/kg IV day 1 before FOLFIRI Repeat cycle every 2	FOLFIRI: Diarrhea, mucositis, neutropenia Cetuximab: papulopustular and follicular rash, asthenia, constipation, diarrhea, allergic reactions, hypomagnesemia Panitumumab: Rash, diarrhea, hypomagnesemia	Only *RAS* wild-type tumor; preferred for patients with pre existing neuropathy or those in which neuropathy may be debilitating to their line of work (eg, musician)

Regimen	Agents	Major-Dose Limiting Toxicities	Comments
	weeks		
Patients NOT Appropriate for Intensive Therapy with *RAS* Mutations			
Infusional fluorouracil + leucovorin +/– bevacizumab[85]	Fluorouracil 400 mg/m^2 IV bolus, after leucovorin on day 1, then 1,200 mg/m^2/day × 2 days CIV (total 2,400 mg/m^2 over 46-48 hours) Repeat cycle every 2 weeks +/– Bevacizumab 5 mg/kg IV day 1 prior to fluorouracil and leucovorin Repeat cycle every 2 weeks	Infusional fluorouracil/leucovorin: neutropenia, diarrhea Bevacizumab: hypertension, bleeding, proteinuria	Infusional fluorouracil/leucovorin regimen preferred to bolus fluorouracil regimen
Patients NOT Appropriate for Intensive Therapy with *RAS* Wild Type			
Cetuximab[83,86]	Cetuximab 400 mg/m^2 IV loading dose, then cetuximab 250 mg/m^2 IV weekly thereafter Or Cetuximab 500 mg/m^2 IV every 2 weeks	Papulopustular and follicular rash, asthenia, constipation, diarrhea, allergic reactions, hypomagnesemia	Only *RAS* wild-type tumor
Panitumumab[87]	6 mg/kg IV over 60 minutes every 2 weeks	Rash, hypomagnesemia, rare allergic reactions	Only *RAS* wild-type tumor

Currently, most metastatic colorectal cancers are incurable, and treatment goals are to control cancer growth, reduce patient symptoms, improve quality of life, and extend survival. The benefit of palliative chemotherapy for metastatic colorectal cancer as compared to observation or supportive care alone with regard to these treatment goals has been established. Results from multiple randomized trials and meta-analyses demonstrate that chemotherapy prolongs life and improves quality of life of patients with metastatic colorectal cancer.[60,88]

Most first-line chemotherapy regimens used for metastatic colorectal cancer incorporate a fluoropyrimidine. Irinotecan or oxaliplatin added to a fluoropyrimidine-based regimen significantly

improves response rates, progression-free survival (PFS), and median survival.[60] Targeted antiangiogenesis agent bevacizumab further improve response rates and survival when combined with chemotherapy as compared to chemotherapy alone. Patients considered appropriate for initial intensive chemotherapy typically receive an oxaliplatin or irinotecan-containing regimen with infusional fluorouracil plus leucovorin and bevacizumab. Capecitabine can be substituted for fluorouracil and leucovorin. Patients that are not considered appropriate candidates for initial intensive therapy may be considered for fluoropyrimidine monotherapy, a fluoropyrimidine regimen combined with bevacizumab, or EGFR inhibitor monotherapy, as appropriate.[58] Patients may receive multiple different regimens, and the sequence of drugs used appears less important than exposure to all active agents during the course of cancer treatments.[60] **Table 130-9** summarizes comparative outcome data from potentially useful chemotherapeutic treatments for metastatic colorectal cancer.[78,83,84,87,89,90,91,92,93,94,95,96,97,98,99,100,101,102] Please refer back to the *Adjuvant Systemic Chemotherapy Section* for more information on the toxicities of the regimens that are used in both the adjuvant and metastatic settings.

TABLE 130-9 Comparative Outcomes from Selected Trials in Metastatic Colorectal Cancer

Trial	Number	Outcome Measures	Results
First-Line			
FOLFOX vs IROX vs IFL Goldberg[89]	795	Primary: TTP; secondary: OS, ORR, time to treatment discontinuation	Median TTP: IFL vs FOLFOX 6.9 vs 8.7 months (P=0.0014). Median survival 15.0 months with IFL vs 19.5 months with FOLFOX (P=0.001). ORR with FOLFOX (45%) higher compared to IFL (31%; P=0.002) and IROX (35%, P=0.03). TTP and OS with IROX (6.5 and 17.4 months) no different from FOLFOX.
Infusional FU/LV ± Oxaliplatin de Gramont[90]	420	Primary: PFS; secondary: ORR, OS, tolerability, QOL	Median PFS: 9.0 vs 6.2 months (P=0.0003); ORR: 50.7 vs 22.3% (P=0.0001), oxaliplatin plus infusional FU/LV vs infusional FU/LV alone; no difference in OS (16.2 vs 14.7 months) or QOL between oxaliplatin plus infusional FU/LV vs infusional FU/LV alone.
Infusional FU/LV ± Irinotecan Douillard[91]	387	Primary: ORR; secondary: TTP, response duration, TTF, OS, QOL	Significantly higher ORR with infusional IFL vs infusional FU/LV alone (35% vs 22%; P<0.005) by ITT; TTP longer with IFL (6.7 vs 4.4 months; P<0.001) and OS longer with IFL vs infusional FU/LV alone (17.4 vs 14.1 months; P=0.031).
Capecitabine vs FU/LV Twelves[92]	1,207	Primary: ORR; secondary: TTP, OS, response duration	Tumor response to capecitabine greater than with FU/LV (25.7 vs 16.7%; P<0.0002), but no difference in median TTP (4.6 vs

Trial	Number	Outcome Measures	Results
			4.7 months) or median survival (392 vs 391 days).
Irinotecan-based regimen ± Bevacizumab Fuchs[93]	547	Primary: PFS; secondary ORR, OS, toxicity	PFS increased with FOLFIRI compared with IFL (7.6 vs 5.9 months, *P*=0.004); addition of bevacizumab improved OS (28 months for FOLFIRI + bevacizumab vs 19.2 months for IFL + bevacizumab; *P*=0.037). CapeIri equivalent to IFL and not included in final analysis and not recommended.
FOLFIRI vs FOLFOX6 Tournigand[94]	226	Test the best sequence of FOLFIRI vs FOLFOX6; primary: second PFS; secondary: PFS, OS, ORR, safety	Median survival 21.5 months with FOLFIRI then FOLFOX6 vs 20.6 months with FOLFOX6 then FOLFIRI; median PFS also no different (14.2 vs 10.9 months), or ORR or median PFS with first treatment: FOLFOX6 54% and 8.0 months, vs 56% and 8.5 months with FOLFIRI.
FOLFIRI vs FOLFOXIRI Masi[83]	244	Primary: ORR; secondary: PFS, OS, rate of surgical resection, QOL	FOLFOXIRI increased median PFS (9.8 months) vs FOLFIRI (6.8 months; *P*<0.001) and median OS (23.4 vs 16.7 months; *P*=0.26). Absolute 5-year survival benefit improved by 7% with FOLFOXIRI.
FOLFOXIRI + Bevacizumab vs FOLFIRI + BevacizumabFalcone[83]	508	Primary: PFS; secondary: OS, efficacy in *BRAF* and *RAS* molecular subgroups, ORR	FOLFOXIRI plus bevacizumab improved median OS (29.8 months) compared to FOLFIRI plus bevacizumab (25.8 months; *P*=0.03). Median OS was longer (37.1 months) in the *RAS* and *BRAF* wild-type subgroup than in the *RAS*-mutation- (25.6 months) or *BRAF*-mutation- (13.4 months) positive subgroups. There was no difference in treatment effect across molecular subgroups.
CapOx or FOLFOX or FU/LV ± BevacizumabHochster[78]	360	Primary: toxicity; secondary ORR, TTP, OS	Grade 3/4 toxicity not increased with bevacizumab. TTP, ORR, and OS all greater when bevacizumab added to CapOx, FOLFOX, or bolus fluorouracil/leucovorin. Median survival with bevacizumab-containing regimens was 24.4 months vs18.4 months without bevacizumab (not a randomized trial).

Trial	Number	Outcome Measures	Results
XELOX or FOLFOX ± Bevacizumab Saltz[83]	1,401	Primary: PFS; secondary ORR, OS	PFS increased from 8 to 9.4 months with bevacizumab added to oxaliplatin-containing regimens (XELOX or FOLFOX); *P*=0.0023. ORR and OS not different between groups.
FOLFOX ± Cetuximab Bokemeyer[95]	337	Primary: ORR; secondary PFS, OS, toxicity	ORR and PFS increased in patients with wild-type *KRAS* treated with FOLFOX + cetuximab compared with FOLFOX alone; *KRAS* mutant patients had no benefit with cetuximab (ORR 33 vs 49%, *P*=0.106 in cetuximab + FOLFOX and FOLFOX treated patients, respectively).
FOLFIRI ± Cetuximab Van Cutsem[96]	1,198	Primary: PFS; secondary OS, toxiocity	Of the 676 KRAS WT patients, median PFS was 9.9 months vs 8.4 months with FOLFIRI plus cetuximab vs FOLFIRI alone (HR = 0.696; *P*=0.0012). OS was also significantly increased with cetuximab (23.5 months vs 20.0 months, HR = 0.797; *P*=0.0093).
Oxaliplatin-based regimen ± Cetuximab Maughan[83]	1,630	Primary: OS in *KRAS* wild-type tumors; secondary, PFS, RR	Oxaliplatin-based chemotherapy + cetuximab had no effect on OS vs the control group of chemotherapy alone (17.9 months vs 17.0 months, *P*=0.67). Additionally, no difference was seen in PFS (*P*=0.60).
mFOLFOX6 + Panitumumab vs mFOLFOX6 + Bevacizumab Schwartzberg LS 2014[83]	285	Primary: PFS; secondary: OS, safety, treatment effects in extended *RAS* analysis	Subjects were previously untreated with wild-type KRAS (codons 12 and 13). PFS was similar for both treatment groups; median OS was 34.2 months in the panitumumab treatment arm and 24.3 months with bevacizumab (HR = 0.89; *P*=0.009). A trend for longer PFS and OS favored panitumumab treatment in the wild-type extended RAS subgroup.
FOLFOX4 ± Panitumumab Douillard[84]	1,183	Primary: PFS	656 patients had *KRAS* wild-type tumors. Panitumumab + FOLFOX4 improved PFS compared with FOLFOX4 (10.0 vs 8.6 months, respectively; HR = 0.80; *P*=0.01). The median OS for individuals with wild-type *KRAS* tumor receiving

Trial	Number	Outcome Measures	Results
			panitumumab + FOLFOX4 was 23.9 months vs 19.7 months with FOLFOX4 alone (HR 0.88; *P*=0.17).
Second-Line			
Irinotecan vs Infusional Fluorouracil Rougier[97]	267	Primary: OS; secondary: PFS, ORR, symptom-free survival, adverse effects, QOL	Irinotecan improved median PFS (4.2 vs 2.9 months; *P*=0.030) compared with infusion fluorouracil and 1-year survival (45% vs 35%; *P*=0.035) but not median OS (10.8 vs 8.5 months). Median pain-free survival was similar (*P*=0.06; 10.3 vs 8.5 months) between irinotecan and fluorouracil, as was QOL.
Irinotecan vs BSC Cunningham[98]	279	Primary: OS; secondary: performance status, body weight, tumor-related symptoms, QOL	Compared to best supportive care, OS was improved with irinotecan (13.8% 1-year survival vs 36.2%; *P*=0.0001); survival without deterioration in performance status, weight loss >5%, and pain-free survival were also improved with irinotecan.
Cetuximab ± Irinotecan Cunningham[99]	829	Primary: ORR; secondary: TTP, OS	Addition of cetuximab to continuing irinotecan associated with 22.9% ORR compared with 10.9% with cetuximab alone (*P*=0.0074); median survival with cetuximab plus irinotecan similar to cetuximab alone (8.6 vs 6.9 months; *P*=0.48), but TTP was longer with cetuximab plus irinotecan (4.1 vs 1.5 months; HR = 0.54; 95% CI, 0.42-0.71).
Cetuximab ± Irinotecan Sobrero[100]	1,298	Primary: OS; secondary: PFS, RR, QOL	No difference in OS was seen between the cetuximab + irinotecan or irinotecan alone group (10.7 months vs 10.0 months, respectively; HR = 0.975; *P*=0.71). Cetuximab + irinotecan significantly improved PFS (median, 4.0 vs 2.6 months; HR = 0.692; *P*≤0.0001) and QOL.
Irinotecan ± Panitumumab Seymour MT 2013[83]	460	Primary: OS; secondary PFS, RR	Original study design amended to allocate subjects with *KRAS* wild-type tumors to one of 2 treatment groups with panitumumab. Individuals receiving panitumumab did not experience

Trial	Number	Outcome Measures	Results
			improved OS compared to those receiving irinotecan alone (10.4 vs 10.9 months: *P*=0.91). PFS was improved with the addition of panitumumab to irinotecan (HR = 0.78; *P*=0.015).
Panitumumab vs BSC Van Cutsem[87]	329	Primary: PFS; secondary: ORR, OS, safety	Panitumumab plus BSC prolonged PFS compared to BSC alone, with a median PFS of 8 weeks with panitumumab (HR = 0.54; 95% CI, 0.44-0.66).
FOLFIRI ± Panitumumab Peeters[83]	1,186	Primary: PFS and OS prospectively analyzed by *KRAS* status	In *KRAS* wild-type patients, the addition of panitumumab to chemotherapy demonstrated a significant improvement in PFS (6.7 months for panitumumab + FOLFIRI vs 4.9 months for FOLFIRI; HR = 0.82; *P*=0.023). Median OS was 14.5 months in the panitumumab group, 2 months longer than with FOLFIRI alone (12.5 months; HR = 0.92; *P*=0.37).
FOLFOX4 ± Bevacizumab Giantonio[83]	463	Primary: OS; secondary: PFS, ORR, toxicity	Addition of bevacizumab to FOLFOX4 in patients previously treated with irinotecan and a fluoropyrimidine improved median OS (12.9 vs 10.8 months; HR, 0.75, *P*=0.001), PFS (7.3 vs 4.7 months; HR, 0.75, *P*<0.0001), and ORR (22.7% vs 8.6%, *P*<0.0001) compared with FOLFOX4 alone.
Bevacizumab + chemotherapy continuation after first progression vs chemotherapy alone Bennouna[83]	820	Primary: OS; secondary, PFS, RR	Median OS was 11.2 months for bevacizumab plus chemotherapy and 9.8 months for chemotherapy alone (HR = 0.81; *P*=0.0062). Second-line chemotherapy choice based on what was administered as first-line therapy (patients who received oxaliplatin-based chemotherapy in the first-line received irinotecan-based therapy in the second-line setting and vice versa). PFS and RR improved with bevacizumab.
FOLFIRI ± Aflibercept Van Cutsem[83]	1,226	Primary: OS; secondary: PFS, ORR, adverse effects	Addition of aflibercept to FOLFIRI improved OS compared to FOLFIRI plus placebo (median survival 13.50 vs 12.06 months, respectively; HR = 0.817;

Trial	Number	Outcome Measures	Results
			P=0.0032). Median PFS extended with the addition of aflibercept to 6.90 months vs 4.67 months with placebo.
FOLFIRI ± Ramucirumab Tabernero 2015[101]	1,072	Primary: OS; secondary: PFS, ORR, disease control, adverse events, patient-reported outcomes (QOL)	Ramucirumab treatment median OS was 13.3 months vs 11.7 months with placebo (HR 0.844; *P*=0.0219). PFS significantly longer with ramucirumab compared to placebo, 5.7 months vs 4.5 months, respectively; HR = 0.793; *P*=0.0005.
Refractory Disease			
Panitumumab vs Cetuximab Price 2014[83]	999	Primary: OS, assessed for noninferiority; secondary PFS, RR	Historical HR for cetuximab plus BSC used for primary endpoint analysis. Panitumumab was noninferior to cetuximab with median OS of 10.4 months vs 10.0 months for panitumumab and cetuximab, respectively. Incidence of any grade and moderate to severe toxicities was similar among treatments.
Regorafenib vs Placbo Grothey[83]	753	Primary: OS; secondary PFS	Median OS was 6.4 months for regorafenib and 5.0 months for placebo (HR 0.77; *P*=0.0052). PFS 1.9 for regorafenib vs 1.7 months for best supportive care (HR, 0.49, *P*<0.001).
Trifluridine/tipiracil (TAS-102) vs Placebo Mayer 2015[102]	800	Primary: OS	Median OS was 7.1 months with trifluridine/tipiracil compared to 5.3 months with placebo (HR 0.68; *P*<0.001). Median time to worsening performance status was longer with trifluridine/tipiracil than with placebo (5.7 months vs 4.0 months; HR 0.66; *P*<0.001).

BSC, best supportive care; CapeIri, capecitabine plus irinotecan; CapOx: capecitabine plus oxaliplatin; CI: confidence interval; FOLFIRI, fluorouracil plus leucovorin plus irinotecan; FOLFOX, fluorouracil plus leucovorin plus oxaliplatin; FOLFOXIRI, fluorouracil plus leucovorin plus oxaliplatin plus irinotecan; FU/LV, fluorouracil plus leucovorin; HR, hazard ratio; IFL, irinotecan plus fluorouracil plus leucovorin; IROX, irinotecan plus oxaliplatin; ITT, intention to treat; ORR, overall response rate; OS, overall survival; PFS, progression-free survival; QOL, quality-of-life; TTF, time-to-treatment failure; TTP, time-to-tumor progression; XELOX, capecitabine plus oxaliplatin.

Fluorouracil-Based Regimens

Fluorouracil can be administered as a bolus, a continuous infusion, or combination of the two in the metastatic setting. Continuous IV infusion fluorouracil regimens increase the duration of drug exposure during the S-phase of the cell cycle, increase cytotoxicity, and are better tolerated than bolus administration. When combined with irinotecan or oxaliplatin, infusional fluorouracil is recommended because of improved efficacy.[58]

Fluorouracil and Leucovorin Plus Irinotecan

Unlike in the adjuvant setting, irinotecan added to fluorouracil plus leucovorin as initial therapy for metastatic disease improves tumor response rates, time-to-progression, and OS (see Table 130-9).[91] The most common adverse effects of irinotecan in these regimens are diarrhea, neutropenia, nausea and vomiting, dehydration, asthenia, abdominal pain, and alopecia; diarrhea and neutropenia are dose limiting.[91] Two distinct patterns of diarrhea have been described. Early-onset diarrhea occurs during or within 2 to 6 hours after irinotecan administration and is characterized by lacrimation, diaphoresis, abdominal cramping, flushing, and/or diarrhea. These cholinergic symptoms, thought to be caused by inhibition of acetylcholinesterase, respond to atropine 0.25 to 1 mg given IV or subcutaneously. About 10% of patients experience the acute symptoms during or shortly following the irinotecan. More commonly, late-onset diarrhea occurs 1 to 12 days after irinotecan administration and may last for 3 to 5 days. Late-onset diarrhea may require hospitalization or discontinuation of therapy, and fatalities have been reported. The incidence of late-onset diarrhea can be decreased with aggressive antidiarrheal intervention. Aggressive intervention with high-dose loperamide therapy should consist of 4 mg taken at the first sign of soft or watery stools, followed by 2 mg orally every 2 hours until symptom-free for 12 hours; this regimen can be modified to 4 mg taken orally every 4 hours during the night.

The severity of delayed diarrhea has been correlated with the systemic exposure (ie, area under the concentration-vs-time curve) of irinotecan and SN-38 (irinotecan's active metabolite) and with genetic polymorphisms in the enzyme uridine diphosphate-glucuronosyltransferase (UGT1A1), which is responsible for the glucuronidation of SN-38 to inactive metabolites. Reduced or deficient levels of the UGT1A1 enzyme are observed in Gilbert syndrome, a familial hyperbilirubinemia disorder, and correlate with irinotecan-induced diarrhea and neutropenia.[103] An FDA-approved test for deficiency in this enzyme is available, and clinicians can consider obtaining these results for individual patients prior to initiating irinotecan-based therapy to see if a dose reduction at initiation of therapy is warranted.

Fluorouracil and Leucovorin Plus Oxaliplatin

Oxaliplatin, in combination with infusional fluorouracil plus leucovorin, is FDA-approved for use in first-line and salvage regimens for metastatic colorectal cancer (see Table 130-8). Oxaliplatin incorporation into fluorouracil-based regimens as first-line therapy for metastatic colorectal cancer is associated with higher response rates and improved PFS, with variable effects on OS (see Table 131-9).[90] Oxaliplatin is not effective as a single agent in colorectal cancer and is, therefore, only used in combination regimens.

Fluorouracil and Leucovorin plus Oxaliplatin plus Irinotecan

8 To further improve survival rates achieved with FOLFOX and FOLFIRI regimens, a four-drug regimen (FOLFOXIRI) was developed and has been compared with FOLFIRI.[83] FOLFOXIRI improved PFS and OS compared to FOLFIRI, and a higher proportion of patients receiving FOLFOXIRI were able to undergo radical resection of metastases. As expected, FOLFOXIRI causes more neutropenia, neurotoxicity, diarrhea, and alopecia, but may be appropriate for medically fit individuals with diffuse aggressive disease to palliate symptoms and as potential conversion therapy.[58,83,88]

Capecitabine

8 Capecitabine is an oral, tumor-activated, and tumor-selective fluoropyrimidine carbamate. Capecitabine can be administered alone or in combination with oxaliplatin (CapeOx also known as XELOX). When administered alone, it has higher response rates but comparable time-to-tumor-progression and median survival.[92] CapeOx has similar OS and PFS when compared with FOLFOX.[58] Hand–foot syndrome is common with capecitabine, whereas grades 3 or 4 neutropenia and stomatitis are more common with fluorouracil plus leucovorin. The convenience of oral administration and different toxicity profile make capecitabine a useful substitution for infusional fluorouracil in regimens for metastatic disease.

Targeted Therapy

8 Current guidelines and clinical practice recommend the addition of targeted therapy to one of the chemotherapy backbones mentioned earlier.[58]

Bevacizumab

9 Bevacizumab is a recombinant, humanized monoclonal antibody that inhibits vascular endothelial growth factor (VEGF). Bevacizumab, in combination with IV fluorouracil-based chemotherapy, was FDA approved in 2004 for initial treatment of patients with metastatic colorectal cancer. Results from randomized trials show increased PFS and OS benefit as compared with chemotherapy alone.[88] An infusional fluorouracil regimen should be used with the combination of bevacizumab and irinotecan. A randomized phase III trial demonstrated a median OS of 28 months compared with 19.2 months with FOLFIRI and IFL, respectively (HR 1.79; $P = 0.037$) when given in combination with bevacizumab.[93] A third arm of this trial replaced fluorouracil and leucovorin with capecitabine and was found to be inferior to FOLFIRI; during accrual the trial was amended to add bevacizumab to all treatment arms. The capecitabine arm remained inferior to FOLFIRI. Based on these results, capecitabine should not be administered with irinotecan, with or without bevacizumab. In contrast to irinotecan-containing regimens, bevacizumab has also been combined with oxaliplatin in a variety of chemotherapy regimens for the initial treatment of metastatic colon cancer. The method of fluorouracil administration (or substitution with capecitabine) does not appear to significantly affect outcomes.

Hypertension is common with bevacizumab.[58] The hypertension is easily managed with oral

antihypertensive agents. Bleeding, thromboembolism, and proteinuria also can occur with bevacizumab. Monitoring for proteinuria is done with urine dipsticks regularly during therapy, and therapy is withheld in patients with 2+ protein or more, confirmed with a 24-hour urine collection. The risk of gastrointestinal perforation is increased by the addition of bevacizumab, and patients complaining of abdominal pain associated with vomiting or constipation should be considered for this rare but potentially fatal complication. Bevacizumab is also associated with a two fold increased risk of arterial thrombotic events, with patients who are older than age 65 or who have a prior history of arterial thrombotic events at greatest risk. Nevertheless, because these individuals derive the same survival benefits with bevacizumab as do other patients, they may be appropriate candidates to receive bevacizumab. Bevacizumab can also interfere with wound healing and it is recommended there be at least a 6 to week interval between the last dose of bevacizumab and elective surgery and wait at least 6-8 weeks to reinitiate bevacizumab after surgery.

EGFR Inhibitors

10 Cetuximab and panitumumab are monoclonal antibodies directed against EGFR. EGFR inhibitors may be used in combination with first-line chemotherapy regimens mFOLFOX4 or FOLFIRI or administered as single agents. The benefit of EGFR inhibitors, however, is limited to patients with wild-type *RAS* tumors and they should not be used in patients with tumor *RAS* mutations.[88] Results of a recent meta-analysis of 14 randomized trials showed that addition of an EGFR inhibitor provides improvement in PFS in patients with *RAS* wild type.[104] See Table 130-9 for information on clinical trials. Tumors harboring *BRAF* mutations are also associated with a poor prognosis and a poor response to EGFR inhibitors in patients with wild-type *RAS*.[57] Therefore, individuals with *BRAF* mutations should not receive EGFR inhibitors.

For reasons that are not well understood, the addition of panitumumab or cetuximab to bevacizumab plus irinotecan- or oxaliplatin-containing chemotherapy reduces PFS and is currently not recommended. The Panitumumab Advanced Colorectal Cancer Evaluation Study trial and the CAIRO2 demonstrated a decrease in PFS of 1.4 months when panitumumab and 1.3 months when cetuximab was added to bevacizumab-containing chemotherapy, respectively.[105,106] Both of these differences were clinically and statistically significant. The results from these trials demonstrate the potential pitfalls of treating patients with multiple targeted agents outside of the setting of a clinical trial and why this practice should be avoided.

Severe infusion reactions, including anaphylaxis, can occur with cetuximab (3%) and panitumumab (1%).[58] Administration of panitumumab seems feasible in those who experienced a reaction with cetuximab based on a small trial.[107] Skin toxicity is also a common side effect with these drugs and is not part of the infusion reaction. The presence of papulopustular skin rash has been shown to correlate with response and survival. It most commonly occurs within 2 to 4 weeks of therapy initiation and preventative therapy with topical corticosteroids with moisturizer, sunscreen and oral doxycycline is recommended unless contraindications exist.[108]

Selection of an Initial Metastatic Regimen

Several factors should be considered when selecting first-line therapy for metastatic colorectal cancer when disease palliation is the primary treatment goal. The first factor that should be considered is whether intensive therapy is appropriate for the patient. Those with multiple comorbidities or low performance status would likely better tolerate a less-intensive therapy. The second consideration then is *RAS* status. Those with *RAS* wild type can receive an EGFR inhibitor therapy and those with *RAS* mutation cannot. Once those two factors are known, the selection of the appropriate regimen is based on toxicity profile and convenience of administration for the patient. Based on the comparable results of FOLFIRI versus mFOLFOX6, either of these regimens is considered the reference standard in metastatic colorectal cancer. Most patients will receive first- and second-line regimens and patient preference for either sequence of treatments based on their different toxicity profiles is important. Preexisting neuropathies may lead to FOLFIRI being chosen initially, whereas increased bilirubin or known UGT1A1 deficiency (known risk factors for delayed diarrhea) may lead to mFOLFOX as the initial choice. Alopecia occurs much more frequently with irinotecan compared to oxaliplatin combinations. Because mFOLFOX can cause persistent neuropathy, a rationale for starting with FOLFIRI is based on the observation that time-to progression is longer with first-line treatment than in second line. Therefore, the time to death during which some patients will have to live with neuropathy may be shorter.[88] Capecitabine is an appropriate substitute for IV fluorouracil in oxaliplatin combination regimens. Because of higher response rates and modest survival benefit with FOLFOXIRI, this 4-drug combination may be useful for patients with initially aggressive and symptomatic disease. Select patients who are candidates for FOLFOXIRI may benefit from the addition of bevacizumab, but the incidence of moderate or severe toxicities is increased.[83]

Metastatic Disease: Second-Line and Subsequent Therapy

Systemic chemotherapy represents the mainstay of therapy for patients whose disease progresses following initial treatment for metastatic disease. **Table 130-10** lists treatment options for refractory metastatic disease.[58,102] Treatment options are based on the type of and response to prior treatments, the site and extent of disease, and patient factors and treatment preferences.

TABLE 130-10 Second-line and Salvage Chemotherapy Regimens for Metastatic Colorectal Cancer[58,102]

Disease Progression with First-Line Regimen	Comments
First-Line Therapy: Oxaliplatin-Based Regimen ± Bevacizumab (ie, FOLFOX, CapeOX)	
Second-line options	
1. FOLFIRI **±** bevacizumab or ziv-afilbercept or ramucirumab	Bevacizumab is preferred antiangiogenic agent based on toxicity and cost
2. Irinotecan **±** bevacizumab or ziv-afilbercept or ramucirumab	Bevacizumab is preferred antiangiogenic agent based on toxicity and cost
3. Single agent cetuximab or panitumumab	Only if *RAS* wild-type; cetuximab improved OS compared to best supportive care

Disease Progression with First-Line Regimen	Comments
4. FOLFIRI ± cetuximab or panitumumab	Only if *RAS* wild type; increased PFS compared to FOLFIRI alone

First-Line Therapy: Irinotecan-Based Regimen ± Bevacizumab (ie, FOLFIRI)

Second-line options

1. FOLFOX or CapOx ± bevacizumab	Bevacizumab FDA-approved to continue with second-line options
2. Irinotecan ± cetuximab or panitumumab	Only if *RAS* wild-type; response rates with combination greater than cetuximab monotherapy
3. Single-agent cetuximab or panitumumab	Only if *RAS* wild type

First-Line Therapy: Fluorouracil-Based Regimen ± Bevacizumab (ie, Fluorouracil/Leucovorin, Capecitabine)

Second-line options

1. FOLFOX or CapOx ± bevacizumab or ziv-afilbercept or ramucirumab	Bevacizumab has least toxicity and lower cost of antiangiogenic agents
2. Irinotecan + oxaliplatin (IROX) ± bevacizumab or ziv-afilbercept or ramucirumab	Bevacizumab has least toxicity and lower cost of antiangiogenic agents
3. Irinotecan ± bevacizumab or ziv-afilbercept or ramucirumab	Bevacizumab has least toxicity and lower cost of antiangiogenic agents
4. FOLFIRI ± bevacizumab or ziv-afilbercept or ramucirumab	Bevacizumab has least toxicity and lower cost of antiangiogenic agents

Therapy After Second Progression or Third Progression

1. Regorafenib	Can be given without regard to *RAS* genotype
2. Irinotecan ± cetuximab or panitumumab	Only if *RAS* wild type; response rates with combination greater than cetuximab monotherapy
3. FOLFOX or CapeOX	Only after second-line irinotecan regimens
4. Cetuximab or panitumumab	Only if *RAS* wild-type and for patients unable to tolerate combination therapy
5. Trifluridine/tipiracil	Only after treatment with fluoropyrmidine-, oxaliplatin-, and irinotecan-based chemotherapy, anti-VEGF biologic

Disease Progression with First-Line Regimen	Comments
	product, and anti EGFR-monoclonal antibody if *RAS* wild type
6. Clinical trial	If available and only if patient eligible
7. Best supportive care	Appropriate for patients who do not want to pursue treatment or quality of life is expected to decrease

CapOx, capecitabine plus oxaliplatin; EGFR, endothelial growth factor receptor; FOLFIRI, fluorouracil plus leucovorin plus irinotecan; FOLFOX, fluorouracil plus leucovorin plus oxaliplatin; OS, overall survival; PFS, profession-free survival; VEGF, vascular-endothelial growth factor.

Systemic Chemotherapy

On disease progression following standard initial therapy, appropriate treatment options depend primarily on the type of prior therapy received (see Table 130-10). Because most patients will have received a combination of a fluoropyrimidine with either irinotecan or oxaliplatin, second-line therapy with the alternate regimen should be considered. Patient survival can exceed 2 years with this approach and it is important for patients to receive all traditional chemotherapy options if possible. Targeted agents can either be added to the aforementioned regimens or used as single agents.

Irinotecan

It was initially FDA approved as a second-line treatment for recurrent or progressive disease following fluorouracil. Two phase III trials compared irinotecan to either best supportive care or continuous-infusion fluorouracil in patients who had progressed within 6 months of treatment with fluorouracil.[58] Both trials demonstrated an improvement in OS with irinotecan as compared to the control arms. However, this approach is rarely used since single agent fluorouracil is rarely given as first-line therapy.

The use of the FOLFIRI regimen after progression with first-line FOLFOX demonstrated an objective response rate of 4% with a median PFS of 2.5 months.[58] These results are consistent with observations that demonstrate improved outcomes in those patients who are able to receive all active cytotoxic agents during the course of their disease.[88]

Based on these results, irinotecan should be considered standard second-line therapy for patients with disease progression with first-line treatment with oxaliplatin-containing regimens. Continuous-infusion fluorouracil (FOLFIRI), with or without targeted therapy, is most commonly given.

Oxaliplatin

The oxaliplatin plus fluorouracil and leucovorin should be considered for patients who received primary treatment with irinotecan plus fluorouracil. Despite the low activity of single-agent oxaliplatin

against fluorouracil-refractory disease, when oxaliplatin has been administered in a bimonthly regimen with high-dose leucovorin and continuous fluorouracil infusion, a 21% response rate with a median survival in excess of 10 months has been reported.[88] The combination of oxaliplatin plus fluorouracil and leucovorin is also effective as salvage therapy after initial treatment with irinotecan plus fluorouracil and leucovorin, with a similar response rate.[114] Although irinotecan can be used effectively as a single agent in colorectal cancer, it should be noted that oxaliplatin does not have substantial activity alone, and should only be given in combination with a fluoropyrimidine.

Trifluridine/Tipiracil

Trifluridine is a thymidine-based nucleoside analog that is incorporated into DNA and inhibits cell proliferation. The addition of tipiracil increases trifluridine exposure by inhibiting its metabolism by thymidine phosphorylase. This combination chemotherapy product has activity in *RAS* wild-type tumors. Trifluridine/tipiracil was FDA approved for treatment of metastatic colorectal cancer patients who have been previously treated with an fluoropyrimidine-, oxaliplatin-, and irinotecan-containing regimens, an anti-VEGF targeted therapy, and an anti-EGFR monoclonal antibody if *RAS* wild type.[102] When compared in a double-blind, placebo-controlled trial of trifluridine/tipiracil and placebo, an improvement in OS was observed (7.1 vs 5.3 months; HR 0.68; $P<0.01$). This chemotherapy product is administered 35 mg/m^2 orally twice daily within 1 hour of completing morning and evening meals on days 1 through 5 and days 8 through 12 of a 28-day cycle. Common adverse effects include myelosuppression, fatigue, diarrhea, nausea/vomiting, abdominal pain, and pyrexia.

Targeted Therapy

10 The addition of targeted therapy to chemotherapy in second and subsequent therapies does improve outcomes, but typically also increases toxicity. EGFR inhibitors may be administered in combination with irinotecan but can be used as single agents in patients who cannot tolerate irinotecan-based chemotherapy. Angiogenesis inhibitors are also used in second-line and subsequent therapy. However, the monoclonal antibodies bevacizumab, ziv-aflibercept, or ramucirumab are not given as single agents.

EGFR Inhibitors

10 Cetuximab is active in chemotherapy-refractory disease as a single agent and in combination with continued irinotecan.[60] As a single agent, cetuximab is associated a 23% improvement in OS compared with best supportive care (HR, 0.77; 95%; $P=0.005$).[60] The combination of cetuximab and irinotecan has also been evaluated in the second-line setting in patients naïve to irinotecan after oxaliplatin-based failures demonstrating significant improvements in PFS with cetuximab.[100] An important caveat for most initial trials with cetuximab is that *RAS* testing was not initially performed. Retrospective analyses of these studies show that antitumor effects are limited to patients with wild-type *RAS*.[88]

Panitumumab, also administered alone or in combination with irinotecan-containing regimens, may

be used as second or subsequent lines of therapy in patients with *RAS* wild type. Results of studies have shown a 46% decrease in the rate of tumor progression with single-agent therapy compared with best supportive care and a 2-month improvement in PFS when compared with FOLFIRI.[83,87]

A randomized, multicenter comparative study of single-agent cetuximab and panitumumab showed noninferiority between agents in terms of OS and similar side effects.[83] Therefore, both monotherapy with panitumumab or cetuximab or combination with chemotherapy regiments such as FOLFIRI or single-agent irinotecan are recommended by current NCCN guidelines as second-line options in patients with wild-type *RAS* who have not had an EGFR as part of initial therapy (see Table 130-10).[58]

Angiogenesis Inhibitors

Angiogenesis inhibitors including VEGF inhibitors bevacizumab, ramucircumab, and ziv-alfibrecept and the multikinase inhibitor regorafenib may be used in patients who have progressed on other therapies (see Table 130-10). VEGF inhibitors may be used as second- or subsequent-line therapies, whereas regorafenib is limited to third- or subsequent-line use. The 2016 NCCN guidelines recommend bevacizumab over ramucircumab and ziv-alfibercept based on toxicity and cost. Continuation of bevacizumab as second-line therapy provides a modest improvement in OS based on several clinical trials.[58,83] Bevacizumab may also be added to another second-line therapy in patients who did not receive it as part of their initial therapy, also resulting in a modest improvement in OS (10.8 to 12.1 months [P = 0.001]).[83] Single-agent bevacizumab is not recommended as it has shown inferior efficacy to combination therapy.[58]

Clinical Controversy

Continuation of bevacizumab after disease progression has recently been FDA approved. Originally justified based on retrospective data that demonstrate improved survival, a confirmatory phase III trial demonstrated a small improvement in OS. Benefit of this strategy versus changing the antiangiogenic therapy to a new agent that targets the same pathway or in combination with other targeted agents will need to be determined.

Ziv-aflibercept is a soluble recombinant fusion protein that was designed to block the angiogenic process. The agent was developed by fusing sections of the VEGFR-1 and VEGFR-2 immunoglobulin domains to the F_c portion of human immunoglobulin G1 (IgG1) and blocks VEGF-A, VEGF-B, and placental growth factor (PlGF) by "trapping" the ligands before they get to the native transmembrane receptors. In a phase III randomized trial, FOLFIRI plus ziv-aflibercept was compared to FOLFIRI after progression on an oxaliplatin-based regimen.[83] The trial met its primary end point with an improvement in OS (13.5 months for FOLFIRI/ziv-aflibercept vs 12.06 months for FOLFIRI/placebo; HR, 0.817; P=0.0032). It is dosed at 4 mg/kg as an IV infusion over 1 hour every 2 weeks and is associated with similar adverse effects as bevacizumab. The addition of ziv-aflibercept to oxaliplatin regimens has not been evaluated and therefore is not recommended. Additionally the addition of ziv-aflibercept following failure of a bevacizumab-containing regimen has not been evaluated. Therefore, ziv-aflibercept should only be used in patients naïve to antiangiogenic regimens and only with irinotecan-containing regimens.

Ramucirumab is a human monoclonal antibody that binds directly to the ligand-binding pocket of VEGFR-2 to block binding of VEGF-A, VEGF-C, and VEGF-D. A phase III randomized placebo-controlled trial of patients who had failed an oxaliplatin-based regimen and bevacizumab were randomized to receive FOLFIRI with or without ramuciumab.[101] A modest improvement in OS (13.3 vs 11.7 months; HR, 0.84; P=0.02) and PFS (5.7 vs 4.5 months; HR, 0.79; P<0.0005) were observed. Ramucirumab is administered as 8 mg/kg IV over 1 hour every 2 weeks and is associated with similar adverse effects as bevacizumab.

Regorafenib, a small-molecule inhibitor of tumor angiogenesis (VEGFR-1, VEGFR-2, and VEGFR-3) and other downstream targets (FGF receptors, PDGF receptors, BRAF, KIT, and RET), is approved for the third- or fourth-line treatment of metastatic colorectal cancer. This oral agent is dosed 160 mg once daily for the first 21 days of each 28-day cycle; although it is common to start at a lower dose (80 or 120 mg) and titrate as tolerated.[58] In a phase III trial of patients with metastatic colorectal cancer and progression during or within 3 months of last chemotherapy, regorafenib demonstrated a 1.4-month improvement in OS when compared to placebo.[83] Patients with mutant or wild-type *RAS* may receive this therapy. Because this is an oral-only regimen, patients must be counseled on its use and potential toxicity. Regorafenib should be taken with a low-fat breakfast and may interact with CYPP450 3A4 inducers and inhibitors. Toxicities include hypertension, hand–foot syndrome, diarrhea, and hepatotoxicity.

Hepatic-Directed Therapies

Patients with unresectable or nonablatable hepatic-predominant metastases or who are unable to undergo surgery may be candidates for chemoembolization, radioembolization, or HAI chemotherapy, as discussed previously.[109] Although various hepatic-directed therapies offer potential disease palliation in select patients with unresectable, yet limited hepatic metastases, no conclusive survival advantage has been demonstrated.

New Strategies and Agents in Development

The number of active cytotoxic agents against cancers of the colon and rectum is limited. These traditional chemotherapy agents, which target rapidly dividing cells, kill both malignant and nonmalignant cells, and new cancer therapies are needed to improve therapeutic outcomes. In particular, targeted therapies aimed at the underlying cancer pathology are increasingly being developed and used in colorectal cancer treatment. A variety of agents targeted toward augmenting the host immune system response have undergone, or are currently undergoing, study for colorectal cancer, including monoclonal antibodies, tumor vaccines, and agents targeting the programmed cell death (PD) receptor or ligand. Additional strategies include regulating tumor growth through the inhibition of various cell proliferation, survival, and death pathways, angiogenesis, and cancer stem cells. Agents that can alter microenvironmental factors that support angiogenesis and tumor metastases may also be of benefit.

PERSONALIZED PHARMACOTHERAPY

Drug therapy for patients diagnosed with colorectal cancers is individualized based on several established tumor and patient pharmacogenetic factors that influence treatment response. In addition, various tumor characteristics, patient genetics, and molecular markers may predict prognosis and/or response to certain therapies and provide the rationale for pharmacogenomic strategies to select appropriate therapies for individual patients. **Table 130-11** summarizes potential predictive markers for individualizing colorectal cancer treatment.[15,30,57,58,59,60,110,111,112]

TABLE 130-11 Potential Predictive Markers for Personalized Pharmacotherapy for Colorectal Cancer

Pathway	Biomarker	Relationship to Response
DNA MMR	MSI (MSI-H)	Improved survival and decreased risk of recurrence following resection; may predict lack of survival benefit (and perhaps detrimental effect) from adjuvant therapy with a fluoropyrimidine alone for stage II disease
DPD	*DPYD* polymorphisms	Absent or reduced DPD associated with risk of severe fluorouracil and capecitabine toxicities; low levels of DPD activity correspond to greater response to fluorouracil-based chemotherapy
EGFR	*KRAS* and *NRAS* mutations (exons 2, 3, and 4)	Predict lack of response to anti-EGFR antibodies
	BRAF exon 15 mutations (including V600E mutation)	Predicts lack of response to anti-EGFR antibodies in *KRAS* wild-type tumors
	PIK3CA mutations (exons 9 and 20)	Predict poor overall response to anti-EGFR inhibitor antibodies
		May predict patients likely to benefit from adjuvant aspirin or aspirin chemoprevention
	PTEN mutation or reduced PTEN expression	May predict lack of response to anti-EGFR antibodies
	AREG, EREG expression Skin rash with EGFR inhibitor	Higher EGFR ligand mRNA expression may correspond to better anti-EGFR antibody efficacy Development of skin rash with anti-EGFR antibodies may predict response to treatment and improved treatment outcome
Folate	*MTHFR* polymorphisms	Polymorphisms linked to reduced intracellular folate pools associated with fluoropyrimidine toxicity; may influence response to FOLFOX
Glutathione-S-Transferase	*GSTP1* polymorphisms	May help predict oxaliplatin-induced neurotoxicity

Pathway	Biomarker	Relationship to Response
Nucleotide Excision Repair	*ERCC1*	Polymorphisms and protein expression associated with resistance to platinum-based chemotherapy
	ERCC2	
	XRCC1	Decreased ERCC1 protein expression associated with improved survival with FOLFOX
Thymidine phosphorylase	TP expression	Associated with response to capecitabine treatment
Thymidylate synthase	TS expression	Increased TS expression associated with reduced response to fluorouracil; low tumor expression associated with increased sensitivity to fluorouracil; may be prognostic for survival
	TYMS polymorphisms and expression	Gene expression in tumor tissue and certain variants modestly prognostic for treatment outcomes; evaluation of haplotypes may improve predictive value for treatment response
UDP-glucuronosyltransferases	*UGT1A1*28*	Homozygous 7-repeat allele associated with increased risk of severe diarrhea with irinotecan

AREG, amphiregulin; DNA MMR, DNA mismatch repair genes; DPYD, dihydropyrimidine dehydrogenase; EGFR, epidermal growth factor receptor; ERCC1, excision repair cross-complementing group 1; ERCC2, excision repair cross-complementing group 2; EREG, epiregulin; FOLFOX, fluorouracil, leucovorin, and oxaliplatin; MSI, microsatellite instability; MTHFR, methylenetetrahydrofolate reductase; TP, thymidine phosphorylase; TS, thymidylate synthase; *TYMP*, thymidine phosphorylase gene; *TYMS*, thymidylate synthase gene; UGT1A1, uridine diphosphate-glucuronosyltransferase; XRCC1, x-ray repair cross-complementing protein 1.

Tumor Genomics

The most important development in biomarkers for colorectal cancer treatment has been validation of *RAS* mutation status as a predictive marker for lack of tumor response to anti-EGFR antibodies.[60,110] Tumors should be genotyped for *RAS* (*KRAS* exon 2 and nonexon 2; *NRAS*) and *BRAF* mutations at diagnosis of stage IV disease; patients with known *KRAS* or *NRAS* mutations should not receive cetuximab or panitumumab.[58] Because fewer than 60% of patients with *KRAS* wild-type tumors respond to cetuximab or panitumumab, additional factors downstream of *RAS* signaling have been explored for their ability to predict response to EGFR inhibitors, including *BRAF* V600E mutation, and mutation or loss of *PTEN* or *PIK3CA*.[30,58] Although the predictive value of *BRAF* mutation status has not been established, retrospective evidence shows its association with a lack of response to anti-EGFR antibodies.[58,110] Also, patients with *BRAF* mutant tumors have a poor prognosis, with shorter survival times.[110] *PIK3CA* mutations are present in up to 30% of tumors; since they are often

detected with coexisting *BRAF* or *RAS* mutations, their prognostic and predictive values are difficult to evaluate.[110] However, activation of the PI3K/PTEN/AKT signaling pathway downstream of EGFR, via *PIK3CA* or *PTEN* mutation may contribute to resistance to anti-EGFR antibodies.

Amphiregulin (AREG) and epiregulin (EREG) are EGFR ligands that have undergone study as biomarkers of efficacy of cetuximab. Patients with wild-type *KRAS* tumors and higher levels of ligand expression experienced greater responses to cetuximab monotherapy.[110] Tumor AREG and EREG mRNA expression may help predict cetuximab efficacy and are under investigation.

About 12% to 22% of stage II and III colorectal cancers show high-frequency microsatellite instability (MSI-H), which is associated with an improved prognosis.[60] Findings from pooled analyses of patients with MSI-H tumors who received adjuvant fluorouracil indicate a lack of response to treatment, perhaps due to an improved overall prognosis and/or additional factors. Nevertheless, some practitioners use MSI status to determine which patients with low-risk stage II colorectal cancer should not receive adjuvant fluorouracil. Current NCCN guidelines recommend MSI testing for stage II colon cancers because MSI-H status confers a good prognosis and those patients do not benefit from adjuvant single agent fluoropyrimidine.[58]

Tumors with *P53* mutations demonstrate a high degree of resistance to radiation, fluorouracil, oxaliplatin, and certain other chemotherapeutic agents and are associated with a less-favorable prognosis. However, because of difficulties with adequately sensitive and specific immunohistochemical analysis to identify P53 mutations, widespread testing, and application of this as a marker is unlikely.[57,112]

Chemotherapy Pharmacogenomics

Polymorphisms or epigenetic modifications in genes involved in drug metabolism and transport, DNA repair, and therapeutic targets are potentially predictive of fluoropyrimidine, irinotecan, and oxaliplatin toxicity and/or efficacy.[111] There are currently no clinically useful predictive markers for fluoropyrimidine efficacy, but DPD deficiency is predictive for toxicity. Patients who are deficient in DPD experience severe and potentially life-threatening toxicities with conventional doses of fluorouracil and capecitabine, but determination of DPD activity is relatively time consuming and the techniques are not amenable to routine clinical practice. However, genetic testing for DPYD polymorphisms can identify patients who would require lower fluorouracil doses to avoid severe toxicity and is recognized by the FDA as an approved pharmacogenomic marker to predict toxicities from fluorouracil.[110,111,112]

Of factors predictive for tumor sensitivity to fluorouracil, TS expression has been most studied. Tumors that overexpress TS, an enzyme that converts deoxyuridine monophosphate to deoxythymidine monophosphate, an essential step for DNA synthesis, are less sensitive to fluorouracil chemotherapy, whereas low TS expression contributes to increased chemosensitivity.[57,110,111] Patients whose cancers have higher levels of TS appear to have a significantly worse overall 5-year survival than patients whose cancers have a low level of TS.[112] However, no large cooperative group trial has identified a subgroup of patients who failed to benefit

from fluorouracil plus leucovorin therapy based on tumor TS levels, probably due to differential results obtained using different analytic techniques. Also, the importance of TS protein expression is difficult to ascertain given that fluorouracil is generally not administered as a single agent. Therefore, tumor testing for TS overexpression is not routinely used to select fluorouracil treatments.

Tests for polymorphisms in other genes that influence fluoropyrimidine activity with potential to predict treatment toxicity or efficacy have been established but are not routinely used.[111,112] Frequencies of germline polymorphisms in *TYMP* and *MTHFR* vary among ethnic populations; their consequential effects on treatment toxicities and/or efficacy are recognized, but the complexities of testing including haplotype analyses, sample size requirements, and applicable study designs have limited efforts to establish their utility as predictive markers.[112]

Nucleotide excision repair genes (eg, *ERCC1*, *ERCC2*, *ERCC5*, *XRCC1*, and *XRCC3*) have been evaluated as prognostic factors in colorectal cancer and genetic variants in some of these genes confer resistance to anticancer agents, including platinum-based chemotherapy.[57,112] Certain *ERCC1* polymorphisms are associated with decreased ERCC1 protein expression, which may predict for response to and improved survival with FOLFOX chemotherapy.[57] Despite findings from several investigations that certain variants within the DNA repair system may serve useful in optimizing chemotherapy treatments, they are still considered exploratory, as most studies were small, conducted in select populations, and studied a limited number of gene variants.[111]

Patients that are homozygous for a *UGT1A1* 7-repeat allele (*UGT1A1*28*), which is associated with reduced levels of UGT1A1 expression, are at increased risk for severe diarrhea with irinotecan. FDA-approved testing to determine *UGT1A1* genotype is commercially available. Although some individuals advocate testing UGT1A1 genotype prior to starting irinotecan, widespread testing has not been adopted.[57] The prescribing information recommends an initial reduced dose of irinotecan in patients with *UGT1A1*28* genotype.

Therapeutic Drug Monitoring

Because of the wide inter- and intrapatient variability in fluorouracil pharmacokinetics and a narrow therapeutic range, pharmacokinetic optimization of fluorouracil represents a potential strategy to individualize dosing and optimize efficacy and minimize adverse effects. Published data suggest that only 20% to 30% of patients treated with fluorouracil achieve therapeutic concentrations.[113] A prospective study that compared pharmacokinetically guided fluorouracil dosing with conventional dosing in patients with metastatic colorectal cancer demonstrated that pharmacokinetically guided dose adjustments reduced grade 3/4 toxicities, increased the objective tumor response rate, and provided a higher yet not significantly increased survival rate.[114] Most recently, a pharmacokinetically guided fluorouracil algorithm was used to adjust doses to achieve a target area-under-the-concentration versus time curve in 70 patients with colorectal cancer.[115] This program showed that pharmacokinetically guided fluorouracil dosing resulted in fewer underdosed patients, reduced gastrointestinal toxicities, and is feasible in the community setting. Valid assay methods that facilitate therapeutic drug monitoring are available and are being used in some centers. Algorithms are available for specific treatment protocols that enable practitioners to determine doses based on

patient physiological and pathophysiological characteristics. Increased awareness and application of this dosing strategy will be required to determine if it will indeed improve therapeutic outcomes for patients with colorectal cancer.

EVALUATION OF THERAPEUTIC OUTCOMES

The goal of monitoring patients is to either evaluate whether the patient is receiving any benefit from the management of the disease or for those who have completed curative intent therapy, to detect recurrence. During treatment for active disease, patients should undergo monitoring for measurable tumor response, progression, or new metastases; these tests may include chest, abdominal or pelvic CT scans, or radiographs, depending on known sites of disease, and CEA measurements every 3 months if the CEA is or was previously elevated. In addition, a complete blood cell count should be obtained prior to each course of chemotherapy administration to ensure that hematologic indices are adequate. Baseline liver function tests and an assessment of renal function should be evaluated prior to and periodically during therapy. These radiologic tests and other selected laboratories should also be evaluated with the development of any new symptoms or significant change in disease status. Patients should be evaluated during every treatment visit for the presence of anticipated side effects, which generally include loose stools or diarrhea, nausea or vomiting, mouth sores, fatigue, and fever, as well as other side effects such as neuropathy, skin rash, and hepatotoxicity that are typically associated with oxaliplatin, EGFR inhibitors, and regorafenib, respectively. Serum electrolytes, including magnesium, should be monitored for during treatment with EGFR inhibitors. Patients receiving bevacizumab, ziv aflibercept, or regorafenib should be evaluated for hypertension and proteinuria.

Symptoms of recurrence such as pain syndromes, changes in bowel habits, rectal or vaginal bleeding, pelvic masses, anorexia, and weight loss develop in less than 50% of patients. A greater percentage of recurrences are detected in asymptomatic patients because of increased serum CEA levels that lead to further examination. Although the value of CEA monitoring for asymptomatic disease recurrence is questioned by some because of the related expense and emotional stress associated with false-positive elevations, CEA monitoring plays an important role in postoperative follow-up studies for most individuals. A PET scan can be considered to identify localized sites of metastatic disease when a rising CEA level suggests metastatic disease but CT scans and other imaging studies are negative.

Patients who undergo curative surgical resection, with or without adjuvant therapy, require close follow-up based on the premise that early detection and treatment of recurrence could still render them cured. In addition, early treatment for asymptomatic metastatic colorectal cancer appears superior to delayed therapy. Specific practice guidelines for postoperative surveillance examinations following successful treatment for stage II or III disease were developed by NCCN and include: history, physical examination, and CEA test every 3 to 6 months for the first 2 years, then every 6 months for a total of 5 years; annual chest and abdominal and pelvic CT scans for up to 5 years following primary therapy; and colonoscopy at about 1 year after surgery. Repeat colonoscopies are recommended at 3 years, unless findings of polyps warrant closer follow-up. Less intensive surveillance is recommended for patients treated for stage I disease because of low risk of

recurrence.[58]

Posttreatment surveillance should also include a survivorship care plan with immunizations for vaccine-preventable diseases, early detection of second primary cancers, and support systems that encourage smoking cessation, establish regular exercise and maintain a healthy BMI, and encourage healthy lifestyle and dietary choices.[58] In addition, if there is a strong family history of colorectal cancer or related malignancies or clinicopathologic findings in an individual consistent with an hereditary syndrome, a consultation with a geneticist is indicated. Recent advances in the treatment for cancer of the colon and rectum now offer the potential to improve patient survival, but for many patients, improved DFS and PFS represent equally important therapeutic outcomes. Although treatment approaches for metastatic colorectal cancer have been historically assessed by their ability to produce a measurable objective tumor response, which is generally believed necessary for any treatment to improve survival, the effects of therapies on survival are clinically more meaningful than their ability to induce a tumor response. However, with the availability of multiple active treatments for metastatic disease, and the likelihood that patients will receive more than one during the course of their treatment, improvements in OS with new therapies will be increasingly difficult to determine.

In the absence of the ability of a specific treatment to demonstrate improved survival, important outcome measures should include the effects of the treatment on patient symptoms, daily activities and performance status, and other quality-of-life indicators, as well as PFS and time-to-treatment failure. Because most metastatic colorectal cancers are incurable, a specific decision regarding an individual patient's care will ultimately be required. This decision should be based on a careful assessment of the balance between risks associated with treatment (or lack thereof) and benefits of treatment. Effort should also be made to ensure that the costs of screening, diagnostic tests, treatments, and procedures for colorectal cancer are consistent with their value in improving patient outcomes.

Chapter 131: Prostate Cancer

LeAnn B. Norris; Jill M. Kolesar

INTRODUCTION

KEY CONCEPTS

- 1 Prostate cancer is the most frequent cancer in men in the United States. African American ancestry, family history, and increased age are the primary risk factors for prostate cancer.
- 2 Prostate-specific antigen can be used to detect prostate cancer at early stages, predict outcome for localized disease, define disease-free status, and monitor response to androgen-deprivation therapy (ADT) or chemotherapy for advanced-stage disease.
- 3 The prognosis for prostate cancer patients depends on the histologic grade, the tumor size, and the disease stage. More than 85% of patients with stage A_1 disease but less than 1% of those with stage D_2 can be cured.
- 4 ADT with a luteinizing hormone-releasing hormone (LHRH) agonist plus an antiandrogen should be used prior to radiation therapy for patients with locally advanced prostate cancer to improve outcomes over radiation therapy alone.
- 5 ADT, with either orchiectomy, an LHRH agonist alone or an LHRH agonist plus an antiandrogen (combined hormonal blockade), can be used to provide palliation for patients with advanced (stage D_2) prostate cancer. The effects of androgen deprivation are most pronounced in patients with minimal disease at diagnosis.
- 6 Antiandrogen withdrawal, for patients having progressive disease while receiving combined hormonal blockade with an LHRH agonist plus an antiandrogen, can provide additional symptomatic relief. Mutations in the androgen receptor can cause antiandrogen compounds to act like receptor agonists.
- 7 Chemotherapy, with docetaxel and prednisone improves survival in patients with castrate-refractory prostate cancer and is considered a first-line therapy option for these patients. Other effective agents include enzalutamide and abiraterone.

Prostate cancer is the most commonly diagnosed cancer in American men.[1] For most men, prostate cancer has an indolent course, and treatment options for early disease include expectant management, surgery, or radiation. With expectant management, patients are monitored for disease progression or development of symptoms. Localized prostate cancer can be cured by surgery or radiation therapy, but advanced prostate cancer is not yet curable. Treatment for advanced prostate cancer can provide significant disease palliation for many patients for several years after diagnosis. The endocrine dependence of this tumor is well documented, and hormonal manipulation to decrease circulating androgens remains the basis for the treatment of advanced disease.

EPIDEMIOLOGY

1 Prostate cancer is the most frequent cancer among American men and represents the second leading cause of cancer-

related deaths in males.[1] In the United States alone, it is estimated that 180,890 new cases of prostate carcinoma will be diagnosed and more than 26,120 men will die from this disease in 2016.[1] Although the incidence of prostate cancer increased during the late 1980s and early 1990s related to widespread prostate-specific antigen (PSA) screening, deaths from prostate cancer have been declining since 1995.[1]

ETIOLOGY

Table 131-1 summarizes the possible factors associated with prostate cancer.[2,3] The widely accepted risk factors for prostate cancer are age, race-ethnicity, and family history of prostate cancer.[2,3] The disease is rare in those younger than 40 years, but the incidence sharply increases with each subsequent decade, most likely because the individual has had a lifetime exposure to testosterone, a known growth signal for the prostate.[2,3]

TABLE 131-1 Risk Factors Associated with Prostate Cancer

Factor	Possible Relationship
Probable Risk Factors	
Age	More than 70% of cases are diagnosed in men older than 65 years old
Race	African Americans have higher incidence and death rate
Genetic	Familial prostate cancer inherited in an autosomal dominant manner
	Mutations *BRCA1*, *BRCA2, MSH2*, and *HOXB13* are associated with an increased risk of prostate cancer
Possible Risk Factors	
Environmental	Clinical carcinoma incidence varies worldwide
	Latent carcinoma similar between regions
	Nationalized males adopt intermediate incidence rates between those of the United States and their native country
Occupational	Increased risk associated with cadmium exposure
Diet	Mediterranean diet associated with reduced risk
	Increased risk associated with high-meat and high-fat diets
	Decreased intake of 25-dihydroxyvitamin D, lycopene, and β-carotene increases risk
Hormonal	Does not occur in castrated men
	Low incidence in cirrhotic patients
	Up to 80% are hormonally dependent; African Americans have 15% increased testosterone
	Japanese have decreased 5-α-reductase activities
	Polymorphic expression of the androgen receptor

Race and Ethnicity

The incidence of clinical prostate cancer varies across geographic regions. Scandinavian countries and the United States report the highest incidence of prostate cancer, while the disease is relatively rare in Japan and other Asian countries.[4] African American men have the highest rate of prostate cancer in the world, and prostate cancer mortality in African Americans is more than twice that seen in white populations in the United States.[1] Hormonal, dietary, and genetic differences, and differences in access to healthcare may contribute to the altered susceptibility to prostate cancer in these populations.[2,3] Testosterone, commonly implicated in the pathogenesis of prostate cancer, is about 15% higher in African American men compared with white males. Activity of 5-α-reductase, the enzyme that converts testosterone to its more active form, dihydrotestosterone (DHT), in the prostate, is decreased in Japanese men compared with African Americans and whites.[2,3]

In addition, genetic variations in the androgen receptor exist. Activation of the androgen receptor is inversely correlated with CAG repeat length. Shorter CAG repeat sequences have been found in African Americans, and a recent meta-analysis

demonstrated that carriers of a short CAG repeat were at increased risk of prostate cancer (odds ratio 1.21, 95% confidence interval [CI] 1.10-1.51) when compared to individuals with long CAG repeats.[3] Therefore the combination of increased testosterone and increased androgen receptor activation may account for the increased risk of prostate cancer for African American men.[2,3] The Asian diet is generally considered to be low in fat and high in fiber with a high concentration of phytoestrogens, potentially explaining their decreased risk.[4]

Family History

Men with a brother or father with prostate cancer have twice the risk for prostate cancer as compared with the rest of the population and 5% to 10% of prostate cancers are thought to be inherited.[5] Familial clustering of a prostate cancer syndrome has been reported, and genome-wide scans have identified potential prostate cancer susceptibility candidate genes. Male carriers of germline mutations of *BRCA1* mutations have about 4-fold increased risk of prostate cancer and an absolute risk of about 10% by age 65 while those with *BRCA2* mutations have a 2.5- to 8.6-fold increase in prostate cancer risk and a 15% absolute risk by age 65.[5] Other genes implicated in hereditary prostate cancer are *MSH2* and *HOXB13*.[5] Common exposure to environmental and other risk factors may also contribute to increased risk among patients with first-degree relatives with prostate cancer.[4]

Diet

The overall dietary factor associated with the lowest risk of developing prostate cancer appears to be adherence with a Mediterranean diet.[6] The typical Mediterranean diet is high in fruits, vegetables, legumes, fish, olive oil and red wine, with low to moderate amounts of red meat, poultry and dairy. In a meta-analysis including about 1.5 million individuals, adherence to a Mediterranean diet was associated with a small, but significantly reduced risk of prostate cancer (relative risk [RR] 0.96, 95% CI: 0.92-0.99).[6]

Many individual dietary factors have been assessed to ascertain their role in the development or prevention of prostate cancer.[7] Green tea and lycopene are currently considered the most useful, and at least not harmful. Green tea consumption was associated with a reduced risk of prostate cancer in a small case-control study. Lycopene, obtained primarily from tomatoes, was shown to decrease the risk of prostate cancer in small cohort studies, although a meta-analysis failed to show a benefit for high tomato consumption.

Consistent with the beneficial effects of the Mediterranean diet, red meat and high milk intake have been clearly and consistently associated with an increased risk of prostate cancer in epidemiological studies.[7]

Other Factors

Benign prostatic hyperplasia (BPH) is a common problem among elderly men, affecting more than 40% of men older than 70 years (see Chapter 84). BPH results in the urinary symptoms of hesitancy and frequency. Because prostate cancer affects a similar age group and often has similar presenting symptoms, the presence of BPH often complicates the diagnosis of prostate cancer, although it does not appear to increase the risk of developing prostate cancer.[2]

Smoking has not been associated with an increased risk of prostate cancer, but smokers with prostate cancer have an increased mortality resulting from the disease when compared with nonsmokers with prostate cancer (RR 1.5-2).[2] In addition, the results of an observational study showed that alcohol consumption was not associated with the development of prostate cancer.

CHEMOPREVENTION

The use of 5-α-reductase inhibitors, finasteride, and dutasteride to prevent prostate cancer has been debated for more than a decade.[8,9,10,11] These drugs inhibit 5-α-reductase, an enzyme that converts testosterone to its more active form, DHT, which is involved in prostate epithelial proliferation. 5-α-reductase exists as two types, type I and type II, and both are implicated in the development of prostate cancer. Finasteride selectively inhibits the 5-α-reductase type II isoenzyme, while

dutasteride inhibits both isoenzymes.[9] Both finasteride and dutasteride can falsely lower the PSA by about 50% in patients, and this must be considered when one interprets PSA in patients on these medications.[12]

The efficacy of 5-α-reductase inhibitors in reducing the risk of prostate cancer was evaluated in a Cochrane review.[8] Eight randomized studies involving 41,638 men were included, including the Reduction by Dutasteride of Prostate Cancer Events (REDUCE) study, which compared dutasteride to placebo in more than 8,000 subjects, and the Prostate Cancer Prevention Trial (PCPT) study, which compared finasteride to placebo in more than 18,000 subjects. Compared with placebo, 5-α-reductase inhibitors reduced the risk of prostate cancers detected by 25% (RR 0.75, 95% CI: 0.67-0.83; absolute risk reduction 1.4%, [3.5% vs 4.9%]). Although the incidence of prostate cancers was reduced in both the PCPT[9] and REDUCE[10] trials, the prostate tumors that were diagnosed were significantly more aggressive grades (Gleason 7-10) than those diagnosed in the placebo arm. The studies were not designed to evaluate prostate cancer mortality and 5-α-reductase inhibitors did not reduce mortality in the combined analysis. Adverse effects, including gynecomastia, decreased libido, and erectile dysfunction, were more common in patients treated with 5-α-reductase inhibitors than in placebo.[8]

Based on the concern for development of more aggressive tumors, lack of survival benefit and increased risk of adverse effects, neither finasteride nor dutasteride are approved for preventing prostate cancer.[11] The American Society of Clinical Oncology and the American Urological Association published a joint practice guideline for prostate cancer chemoprevention.[13] The guideline recommends that asymptomatic men with a PSA less than or equal to 3.0 ng/mL (mcg/L) who are regularly screened with PSA for early detection of prostate cancer may benefit from a discussion of both the benefits and the potential risks of dutasteride or finasteride for 7 years for the prevention of prostate cancer.[13] Notably, the guideline does not recommend either chemoprevention or prostate cancer screening. The data from PCPT and REDUCE have been criticized for both selection bias and altered differential sensitivity in diagnosis.[11,12] Additional post-hoc analyses that account for these potential biases have generally reported that the inherent biases in the trials were most likely responsible for the increased risk of high grade prostate cancer observed in the treatment arms. However, in the current environment where overdiagnosis and overtreatment of prostate cancer are of concern, these analyses have not generated sufficient interest in 5-α-reductase inhibitors as chemoprevention agents. Current research focuses on the ability of the 5-α-reductase inhibitors to reduce the risk of progression in patients with low grade prostate cancers and in those who fail initial therapy.

Selenium and vitamin E alone or in combination were evaluated as possible chemopreventive agents in the *Sel*enium and Vitamin *E* Cancer Prevention *T*rial (SELECT), a clinical trial investigating in healthy men. The data and safety monitoring committee found that, after 5 years, selenium or vitamin E taken alone or together did not prevent prostate cancer. Based on these data and safety concerns, the trial was halted. With longer follow-up of that trial, dietary supplementation with vitamin E significantly increased the risk of prostate cancer by 17% (P=0.008).[14] Other agents, including lycopene, green tea, nonsteroidal anti-inflammatory agents, isoflavones, and statins, are under investigation for prostate cancer and show some promise, but none are currently recommended for routine use outside of a clinical trial.[15]

SCREENING

2 PSA can be used for detecting prostate cancer at early stages, predicting outcome for localized disease, defining disease-free status, and monitoring response to androgen-deprivation therapy (ADT) or chemotherapy for advanced-stage disease. If prostate cancer screening is performed, PSA is the method of choice, although low specificity is a major limitation.[16,17] PSA may be elevated in men with acute urinary retention, acute prostatitis, and prostatic ischemia or infarction, as well as BPH, a nearly universal condition in men at risk for prostate cancer. PSA elevations between 4.1 and 10 ng/mL (mcg/L) cannot distinguish between BPH and prostate cancer, limiting the utility of PSA alone for the early detection of prostate cancer. Additionally, many men with clinically significant prostate cancer do not have a serum PSA outside the reference range.[18]

Early detection of potentially curable prostate cancers is the goal of prostate cancer screening. For cancer screening to be beneficial, it must reliably detect cancer at an early stage, when intervention would decrease mortality. Whether prostate cancer screening fits these criteria is debatable.[17,19,20,21,22] The European Randomized Study of Screening for Prostate Cancer (ERSPC) evaluated the effect of PSA screening on prostate cancer mortality.[23] More than 182,000 men from seven

different European countries were randomized between being offered screening with PSA to no screening. The frequency of screening and PSA threshold for a biopsy varied by country. Most centers used a PSA cutoff of 3 ng/mL (mcg/L), but Belgium allowed up to 10 ng/mL (mcg/L). Most centers screened every 4 years, although Sweden screened every 2 years. Most (82%) of the men in the screening group had at least one PSA performed. With a median follow-up of 11 years, the cumulative incidence of prostate cancer was 9.6% in the screening group and 6.0% in the control group.[23] The rate ratio for death from prostate cancer in the screening group, compared with the control group, was 0.79 (95% CI: 0.68-0.91, adjusted *P*=0.001), which corresponds to about one death from prostate cancer per 1,000 men (at a median follow-up of 11 years) prevented in the screened group compared with the unscreened group. Of the 136,689 PSA tests performed, 16.6% of the tests were positive; biopsies were performed for 86% of men with elevated PSAs. Overall mortality was similar in the two study groups (rate ratio 0.99, 95% CI: 0.97-1.01).[23]

In the United States, the Prostate, Lung, Colon and Ovarian Screening (PLCO) study randomized 76,693 men to receive either annual screening (38,343 subjects) or usual care as the control (38,350 subjects).[24] In the screening group, men were offered annual PSA testing for 6 years and DRE for 4 years. Compliance with screening was 85%. Men in the usual care group were able to receive screening, with the rate of PSA testing ranging from 40% to 52% and DRE from 41% to 46%. After 13 years of follow-up, the incidence of death per 10,000 person-years was not significantly different between the two groups with 3.7 (158 deaths total) in the screening group and 3.4 (145 deaths total) in the control group (RR 1.09; 95% CI: 0.87-1.36).[24]

The ERSPC demonstrated that PSA testing every 4 years was better than no PSA testing, decreasing prostate cancer deaths in the screened group by about 1 per 1,000 men screened compared with the unscreened group, but the false-positive rate was 76%, resulting in more than 13,000 unnecessary biopsies.[23] The PLCO screening study showed no reduction in prostate cancer death between the annual (PSA and DRE) screening group and the usual care group, which is not surprising given the small reduction in death expected and that about one-half of the patients in the usual screening groups had PSA and/or DRE screening performed.[24] Both studies demonstrated that screening identifies more prostate cancers than not screening.[23,24] PSA measurements can identify small, subclinical prostate cancers, where no intervention may be required. Detecting prostate cancer in those not needing therapy not only increases the cost of care through unnecessary screening and workups, but also increases harm by subjecting some patients to unnecessary therapy. Based on this evidence, the United States Preventive Services Task Force (USPSTF) recommended against screening for prostate cancer (grade D recommendation) in 2012, based on moderate or high certainty that screening has no net benefit or that the harms outweigh the benefits.[21] The American Urologic Association (AUA) does not recommend routine screening in men between the ages of 40 and 54 years of average risk. In men aged 55 to 69 years, the AUA recommends that the risks and benefits of prostate cancer screening are discussed.[17] For men who elect to be screened, the frequency should be no more than 2 years, and a recent study suggests that screening every 5 years may be adequate. The American Cancer Society recommends that asymptomatic men who have at least a 10-year life expectancy have an opportunity to make an informed decision about prostate cancer screening, including discussion of the uncertainties, risks, and potential benefits associated with screening.[20]

In the United States, PSA screening data from the National Health Interview Survey showed a decline in the prevalence of prostate cancer screening, decreasing from 36% of men undergoing annual PSA screening in 2010 to 31% of men in 2013. The authors suggest that changes in screening patterns were associated with USPSTF guidelines recommending against PSA screening.[22]

Clinical Controversy…

Prostate cancer screening with prostate-specific antigen (PSA) tests is controversial. The USPSTF recommends no PSA screening, while the AUA recommends shared decision making with a discussion of risk and benefits for men aged 55 to 69 years. An additional trial of PSA screening (CAP/ProtecT trial) is expected to report initial results in 2016 and may help resolve these issues.

Based on the available evidence, Gulati et al recently evaluated the comparative effectiveness of alternative PSA screening strategies.[25] Examples of alternative screening strategies include the use of higher PSA thresholds for biopsy referral or longer screening intervals. Several of the screening scenarios were predicted to produce similar reductions in prostate

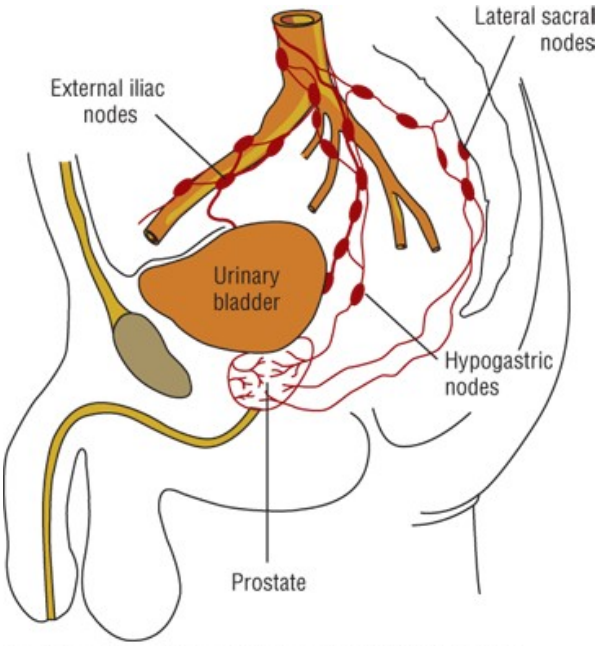
cancer mortality and reduce harms.

PATHOPHYSIOLOGY

The prostate gland is a solid, rounded, heart-shaped organ positioned between the neck of the bladder and the urogenital diaphragm (**Fig. 131-1**). The normal prostate is composed of acinar secretory cells arranged in a radial shape and surrounded by a foundation of supporting tissue. The size, shape, or presence of acini is almost always altered in the gland that has been invaded by prostatic carcinoma. Adenocarcinoma, the major pathologic cell type, accounts for more than 95% of prostate cancer cases.[26,27] Much rarer tumor types include small cell neuroendocrine cancers, sarcomas, and transitional cell carcinomas.

FIGURE 131-1

The prostate gland.



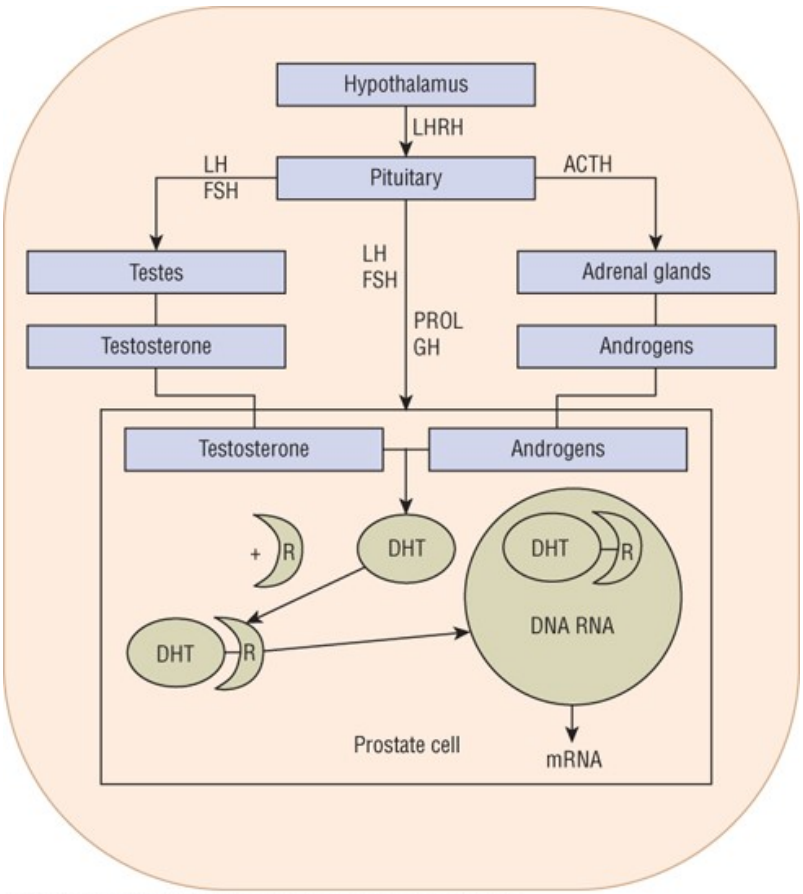
Prostate cancer can be graded systematically according to the histologic appearance of the malignant cell and then grouped into well, moderately, or poorly differentiated grades.[27,28] Gland architecture is examined and then rated on a scale of 1 (well differentiated) to 5 (poorly differentiated). Two different specimens are examined, and the score for each specimen is added. Groupings for total Gleason score are 2 to 4 for well differentiated, 5 or 6 for moderately differentiated, and 7 to 10 for poorly differentiated tumors. Poorly differentiated tumors grow rapidly (poor prognosis), while well-differentiated tumors grow slowly (better prognosis).

Metastatic spread can occur by local extension, lymphatic drainage, or hematogenous dissemination.[28,29] Lymph node metastases are more common in patients with large, undifferentiated tumors that invade the seminal vesicles. The pelvic and abdominal lymph node groups are the most common sites of lymph node involvement (see Fig. 131-1). Skeletal metastases from hematogenous spread are the most common sites of distant spread. Typically, the bone lesions are osteoblastic or a combination of osteoblastic and osteolytic. The most common site of bone involvement is the lumbar spine. Other sites of bone involvement include the proximal femur pelvis, thoracic spine, ribs, sternum, skull, and humerus. The lung, liver, brain, and adrenal glands are the most common sites of visceral involvement, although these organs are not usually initially involved. About 25% to 35% of patients will have evidence of lymphangitic or nodular pulmonary infiltrates at autopsy. The prostate is rarely a site for metastatic involvement from other solid tumors.

Normal growth and differentiation of the prostate depend on the presence of androgens, specifically DHT.[29,30] The testes and the adrenal glands are the major sources of circulating androgens. Hormonal regulation of androgen synthesis is mediated through a series of biochemical interactions between the hypothalamus, pituitary, adrenal glands, and testes (**Fig. 131-2**). Luteinizing hormone-releasing hormone (LHRH) released from the hypothalamus stimulates the release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from the anterior pituitary gland. LH complexes with receptors on the Leydig cell testicular membrane and stimulates the production of testosterone and small amounts of estrogen. FSH acts on the Sertoli cells within the testes to promote the maturation of LH receptors and to produce an androgen-binding protein. Circulating testosterone and estradiol influence the synthesis of LHRH, LH, and FSH by a negative feedback loop operating at the hypothalamic and pituitary level.[31] Prolactin, growth hormone, and estradiol appear to be important accessory regulators for prostatic tissue permeability, receptor binding, and testosterone synthesis.

FIGURE 131-2

Hormonal regulation of the prostate gland. (ACTH, adrenocorticotropic hormone; DHT, dihydrotestosterone; FSH, follicle-stimulating hormone; GH, growth hormone; LH, luteinizing hormone; LHRH, luteinizing hormone-releasing hormone; PROL, prolactin; R, receptor.)



Testosterone, the major androgenic hormone, accounts for 95% of the androgen concentration. The primary source of testosterone is the testes, but 3% to 5% of the testosterone concentration is derived from direct adrenal cortical secretion of testosterone or C19 steroids such as androstenedione.[28,29,30]

In early-stage prostate cancers, aberrant tumor cell proliferation is promoted by the presence of androgens. For these tumors, blockade of androgens induces tumor regression in most patients. Hormonal manipulations to ablate or reduce circulating androgens can occur through several mechanisms[29,30] (**Table 131-2**). The organs responsible for androgen production can be removed surgically (orchiectomy, hypophysectomy, or adrenalectomy). Hormonal pathways that

modulate prostatic growth can be interrupted at several steps (see Fig. 131-2). Interference with LHRH or LH can reduce testosterone secretion by the testes (estrogens, LHRH agonists, progestogens, and cyproterone acetate). Estrogen administration reduces androgens by directly inhibiting LH release, by acting directly on the prostate cell, or by decreasing free androgens by increasing steroid-binding globulin levels.[28,29,30]

TABLE 131-2 Hormonal Manipulations in Prostate Cancer

Androgen source ablation	
Orchiectomy	
Adrenalectomy	Antiandrogens
Hypophysectomy	Flutamide
LHRH or LH inhibition	Bicalutamide
Estrogens	Enzalutamide
LHRH agonists	Nilutamide
Progesterones[a]	Cyproterone acetate[b]
Cyproterone acetate[b]	Progesterones
Androgen synthesis inhibition	5-α-Reductase inhibition
Aminoglutethimide	Finasteride[b]
Ketoconazole	Dutasteride
Abiraterone Acetate	
Progesterones[a]	

LH, luteinizing hormone; LHRH, luteinizing hormone-releasing hormone.

[a]Minor mechanisms of action.

[b]Investigational compounds or use.

Isolation of the naturally occurring hypothalamic decapeptide hormone, LHRH has provided another group of effective agents for advanced prostate cancer treatment. The physiologic response to LHRH depends on both the dose and the mode of administration. Intermittent pulsed LHRH administration, which mimics the endogenous release pattern, causes sustained release of both LH and FSH, whereas high-dose or continuous IV administration of LHRH inhibits gonadotropin release due to receptor downregulation.[23] Structural modification of the naturally occurring LHRH and innovative delivery have produced a series of LHRH agonists that cause a similar downregulation of pituitary receptors and a decrease in testosterone production.[31]

Androgen synthesis can also be inhibited in the testes or in the adrenal gland. Aminoglutethimide inhibits the desmolase-enzyme complex in the adrenal gland, thereby preventing the conversion of cholesterol to pregnenolone. Pregnenolone is the precursor substrate for all adrenal-derived steroids, including androgens, glucocorticoids, and mineralocorticoids. Ketoconazole, an imidazole antifungal agent, causes a dose-related reversible reduction in serum cortisol and testosterone concentration by inhibiting both adrenal and testicular steroidogenesis.[31] Megestrol is a synthetic derivative of progesterone that exhibits a secondary mechanism of action by inhibiting androgen synthesis. This inhibition appears to occur at the adrenal level, but circulating levels of testosterone are also reduced, suggesting that inhibition at the testicular level may also occur.[31]

Antiandrogens inhibit the formation of the DHT-receptor complex and therefore interfere with androgen activity at the cellular level.[31] The conversion of testosterone to DHT may be inhibited by 5-α-reductase inhibitors.[7]

In advanced stages of disease, prostate cancer cells may be able to survive and proliferate without the signals normally provided by circulating androgens.[31] When this occurs, the tumor is no longer sensitive to therapies that depend on androgen blockade. These tumors are often referred to as hormone refractory or androgen independent.

CLINICAL PRESENTATION Prostate Cancer Localized Disease

- Asymptomatic

Locally Invasive Disease

- Ureteral dysfunction, frequency, hesitancy, and dribbling
- Impotence

Advanced Disease

- Back pain
- Cord compression
- Lower extremity edema
- Pathologic fractures
- Anemia
- Weight loss

Prior to the implementation of routine screening, prostate cancers were frequently identified on the investigation of symptoms, including urinary hesitancy, retention, painful urination, hematuria, and erectile dysfunction. With the introduction of screening techniques, most prostate cancers are now identified prior to the development of symptoms, although this may change as routine screening is no longer the norm.

The information obtained from the diagnostic tests is used to stage the patient (**Table 131-3**). There are two commonly recognized staging classification systems (**Table 131-4**). The formal international classification system (tumor, node, metastases [TNM]), adopted by the International Union Against Cancer in 1974, was last updated in 2010. The AUS classification is the most commonly used staging system in the United States. Patients are assigned to stages A through D and corresponding subcategories based on size of the tumor (T), local or regional extension, presence of involved lymph node groups (N), and presence of metastases (M). Based on men diagnosed with prostate cancer at Walter Reed Army Medical Center from 1988 to 1998, including more than 2,042 prostate cancer diagnoses, localized prostate cancer (stage T_1 and T_2) was diagnosed more frequently (89% vs 68%), and advanced disease (stages T_3, T_4, and D) was diagnosed less frequently (11% vs 32%) in 1998 as compared to 1988.

TABLE 131-3 Diagnostic and Staging Workup for Prostate Cancer

Initial tests	DRE
	PSA TRUS if either DRE is positive or PSA is elevated
	Biopsy
Staging tests	Gleason score on biopsy specimen
	Bone scan
	Complete blood count
	Liver function tests
	Serum phosphatases (acid/alkaline)

Additional staging tests (depends on tumor classification, PSA, and Gleason score)	Excretory urogram Chest x-ray Skeletal films Lymph node evaluation Pelvic computed tomography ^{111}In-labeled capromab pendetide scan Bipedal lymphangiogram Transrectal magnetic resonance imaging

DRE, Digital rectal examination; PS, Prostate-specific antigen; TRUS, transrectal ultrasonography.

TABLE 131-4 Staging and Classification Systems for Prostate Cancer

AUS[a] Stage (A–D)	**AJCC-UICC[b] Classification (TNM)**
A (occult, nonpalpable)	$T_xN_xM_x$ (cannot be assessed)
A_1: Focal	$T_0N_0M_0$ (nonpalpable)
A_2: Diffuse	T_0: Focal or diffuse
B (confined to prostate)	$T_1N_0M_0$, $T_2N_0M_0$
B_1: Single nodule in one lobe, < 1.5 cm	T_1 (Clinically inapparent tumor not palpable or visible by imaging)
	T_{1a}: Tumor incidental histologic finding in 5% or less of tissue resected
	T_{1b}: Tumor incidental histologic finding in 5% or more of tissue resected
	T_{1c}: Tumor identified by needle biopsy (eg, because of elevated PSA)
	T_2: (Tumor confined within the prostate[c])
B_2: Diffuse involvement of whole gland, > 1.5 cm	T_{2a}: Tumor involves half of a lobe or less
	T_{2b}: Tumor involves more than half a lobe, but not both lobes
	T_{2c}: Tumor involves both lobes
C (localized to periprostatic area)	$T_3N_0M_0$, $T_4N_0M_0$
C_1: No seminal vesicle involvement, < 70 g	T_3: (Tumor extends through the prostatic capsule[d])
	T_{3a}: Unilateral extracapsular extension
	T_{3b}: Bilateral extracapsular extension
	T_{3c}: Tumor invades the seminal vesicle(s)
C_2: Seminal vesicle involvement, > 70 g	T_4: (Tumor is fixed or invades adjacent structures other than the seminal vesicles)
	T_{4a}: Tumor invades any of bladder neck, external sphincter, or rectum
	T_{4b}: Tumor invades levator muscles and/or is fixed to the pelvic wall
D (metastatic disease)	Any T, $N_{1–4}$, M_0, or $N_{0–4}$, M_1
D_1: Pelvic lymph nodes or ureteral obstruction	N_1: Metastasis in a single lymph node, 2 cm or less in greatest dimension
D_2: Bone, distant lymph node, organ, or soft tissue metastases	N_2: Metastasis in single lymph node more than 2 cm but not more than 5 cm in greatest dimension; or multiple lymph node metastases, none more than 5 cm in greatest dimension
	N_3: Metastasis in lymph node more than 5 cm in greatest dimension
	M_{1a}: Nonregional lymph node(s)
	M_{1b}: Bone(s)

AUS[a] Stage (A–D)	AJCC-UICC[b] Classification (TNM)
	M_{1c}: Other site(s)

PSA, prostate-specific antigen.

[a]American Urologic System.

[b]American Joint Committee on Cancer–International Union Against Cancer.

[c]Note: Tumor found in one or both lobes by needle biopsy, but not palpable or visible by imaging, is classified as T_{1c}.

[d]Note: Invasion into the prostatic apex or into (but not beyond) the prostatic capsule is not classified as T_3 but as T_2.

3 The prognosis for patients with prostate cancer depends on the histologic grade, the tumor size, and the local extent of the primary tumor.[27] The most important prognostic criterion appears to be the histologic grade, because the degree of differentiation ultimately determines the stage of disease. Poorly differentiated tumors are highly associated with both regional lymph node involvement and distant metastases.[27]

From 1999 to 2005, 5-year overall survival rates were estimated at 100% for whites and 97% for African Americans.[1] For almost the same period, the survival rates for localized or regional disease (100%), and distant disease (30%) in white males were about the same as the survival rates for localized or regional disease (100%), and distant disease (29%) in African American males.[1] A 4.1% decline in age-adjusted mortality has been observed for the period 1994 to 2006. Ten-year cancer-specific survival is estimated as 95% for stage A_1, 80% for stages A_2 to B_2, 60% for stage C, 40% for stage D_1, and 10% for stage D_2. It is estimated that more than 85% of patients with stage A_1 can be cured, while less than 1% of patients with stage D_2 will be cured.

Treatment

Desired Outcomes

The desired outcome in early-stage prostate cancer is to minimize morbidity and mortality caused by prostate cancer.[32,33] The most appropriate therapy of early-stage prostate cancer is controversial. Early-stage disease may be treated with surgery, radiation, or expectant management. While surgery and radiation are curative, they are associated with significant morbidity and mortality. Because the overall goal is to minimize morbidity and mortality associated with the disease, watchful waiting is appropriate in selected individuals. Advanced prostate cancer (stage D) is not currently curable, and treatment should provide symptom relief and maintain quality of life. The mainstay of treatment for advanced prostate cancer is ADT, with a goal of reducing testosterone to castrate levels, with either an orchiectomy or an LHRH agonist.

General Approach to Treatment

The initial treatment for prostate cancer depends primarily on the disease stage, the Gleason score, the presence of symptoms, and the life expectancy of the patient.[32] Prostate cancer is usually initially diagnosed by PSA and DRE and confirmed by a biopsy, where the Gleason score is assigned. Asymptomatic patients with a low risk of recurrence, those with a T_1 or T_{2a}, with a Gleason score of 2 through 6, and a PSA of less than 10 ng/mL (mcg/L) may be managed by observation, radiation, or radical prostatectomy (**Table 131-5**). As patients with asymptomatic early-stage disease generally have an excellent 10-year survival, immediate morbidities of treatment must be balanced with the lower likelihood of dying from prostate cancer. More aggressive treatment of early-stage prostate cancer is generally reserved for younger men, although patient preference is a major consideration in all treatment decisions. In a patient with a normal life expectancy of less than 10 years, observation or radiation therapy may be offered. In those with a normal life expectancy of equal to or greater than 10 years, either observation, radiation (external beam or brachytherapy), or radical prostatectomy with a pelvic lymph node dissection may be offered. Radiation and radical prostatectomy therapy are generally considered therapeutically equivalent for localized prostate cancer, although neither has been proven to be better than observation alone.[34]

TABLE 131-5 Initial Management of Prostate Cancer Based on Expected Survival and Recurrence Risk

Recurrence Risk	Expected Survival (Years)	Initial Therapy
Very Low		
T_{1c}	< 20	Observation
T_{1c}	20 or more	Observation or Radical prostatectomy with or without pelvic lymph node dissection or Radiation therapy
Low		
T_1–T_{2a} and Gleason 2-6 and PSA less than 10 ng/mL (mcg/L) and < 5% tumor in specimen	10 or more	Observation or Radical prostatectomy with or without pelvic lymph node dissection or radiation therapy
	<10	Observation
Intermediate		
T_{2b}–T_{2c} or Gleason 7 or PSA 10-20 ng/mL (mcg/L)	10 or less	Observation or Radical prostatectomy with pelvic lymph node dissection or Radiation therapy with or without 4-6 months of neoadjuvant androgen deprivation therapy with or without brachytherapy
T_{2b}–T_{2c} or Gleason 7 or PSA 10-20 ng/mL (mcg/L)	10 or more	Radical prostatectomy with pelvic lymph node dissection or Radiation therapy with or without 4-6 months of neoadjuvant androgen deprivation therapy with or without brachytherapy
High		
T_{3a}, Gleason 8-10, PSA > 20 ng/mL (mcg/L)		Radiation therapy and ADT[a] (2-3 years) with or without brachytherapy or Radical prostatectomy and pelvic lymph node dissection
Very High		
T_{3b}-T_4		Radiation therapy and ADT (2-3 years) with or without brachytherapy or

Recurrence Risk	Expected Survival (Years)	Initial Therapy
Very High		Radical prostatectomy and pelvic lymph node dissection or ADT
Any T, N_1		ADT (2-3 years) or Radiation therapy and ADT (2-3 years) ADT with orchiectomy or LHRH agonist[b] + 7 days antiandrogen therapy
Any T, Any N, M_1		or LHRH agonist + antiandrogen or LHRH agonist

ADT, androgen-deprivation therapy; LHRH, luteinizing hormone-releasing hormone; PSA, prostate-specific antigen.

[a]Androgen deprivation therapy to achieve serum testosterone levels < 50 ng/dL (1.7 nmol/L).

[b]LHRH agonist, medical castration, or surgical castration are equivalent.

Wilt and colleagues conducted a systematic review of 18 randomized trials and 473 observational studies to compare the effectiveness and potential complications from treatment options from prostate cancer. This study showed that the effectiveness of radiation, radical prostatectomy, and ADT could not be compared because of the paucity of high-quality evidence available for analysis. Adverse effect profiles were similar, although severity varied among the treatments.[35] Complications from radical prostatectomy include blood loss, stricture formation, incontinence, lymphocele, fistula formation, anesthetic risk, and impotence. Nerve-sparing radical prostatectomy can be performed in many patients; 50% to 80% regain sexual potency within the first year. However, a recently published prospective study showed that even in patients with good preoperative sexual health, many do not return to baseline after surgery even with the assistance of erectile dysfunction treatments.[36] Acute complications from radiation therapy include cystitis, proctitis, hematuria, urinary retention, penoscrotal edema, and impotence (30% incidence).[27] Chronic complications include proctitis, diarrhea, cystitis, enteritis, impotence, urethral stricture, and incontinence.[27] In addition, ADT can cause cognitive impairment, mood disturbances, and lack of initiative.[35] Because radiation and prostatectomy have significant and immediate mortality when compared with expectant management alone, many patients may elect to postpone therapy until symptoms develop.

Individuals with T_{2b} and T_{2c} disease or a Gleason score of 7 or a PSA ranging from 10 to 20 ng/mL (mcg/L) are considered at intermediate risk for prostate cancer recurrence.[32] Individuals with less than a 10-year expected survival may be offered observation or radical prostatectomy with pelvic lymph node dissection or radiation therapy with or without 4 to 6 months of neoadjuvant ADT with or without brachytherapy, and those with a greater than or equal to 10-year life expectancy may be offered either radical prostatectomy with or without a pelvic lymph node dissection or radiation therapy with or without 4 to 6 months of neoadjuvant ADT with or without brachytherapy (see Table 131-5).

The treatment of patients at high risk of recurrence (stage T_3, a Gleason score ranging from 8 to 10, or a PSA value greater

than 20 ng/mL [mcg/L]) should be treated with androgen ablation for 2 to 3 years combined with radiation therapy with or without brachytherapy (Table 131-5). Selected individuals with a low tumor volume may receive a radical prostatectomy with or without a pelvic lymph node dissection.
